Mucosal cytoprotection depends primarily on adequate mucosal blood flow, which permits normal secretion of mucus and bicarbonate (HCO_3^-) as well as the delivery of protective factors, especially prostaglandins. The process of mucus secretion involves extrusion of the apical portions of the mucus-secreting gastric surface cells and mucous neck cells. The mucus contained within the cells streams out through the apical defects to form the gastric mucus layer, consisting of an adherent semisolid glycoprotein gel overlaid by soluble mucus. Bicarbonate secretion by surface mucus cells under and within the mucus layer may permit neutralization of the pH near the gastric surface mucosa. Thus, the combination of mucus and bicarbonate secretion, by providing a less acidified environment near the cell surface than in the lumen, helps the gastroduodenal mucosa defend itself from damage.

Stimuli of mucus and bicarbonate secretion in vivo include reflexes induced by gastric mucosal irritation, cholinergic stimulation, and acid secretion. Prostaglandins are the major stimulants of bicarbonate and mucus secretion and are thus the primary underlying mediators of mucosal cytoprotection. Pepsin can partially digest the mucus gel, suggesting that increased peptic activity may decrease the thickness of the mucus layer predisposing to ulceration. However, dissolving gastric mucus with mucolytic agents has had no apparent adverse effects in animal models of peptic ulcer. In contrast, studies have shown that both gastric and duodenal ulcer patients secrete less bicarbonate than do control subjects, and pH levels at the mucosal cell surfaces of peptic ulcer patients are lower than in normal subjects.

Growth factors including fibroblast growth factor, transforming growth factor- α , heparin-binding growth factor, and hepatocyte growth factor contribute to mucosal integrity by promoting normal proliferation of mucosal cells and promoting healing of mucosal lesions.

GASTRITIS

Patients with either gastric or duodenal ulcer usually also have gastritis. Gastritis is best defined as chronic inflammation of the gastric mucosa and therefore is a histologic diagnosis. Acute gastritis (or gastropathy) is typically a consequence of gastric mucosal irritation by noxious substances such as NSAIDs (including aspirin), alcohol, or bile, but the histologic findings are typically quite bland. An exception to this rule is the marked inflammation that occurs with acute *H. pylori* infection, although this syndrome is rarely recognized clinically. Chronic gastritis is almost always caused by *H. pylori* infection, and it resolves after cure of the infection. In chronic *H. pylori* gastritis, the antral mucosa is infiltrated with inflammatory cells. Patients with *H. pylori*-induced duodenal ulcers also have histologic evidence of duodenal inflammation associated with gastric metaplasia of the duodenal bulb that may be colonized by *H. pylori* organisms. Patients with *H. pylori*-induced gastric ulcers often have chronic gastritis in association with intestinal metaplasia of the gastric mucosa with varying degrees of gastric atrophy (loss of glands). Other specific causes of chronic gastritis are rare and tend not to be associated with peptic ulcer disease.

HELICOBACTER PYLORI GASTRITIS

Helicobacter pylori is a gram-negative spiral bacterium 1.5 to 3.5 μm in size. Its appearance is characterized by its helical shape as well as by six sheathed unipolar flagella that provide motility (Fig. 107.4). The organism produces urease, which appears to be important in colonization of the gastric mucosa. Although difficult to culture, organisms are detectable with standard histologic stains (hematoxylin and eosin) but are best seen if special silver-based stains such as Giemsa, Warthin Starry, or Genta stains are used. *H. pylori* appears to be pathogenic for humans exclusively, but a number of other members of the *Helicobacter* genus that infect other mammalian species have been discovered. For example, *H. felis* infects cats, *H. mustelae* infects ferrets, and *H. acinonyx* infects cheetahs. *H. heilmannii* (formerly *Gastrospirillum hominis*) is another human *Helicobacter* species, which is not felt to be pathogenic.

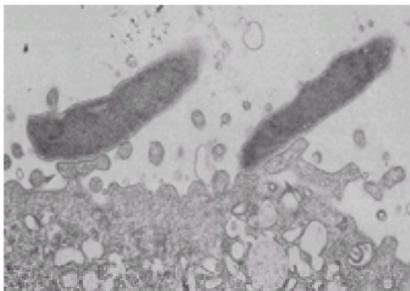

FIGURE 107.4. Electron micrograph of adherence. *Helicobacter pylori* has a unique habitat: it lives only in gastric epithelium, including metaplastic gastric epithelium, wherever it occurs. Only gastric epithelium expresses specific adherence receptors in vivo that can be recognized by the organism. Note the organism adhering to gastric epithelium. (From American Gastroenterological Association. Digestive health initiative: *Helicobacter pylori*: the new factor in management of ulcer disease. Bethesda, MD, 1995, with permission.)

Epidemiology of Helicobacter pylori Infection

Helicobacter pylori gastritis is one of the most common human infections, with over 2 billion people infected worldwide. In developing countries with low standards of hygiene, the prevalence of *H. pylori* infection increases dramatically in early childhood (Fig. 107.5). In certain countries, up to 90% of the population is infected by age 10. Spontaneous clearance of the organism is extremely uncommon, resulting in chronic life-long infection in untreated persons. In developed countries such as the United States, the prevalence of *H. pylori* infection is lower, with approximately 30% of the adult population infected. The age-specific prevalence of *H. pylori* increases by roughly 1% per annum until late middle age when it increases sharply (Fig. 107.5). This increase is likely due to the poorer living standards prevalent in the United States when this cohort of people were young. The risk of acquiring *H. pylori* infection in adulthood in the developed world is low, roughly 0.5% per annum.

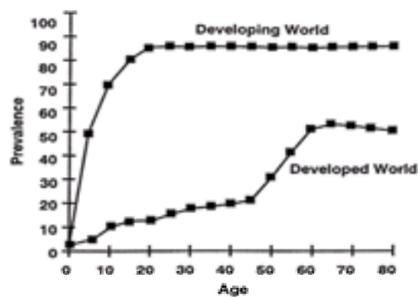

FIGURE 107.5. Age-specific prevalence of *Helicobacter pylori* infection in developing and developed countries of the world. (Modified from Marshall BJ. *Helicobacter pylori* gastritis. *Am J Gastroenterol* 1994;89(suppl):S116–S128.)

Overcrowding and low socioeconomic status appear to be important factors in the development of *H. pylori* infection. Members of large families tend to have a higher prevalence of infection, and the last in a series of siblings is more likely to be infected than first-borns. Institutional outbreaks of the infection have also demonstrated a higher prevalence in overcrowded conditions.

Some racial and ethnic groups have an increased risk for harboring *H. pylori* infection, although this may reflect socioeconomic status in childhood (when the infection is acquired) rather than ethnicity per se. African Americans have a higher prevalence of infection than Hispanics, and whites have the lowest prevalence. *H. pylori* infection appears to occur equally in both sexes.

Because *H. pylori* infects only humans, it must be transmitted directly from one person to another. The method of transmission is not well understood, but epidemiologic studies support fecal–oral spread and the organism has been isolated from human feces. Iatrogenic transmission has been documented through contaminated endoscopes, pH probes, biopsy forceps, and nasogastric tubes. These data suggest that exposure to gastric secretions may be required for oral–oral spread. The organism can survive in milk for up to 6 days and in water for up to 14 days. There is no evidence of sexual transmission.

Pathophysiology of *Helicobacter pylori* Infection

Although most persons infected with *H. pylori* are asymptomatic, approximately 15% develop peptic ulcer disease (both gastric and duodenal ulcers) and about 0.05% develop gastric cancer or lymphoma. The World Health Organization has categorized *H. pylori* as a class 1 carcinogen.

H. pylori infection can be divided into an early stage, characterized by colonization of the host stomach, and a late stage, characterized by clinical disease. Colonization requires that the organism overcome normal host defenses. Urease may be important in early colonization by creating a protective nonacidic microenvironment shielding the organism from gastric juice. Urease-negative *H. pylori* mutants are unable to colonize the stomachs of experimental animals. Motility is another important colonization factor. Amotile mutant organisms without flagella are poor colonizers, presumably because these organisms cannot penetrate the mucus layer overlying the gastric epithelium. Adherence to the gastric epithelial layer is another essential factor enabling *H. pylori* to colonize the human stomach, because without this ability, organisms would be washed out with normal gastric emptying.

Various bacterial adhesion molecules that bind specifically to receptors on the gastric surface of mucus cells have been described. Thus, although organisms can be seen swimming freely in the gastric lumen, it appears that most are located within the unstirred mucous layer lining the gastric epithelium where ideal growth conditions prevail (i.e., low oxygen and high carbon dioxide tensions). Colonization also occurs in areas of gastric metaplasia containing surface mucus cells outside the stomach. The organism is noninvasive, and its subsequent effects are due to its products or possibly due to phagocytosis by mucosal immune cells.

Virulence factors associated with *H. pylori* infection can be divided into those that lead to gastritis (occurring in all infected persons) and those that lead to additional clinical disease entities (occurring only in some persons). Urease and various other enzyme products of *H. pylori* organisms are important in undermining mucosal integrity, thereby leading to gastritis. These effects all lead to an undermining of mucosal integrity, which predisposes to acid-peptic disease by decreasing mucosal cytoprotection. The Vac A gene, which encodes for a toxin that causes vacuolization of infected culture cells, is present in all *H. pylori* isolates, but only 50% of them express the toxin. Vac A cytotoxin has been associated with the development of peptic ulcer disease. Cag A is also a marker for pathogenicity. The precise function of the Cag A protein has not yet been elucidated, but expression of Cag A is associated with peptic ulcer disease as well as gastric cancer and lymphoma. Two other virulence genes have been described: the Pic B gene, which may act as an amplifier of Cag A, and the Ice A gene, which appears to be important in bacterial adherence.

One of the unique features of *H. pylori* infection is the organism's ability to survive symbiotically within its human host despite inducing a robust immune response. Because the organism itself is not invasive, the host response must be due to bacterial products that diffuse across the basement membrane into the gastric mucosa or are taken up by M cells in Peyer's patches of the intestine. The immune response is probably ineffective because the organism stimulates a predominantly TH2 (antibody) response, which is unable to eradicate the infection even though secretory immunoglobulin (IgA) is produced. Tissue injury is probably mediated by the organism's ability to induce host production of interleukin-8 and other cytokines from cells within the gastric mucosa. This results in chemotaxis of activated polymorphonuclear leukocytes, which release various secondary substances that induce an inflammatory response. A lymphoproliferative response is also characteristic of chronic *H. pylori* infection.

The host inflammatory response is probably important in altering membrane permeability, permitting “off shore” organisms to obtain nutrition from the colonized host. For the development of disease processes other than gastritis, additional host factors may be required. In support of this theory, gastric metaplasia of the duodenal bulb and gastric acid hypersecretion appear to be important for the development of duodenal ulceration, whereas gastric atrophy (and relative hypochlorhydria) may be important for the development of gastric ulceration or gastric carcinoma. Patients with an excessive lymphoproliferative response may be predisposed to the development of gastric lymphoma.

OTHER SPECIFIC CAUSES OF GASTRITIS

Specific infiltrative diseases of the stomach may cause gastritis associated with pain. Me(c)ne(c)trier's disease (hypertrophic gastritis associated with protein-losing enteropathy), tuberculosis, syphilis, sarcoidosis, and eosinophilic granuloma of the stomach are rare gastric diseases that may be symptomatic. Chronic autoimmune gastritis (with or without pernicious anemia) is characterized by infiltration of the gastric mucosa by chronic inflammatory cells early on leading to loss of gastric glands and intestinal metaplasia as it progresses. The condition is generally asymptomatic and is associated with achlorhydria due to autoimmune-mediated loss of parietal cells. *Helicobacter heilmanni*, (formerly *Gastrospirillum hominus*) is another spiral bacterium that occasionally infects humans. It is far more rare than *H. pylori* infection, tends to cause a less exuberant inflammation, and is believed to be nonpathogenic. Peptic ulceration is rare with all these other specific causes of gastritis.

EFFECTS OF *HELICOBACTER PYLORI* GASTRITIS ON NORMAL GASTRIC PHYSIOLOGY

In acute *H. pylori* infection, hypochlorhydria may accompany the acute gastritis, which is mediated by bacterial proteins. Epidemic achlorhydria has been described in institutional outbreaks as well as in studies in which the organism has been iatrogenically transmitted through nasogastric tubes. The inhibition of acid output in these patients continues for weeks to months but recovers in most individuals within about 9 months. It is unclear whether persons with persistent hypochlorhydria are especially predisposed to ultimately developing gastric atrophy.

The effects of chronic *H. pylori* infection on gastric acid secretion results in a spectrum of effects from hypergastrinemia and gastric acid hypersecretion on one extreme to hypo- or even achlorhydria on the other extreme. In antral predominant gastritis, a major effect appears to be exerted on somatostatin-secreting D cells, such that the feedback inhibition of luminal acid on antral gastrin release is altered. Consequently, hypergastrinemia leads to excessive stimulation of ECL and parietal cells and mild acid hypersecretion. Meal-stimulated gastrin release is also excessive in patients with chronic *H. pylori* infection. Thus, chronic antral predominant infection leads to antral G-cell hyperfunction, inappropriate hypergastrinemia, hypersecretion of acid, and the potential for duodenal ulcer disease.

Progressively lesser degrees of hypergastrinemia and hypersecretion have been noted in patients with *H. pylori*-positive nonulcer dyspepsia and asymptomatic infections.

In pangastritis or corpus-predominant infection, parietal cell function is altered by local *H. pylori*-induced inflammation, and secretory responses are inhibited. Tumor necrosis factor- α is felt to be one of the more important mediators of this effect. Thus, chronic *H. pylori* infection involving the acid secretory component of the stomach ultimately leads to hypo- or achlorhydria and gastric atrophy. Gastric ulceration may develop in affected patients owing to a loss of mucosal cytoprotection as long as the environment is not totally anacidic. Hypergastrinemia in these patients may result from both a physiologic response to a decrease in acid output and antral D-cell dysfunction leading to G-cell hyperfunction. Long-standing gastric atrophy may ultimately progress to intestinal metaplasia and possibly gastric carcinoma. *H. pylori* is also associated with gastric lymphomas, which sometimes occur in mucosa-associated lymphoid tissue, called *maltomas*. *Maltomas* may regress after *H. pylori* eradication. [Figure 107.6](#) summarizes the disease states associated with *H. pylori* infection.

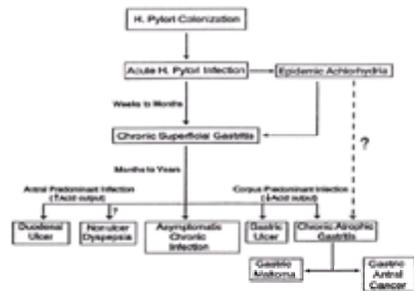

FIGURE 107.6. Algorithm describing the potential outcomes of *Helicobacter pylori* infection in susceptible persons. Acute gastritis (sometimes with epidemic achlorhydria) develops in virtually all colonized persons and progresses to chronic superficial gastritis. Patients with antral-predominant infection develop relative gastric hypersecretion and become predisposed to duodenal ulceration (and possibly nonulcer dyspepsia). Patients with corpus-predominant pangastritis develop relative gastric hyposecretion and become predisposed to gastric ulceration (and possibly gastric carcinoma or maltoma). Most patients with chronic infection remain asymptomatic throughout life.

ULCER PATHOPHYSIOLOGY

Ulcers are formed when the mucosa of the stomach or duodenum cannot resist the corrosive effects of acid on its surface. Exogenous factors, primarily *H. pylori* infection and NSAID usage, contribute to the formation of most peptic ulcers. Peptic ulceration occurs in about one in six patients with *H. pylori* infection. Conversely, approximately 70% of all gastric ulcers and about 90% of all duodenal ulcers are a consequence of *H. pylori* infection. Most non-*H. pylori*-associated peptic ulcers are due to NSAIDs. Hypersecretory states such as Zollinger–Ellison syndrome account for a minority of cases of peptic ulcer. In approximately 20% of patients with duodenal ulcers, none of these predisposing factors can be identified.

Gastric ulcer is not associated with any consistent abnormality in acid secretion, although some acid is needed for gastric ulcer formation. Gastric ulcer in the setting of achlorhydria, therefore, usually indicates gastric cancer. Ulcers of the gastric body are associated with altered mucosal defenses (due to *H. pylori* infection or NSAID use) with sufficient acid secretion to account for pepsin activation and autodigestion of the gastric mucosa. However, patients with distal antral ulcers, pyloric channel ulcers, or gastric ulcers associated with duodenal ulcers have mild gastric acid hypersecretion, similar to those found in idiopathic duodenal ulcer disease wild.

After *H. pylori* gastritis, prostaglandin deficiency is the next most important cause of altered mucosal defense leading to peptic ulceration in the presence of activated pepsin. Prostaglandins are produced by cyclooxygenases in the gastric mucosa. Inhibition of cyclooxygenase by aspirin or other NSAIDs is associated with acute gastropathy and peptic ulcers. Elderly patients taking high doses or combinations of NSAIDs, especially those with a history of peptic ulcer disease, have a particular risk for peptic ulceration ([Table 107.1](#)). The pathophysiologic mechanism for ulcer formation is presumed to be decreased mucosal production by cyclooxygenase of prostaglandin E₁ and E₂. These prostaglandins normally inhibit acid secretion, stimulate bicarbonate secretion, and mucous secretion, and maintain mucosal blood flow. Two forms of cyclooxygenase are in the stomach. The constitutively expressed cyclooxygenase-1 (COX-1) appears to be more important in maintaining mucosal integrity than the inducible COX-2. NSAIDs that inhibit COX-2 more than COX-1 may produce fewer ulcers than those that are very active against COX-1 ([Table 107.2](#)).

Ulcer history
Older age
High-dose NSAID therapy
Combinations of NSAIDs
Recent use of NSAIDs
Corticosteroid use

NSAIDs, nonsteroidal anti-inflammatory drugs.
The role of alcohol consumption, tobacco use and low socioeconomic status in promoting NSAID damage remains unproven. There is no evidence for synergy between NSAIDs and *Helicobacter pylori* infection.

TABLE 107.1. ESTABLISHED RISK FACTORS FOR NSAID-RELATED DAMAGE

Very low	COX II inhibitors*
Low	Diflunisal (Dolobid) Diclofenac (Voltaren) Ibuprofen (Motrin) Salsalate (Disalcid)
Medium	Fenoprofen (Nalfon) Ketoprofen (Orudis) Naproxen (Naprosyn) Sulindac (Clinoril) Aspirin
High	Azapropazone Meclofenamate (Meclomen) Indomethacin (Indocin) Piroxicam (Feldene) Tolmetin (Tolectin)

COX, cyclooxygenase.
*COX II inhibitors may delay healing of active ulcers.

TABLE 107.2. RELATIVE ULCEROGENIC RISK OF NSAIDS AND ASPIRIN

As mentioned previously, bicarbonate secretion into the unstirred mucous layer adjacent to the gastric mucosa maintains local pH close to 7 until the pH of the gastric contents falls below 2. Decreased local secretion of bicarbonate in both gastric and duodenal ulcer patients undermines this protective pH gradient. The decreased bicarbonate release typical of idiopathic duodenal ulcer disease can be reversed by cure of *H. pylori* infection, suggesting that it is a secondary phenomenon. On the other hand, pancreatic bicarbonate secretion is normal or increased in patients with ordinary duodenal ulcer disease.

Most patients with idiopathic duodenal ulcer disease have normal to slightly elevated rates of basal acid secretion. The average maximal acid secretion rate in duodenal ulcer patients is 50% to 100% higher than that in the normal population, and the average basal acid secretion rates also are higher than those in the normal population to about the same extent. The mild acid hypersecretion in idiopathic peptic ulcer disease is most likely due to antral-predominant *H. pylori* infection, which accounts for most cases.

Rarely, peptic ulceration does occur exclusively from excessive acid hypersecretion. Zollinger–Ellison syndrome is the prototypical example of such a condition. The continuously high rate of acid secretion accounts for the especially severe duodenal ulcers seen in patients with this syndrome. In addition, delivery of large acid loads to the small intestine results in an osmotic diarrhea, inactivation of pancreatic lipase with resultant fat malabsorption, and proximal small intestinal dilatation. Acid hypersecretion is the only important pathophysiologic factor in Zollinger–Ellison syndrome, and control of the acid hypersecretion with antisecretory drugs abolishes all the symptoms of gastrinoma. Hyperhistaminemia is another rare cause of basal acid hypersecretion. Patients with systemic mastocytosis or basophilic leukemia may have a clinical syndrome that resembles Zollinger–Ellison syndrome with acid hypersecretion due to excessive histamine stimulation of parietal cells but without hypergastrinemia. Idiopathic hypersecretion, defined as a basal acid output of more than 10 mmol per hour without hypergastrinemia or other obvious explanation, is much more common than Zollinger–Ellison syndrome. Most, if not all, of these persons have antral-predominant *H. pylori* infection. Vagal hyperactivity is an alternative cause of the hypersecretion in these patients.

Increased psychological stress has often been associated with gastrointestinal symptoms suggestive of peptic ulcer. It has been difficult to demonstrate any consistent pattern of environmental stress associated with new ulcer craters in patients on ulcer maintenance trials receiving either antiulcer drugs or placebos. It is likely that some subpopulations of ulcer patients have psychological trigger mechanisms that favor recurrence of ulcers. However, no mechanism for the psychological induction of ulcers has been defined. Symptoms of nonulcer dyspepsia, a form of functional bowel disease, often are worsened by stress and may be confused with stress-induced ulcer symptoms.

Stress ulcer is the term given to gastric mucosal lesions that arise in the setting of trauma, shock, hemorrhage, sepsis, burns, or other severe medical illness. The lesions may be diffuse or solitary ulcers or erosions. The body of the stomach rather than the antrum is involved most often. These lesions often bleed. The incidence of stress ulcer has decreased markedly in recent years. This improvement may be due to better management of hypovolemia and sepsis, but it also may reflect increased prophylactic use of antacids and antisecretory agents in patients at risk in intensive care settings. Gastric acid is required for stress ulcers to form, but patients rarely have acid hypersecretion. The formation of these lesions probably can be explained best by a combination of mucosal ischemia and systemic acidosis. Lesions do not form if the pH in the gastric lumen is kept above 3.5 to 4. Lesions appear to form only when mucosal blood flow is diminished. Acidosis increases the severity of the lesions, and correction of acidosis decreases their formation. The presence of bile acids, alcohol, or NSAIDs in the gastric lumen may accentuate the lesions. Also, cancer chemotherapeutic agents can enhance formation of such lesions.

PEPTIC ULCER

NATURAL HISTORY

Initial Healing

About 80% of cases of duodenal ulcer treated with H₂-receptor antagonists, H⁺,K⁺-ATPase inhibitors, antacids, sucralfate, or bismuth compounds heal within 4 weeks, and more than 90% heal within 12 weeks. Untreated patients with duodenal ulcer often have no symptoms within 2 weeks of diagnosis, but only 20% to 50% of untreated duodenal ulcers heal within 4 weeks. Treated patients become asymptomatic more rapidly than the ulcer heals. Patients with gastric ulcer take longer to heal than those with duodenal ulcer. Large ulcers take longer to heal than small ulcers, and smoking is the major environmental factor associated with slow ulcer healing. Young women and patients with NSAID-induced gastric ulcers exhibit especially rapid healing.

About 15% to 20% of duodenal ulcers and about 30% of gastric ulcers fail to heal after 4 to 6 weeks of treatment with H₂-receptor antagonists. Proton pump inhibitors produce somewhat better initial healing rates. About 50% of the unhealed ulcers heal after the treatment period is doubled. Less than 5% of patients are extremely resistant to treatment with standard medical therapy. Patients with Zollinger–Ellison syndrome fall into this category. Such patients often respond to more complete inhibition of acid secretion with higher doses of proton pump inhibitors. Occasionally, they may require surgery. Patients with a gastric ulcer that does not heal after 12 weeks should receive special consideration for surgery because of the possibility of an undiagnosed cancer.

Recurrence

Peptic ulcer disease is characterized by recurrent episodes of ulceration. About 75% of patients with a single prior episode of gastric or duodenal ulcer experience a second ulceration if *H. pylori* is not eradicated. The usual site of recurrence is close to the initial crater. Recurrences occur in about one-third, one-half, and two-thirds of patients within 3, 6, and 12 months of ulcer healing, respectively. Most of these recurrences are symptomatic, but about one-fourth are painless.

Factors that decrease the likelihood of ulcer relapse include first episode of ulcer, youth, female sex, discrete use of NSAIDs that are subsequently avoided, and not smoking. Maintenance therapy with nocturnal H₂-receptor antagonists reduce the recurrence rate from over two-thirds at 1 year to approximately one-fourth, although cure of *H. pylori* infection is the most important factor in preventing recurrence. Older studies showed that cure of *H. pylori* infection reduces the recurrence rate to less than 10%, although more recent studies in the United States have uncovered a curious form of peptic ulcer that recurs after effective cure of *H. pylori* infection in up to 25% of patients. Patients with a history of chronic, recurrent ulcer disease, smokers who continue to smoke, NSAID users who continue to use NSAIDs, and patients with endoscopic or radiographic evidence of a scarred duodenal bulb are more likely to have early recurrences.

Complications

Gastrointestinal hemorrhage is the most common complication of peptic ulcer disease and is the leading cause of death associated with ulcers. The incidence of bleeding in patients with peptic ulcer may be as high as 10% to 20%. This figure is difficult to establish because many ulcers are discovered only because of bleeding (i.e., patients present with bleeding de novo). Patients who have one episode of bleeding are more likely to have bleeding from recurrent ulcers than are patients who have experienced peptic ulcers without bleeding. In patients with recurrent symptomatic ulcer disease, the incidence of bleeding probably is less than 2% over 10 years. In contrast, up to one-third of patients with a single episode of bleeding have more bleeding within 1 or 2 years.

Ulcer bleeding is caused by erosion of the ulcer (diameter ≥0.5 mm) into an artery. About 80% of bleeding ulcers stop without specific treatment; the rest require either endoscopic hemostasis or surgery. There is some evidence that high doses of proton pump inhibitors decrease persistent or recurrent bleeding, but the usual antisecretory therapy has little or no effect. Twenty percent of patients with a bleeding ulcer that stops have recurrent bleeding within 2 weeks. The most useful endoscopic sign that predicts recurrent bleeding is the visible vessel, a segment of artery that protrudes into the base of the ulcer crater. Patients with this sign may benefit especially from prophylactic endoscopic hemostasis.

The mortality rate from bleeding peptic ulcers (for many years, about 8% to 10%) may now be starting to decline as a consequence of aggressive endoscopic management in recent years. The cause of death has also changed. Otherwise healthy patients rarely die of ulcer hemorrhage. Death most often occurs in older patients with one or more associated serious illnesses, such as cardiorespiratory failure, malignancy, or burns.

Recurrence of bleeding after healing of an actively bleeding ulcer also is common. This type of rebleeding may occur at any time but is most common in the first 2 years after an initial bleeding episode. Each episode of bleeding carries about a 30% to 40% risk of another bleeding episode in the patient's lifetime. Continued use of NSAIDs increases the chance of rebleeding. Recurrent bleeding can be decreased by diminishing acid secretion surgically or by long-term treatment with antisecretory drugs. *H. pylori* eradication also decreases the risk of recurrent bleeding.

Delayed gastric emptying can be caused either by mechanical obstruction to gastric outflow or by functional disturbances of gastroduodenal motility. In peptic ulcer disease, mechanical obstruction results from scarring or edema of the duodenal bulb or pyloric canal. Duodenal ulcer is the most common cause, but gastric ulcer, especially in the pyloric channel, may also cause obstruction. Acute antisecretory therapy may reduce edema and restore normal gastric emptying in some patients. Patients who do not respond rapidly and who do not develop normal gastric emptying within 2 or 3 days of continuous nasogastric suction and acid inhibition usually require surgical treatment.

Gastric outlet obstruction is a relatively rare complication of peptic ulcer disease in the United States, occurring in less than 2% of patients with duodenal or gastric ulcer. Recurrent obstruction is common in patients with a previous episode of obstruction managed by medical treatment. Many of these patients require surgical treatment.

Perforation, a dramatic complication of peptic ulcer disease, is relatively rare, affecting less than 2% of peptic ulcer patients. Although patients may develop de novo perforation, a history of ulcer symptoms is common. The average duration of symptoms before perforation is 5 years. Patients with Zollinger–Ellison syndrome are more likely to present initially with an ulcer complication such as perforation than are patients with idiopathic peptic ulcer disease. Penetration of ulcers into the pancreas may cause pancreatitis or pain that mimics pancreatitis. Leakage into the lesser sac can lead to the formation of an inflammatory mass or abscess.

Penetration or perforation can also lead to the formation of fistulae between the stomach or duodenum and nearby organs. Gastrocolic fistula may be secondary to gastric ulcer, but this complication is far more commonly due to malignant tumors. Fistulae may develop between the duodenum and the bile duct in patients with duodenal ulcer. Perforation almost always is treated surgically, but penetration may be treated medically unless a specific complication develops that requires surgical therapy.

CLINICAL PRESENTATION OF PEPTIC ULCER DISEASE

Peptic ulcer is a major consideration in the differential diagnosis of epigastric pain or discomfort. Although the characteristic pain is a dull ache in the epigastrium relieved by food or antacids, there are many variations. For example, duodenal ulcer pain is midepigastric in only about 80% of patients. About 15% of patients have right upper quadrant pain, and 5% have left upper quadrant pain. In addition, about 25% of duodenal ulcer patients have pain that sometimes radiates into the back, and up to 50% have heartburn in association with epigastric pain. Bleeding ulcers may be painless and manifest as hematemesis, melena, anemia, or even hematochezia. Patients with perforated ulcers typically present with severe generalized abdominal pain associated with signs of peritonitis (the acute abdomen). Patients with ulcer-induced gastric outlet obstruction may present with repeated episodes of vomiting, leading to dehydration and chloride depletion.

It is usually impossible to distinguish between duodenal ulcer and gastric ulcer by symptoms alone. The pain of both gastric and duodenal ulceration is typically located in the epigastrium and is episodic. Other features common to both gastric and duodenal ulcers include the intensity and quality of the pain, its radiation to the back (in about 25%), the high frequency of symptom relief with antacids and association with other symptoms such as bloating or belching (in about 50%).

However, the occurrence of certain features of peptic ulcer disease differs between duodenal and gastric ulcer patients. Duodenal ulcer pain typically occurs at night, especially within the first few hours of reclining. It is less common on arising. Food ingestion does not tend to induce duodenal ulcer pain and often relieves it. One-fourth to one-third of patients cannot relate their pain to any variable such as diet or time of day. About 50% of duodenal ulcer patients complain of intense pain at some time, but less than 20% describe the pain as “gnawing.” Duodenal ulcer pain characteristically occurs in clusters, interspersed with relatively symptom-free intervals but about 30% of patients with duodenal ulcer have pain almost every day. Anorexia, nausea, vomiting, and weight loss are not typically considered symptoms of uncomplicated duodenal ulcer, but surveys of duodenal ulcer patients find that between 25% and 50% of patients report these symptoms in various combinations. About 20% of patients with duodenal ulcer have increased appetite, possibly because food relieves their symptoms.

Symptoms that may suggest gastric ulcer are pain that occurs within 30 minutes after eating, continuous rather than episodic pain, anorexia, nausea, vomiting, and weight loss. These symptoms also are more common in gastric cancer. Heartburn is somewhat less common in gastric ulcer than in duodenal ulcer. Ulcers that lie in the pyloric channel are a subtype of gastric ulcer that are especially likely to produce food-induced symptoms, including pain, nausea, and vomiting. A history of NSAID ingestion is more common in patients with gastric ulcer than in those with duodenal ulcer, but nonspecific epigastric symptoms commonly occur with no ulceration at all in patients who take these agents.

The physical examination is not useful in establishing the diagnosis of uncomplicated peptic ulcer. Midepigastric tenderness is a common but nonspecific finding. The physical examination is useful to exclude other potential causes of epigastric pain, such as musculoskeletal tenderness, neuropathy, and abdominal masses. The succussion splash, a sign that the stomach contains excessive air and fluid, is suggestive of gastric outlet obstruction. Patients with free perforation of ulcers usually have abdominal rigidity and signs of generalized peritonitis. Patients with localized ulcer perforations may have more subtle and localized physical findings.

DIFFERENTIAL DIAGNOSIS OF PEPTIC ULCER

Because of the significant variation in presentation of patients with duodenal or gastric ulcer, no rigid set of symptoms and signs can be considered typical of an ulcer. The only reliable method of definitively diagnosing a gastric or duodenal ulcer, nonulcer dyspepsia, or gastric cancer is endoscopic or radiographic examination (see “Diagnosis of Peptic Ulcer Disease”). The differential diagnosis of peptic ulceration is thus an important consideration in all patients presenting with epigastric pain ([Table 107.3](#)).

Peptic ulcer disease (gastric and duodenal)
Nonulcer (functional) dyspepsia
Gastroesophageal reflux disease
Drug-induced dyspepsia and gastropathy
Gastric or duodenal tumors (benign, malignant)
Crohn's disease of the stomach and duodenum
Pancreatic disease (benign, malignant)
Hepatobiliary disease
Neuromuscular pain

TABLE 107.3. DIFFERENTIAL DIAGNOSIS OF DYSPEPSIA

Nonulcer Dyspepsia

Ulcerlike symptoms without evidence of an ulcer crater is known as nonulcer dyspepsia (NUD). This condition is at least as common as peptic ulcer and cannot be distinguished by history. The cause of NUD is unknown. Up to 50% of affected patients have delayed gastric emptying. However, there is a very poor correlation between changes in symptoms and changes in gastric emptying rates after administration of agents that accelerate gastric emptying; this suggests that motility disturbances may be an effect rather than a cause of the syndrome. Patients with NUD often are hypersensitive to balloon distention of the stomach, suggesting an important neural role in the pathogenesis of this condition. The diagnosis of NUD usually is applied to patients who have epigastric symptoms lasting for more than 4 weeks and in whom appropriate diagnostic evaluation, including upper gastrointestinal endoscopy, reveals no obvious cause for the pain. There are no definite clinicopathologic correlates for patients with NUD. Features that suggest NUD rather than peptic ulcer are onset at an earlier age, female sex, precipitation by food, daily occurrence, impaired sleep pattern, relative rarity of gnawing pain, and worsening of symptoms during periods of stress.

Attempted *H. pylori* eradication often is the initial approach to management of dyspeptic patients with positive *H. pylori* serology without further diagnostic workup. This treatment effectively prevents recurrent peptic ulcer but produces long-term benefit in only a minority of patients with *H. pylori*-positive NUD. Patients with NUD

often respond to antacids or H₂-receptor antagonists in about the same way as patients with peptic ulcer. This therapeutic approach may suffice for symptomatic treatment, but it does not provide useful diagnostic information or guidance for treatment if the pain recurs. Other drugs that may be useful are prokinetic drugs to increase gastric emptying and low doses of tricyclic antidepressants to reduce the pain threshold.

Gastroesophageal Disease

The cardinal symptom of reflux esophagitis is heartburn (also called pyrosis). Reflux pain may arise in the epigastrium, but it typically radiates into the chest. It is generally burning in nature, but it may also be felt as a constriction. Associated symptoms include regurgitation of food and acid into the mouth, difficulty swallowing (dysphagia), laryngeal or pulmonary symptoms (e.g., wheezing, coughing, hoarseness), and bleeding. Heartburn is typically caused by reflux of gastric juice (containing acid and activated pepsin) into the lower esophagus, but it may also be caused by reflux of bile or by local fermentation of ingested foodstuffs (as can occur in achalasia). Symptoms of heartburn are increased under conditions of increased abdominal pressure (e.g., during pregnancy, when bending over or straining), during food ingestion (food increases acid secretion and certain foodstuffs such as garlic, fat, and chocolate decrease lower esophageal sphincter tone), or when the person is supine rather than upright. Thus, heartburn commonly occurs at night, and it may awaken the person from sleep.

Distinguishing typical heartburn from the abdominal symptoms of peptic ulcer is generally not difficult because typical ulcer pain does not have a retrosternal radiation. However, up to 50% of ulcer patients (especially those with duodenal ulcer) also have heartburn. These patients are likely to have both esophageal reflux and peptic ulcer. Therefore, the presence of heartburn should not sway the physician away from considering a peptic ulcer.

Gastritis and Drug-Induced Dyspepsia

Except for the typical endoscopic findings that occur with erosive gastropathy due to NSAID ingestion, gastritis is a histologic diagnosis that requires tissue biopsy. Erythema found on endoscopic examination is insufficient for a diagnosis of gastritis, whether it occurs with or without abdominal pain. Moreover, a clinical diagnosis of gastritis cannot be made based on the presence of epigastric pain with or without a history of ingestion of noxious agents, such as alcohol or NSAIDs.

There appears to be a poor correlation between the amounts of NSAIDs ingested and the subsequent development of pain or mucosal disease. Endoscopic studies have shown that NSAID-induced mucosal disease occurs in up to 50% of patients, but most often the lesions are asymptomatic and of unclear clinical significance. Furthermore, NSAID-associated pain may or may not be associated with mucosal disease. The ulcerogenic potential of aspirin is less than that of certain NSAIDs (e.g., indomethacin and piroxicam) but is greater than that of ibuprofen ([Table 107.2](#)). Thus, the only sure way of determining whether NSAID use is the cause of epigastric pain in a particular individual is to discontinue the agent.

Many other drugs cause epigastric distress, nausea, and sometimes vomiting, often in the absence of endoscopic findings. Nausea and vomiting are symptoms that typically occur with digitalis or theophylline toxicity or after chemotherapy for various malignancies. Certain chemotherapeutic agents (e.g., 5-fluorouracil) typically cause mucositis, which may occur anywhere along the gastrointestinal tract. Acute epigastric pain may also result from acute gastric inflammation (gastropathy) after ingestion of other noxious agents such as alcohol. However, there also is no way of clinically distinguishing the pain of acute gastropathy from that of peptic ulceration without an endoscopy. It is important to obtain a complete recent drug history in all patients with epigastric pain.

H. pylori gastritis is associated with abdominal pain when there is either gastric or duodenal ulceration. However, the association between *H. pylori* gastritis and NUD is controversial, with the prevailing view that pain is generally not a typical feature of the chronic gastritis of *H. pylori* infection but that a small subgroup of patients with NUD may have *H. pylori* gastritis-induced symptoms.

Epigastric pain indistinguishable from that of peptic ulceration is a feature of certain specific infiltrative diseases of the stomach, including Ménétrier's disease (hypertrophic gastritis associated with protein-losing enteropathy), tuberculosis, syphilis, sarcoidosis, and eosinophilic granuloma of the stomach. These conditions all are diagnosed by endoscopic or surgical biopsy.

Gastrointestinal Neoplasia

Upper gastrointestinal cancer (especially gastric carcinoma) is found in less than 2% of patients with epigastric pain. Symptoms especially suggestive of gastric cancer include continuous pain, early satiety, a persistent sensation of a full stomach, pain increased by food, nausea, vomiting, and weight loss. Age is not useful in distinguishing the pain of benign from malignant gastric disease because both are most common in the elderly. Most gastric carcinomas are seen as infiltrative lesions that are easily recognized endoscopically or by barium radiography. A small proportion of patients present with gastric ulceration that can be difficult to distinguish from a benign gastric ulcer. Patients known to be achlorhydric almost never develop benign gastric ulcers. On the other hand, most patients with gastric carcinoma produce some gastric acid. Therefore, achlorhydria is a useful finding in patients presenting with gastric ulceration, indicating probable malignancy, but the presence of acid is not helpful in distinguishing benign from malignant disease. Malignant ulcers commonly have heaped-up irregular margins, but this also may occur with benign ulcers. Failure of a gastric ulcer to heal with standard ulcer treatment is believed to be relatively specific for malignant ulcer. Therefore, histologic examination of biopsies taken from the ulcer base and margins and endoscopic confirmation of complete healing is recommended to rule out malignancy for gastric ulcers that occur in a setting of chronic *H. pylori* gastritis. In contrast, duodenal ulcers are almost never malignant.

Gastric lymphoma also may cause ulcerlike symptoms or may present with symptoms of gastric outlet obstruction, including vomiting and electrolyte depletion. Some gastric lymphomas (maltomas or other gastric non-Hodgkin's lymphomas) appear to be related to *H. pylori* infection and may regress after the organism is eradicated. Other malignant lesions that cause gastric outlet obstruction include pancreatic carcinoma and primary carcinoma of the duodenum, which is exceedingly uncommon.

Crohn's Disease

Crohn's disease may involve any portion of the alimentary tract from lips to anus. However, gastroduodenal Crohn's disease is uncommon; when it does occur, antecedent disease is commonly elsewhere in the gastrointestinal tract. Rarely, patients with primary gastroduodenal Crohn's disease present with epigastric symptoms indistinguishable from peptic ulceration. Radiologic studies may be useful in distinguishing gastroduodenal Crohn's disease from typical peptic ulcer disease in patients with established Crohn's disease elsewhere. However, duodenal involvement may produce a radiographic appearance resembling chronic duodenal ulcer disease so that endoscopic biopsy is generally more helpful. Duodenal or gastric biopsies may reveal inflammation with granulomas.

Pancreatic Disease

Acute or chronic pancreatitis, pancreatic pseudocyst, and pancreatic carcinoma all may produce upper abdominal pain. Pancreatic pain usually radiates into the back, but it may be primarily epigastric. Alternatively, peptic ulcer pain also sometimes radiates to the back. For example, penetration of a duodenal ulcer into the pancreas may lead to back pain and even cause pancreatitis. Pancreatic disease always should be considered in the differential diagnosis of epigastric pain, especially before making the diagnosis of NUD.

Hepatobiliary Disease

Symptoms of cholecystitis, biliary colic, or hepatitis can usually be distinguished readily from those of peptic ulceration. However, the pain of peptic ulceration is occasionally located in the right upper quadrant pain. Furthermore, nausea and vomiting may accompany hepatobiliary disease in addition to peptic ulceration.

Neurologic Syndromes

Acute or chronic pain arising from diseases of the lower thoracic spine may refer to the anterior abdomen. Nerve entrapment at the border of the rectus abdominis sheath or in surgical scars can also cause chronic abdominal pain. Epigastric pain should be distinguished from pain in the ribs or costochondral cartilage. Neuritis from herpes zoster or diabetic mononeuritis multiplex may involve the epigastric region. Careful examination including attention to the thoracic cage and vertebrae usually reveals the nature of the pain in these situations.

DIAGNOSIS OF PEPTIC ULCER DISEASE

Routine laboratory studies are not generally useful in establishing a primary diagnosis of peptic ulcer disease, but they may be useful in defining the specific cause of an ulcer or in classifying genetic subtypes of ulcer. *H. pylori* testing is essential in all patients with documented ulceration because cure of the infection significantly reduces the likelihood of a subsequent recurrence. Fasting serum gastrin and acid secretory measurements are the major methods for identifying or excluding a gastrinoma or other hypersecretory state. Serum calcium measurement is a good screening test for the presence of MEN-I-associated hyperparathyroidism. Hemoglobin and hematocrit measurements are useful for monitoring chronic or recurrent ulcer bleeding. Ultimately, however, peptic ulceration can be diagnosed only by endoscopy or by a barium radiographic study.

Diagnosis of *Helicobacter pylori* Gastritis

The diagnosis of *H. pylori* gastritis may be made using either invasive or noninvasive methods (Table 107.4). Invasive diagnostic methods detect organisms either directly (e.g., by histologic identification with appropriate stains or bacterial culture) or indirectly (e.g., by rapid urease testing of biopsy specimens). Noninvasive methods detect organisms indirectly either by identifying a humoral immune response to the infection (e.g., by serum antibody testing) or by detecting metabolites of the bacterial enzyme urease (e.g., by urea breath testing). Recently, a direct noninvasive stool antigen test that identifies bacterial antigens in stool has also become available.

Test	Sensitivity (%)	Specificity (%)
Invasive		
Histology	95	<100 ^b
Culture	~60	100
Biopsy urease test	90-95	98-100
Noninvasive		
Serology ^c	95	95
Urea breath test	95-98	95-98
Stool antigen	95	95

^a Published values in clinical trials may be somewhat higher than those encountered in clinical practice.
^b Limited by observer error and histologic stains used.
^c Not useful for post-therapy cure determination.

TABLE 107.4. DIAGNOSTIC TESTS FOR *HELICOBACTER PYLORI* INFECTION^a

The gold standard for the diagnosis of *H. pylori* infection is identification of organisms on endoscopic biopsy (at least two antral specimens taken 3 to 5 cm from the pylorus). Gastritis is readily apparent on standard histologic slides stained with hematoxylin and eosin, but it may be difficult to identify organisms with certainty using standard stains. Special silver-based stains including Giemsa, Warthin Starry, and Genta stains provide adequate sensitivity and specificity for diagnosing the infection histologically. Studies evaluating these special staining techniques have shown an accuracy of almost 100%, although certain investigators believe that inter- and intraobserver variability may confound the detection of organisms histologically.

The most specific method of diagnosing *H. pylori* infection is culture of antral biopsy specimens. However, this method has not become routine in clinical practice because the organism is fastidious and false-negative results are common. Cultures may become more important in future clinical practice because the likelihood of encountering a resistant organism increases (at present, metronidazole resistance can be as high as 60% in certain populations and clarithromycin resistance as high as 10% or more).

Rapid urease testing of biopsy specimens is a highly effective method of detecting *H. pylori* infection that is independent of pathologic interpretation bias. These tests all contain urea-impregnated agar and a pH indicator leading to a change in color if urease is present in the biopsy specimen. The sensitivity and specificity of rapid urease testing are more than 90%.

Antral biopsies should always be obtained if an ulcer is identified during upper endoscopy. However, noninvasive testing should be the primary diagnostic approach in patients who do not need endoscopy. Serologic testing is simple and widely available. The major factor determining the accuracy of antibody testing is the specificity of the antigen used. Early *H. pylori* antibody assays using sonicated extract of *H. pylori* organisms suffered from cross-reactivity with other *Helicobacter*-like organisms. The HMCAP antigen has been shown to be highly specific and is used in a number of commercially available antibody tests. Serologic tests are highly sensitive and specific, but they cannot distinguish between a previously treated *H. pylori* infection and a currently active one. However, with no prior course of therapy specifically directed against *H. pylori* infection, a positive antibody test implies active infection, because spontaneous bacterial clearance is extremely rare and monotherapy with antibiotics given for other reasons generally fails to cure the infection. Quantitative serologic tests are available as laboratory-based enzyme-linked immunosorbent assays (ELISAs), but rapid qualitative office-based immunoprecipitation serologic tests are almost as accurate.

Office-based qualitative testing kits either use serum that requires centrifuged blood specimens or whole blood that requires only a fingerstick to provide a capillary tube of blood. These testing kits are potentially the diagnostic antibody tests of choice because of low cost and ease of performance, but they may not be as accurate as the serum tests. A potential limitation of all methods of antibody testing is the occasional patient who fails to generate a normal humoral immune response (less than 5% of patients).

The principle of urea breath testing relies on the fact that *H. pylori* organisms produce large amounts of urease. In the presence of *H. pylori* infection, ingested urea is acted on by bacterial urease releasing labeled carbon, which is absorbed, circulates as bicarbonate, and is exhaled as carbon dioxide. With no *H. pylori* infection, the ingested urea passes through the stomach, is absorbed in the small bowel, and is excreted unchanged in the urine. However, a fraction enters the colon and is metabolized to ammonia and carbon dioxide, so that urea breath testing is most accurate during the first hour after urea ingestion. Breath testing is especially useful for documenting cure of *H. pylori* gastritis after antibiotic therapy in addition to confirming active infection in patients who have negative antibodies.

Urea breath testing can be performed using two types of carbon labeling, the carbon-13 (¹³C) urea breath test and the ¹⁴C urea breath test. The ¹³C test is nonradioactive, but the ¹⁴C test available in the United States uses only 1 μCi of C¹⁴ providing a radiation exposure that is equivalent to 1/30 of a chest x-ray per test. C¹³ breath analysis requires a mass spectrometry unit that is expensive and not generally available although breath samples can be mailed to an off-site laboratory for analysis. ¹⁴C breath analysis is performed using a standard scintillation counter, which is available in most medical centers.

Stool antigen testing for *H. pylori* gastritis has also received approval by the Food and Drug Administration (FDA). Trials have shown this test to be extremely accurate for initial diagnosis and for confirming cure of *H. pylori* infection after antibiotics. The test identifies bacterial antigens in stool with an immunoprecipitation assay. Its cost is highly competitive, and it may become the noninvasive diagnostic modality of choice if patients demonstrate willingness to provide stool (instead of breath) for diagnosis.

H. pylori testing must be done without confounding factors that may cause false-negative results. For determination of cure, testing should not be performed any earlier than 4 weeks after completion of the antibiotic regimen. Testing earlier than 4 weeks cannot distinguish between antibiotic-induced suppression of infection and true cure. Furthermore, exposure to proton pump inhibitor medications, monotherapeutic antibiotic regimens, sucralfate, or bismuth compounds may also suppress an infection sufficiently to cause a false-negative test. These caveats apply similarly to biopsy and breath testing methods.

Fasting Serum Gastrin Measurements

Radioimmunoassay measurement of serum or plasma gastrin should be made in patients in whom gastrinoma is suspected on clinical or genetic grounds. Examples include duodenal ulcer patients with hypercalcemia or a family history of MEN-I, with suspected or documented gastric acid hypersecretion (unexplained diarrhea or enlarged gastric folds), with ulcers refractory to ordinary medical management and any patient in whom ulcer surgery is planned.

Normal fasting serum gastrin concentrations are less than 100 pg per milliliter in most laboratories. Values are much higher in most patients with gastrinoma, but

some gastrinoma patients have only a modest elevation of serum gastrin levels. Hypergastrinemia may be appropriate (i.e., a physiologic response to absent gastric acid secretion) or inappropriate (i.e., in the presence of gastric acid secretion; [Table 107.5](#)). Prolonged neutralization of gastric contents interrupts the normal inhibition of gastrin release by luminal acid and leads to increased serum gastrin and eventually to hyperplasia of G cells. Potent antisecretory drugs, including H₂-receptor antagonists and H⁺,K⁺-ATPase inhibitors, are the major causes of appropriate hypergastrinemia. H₂-receptor antagonists typically cause only mild elevations that do not persist for more than 24 hours.

Appropriate Hypergastrinemia
Antisecretory therapy (H ₂ -receptor antagonists or proton pump inhibitors)
Atrophic gastritis (with or without pernicious anemia)
Vagotomy
Chronic renal failure
Chronic <i>Helicobacter pylori</i> infection (pangastritis)
Inappropriate Hypergastrinemia
Zollinger-Ellison syndrome (gastrinoma)
Chronic <i>H. pylori</i> infection (antral predominant)
Retained antrum syndrome (after Billroth II gastrectomy)
Massive intestinal resection (transient)
Gastric outlet obstruction (reversible)

TABLE 107.5. DIFFERENTIAL DIAGNOSIS OF HYPERGASTRINEMIA

The most common natural cause of appropriate hypergastrinemia is atrophic gastritis, especially the type associated with pernicious anemia. Other common causes of appropriate hypergastrinemia are surgical vagotomy, chronic renal failure, and the chronic pangastritis sometimes associated with *H. pylori* infection. Gastrinoma is the prototypical cause of inappropriate hypergastrinemia, but other causes exist as well. The most important of these is chronic antral-predominant *H. pylori* infection in which prolonged low-grade hypergastrinemia leads to antral G-cell hyperfunction. The retained antrum syndrome should also be considered in patients who previously have undergone ulcer surgery (specifically a Billroth II resection).

Most gastrinoma patients have an abnormal serum gastrin response to intravenous secretin injection. After a bolus injection of 2 units per kilogram of secretin, a prompt increase in serum gastrin of more than 200 pg per milliliter occurs in 87% of patients with gastrinoma. Similar increases are rarely obtained in patients with hypergastrinemia from other causes including achlorhydria, which highlights the fact that gastrinoma is best diagnosed by measuring serum gastrin and acid secretory measurements at the same time to confirm inappropriate hypergastrinemia.

Acid Secretory Studies

Measurements of basal and stimulated gastric acid output can be made directly by nasogastric intubation and pentagastrin stimulation. Absence of acid after stimulation virtually excludes the diagnosis of peptic ulcer because it signifies true achlorhydria. MAO of less than 10 mmol per hour after pentagastrin stimulation is rare in patients with duodenal ulcer, but it does not rule out gastric ulcer in which the primary defect is due to a loss of mucosal cytoprotection. Increased acid output levels occur in about one-third of patients with duodenal ulcer. Increased basal acid output to above 10 mEq per hour is found in almost all patients with gastrinoma. However, most patients with basal acid output levels of more than 10 mEq per hour have idiopathic hypersecretion. Idiopathic hypersecretion is generally distinguished from gastrinoma by a normal serum gastrin level. Increasing the diagnostic threshold for gastrinoma to a basal acid output of 15 mEq per hour improves the diagnostic specificity but reduces the sensitivity of acid secretory testing.

Endoscopy

Upper gastrointestinal endoscopy permits direct visual examination of the esophageal, gastric, and proximal duodenal mucosa. Ulcers are seen as depressions with white or yellow bases surrounded by normal gastric or duodenal mucosa, often with erythematous or edematous edges. The sensitivity and specificity of endoscopic examination for the diagnosis of gastric and duodenal ulcers are over 90% in the hands of experienced endoscopists. Endoscopic criteria distinguishing ulcers from erosions include the appearance of depth and a size over 5 mm. Upper gastrointestinal endoscopy provides an opportunity to rule out other structural disease that may cause abdominal pain (e.g., erosive esophagitis and gastric cancer) and permits access for endoscopic biopsy of the gastrointestinal mucosa (i.e., to identify malignancy, Barrett's metaplasia, infiltrative gastropathies, Crohn's disease, or *H. pylori* infection). Material can also be obtained for culture.

Radiographic Examination

Most gastric and duodenal ulcers can be diagnosed by ordinary barium radiographic examinations. The greatest precision can be achieved by optimizing the radiographic technique and by using double-contrast radiography. Radiographic examination is somewhat less accurate than endoscopy for the diagnosis of small ulcers, especially those in scarred duodenal bulbs. Radiography is especially useful for identifying infiltrative diseases, such as lymphoma or linitis plastica and extrinsic compression of the stomach and duodenum by mass lesions.

TREATMENT OF PEPTIC ULCER DISEASE

Nonspecific Measures

Dietary manipulations are not of proven benefit in peptic ulcer disease. Milk and cream diets used in the past may have been harmful, because milk is a strong stimulant for acid secretion and cream can cause hyperlipidemia. High-fiber diets may be of modest benefit. Bland diets have no rationale or effectiveness and should not be prescribed for ulcer treatment. Because smoking is associated with poor healing and increased ulcer recurrence rates, discontinuation of smoking is a reasonable adjunct to ulcer treatment. However, no study has yet demonstrated a specific benefit in this approach. The role of alcohol restriction in patients with documented peptic ulcer is controversial. Patients with alcoholic cirrhosis have a higher rate of duodenal ulcer than does the general population, but ingestion of 1 to 2 ounces of alcohol per day by noncirrhotic persons does not adversely affect healing. However, heavy alcohol intake may increase the rate of ulcer recurrence after initial healing.

Discontinuation of aspirin or NSAIDs is important both for ulcer healing and for reducing recurrence rates. They should be replaced by acetaminophen, if possible. If they cannot be discontinued, an NSAID with relatively low ulcerogenic potential, such as ibuprofen, should be used. Studies are currently underway regarding specific COX-2 inhibitor NSAIDs that are likely to have a lower risk for peptic ulcer complications. Other measures that may decrease ulcer formation in NSAID-dependent patients are *H. pylori* eradication and chronic treatment with misoprostol or acid-inhibiting drugs.

Cure of *Helicobacter pylori* Infection

Cure of *H. pylori* gastritis accelerates the healing of *H. pylori*-associated duodenal and gastric ulcers, greatly diminishes the likelihood of ulcer relapse and may also decrease the likelihood of ulcer complications. Thus, effective antibiotic therapy in patients with active or remote peptic ulcers cures the disease as opposed to the use of maintenance antisecretory therapy which only limits ulcer diatheses by controlling acid output ([Fig. 107.7](#)). Recent studies in the United States have found that peptic ulcers may recur after effective cure of *H. pylori* infection in up to one-fourth of patients.

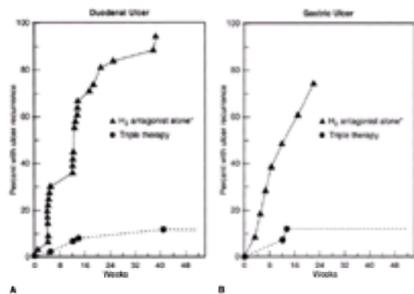

FIGURE 107.7. A: Life-table recurrence of duodenal ulcers for the year after successful healing with H₂-antagonist alone or triple therapy plus H₂-antagonist. **B:** Life-table recurrence of gastric ulcers for the year after successful healing with H₂-antagonist alone or triple therapy plus H₂-antagonist. (From Graham DY, Lew GM, Klein PD, et al. Effect of treatment of *Helicobacter pylori* infection on the long-term recurrence of gastric or duodenal ulcer: a randomized, controlled study. *Ann Intern Med* 1992;116:705–708, with permission.) Recent US data have suggested that the recurrence rate after cure of *H. pylori* infection may be somewhat higher (approaching 20%).

Evidence in support of anti-*H. pylori* therapy for other *H. pylori*-associated conditions also exists. For example, effective antibacterial therapy in patients with gastric lymphoma (90% of whom are infected with *H. pylori*) causes tumor regression in about 50% without the need for chemotherapy. In addition, many authorities recommend therapy for young *H. pylori*-positive undifferentiated dyspeptic patients without significant risk factors for serious underlying disease (i.e., no bleeding, dysphagia, weight loss, or anemia). The rationale for this approach is that it definitely benefits the 15% who have ulcers, and it may benefit some of the remainder who likely have functional pain, thus avoiding upper endoscopy in those who respond. The downside of this approach is that the precise cause of the pain may not be elucidated, that other non-*H. pylori*-associated conditions (e.g., Barrett's esophagus) may be missed, that antibiotic resistance may become a problem, and that this approach may not be cost-effective in the long term because patients may ultimately need endoscopy anyway. Because a relation between NUD and *H. pylori* is not generally accepted, most authorities would not favor treating nonulcer dyspeptics with antibiotics until all other possible causes for their dyspepsia have been excluded.

Further indications for anti-*H. pylori* therapy are somewhat controversial. These include elderly infected patients who require NSAIDs for long-term arthritic complaints and persons at significant risk for gastric antral cancer (e.g., persons with a strong family history of gastric cancer, persons from high-risk areas, or persons with previously recognized premalignant conditions diagnosed on endoscopic evaluation for some other indication). The prevailing thought is that there is insufficient evidence to recommend therapy for esophageal reflux patients who require maintenance proton pump inhibitor therapy (both conditions may predispose to atrophy but whether this is of any concern or not has not yet been shown). Despite these areas of controversy, there is clear agreement that one should test for *H. pylori* infection only if one is planning on treating a patient with a positive result.

The optimal therapeutic regimen for curing *H. pylori* infection is not yet established, but consensus is emerging that triple-therapy combinations should be used to ensure adequate cure rates. In addition to having a cure rate of over 90%, the ideal regimen should be simple and easily tolerated and have a low likelihood of inducing bacterial resistance. Standard triple therapy with metronidazole (250 mg t.i.d.), a bismuth compound (e.g., two chewable Pepto-Bismol tablets q.i.d.), and tetracycline (500 mg q.i.d.) with meals (with standard doses of antisecretory therapy to heal ulcers as well) provides excellent results. The cure rate after completion of 14 full days of triple therapy was as high as 95% in controlled trials. In clinical practice, however, the true cure rate is lower because this regimen is poorly tolerated and patient compliance is a significant problem. Tetracycline can be replaced with amoxicillin (2 g per day in divided doses) for an improved side-effect profile, although efficacy is sacrificed slightly by making this substitution. Substituting clarithromycin instead (500 mg t.i.d.) may improve the side-effect profile without reducing overall efficacy. The FDA has approved a blister pack containing all the drug components of standard triple therapy (including the antisecretory agent for ulcer healing) under one label, called Helidac (Proctor & Gamble) with eradication rates of 77% to 82%, as detailed in the product labeling. Whether this packaging results in improved compliance is unknown.

An important component of standard triple therapy is bismuth. Bismuth has no efficacy as monotherapy for *H. pylori*, but it is extremely useful in combination regimens. Resistance to bismuth preparations has not been reported. Thus, by reducing the overall *H. pylori* burden significantly, this highly effective lumenally active agent may limit the likelihood of resistance developing to other regimen components during therapy. Triple-therapy regimens consisting of 400 mg b.i.d. of ranitidine bismuth citrate (Tritec) with clarithromycin (500 mg q.i.d.) and a second antibiotic (metronidazole or amoxicillin) also have excellent cure rates and are better tolerated than standard triple therapy.

Proton pump inhibitor–based triple therapy regimens are arguably the current regimens of choice for *H. pylori* therapy. The rationale for combining antibiotics with proton pump inhibitors such as omeprazole or lansoprazole is that the proton pump inhibitors appear to have independent activity against *H. pylori* organisms in vitro, possibly secondary to increasing gastric pH. Proton pump inhibitor therapy alone does not cure *H. pylori* gastritis. The FDA has approved proton pump inhibitor–based triple-therapy regimens consisting of lansoprazole (30 mg b.i.d.) or omeprazole (20 mg b.i.d.) combined with two antibacterial agents; amoxicillin (1 g b.i.d.); clarithromycin (500 mg b.i.d.); or metronidazole (500 mg b.i.d.). For example, 14 days of lansoprazole (30 mg b.i.d.) with amoxicillin (1 g b.i.d.) and clarithromycin (500 mg b.i.d.) was approved based on a cure rate of 86% to 92%. The MOC regimen, consisting of metronidazole (500 mg b.i.d.), omeprazole (20 mg b.i.d.), and clarithromycin (250–500 mg b.i.d.) also appears to be effective (over 90% cure rate) and well tolerated. A 7-day course of treatment may be sufficient.

Metronidazole should be avoided in patients who previously received metronidazole monotherapy for other indications (e.g., for vaginitis), because pretreatment resistance may be important in limiting efficacy. Metronidazole-containing regimens should also be avoided in patients who drink alcohol and who are unlikely to stop alcohol intake during treatment to avoid the possibility of a disulfuram effect from therapy. Little is known about the possible effect of clarithromycin resistance on the efficacy of second-generation triple-therapy regimens. Clarithromycin resistance is relatively uncommon at present but in time, with widespread use of clarithromycin monotherapy for other indications (e.g., respiratory tract infections), resistance may become more of a problem. In this situation, clarithromycin could be replaced with amoxicillin, although overall efficacy may be reduced. Amoxicillin resistance has been described but is extremely rare. An anti-*H. pylori* regimen for patients who have failed therapy with other regimens has been described by European investigators to include standard triple therapy plus omeprazole (so-called quadruple therapy). There is little experience with this regimen in the United States.

Monotherapy or dual therapy for *H. pylori* infection should be avoided (even though certain proton pump inhibitor dual therapy regimens with clarithromycin have been approved by the FDA). The most effective single agent appears to be clarithromycin with an efficacy of less than 50% (in doses of 500 mg q.i.d.). In addition to being relatively ineffective, these regimens run the risk of inducing organism resistance.

There is no evidence yet that widespread treatment of all patients with documented *H. pylori* infection leads to the elimination of, or even a significant reduction in, the worldwide prevalence of this ubiquitous infection. For worldwide eradication of *H. pylori* infection to occur, vaccine development will need to be successful. Currently, there are many problems involved in developing effective vaccines for *H. pylori*; nevertheless, ongoing work is promising.

Medical Management of Peptic Ulcer Disease

Several drugs are effective for healing active peptic ulcers. Some may also decrease the rate of ulcer recurrence if given on a continuous basis after healing. Drugs that are effective fall into three major categories: those that inhibit acid secretion, those that neutralize acid secretion, and those that improve cytoprotection resulting in a local environment that permits healing to occur ([Table 107.6](#)).

Histamine₂-receptor antagonists (cimetidine, ranitidine, famotidine, nizatidine)
 Proton pump inhibitors (omeprazole, lansoprazole)
 Antacids
 Prostaglandins (misoprostil)
 Anticholinergics
 Sucralfate
 Bismuth formulations

TABLE 107.6. ANTIULCER THERAPY

H₂-Receptor Antagonists

Antagonism of the H₂-receptor on the gastric parietal cell markedly inhibits basal and stimulated gastric acid secretion. H₂-receptor antagonists including cimetidine, ranitidine, famotidine, and nizatidine all have similar activities but vary in potency. However, they are nearly equipotent in prescribed dosage formulations. A single dose of a H₂-receptor antagonist can inhibit acid secretion for 6 to 12 hours. H₂-receptor antagonists can produce prolonged inhibition if given as continuous intravenous infusions.

Oral H₂-receptor antagonist regimens for duodenal ulcer disease have evolved from multiple daily doses to a single nocturnal administration. A single nocturnal dose of drug produces the same healing response as do multiple doses. The most frequently recommended nocturnal doses that produce equivalent healing rates are 800 mg cimetidine (Tagamet), 300 mg ranitidine (Zantac) or nizatidine (Axid), and 40 mg famotidine (Pepcid). Night-time administration inhibits nocturnal acid secretion but has no effect on secretion during the subsequent day. Experience with treatment of duodenal ulcer has indicated that nocturnal acid has a special role in duodenal ulcer pathogenesis.

After 4 weeks of treatment, about 80% of duodenal ulcer patients treated with H₂-receptor antagonists have complete healing of their ulcers, compared with about 40% healing in patients treated with placebo. About 50% of the remaining patients who have not healed at 4 weeks heal after another 2 to 4 weeks of treatment. Regardless of healing, most patients become asymptomatic within 2 weeks of treatment with active drug or placebo. The optimal H₂-receptor antagonist dosage schedule for treating gastric ulcers has not been established with certainty. Gastric ulcers heal more slowly than duodenal ulcers do, and most authorities recommend 6 to 8 weeks of therapy. With gastric ulcer, the healing rate is related to the size of the ulcer. Patients with a gastric ulcer larger than 1 cm may require 3 months or more for complete healing. The effectiveness of H₂-receptor antagonists for the management of acutely bleeding ulcers has not been shown conclusively. There is little, if any, effect on the percentage of patients with acute bleeding who stop bleeding spontaneously, even with high doses of drugs given by continuous intravenous infusion.

Maintenance therapy for recurrent ulcer prevention is also usually given as a single nocturnal dose. However, the dose itself is generally reduced by 50% (i.e., 400 mg cimetidine, 150 mg ranitidine or nizatidine, and 20 mg famotidine). Prophylactic H₂-receptor antagonists reduce the recurrence rate at 1 year from over two thirds to about one fourth of patients (Fig. 107.8). The effects of maintenance therapy on the occurrence of complications have not been established fully, but decreased incidence of recurrent bleeding from ulcers has been reported. Certain hypersecretory states, including Zollinger–Ellison syndrome (see text that follows), require more frequent administration of high-dose H₂-receptor antagonists (up to 7 g per day in divided doses up to every 4 hours). Patients with severe reflux esophagitis may also require multiple daily doses for good symptomatic responses. These patients and patients with Zollinger–Ellison syndrome may be managed more effectively with omeprazole or lansoprazole, longer-acting H⁺,K⁺-ATPase inhibitors.

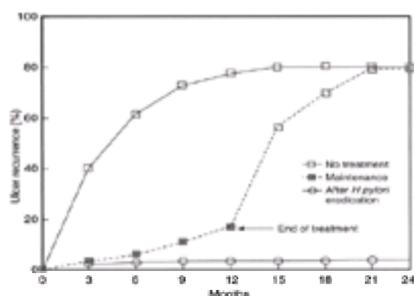

FIGURE 107.8. Recurrence rates for patients with healed duodenal ulcer are high during the first year after healing, but recurrences can be suppressed by nightly H₂-receptor blocker treatment. As soon as the H₂-blocker treatment is stopped, ulcers recur at their previous rapid rate.

The side effects of single nocturnal doses of H₂-receptor antagonists are minimal. Used in larger doses, such as for treatment of Zollinger–Ellison syndrome, cimetidine has some side effects not usually associated with the other agents. These include alterations in drug metabolism resulting from inhibition of hepatic production of cytochrome P-450 enzymes, gynecomastia due to a direct antiandrogen effect of the drug, and possibly increased confusion in older patients or metabolic encephalopathy in hospitalized patients with serious liver or kidney disease. All H₂-receptor antagonists can elicit allergic reactions, such as drug rash and hepatitis, but these are rare. Thrombocytopenia has been reported as well, but its clinical significance is small.

H⁺,K⁺-ATPase (Proton Pump) Inhibitors

Omeprazole (Prilosec) and lansoprazole (Prevacid) are two H⁺,K⁺-ATPase inhibitors that are FDA-approved for use in patients with peptic ulcer disease in the United States. Additional H⁺,K⁺-ATPase inhibitors that may soon become available for general use are rabeprazole and pantoprazole. H⁺,K⁺-ATPase inhibitors have been used extensively in hypersecretory forms of peptic ulcer disease (in addition to gastroesophageal reflux disease). H⁺,K⁺-ATPase inhibitors are substituted benzimidazoles, which bind covalently to lumenally active proton pumps via disulfide bonds at one of three essential transmembrane cysteines in the fifth or sixth transmembrane portion of the a subunit of the enzyme. This inactivates the parietal cell acid pump irreversibly with inhibition of all types of acid stimulation (Fig. 107.9). H⁺,K⁺-ATPase inhibitors have a prolonged half-life approximately equal to the time taken to regenerate intracellular H⁺,K⁺-ATPase, about 48 to 72 hours.

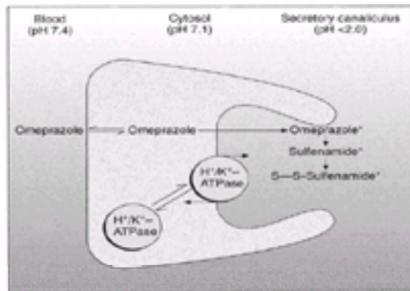

FIGURE 107.9. Action of omeprazole on a gastric parietal cell. With the appropriate stimulus, the H^+,K^+ -ATPase can move from cytoplasmic vesicles (where it is inactive) to the secretory canaliculus membrane (where it is active). Omeprazole enters the cytoplasm freely. In the canaliculus, it is protonated and converted to a sulfenamide, which then is bound covalently by disulfide bonds to H^+,K^+ -ATPase and inhibits secretion. (From Maton PN. Omeprazole. *N Engl J Med* 1991;324:965–975, with permission.)

Proton pump inhibitors cause more rapid healing of duodenal and gastric ulcers than H_2 -receptor antagonists and are now more commonly used than H_2 -receptor antagonists for primary ulcer treatment. For example, ulcer healing rates after 2 weeks of therapy with proton pump inhibitors (omeprazole 20 mg or lansoprazole 30 mg once daily in the morning before breakfast) are roughly equal to the 4-week healing rates produced by H_2 -receptor antagonists. Their efficacy in H_2 -receptor antagonist–refractory duodenal ulcers has also been shown. The long-lasting profound inhibition of acid by omeprazole or lansoprazole has made these agents the drugs of choice for the treatment of Zollinger–Ellison syndrome. The therapeutic goal is to reduce acid secretion rates at less than 10 mEq per hour in patients with intact stomachs (less than 5 mEq per hour in those with prior gastric surgery). This generally requires twice-daily dosing. Proton pump inhibitors are also more effective than H_2 -receptor antagonists for the treatment of erosive esophagitis.

Proton pump inhibitors have a better side-effect profile than do H_2 -receptor antagonists. Hypochlorhydria-induced hypergastrinemia is more pronounced with proton pump inhibitors than with H_2 -receptor antagonists because of a more profound and longer inhibition of gastric acid output. Achlorhydria causes hypergastrinemia as a consequence of loss of feedback inhibition of gastric mucosal G cells. In rats, high-dose H^+,K^+ -ATPase inhibitor therapy given for 2 years produces severe ECL cell hyperplasia associated in some instances with carcinoid tumors of the stomach. In humans treated for up to 11 years, changes in ECL cells are minimal. ECL cell carcinoids occur in humans under only two hypergastrinemic conditions: MEN-I syndrome with Zollinger–Ellison syndrome and pernicious anemia. Other side effects of proton pump inhibitor used for brief periods to heal peptic ulcers are not significant.

Antacids

Antacids were the first agents proved to be more effective than placebo for acute duodenal ulcer healing. They have been used for centuries to treat dyspepsia. Development of H_2 -receptor antagonists led to some loss of enthusiasm for antacids. A major objection to antacids was the high incidence of diarrhea caused by the large doses considered necessary for adequate neutralization of acid. Low-dose antacids have been found to heal ulcers effectively, a finding that could lead to an increased use of antacids as single agents for ulcer treatment because of the low cost and acceptable side effects of lower doses.

Most antacids are combinations of magnesium and aluminum hydroxides. The most prominent side effect of magnesium is diarrhea. The most obvious side effect of aluminum is constipation, but other metabolic effects may be more important. Aluminum hydroxide can lead to phosphate depletion and may cause metabolic bone disease in patients with renal failure. Calcium carbonate is an effective antacid, but it may cause hypercalcemia and acid rebound due to stimulation of gastrin release if large doses are used.

When antacids are given during fasting, neutralization of gastric pH is brief, lasting less than 30 minutes. On the other hand, antacids given 1 hour after meals can produce gastric neutralization for the next 2 hours. An additional dose 3 hours after a meal can add another hour of neutralization. Small doses of antacid, such as two antacid tablets four times a day, are as effective as higher doses. This dose of antacid does not neutralize gastric acidity well, despite its efficacy for healing. Since all low-dose antacid regimens shown to heal ulcers have contained aluminum, the aluminum rather than the neutralization may be the important therapeutic factor. Low-dose antacid therapy is effective for duodenal or gastric ulcers. Tablets are as effective as liquids.

Prostaglandins

Prostaglandins are best known for their cytoprotective properties, but they may act primarily as acid inhibitors. Misoprostol, a prostaglandin E_1 analogue, inhibits acid secretion by activating the adenylate cyclase inhibitory guanosine triphosphate–binding protein, G_i . Prostaglandins inhibit direct mucosal damage produced by aspirin or alcohol in rats. The major beneficial effect may be to maintain mucosal blood flow rather than to prevent damage to the surface epithelial cells. However, prostaglandins may have a special protective action on damage produced by NSAIDs. The healing rates of peptic ulcer produced by prostaglandins and by doses of H_2 -receptor antagonists that inhibit acid secretion to a similar extent are about equal, but these doses of prostaglandins produce abdominal cramps and diarrhea in many patients. Another potential effect that arouses concern is the ability to cause uterine contraction and thus induce abortion.

Anticholinergic Agents

Anticholinergic drugs that inhibit acid secretion have been available for many years. The maximal inhibition of acid secretion produced by these drugs is only about 30% to 40%. These agents also have side effects that reduce their acceptability to patients, the most common being dryness of the mouth because of inhibition of salivary secretion. Used alone, ordinary anticholinergic agents are not recommended for ulcer treatment. They have been used as adjuncts to other agents, especially H_2 -blockers, in patients with gastric acid hypersecretion that is difficult to control with a single agent. This situation used to occur commonly in patients with Zollinger–Ellison syndrome but is now managed more effectively with proton pump inhibitors.

Sucralfate

Sucralfate is an aluminum sulfate disaccharide that has minimal acid-neutralizing capacity, does not alter acid or pepsin secretion, but is effective for ulcer treatment. Its mechanism of action is unknown, but it is presumed to act locally on the gastric and duodenal mucosa. Possible mechanisms include binding to the ulcer base, local neutralization of pepsin, stimulation of mucosal prostaglandin synthesis, and local effects of the aluminum component. No specific side effects have been noted. Sucralfate and H_2 -receptor antagonists produce similar rates of ulcer healing. The only apparent disadvantages to sucralfate are the need to give it at least twice a day, the large size of the tablet, and the lack of *H. pylori* eradication regimens that include sucralfate.

Bismuth Formulations

Colloidal bismuth, formulated as tripotassium dicitratobismuthate, can produce ulcer healing rates as high as those of other ulcer treatments. Periods of remission after ulcer healing may be longer after bismuth treatment than after H_2 -blockers. The mechanisms for ulcer healing by bismuth are unclear but may include its known antibacterial effect against *H. pylori*. Other bismuth compounds, including bismuth subsalicylate, share this antibacterial effect. Regimens that include bismuth plus one or more antibiotics have been effective in eradicating *H. pylori* infections, although bismuth compounds alone rarely produce true eradication. Bismuth compounds also appear to have mucosal protective effects that are independent of antibacterial effects. Bismuth compounds do not inhibit acid secretion. One major side effect of bismuth is blackening of the tongue and stool. More serious side effects could result from absorption of bismuth into the circulation. Colloidal bismuth compounds are absorbed poorly, and blood levels rarely approach toxic concentrations; however, bismuth is excreted into the urine and stool for several weeks after treatment is stopped.

Surgical Management of Peptic Ulcer Disease

Some of the complications arising from ulcer disease require surgical treatment. The most definite indications for surgery are hemorrhage not responsive to medical management (including endoscopic hemostasis), gastric outlet obstruction not reversed by medical management, perforation, and malignancy. Other potential indications for surgery include recurrent episodes of self-limited hemorrhage, potentially resectable gastrinoma (unresponsiveness to medical therapy is extremely uncommon in the proton pump inhibitor era), and symptomatic ulcers in patients who are unwilling to take or are refractory to medical therapy (especially smokers).

Partial or Total Gastrectomy

The most effective operation for treatment of gastric ulcer is simple antrectomy. The major goal of surgery for gastric ulcer is to remove the region of the stomach most affected by gastritis and susceptible to ulceration. Decreasing acid secretion is a secondary goal. Vagotomy is unnecessary for treatment of ordinary gastric ulcer, but it may be useful in treating distal antral ulcers and pyloric channel ulcers that biologically resemble duodenal ulcer. The stomach usually is anastomosed directly to the duodenum (a Billroth I anastomosis). In most cases, the gastric ulcer can be included in the resection. When it is located high in the stomach, the ulcer may need to be resected separately, or a bleeding site may need to be oversewn.

Partial gastric resection also is effective for treatment of duodenal ulcer. The goal of surgery for duodenal ulcer is to decrease the amount of acid emptied from the stomach into the duodenum or jejunum. The rate of recurrence is lower if resection is combined with vagotomy. The amount of stomach resected usually is more than the antrum alone, and the operation is known as a *subtotal gastrectomy* rather than an antrectomy. Anastomosis may be performed with a Billroth I (gastroduodenal) or a Billroth II (gastrojejunal) anastomosis.

Total gastrectomy is the treatment of choice for patients with Zollinger–Ellison syndrome unresponsive to medical management, but this is rarely required in the proton pump inhibitor era. A better surgical option for carefully selected gastrinoma patients (non–MEN-I patients with unifocal, nonmetastatic primary tumors) is local tumor resection. This nongastric approach to gastric acid hypersecretion has low morbidity and can lead to cure, defined as normalization of serum gastrin levels, negative secretin testing, and negative imaging in up to 50% of patients. Total gastrectomy is also used for some patients with more than one recurrent ulcer despite a prior subtotal gastrectomy. However, postoperative symptoms and complications tend to be greater for total than for subtotal gastrectomy.

Vagotomy

Vagotomy removes the cephalic phase of gastric secretion and is one of the oldest forms of surgical treatment for ulcer. It may be performed as the only operation for treatment of duodenal ulcer, or it may be combined with a subtotal gastrectomy. Truncal vagotomy involves cutting both major trunks of the vagus nerve, either in the abdomen just below the diaphragm or in the chest. This operation impairs normal gastric emptying and must be combined with a second procedure to enhance emptying, either pyloroplasty or gastrojejunostomy. Highly selective vagotomy minimizes the side effects of vagotomy caused by the need for an emptying procedure and by gastric and intestinal vagal denervation. This type of vagotomy is also known as a proximal gastric vagotomy or a parietal cell vagotomy. Individual branches of the vagus nerve that innervate the stomach proximal to the antrum are dissected along the blood vessels and cut. If performed properly, this operation causes a decrease in acid secretion similar to that achieved with truncal vagotomy and does not require a separate procedure to enhance gastric emptying.

Closure of Perforation

Perforated ulcers often require only simple closure with an omental patch. Sometimes closure is combined with a more definitive operation, such as vagotomy. Bleeding ulcers not included in resections can be oversewn to achieve hemostasis in the operating room.

Complications of Ulcer Surgery

Recurrent ulceration after ulcer surgery is of major concern. The operation associated with the lowest rate of symptomatic ulcer recurrence, other than total gastrectomy, is subtotal gastrectomy combined with vagotomy. Recurrences occur in less than 5% of such patients. They tend to occur early and are rare more than 2 years after surgery. The trade-off for lower recurrence rates is the higher morbidity associated with motility disorders because of the more extensive resection. Truncal vagotomy with pyloroplasty and highly selective vagotomy are associated with higher recurrence rates than is resection plus vagotomy. Recurrences occur at a relatively steady rate of about 1% per year. Unless the surgeon is especially experienced with the operation, highly selective vagotomy tends to produce higher recurrence rates than truncal vagotomy.

The rate of recurrence of bleeding in patients who undergo surgery for bleeding ulcers is higher than the rate of recurrence of symptomatic ulcer in patients operated on for other reasons. It is difficult to obtain an accurate estimate of postoperative bleeding rates from ulcer, but they probably are at least 10% in patients treated with subtotal gastrectomy and vagotomy and considerably higher in patients treated with vagotomy alone. It is unknown whether surgical treatment is more effective than medical maintenance treatment for prevention of recurrent ulcer bleeding. The effects of combining surgery with *H. pylori* eradication have not been determined.

Mortality rate in patients requiring emergency surgery for bleeding ulcers may be as high as 20% to 25%, depending on other medical conditions associated with the bleeding. Mortality rate of those having elective operations for ulcer is only about 1%. The perioperative mortality and morbidity are greatest for subtotal gastrectomy, intermediate for vagotomy with pyloroplasty, and lowest for highly selective vagotomy without pyloroplasty.

Diarrhea and dumping syndromes are relatively common in patients who have had gastric resections or pyloroplasty. They are relatively uncommon in patients with highly selective vagotomy without pyloroplasty.

Ulcer operations routinely lead to early postoperative weight loss. This weight loss is due chiefly to decreased food intake rather than to malabsorption of nutrients. Malabsorption of calcium and iron leads to metabolic bone disease and iron-deficiency anemia in many patients with subtotal gastrectomy and in fewer patients with vagotomy alone. These late complications develop slowly and may not be appreciated for several years.

Reflux of bile into the stomach produces an endoscopic picture often known as *bile gastritis*, which is characterized by edema and erythema. It is unclear whether this endoscopic picture is associated with any specific symptoms.

Marginal or anastomotic ulcers, also known as *stomal ulcers*, are ulcers that develop at a gastroenteric stoma after an operation that includes gastroenteric anastomosis. Usually, these ulcers form on the intestinal side of the anastomosis. They result from exposure of the intestinal mucosa to acid. The jejunal mucosa is less resistant to acid than is the duodenal bulb, probably because the duodenal bulb mucosa can secrete bicarbonate. The highest rates of marginal ulcers occur in patients treated with gastrojejunostomy without gastric resection or vagotomy. After partial gastrectomy and vagotomy, the rate of marginal ulceration is only 1% to 2%. The major causes of anastomotic ulcers are incomplete vagotomy or ingestion of NSAIDs. Treatment in the past always included reoperation to complete the vagotomy, to resect more stomach, or both. However, most patients with anastomotic ulcer can now be managed suitably with H⁺,K⁺-ATPase antagonists.

Cancer in the residual stomach is a potential late complication of subtotal gastrectomy. Several recent surveys have indicated that the risk of this complication is low, and some have questioned whether it is a significant risk. If it occurs, the interval from operation to carcinoma is almost always more than 15 years and often more than 20 years. Untreated *H. pylori* infection may play a role in the development of postgastrectomy gastric carcinomas.

CHAPTER 108: MOTOR DISORDERS OF THE GASTROINTESTINAL TRACT

CHUNG OWYANG

[Gastric Dysmotility](#)
[Delayed Gastric Emptying](#)
[Rapid Gastric Emptying](#)
[Intestinal Dysmotility](#)
[Acute Intestinal Pseudo-Obstruction](#)
[Chronic Intestinal Pseudo-Obstruction](#)
[Intestinal Dysmotility in Diabetes](#)

Disorders of gastric and intestinal motility are associated with a number of common gastrointestinal complaints, including heartburn, nausea, vomiting, chest and abdominal pain, diarrhea, and constipation. Historically, inadequate methods to record gut motor activity made it difficult to establish a connection between the patient's symptoms and dysfunctional motility. Interest in gastrointestinal motility problems has increased largely because of advances in monitoring techniques that have led to improved understanding of the normal patterns of motor activity in the gastrointestinal tract.

Gastrointestinal motor function is regulated by a complex hierarchy of interdependent pathways, including the inherent properties of the longitudinal and circular muscle layers, extraintestinal and enteric neural elements, and substances that act in endocrine and paracrine capacities. The enteric nervous system is the repository of the motor "programs" that result in luminal transit. Dysfunction can occur at all levels of this hierarchy, resulting in altered gastrointestinal transit and thereby disruption of the secretory and absorptive events that complete the intraluminal digestive process.

Classification of clinical disorders associated with altered gastrointestinal motility has been hampered by inadequate knowledge of the normal motility patterns in the gut and the mechanisms of their regulation. One approach to classifying these clinical syndromes ([Table 108.1](#)) is based on whether transit in the involved region of the gastrointestinal tract is delayed, accelerated, or reversed (retrograde). This approach is useful because the practical consequence of disordered motility is abnormal transit of the luminal contents, though the relationship between transit and the patterns of muscle contractions that determine transit remains unclear. Other classifications of gastrointestinal motility disorders are based on descriptions of abnormal contractile patterns. To understand motor dysfunction by these criteria, it is necessary to have some knowledge of the normal myoelectrical and motor activities of the gastrointestinal tract.

TABLE 108.1. CLINICAL SYNDROMES OF DISORDERED GASTROINTESTINAL MOTILITY

Gastric electrical pacemaker activity originates on the greater curvature at the junction between the proximal and distal stomach. Rhythmic depolarizations generated by the pacemaker, known as slow waves, cycle at a frequency of 3 cycles per minute (cpm) in humans. Under quiescent conditions, slow waves partially depolarize gastric smooth muscle but do not cause contraction. Additional depolarizations provided by neurohumoral stimulation (action potentials) are the triggers for phasic gastric contractions, which follow the spread of the slow waves and are peristaltic. Thus, gastric slow waves control the maximal frequency and the direction of contractions in the distal stomach, whereas action potentials determine the amplitude and duration of contractions.

In the fasting state, the stomach and small intestine have a rhythmic, periodic contractile activity that is divided into three phases: phase I is defined by the absence of motor activity, phase II by irregular contractions, and phase III by a brief burst of regular contractions lasting about 5 minutes, which begins at a pacemaker site along the greater curvature of the gastric body and migrates down the intestine—hence the name *interdigestive migratory motor complex* (IMMC). Occasionally, phase III activity begins in the duodenum and not at the gastric pacemaker. Gastric phase III activity appears to be initiated by the gastrointestinal peptide motilin. The entire cycle repeats about every 90 to 120 minutes, until the pattern is interrupted by the ingestion of food. The IMMC has been referred to as the "intestinal housekeeper" because of its action of sweeping the stomach and small intestine of debris in the fasting state. Loss of phase III activity is associated with gastric bezoar and bacterial overgrowth in the small intestine and subsequent malabsorption. The postprandial motor pattern features persistent irregular contractions that are thought to be necessary for proper mixing and absorption of the intraluminal contents. The periodicity, propagation, and duration of the IMMC are functions of the enteric nervous system. Interruption of the fasting pattern by eating requires an intact vagovagal axis and probably intact enteroenteric reflexes as well. The duration of phases I and II is affected by whether the person is awake or asleep; phase II activity is more prominent during the waking state.

These motor patterns are altered during abnormal circumstances in different ways, depending on the location of the abnormality. For example, as with the heart, ectopic pacemakers in other gastric regions will cause tachygastria resulting in the dissociation of electro-mechanical activities and gastric atonia. Alterations in CNS modulation of gut motor function are associated with abnormal clusters of contractions and loss of IMMC activity. This type of abnormality has been reported in patients with irritable bowel syndrome. Disorders of extrinsic innervation, such as truncal vagotomy and diabetic neuropathy, can be associated with an altered response to food. Diseases that cause an enteric neuropathy (eg, visceral aganglionosis) are associated with disturbed IMMC activity, which can take the form of abnormal periodicity, propagation, or duration of phase III activity. Finally, intestinal myopathic disorders, such as hollow visceral myopathy and progressive systemic sclerosis, are associated with abnormalities in electrical slow-wave activity, resulting in infrequent, weak contractions and leading to poor intestinal propulsion but normal contractile patterns.

Diagnosis of gut motor disorders generally relies on evidence of abnormalities in gastrointestinal transit or in the contractile patterns that are typical of each region of the gastrointestinal tract. Tests commonly used to assess gastrointestinal transit include barium transit and radioscinigraphy. Both techniques require exposing the patient to ionizing radiation. Barium transit studies generally provide only qualitative information because of the wide variation in results noted in normal subjects. In addition, these studies are diagnostic only if marked delay or acceleration of transit is observed. Radioscinigraphy requires isotopic labeling of standardized solid or liquid meals and following with a gamma camera. This test is considered more sensitive than the use of barium and is the test of choice for measuring gastric emptying.

Evaluation of contractile activity requires the placement of pressure-sensitive sensors within the lumen of the gut, typically in the form of a multilumen, perfused tube attached to pneumohydraulic pumps and external pressure transducers. This technique allows continuous recording of changes in intraluminal pressure and thus provides an indirect measurement of contractile activity. Recent improvements in monitoring techniques using advanced, solid-state devices permit prolonged (up to several days), ambulatory recordings of upper gastrointestinal motility. It is also possible to record electrical slow waves emanating from gastrointestinal smooth muscle using electrodes attached to the skin overlying the stomach (electrogastrography). The electrical slow waves establish the frequency with which muscle contractions occur, which varies depending on the region of the gastrointestinal tract examined. Tachydysrhythmias and bradydysrhythmias can develop in the gastrointestinal tract and may result in delayed gastric emptying.

GASTRIC DYSMOTILITY

The stomach plays an important role in the early stages of digestion because of its ability to store, triturate, and deliver nutrients to the duodenum. Normal gastric emptying is the result of a well-coordinated interplay of hormonal, secretory, and neuromuscular events. The emptying of liquids and solids is controlled by different regions of the stomach. The proximal stomach acts as a reservoir that allows food to be accommodated without a significant change in intragastric pressure; this is referred to as *receptive relaxation*. In addition, this region of the stomach evidences sustained or tonic contractions that exert a steady pressure on the proximal gastric contents, regulate the pressure gradient between the stomach and duodenum, and control gastric emptying of liquids. Loss of receptive relaxation in the proximal stomach can result in rapid emptying of liquids and symptoms of “dumping.” Emptying of solids is regulated by the phasic motor activity of the distal stomach. The churning action of this region triturates the solid food particles until they are about 1 mm in diameter and can pass through the pylorus. Abnormalities of motor function of the distal stomach may result in retention of solid food particles.

DELAYED GASTRIC EMPTYING

ETIOLOGY

Disorders of delayed gastric emptying are more common than those associated with rapid emptying. Mechanical or outlet obstruction as well as functional obstruction can cause delayed gastric emptying. In adults, mechanical obstruction is typically a complication of peptic ulcer disease, though tumors of the distal stomach and gastric bezoars should be considered when making the diagnosis. Bezoars, which are concretions of food or foreign matter formed as a result of functional and mechanical gastric obstruction, can produce gastric ulceration, bleeding, and, in rare cases, perforation.

Functional obstruction, or gastroparesis, is associated with several clinical situations; the common denominator is the presence of ineffective electromechanical activity. Gastric atonia may be a result of tachygastria, which develops when a rival ectopic pacemaker, usually in the antrum, generates an oscillatory pattern at an abnormally high frequency (more than 4 cpm) that overdrives the rest of the stomach. During tachygastria, the stomach is atonic, because the electrical activity is of insufficient amplitude to induce contraction. Clinical conditions associated with the development of gastric slow-wave dysrhythmias are listed in [Table 108.2](#). Reversible causes of gastroparesis include medications, such as opiates, anticholinergics, calcium channel blockers, b-adrenergic agonists, and dopaminergic agonists. Altered metabolism from diabetes mellitus, hypothyroidism, hypoparathyroidism, and pregnancy may delay gastric emptying, as can electrolyte disturbances, including hypokalemia, hypocalcemia, and hypomagnesemia.

Anorexia nervosa
 Diabetic gastroparesis
 Idiopathic gastroparesis
 Functional dyspepsia
 Gastric ischemia
 Gastroparesis associated with abdominal malignancy
 Unexplained nausea and vomiting
 Nausea of the first trimester of pregnancy
 Motion sickness
 Renal failure

TABLE 108.2. CLINICAL CONDITIONS ASSOCIATED WITH THE DEVELOPMENT OF GASTRIC SLOW-WAVE DYSRHYTHMIAS

Postvagotomy gastroparesis is occasionally a complication of peptic ulcer surgery. Gastroparesis is also found in the context of neuromuscular disorders, such as chronic idiopathic pseudo-obstruction and myotonic dystrophy. Patients with diabetes mellitus can experience gastric stasis as a result of autonomic neuropathy or poorly controlled blood glucose in the absence of neuropathy, a condition that frequently is associated with tachygastria. Occasionally, infiltrative disorders, such as amyloidosis, and collagen vascular diseases, such as progressive systemic sclerosis and dermatomyositis, are associated with delayed gastric emptying. Many patients have idiopathic gastroparesis, which may be the result of a viral or other insult leading to temporary or permanent gastric neural or muscular damage.

CLINICAL FEATURES

Delayed gastric emptying should be suspected in patients who complain of nausea, vomiting, postprandial abdominal pain, early satiety, or bloating. It can be accompanied by reflux of acidic gastric contents into the esophagus, resulting in heartburn or chest pain. The vomitus in gastroparesis may be foul smelling or contain bits of food ingested more than 12 hours previously. The medical history should be reviewed carefully for evidence of previous gastric surgery, peptic ulcer disease, diabetes mellitus, thyroid disease, or psychiatric illness. Physical examination is generally not helpful unless the symptoms are severe, resulting in dehydration or malnutrition. Abdominal distention may be present, and occasionally a succussion splash is present several hours after a meal.

Peptic ulcer disease and mechanical gastric outlet obstruction should be ruled out before the diagnosis of gastroparesis is made. This is typically accomplished with an upper barium study or endoscopic examination. Abdominal radiographs in the supine and upright positions can be useful, particularly if a perforation is suspected. Other tests to consider include serum glucose to rule out diabetes; serum calcium, potassium, and magnesium to rule out electrolyte disturbances; and thyroid function tests if they are clinically indicated.

Delayed gastric emptying is best diagnosed using radioscintigraphy methods. Incorporation of a radioisotope into a test meal allows for quantitative, noninvasive measurement of solid- and liquid-phase gastric emptying ([Fig. 108.1](#)). Solid-phase gastric emptying provides a more accurate gauge of clinical disease than liquid-phase emptying. Generally, gastric emptying is considered to be delayed if the time for emptying half the gastric contents exceeds normal values by two standard deviations. If gastric scintigraphy is equivocal, manometry of the stomach and duodenum may confirm the diagnosis. Patients with gastroparesis may have less frequent, lower-amplitude contractions and loss of antral phase III activity ([Fig. 108.2](#)). They may also evidence a reduced contractile response to a meal during gastrointestinal manometry. Patients with gastric neuropathy may show irregularity of the IMMC, whereas those with gastric myopathy may have a low amplitude of antral contractions but normal frequency of antral phase III activity. In questionable cases, electrogastrography studies may indicate that some forms of gastroparesis are related to electrical dysrhythmia. The normal frequency of electrical slow waves in the antrum is 3 cpm. Some patients with gastroparesis have a frequency in excess of 6 cpm—hence the designation *tachygastria* ([Fig. 108.3](#)). These diagnostic tests are complementary and may help identify specific causes of gastroparesis, thereby helping to individualize treatment.

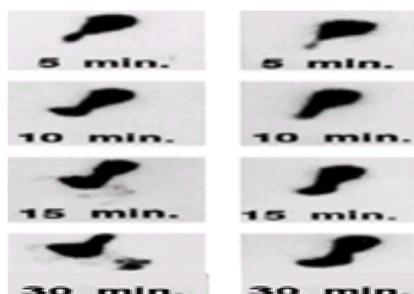

FIGURE 108.1. Solid-phase gastric emptying study: films taken 5, 10, 15, and 30 minutes after ingestion of Tc-99m sulfur colloid–labeled scrambled eggs with toast. Early movement of the meal from the proximal to the distal stomach is apparent. The sequence on the left shows normal gastric emptying. Tracer is present in the

small bowel after 30 minutes. On the right, no gastric emptying is apparent after 30 minutes. Subsequent scans can be obtained after 60 and 120 minutes.

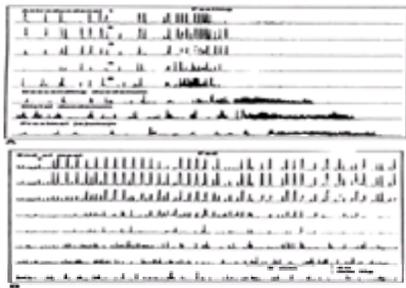

FIGURE 108.2. Normal gastrointestinal motility. **A:** Normal interdigestive migrating motor complex (fasting). Phase III activity is visible in the antrum, pressure activity is gradually moving into the duodenum, and gradual change is occurring in the configuration of the waves as they move through the antroduodenal junction. **B:** Normal fed activity. Irregular, but persistent phasic pressure activity is seen in the distal antrum and proximal small bowel. (From Malagelada JR, Camilleri M, Stanghellini V. *Manometric diagnosis of gastrointestinal motility disorders*. New York: Thieme, 1986:45, with permission of the Mayo Foundation.)

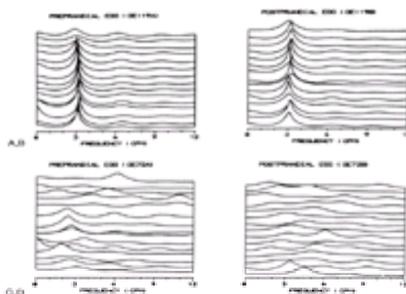

FIGURE 108.3. Frequency spectra of electrogastric recordings of a person with normal gastric emptying and a patient with diabetes and delayed gastric emptying. Under fasting conditions, the rhythm is regular at 3 cycles per minute (cpm) for the person with normal emptying (**A**), whereas the patient with delayed emptying exhibits dysrhythmic activity without dominant frequency (**C**). After eating, the person with normal emptying continues to show 3-cpm activity with increased signal amplitude (**B**), whereas the person with diabetes and delayed emptying shows a chaotic slow-wave rhythm (**D**). (From Chen JD, Lin Z, Pan J, McCallum RW. Abnormal gastric myoelectric activity and delayed gastric emptying in patients with symptoms suggestive of gastroparesis. *Dig Dis Sci* 1996;41:1538–1545, with permission).

TREATMENT

Management of gastroparesis initially should be directed toward correcting reversible causes, such as electrolyte imbalances, removing causative medications, and optimizing care of underlying medical illnesses, such as diabetes mellitus. Correction of hyperglycemia may improve gastric motor function in diabetic patients, since an elevated blood glucose level has been shown to evoke gastric dysrhythmias and impair gastric contractions. Prokinetic drugs that stimulate gastric emptying are effective in many patients. Cholinomimetic drugs, such as bethanechol, increase the amplitude of contractions in gastrointestinal smooth muscle, but the contractions are often not coordinated and therefore are rarely used for the treatment of gastroparesis.

Metoclopramide, the prototypical dopamine receptor antagonist, has cholinergic agonist properties. It stimulates antral contractility, promotes antroduodenal coordination, and also has a central antiemetic action. Metoclopramide (5 to 30 mg) is taken about 30 minutes before eating (to achieve adequate drug levels by mealtime) and at bedtime (to help prevent bezoar formation). Side effects are seen in up to 20% of patients. They include agitation; irritability; drowsiness; extrapyramidal signs, such as restlessness and dystonic reactions; menstrual disorders; and galactorrhea. Parkinsonism and tardive dyskinesia have been reported in the elderly. Tachyphylaxis may develop after prolonged use.

Domperidone is a second-generation prokinetic drug with antidopaminergic properties that crosses the blood–brain barrier poorly and therefore has fewer side effects than metoclopramide. Unlike metoclopramide, domperidone has no cholinomimetic effects. Antiemetic properties are maintained because of its effect on the chemoreceptor trigger zone. The usual dose is 10 to 30 mg, 30 minutes before meals and at bedtime. At present, domperidone is an investigational drug in the United States.

Cisapride is effective for treating gastroparesis and other motility disorders. It appears to act in part by stimulating acetylcholine release by myenteric plexus fibers. Cisapride has no known antidopaminergic properties and does not cross the blood–brain barrier. The usual dose is 10 to 20 mg, 30 minutes before meals and at bedtime. The most common reported side effect is mild diarrhea. Cisapride may cause cardiac arrhythmias, especially in patients who have preexisting heart disease, renal failure, and diabetic neuropathy. The likelihood of cardiac complication increases if cisapride is used with certain medications that use the cytochrome P450 system for metabolism. These medications include antibiotics, such as erythromycin, clarithromycin, and troleandomycin, and antifungals, such as fluconazole, intracomazole, and ketoconazole.

Considerable interest has been shown in macrolide analogs of the antibiotic erythromycin as prokinetic agents. These drugs have weak antibiotic activity but a potent stimulatory effect on gastrointestinal motility. Their prokinetic effect may be mediated by their ability to mimic the action of the gastrointestinal peptide motilin by initiating gastric phase III activity; hence, they are called *motilides*. These drugs are in the latter phases of testing and will not be available for routine clinical use for several years.

In addition to prokinetic medications, patients should eat a low-residue diet to prevent bezoars and ingest several small, low-fat meals to minimize symptoms caused by the delay in gastric emptying. Some studies suggest that gastric pacing may improve symptoms and gastroparesis and accelerate gastric emptying in patients with gastroparesis. More controlled studies are necessary to further investigate the role of gastric pacing in clinical practice. Surgery is seldom indicated for the treatment of nonmechanical gastroparesis and should be considered only after other options have failed and a thorough evaluation suggests that normal motility exists in other regions of the digestive tract.

RAPID GASTRIC EMPTYING

ETIOLOGY

Dumping syndrome is a complication of vagotomy and drainage procedures for peptic ulcer disease or malignancy. All standard anti-ulcer procedures cause dumping syndrome, but superselective vagotomy appears to have a lower incidence than truncal vagotomy. Persistent dumping syndrome generally occurs in 8% to 15% of

patients after gastric surgery.

CLINICAL FEATURES

Symptoms may develop in both the early and late postprandial periods. Early symptoms typically occur within 15 to 30 minutes after starting a meal and include nausea, nonproductive vomiting, anxiety, dizziness, sweating, flushing, abdominal cramping, and diarrhea. The pathophysiologic basis for these symptoms appears to be related to disruption of the normal neuromuscular pathways that regulate gastric emptying. Truncal vagotomy disrupts receptive relaxation in the proximal stomach and thereby diminishes gastric reservoir capacity. Furthermore, resection of the pyloric sphincter results in decreased resistance to the flow of liquids and altered processing of solid particulates. This combination culminates in the dumping of hypertonic solutions into the jejunum. The early vasomotor symptoms associated with dumping probably are caused by rapid blood volume contraction due to rapid secretion of fluid into the bowel caused by the presence of a hypertonic solution. This is associated with reflex splanchnic vasodilatation stemming from jejunal distention, plasma hyperosmolarity, and acute release of vasoactive gut peptides.

The late symptoms associated with the dumping syndrome generally occur about 2 hours after a meal and include hypoglycemic symptoms, such as diaphoresis, hunger, tremulousness, weakness, and confusion. The pathophysiologic basis for these symptoms appears to be related to the rapid delivery and absorption of simple sugars from the jejunum, causing a sudden rise in serum glucose and an exaggerated insulin response, resulting in hypoglycemia. Rapid caloric delivery to the intestine also releases numerous vasoactive hormones, which may further increase lightheadedness or even lead to syncope and shock. The diagnosis of dumping syndrome is based on a clinical constellation of symptoms and signs in patients who have undergone vagotomy. Evidence of a postprandial increase in hematocrit or plasma osmolarity, indicating hemoconcentration, is consistent with the diagnosis. Gastric scintigraphy confirms rapid emptying of a liquid meal in most cases.

TREATMENT

Treatment of the dumping syndrome focuses on slowing gastric emptying and lessening the volume and hypertonicity of the liquid boluses entering the small intestine. Eating six to eight small, low-carbohydrate meals per day, avoiding large amounts of liquids (especially hypertonic fluids), and separating ingestion of the liquid and solid components of the meal are effective strategies for many patients. Some patients report that assuming a recumbent posture after a meal has benefit, possibly by helping maintain intravascular volume and slowing gastric emptying. Late dumping symptoms are managed by avoiding simple carbohydrates at mealtime. Medications that delay gastric emptying, such as opiates and anticholinergics, and gel-forming fiber products, such as pectin, that slow gastrointestinal transit and postpone carbohydrate absorption may be useful in selected patients. In some studies, the somatostatin analog octreotide has been found to be effective in difficult cases, since it not only delays gastric emptying but also has inhibitory effects on meal-stimulated release of vasoactive hormones, which may be important pathogenetic factors.

INTESTINAL DYSMOTILITY

Disorders of intestinal motility have symptoms of nausea, bloating, and abdominal pain in addition to malabsorption and diarrhea, owing to bacterial overgrowth from intestinal stasis. Many conditions lead to acute intestinal dysmotility, but the most common is acute intestinal pseudo-obstruction in the postoperative period or accompanying severe illness. As with gastroparesis, severe localized or generalized neuromuscular disease can lead to chronic intestinal dysmotility, such as advanced diabetic visceral neuropathy or chronic intestinal pseudo-obstruction.

ACUTE INTESTINAL PSEUDO-OBSTRUCTION

ETIOLOGY

Acute intestinal pseudo-obstruction was first described by Ogilvie in 1948 and is also referred to as Ogilvie's syndrome. Typically, it involves the small and large intestines and develops in older patients who have undergone surgery or suffer from a severe systemic illness or infection that inhibits intestinal neuromuscular function. It may be associated with or exacerbated by electrolyte disturbances (hypokalemia, hypocalcemia, hypomagnesemia) or medications, such as antidepressants, anticholinergics, calcium channel antagonists, or opiates.

CLINICAL FEATURES

Patients with acute intestinal pseudo-obstruction show signs of abdominal distention with or without nausea during an acute illness or after surgery. The abdomen is tympanic on examination, and bowel sounds are often minimal or absent. Serum electrolytes should be obtained to rule out metabolic abnormalities, and abdominal radiographs should be examined to exclude perforation and to assess the magnitude of luminal distention. Most patients have a moderately dilated colon without air-fluid levels. The cecum is usually dilated to larger than 10 cm in diameter. If obstruction is suspected, a Gastrografin enema or gentle sigmoidoscopy without air insufflation is performed. Barium should be avoided, because it may form an impaction or induce a peritoneal reaction if perforation has occurred.

TREATMENT

Initial management should be conservative. Oral intake should be discontinued, and decompression through nasogastric and rectal tubes should be initiated. Metabolic and electrolyte disturbances should be corrected and medications that slow bowel motility discontinued. Contrast studies should be avoided, but a Gastrografin or equivalent enema sometimes is required to rule out mechanical obstruction. If the cecal diameter exceeds 12 cm, colonoscopic decompression may be attempted to lower the risk of perforation. If the condition persists, tube cecostomy has been used with some success. Occasionally, in the presence of necrosis or perforation, a right hemicolectomy may be required. Perforation occurs in about 15% of patients.

One double-blind, placebo-controlled trial confirmed rapid and dramatic improvement of acute colonic pseudo-obstruction in patients treated with intravenous neostigmine (2 mg). All treated patients had prompt evaluation of flatus and/or stool, with reduction of abdominal distention and only minimal side effects. This treatment should be considered before colonoscopic or surgical intervention in patients whose conditions do not improve with conservative management.

CHRONIC INTESTINAL PSEUDO-OBSTRUCTION

ETIOLOGY

Chronic intestinal pseudo-obstruction may be idiopathic and familial, or it may be due to systemic disease or medications that inhibit intestinal motility. Familial and idiopathic cases often develop in childhood or adolescence and result from damage to the myenteric plexus (visceral neuropathy) or smooth-muscle layers, with replacement of myocytes by fibrosis (visceral myopathy). There may be dysfunction of smooth muscle in other organs, such as the ureters, bladder, and urethra; fibrosis of the ocular lens; and periportal fibrosis of the liver. Scleroderma is the most common systemic disease leading to chronic intestinal pseudo-obstruction, but other conditions include rheumatologic diseases; infiltrative diseases, such as amyloidosis; and neuromuscular diseases, such as myotonic dystrophy, muscular dystrophy, Chagas' disease, and Parkinson's disease. The abrupt onset of chronic pseudo-obstruction in an older patient should raise the suspicion of a paraneoplastic reaction, most often due to small-cell lung carcinoma. Many commonly used drugs can affect gastrointestinal motility. Phenothiazines and antiparkinsonian drugs can inhibit colonic and small-bowel motility and thus cause colonic pseudo-obstruction and adynamic ileus. Other agents, such as anticholinergics, calcium channel antagonists, and smooth-muscle relaxants, also can diminish intestinal tone as well as the amplitude and frequency of peristaltic contractions. Chronic intestinal pseudo-obstruction may affect the entire gut, including the esophagus, stomach, small intestine, and colon.

CLINICAL FEATURES

At one end of the spectrum of intestinal pseudo-obstruction, patients may be asymptomatic; at the other end, they may show recurrent symptoms and signs of small-intestinal obstruction. Symptomatic patients usually have varying amounts of abdominal pain, distention, and vomiting. As a rule, the symptoms are related to eating. Chronic intestinal pseudo-obstruction often leads to intestinal bacterial overgrowth, which may cause diarrhea and steatorrhea. Patients with predominantly colonic involvement have initial symptoms of constipation. When both the small bowel and colon are affected, diarrhea may alternate with constipation, depending on the severity of steatorrhea and the relative involvement of the small intestine and colon. Many patients with small-intestinal pseudo-obstruction have esophageal symptoms, including dysphagia, chest pain, heartburn, and regurgitation. Gastric involvement may further aggravate the symptoms of vomiting and bloating. This limits food intake, and weight loss and malnutrition can be profound. On physical examination there is evidence of malnutrition, with pallor, cheilosis, and edema. The

abdomen may be distended and tympanitic, with varying bowel sounds.

Laboratory studies show evidence of malnutrition with hypoalbuminemia, anemia, and vitamin B₁₂ deficiency. Electrolyte abnormalities and acid–base disturbances result from diarrhea or vomiting. There may be excessive fecal fat. Abdominal radiographs with or without barium often show diffuse dilatation of the stomach, small intestine, and colon with or without air–fluid levels, though selective gastric and duodenal dilatation is noted in some cases. Scleroderma or infiltrative diseases may cause thickened small-intestinal folds. Diverticular disease or pneumatosis intestinalis may be present. Absent fasting IMMC activity and failure to convert to the fed motor pattern with meal ingestion are seen with gastrointestinal manometry. Intravenous pyelography may show a dilated bladder or ureters. Patients with bacterial overgrowth are diagnosed by hydrogen breath testing or jejunal cultures. In patients with known systemic diseases, the clinical scenario coupled with judicious use of radiographic and functional tests can provide an accurate diagnosis. Diagnosis of idiopathic and familial cases, however, may require a full-thickness intestinal biopsy taken at laparotomy to examine for destruction of the muscle layers or myenteric plexus.

TREATMENT

Nutrition supports are key to the treatment of patients whose abdominal symptoms frequently are worsened by eating. Adult patients should consume 1,500 to 1,800 calories/day, divided into four equal feedings. At least half of the calories should come from supplemental formulas, such as Ensure, Isocal, or Vivonex, because liquid empties faster from the stomach and moves more easily through the small bowel. In severe cases, long-term parenteral nutrition is needed. Broad-spectrum antibiotics are useful in treating the bacterial overgrowth syndrome: a 10-day course often results in weight gain and cessation of diarrhea, a remission that may last weeks to months. Metabolic or electrolyte disturbances should be corrected, and medications that inhibit motility should be discontinued. Prokinetic medications are used with varying degrees of success. Cisapride may be more effective than metoclopramide for treating intestinal motor dysfunction. The somatostatin analog octreotide decreases bacterial overgrowth and minimizes symptoms in scleroderma patients with intestinal pseudo-obstruction.

INTESTINAL DYSMOTILITY IN DIABETES

ETIOLOGY

Up to 20% of patients with long-standing diabetes have diarrhea or constipation. There are many potential causes of diarrhea, including bacterial overgrowth from intestinal stasis, bile acid delivery to the colon, or impaired autonomic neural regulation of intestinal absorption leading to active secretion. Constipation probably is due to impaired colonic neural function. A defect in the colonic motor response to a meal is noted in some diabetics.

CLINICAL FEATURES

Diabetic diarrhea is watery and nonbloody and may be associated with tenesmus. The diarrhea may awaken the patient at night. Constipation and diarrhea can be intermittent or alternating. The physical examination typically shows peripheral or autonomic neuropathy. Patients with diabetic diarrhea should undergo stool analysis for total volume and fecal fat content. Most patients have a near-normal daily volume, but some excrete 500 to 1,000 mL/day, suggesting a secretory process. The presence of steatorrhea warrants evaluation for small-intestinal bacterial overgrowth with a culture of a jejunal aspirate or with a hydrogen breath test after ingestion of glucose. In a healthy patient, ingested glucose is absorbed by intestinal enterocytes and metabolized without production of hydrogen. In the patient with bacterial overgrowth, the glucose is metabolized by luminal bacteria, which produce hydrogen that is absorbed, transported to the lungs, and exhaled in the breath. Bacterial overgrowth usually occurs only in the presence of abnormal small-intestinal motility in diabetics. This may be confirmed with gastrointestinal manometry showing the absence of IMMC activity in the small intestine during the fasting state. Secretory diarrhea in diabetics can be documented by intestinal perfusion studies using the nonabsorbable marker polyethylene glycol to determine whether active secretion is taking place in the small intestine.

TREATMENT

Intestinal complications of diabetes are markers of advanced disease. Once intestinal symptoms begin, they are likely to recur. Bacterial overgrowth is treated with oral antibiotics. Recurrent episodes of bacterial overgrowth can be treated with prokinetic agents, but they are less effective in the context of intestinal dysmotility than in cases of gastroparesis. A trial of cholestyramine may be useful to rule out bile acid diarrhea. For mild diarrhea, antidiarrheal opiates, such as loperamide, are useful. The α -adrenoceptor agonist clonidine is effective in some diabetics with secretory diarrhea that is presumed to stem from impaired mucosal adrenergic innervation. In patients with constipation with or without alternating diarrhea, fiber supplementation is the simplest and most reliable therapy.

CHAPTER 109: IRRITABLE BOWEL SYNDROME

YEHUDA RINGEL AND DOUGLAS A. DROSSMAN

[Irritable Bowel Syndrome as a Functional Gastrointestinal Disorder](#)

[Definition](#)

[Epidemiology](#)

[Etiology and Pathogenesis](#)

[Diagnosis](#)

[Treatment Strategy](#)

IRRITABLE BOWEL SYNDROME AS A FUNCTIONAL GASTROINTESTINAL DISORDER

Functional gastrointestinal disorders (FGIDs) are the clinical conditions seen most frequently in gastroenterology practice, and they account for a major portion of primary care. FGIDs are defined as a “variable combination of chronic or recurrent gastrointestinal (GI) symptoms not explained by structural or biochemical abnormalities.” In the absence of any obvious, specific morphologic or physiologic marker for the disorder, the diagnosis is mainly based on the clinical signs and symptoms. Symptom-based criteria for defining and diagnosing FGIDs, later known as “Rome criteria,” were first developed by a multinational working team in 1990. The Rome criteria subclassified FGIDs into five groups according to the anatomical region (esophageal, gastroduodenal, bowel, biliary, and anorectal) and a separate category, functional abdominal pain ([Table 109.1](#)).

Esophageal disorders
Glossitis
Rumination syndrome
Functional chest pain of presumed esophageal origin
Functional heartburn
Functional dysphagia
Unspecified functional esophageal disorder
Gastroduodenal disorders
Functional dyspepsia
Aerophagia
Functional vomiting
Bowel disorders
Irritable bowel syndrome
Functional abdominal bloating
Functional constipation
Functional diarrhea
Unspecified functional bowel disorder
Functional abdominal pain
Functional abdominal pain syndrome
Unspecified functional abdominal pain
Functional biliary disorders
Cholelithiasis dysfunction
Oddi's sphincter dysfunction
Anorectal disorders
Functional incontinence
Functional anorectal pain
Pilon, floor dyspareunia

TABLE 109.1. FUNCTIONAL GASTROINTESTINAL DISORDERS

Although many hypotheses have been proposed to explain the pathogenesis of the various symptoms experienced by patients with FGIDs, their pathophysiologic basis is still unclear. At present, the evolving theory suggests that the symptoms result from dysregulation of intestinal motor, sensory, and central nervous system (CNS) function. Irritable bowel syndrome (IBS) is the most common and best-studied disorder among the group of FGIDs. It is characterized by symptoms of abdominal pain, bloating, and disturbed defecation (diarrhea or constipation). Many of the physiologic aspects of IBS as well as our biopsychosocial understanding of the disease and general approach to diagnosis and treatment also may be relevant to other FGIDs.

DEFINITION

IBS is a group of functional bowel disorders in which abdominal discomfort or pain is associated with defecation or change in bowel habit and with features of disordered defecation (Rome II). Since there are no markers for IBS, the disorder is defined by a cluster of clinical symptoms. The first symptom-based criteria for the diagnosis of IBS were developed by Manning in 1978. The Manning criteria include abdominal distention, relief of pain with bowel movement, more frequent stools with onset of pain or looser stools with onset of pain, the passage of mucus, and the sensation of incomplete evacuation. These criteria have been used widely in epidemiologic and clinical studies. A consensus and more comprehensive criteria for the definition of patients with IBS and other functional GI disorders were developed by the Rome multinational working team in 1990. The revised Rome criteria for IBS are shown in [Table 109.2](#).

Twelve weeks or more in the past 12 months of abdominal discomfort or pain that has two of three features^a
Relieved with defecation
Onset associated with a change in frequency of stool
Onset associated with a change in form (appearance) of stool
The following symptoms are not essential for the diagnosis, but when present they increase confidence in the diagnosis and may be used to identify subgroups of IBS
Abnormal stool frequency ($\geq 3/day$ or $< 3/week$)
Abnormal stool form (lumpy/hard or loose/watery stool) more than one-fourth of defecations
Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation) more than one-fourth of defecations
Passage of mucus more than one-fourth of defecations
Bloating or feeling of abdominal distension more than one-fourth of days

^a In the absence of structural or metabolic abnormalities to explain the symptoms.
^b The 12 weeks need not be consecutive.

TABLE 109.2. DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

EPIDEMIOLOGY

IBS affects about 10% to 20% of adolescents and adults in Western countries (14% to 24% of women and 5% to 19% of men). There are no reported ethnic differences, and the rate appears to decline among older subjects. Although only 30% of IBS patients seek medical attention, IBS is still one of the most commonly seen disorders in the general population and in medical settings. It accounts for 12% of primary care visits and 28% of cases seen in gastroenterology practice. Whether a patient seeks health care is influenced by social and cultural factors, the presence and severity of pain, and psychosocial disturbances.

Patients most often report going to the doctor because of severe pain, bloating, bowel symptoms, and associated psychological distress. Women see physicians for symptoms of IBS more often in Western countries, whereas in India and Sri Lanka it is primarily men. The disorder poses a considerable socioeconomic burden. On average, IBS patients take off three times more workdays in a year, pay significantly more average annual visits to physicians, and spend 42% more on health care than people without bowel symptoms.

ETIOLOGY AND PATHOGENESIS

Although no unique pathophysiologic mechanism of action has been identified, IBS can be understood in terms of several contributing features. Motility disorders traditionally have been implicated in the etiologic picture of IBS. Patients with IBS have exaggerated intestinal motor activity in response to intrinsic stimuli (meals, intraluminal balloon distention) or environmental stimuli (psychological stress). Specific motility patterns are associated with different subtypes of IBS: slowed or

delayed intestinal transit occurs in constipation-predominant IBS, and accelerated transit is present in diarrhea-predominant IBS. These findings are not unique to IBS, however, and there is little correlation between pain and motor abnormalities.

Visceral hypersensitivity and altered pain perception have been suggested as another major factor in the pathophysiologic origin of IBS. Several studies have shown that patients with IBS experience the urge to defecate at lower rectal volume and have lower pain thresholds to rectal distention. The pathophysiologic mechanisms by which visceral hypersensitivity and pain are generated and modulated are still poorly understood. This may involve dysregulation of the gut control mechanism at different levels between the enteric nerve system and the brain.

The CNS has a major role in conducting and processing afferent visceral information, including pain signals. Studies using functional brain imaging (positron emission tomography, functional magnetic resonance imaging) have shown differences in regional brain activity between patients with IBS and normal controls in response to rectal distention. These findings emphasize the role of the CNS in modulating the conscious sensory experience of visceral sensation and pain in IBS. Symptoms of IBS and other FGIDs can be produced not only by peripheral dysfunction at the level of the gut (abnormal intestinal motor or sensory function) but also by dysfunction at any level of the gut control mechanism, including the autonomic nervous system, spinal pathways, and CNS.

The gut is physiologically responsive to stressful stimuli and emotions. A variety of studies have shown that psychological distress can cause prolonged motor abnormalities as well as a reduction in the threshold at which people experience afferent GI sensations. Moreover, psychological factors, through their effects on the CNS, also can influence patients' symptom perception (sensation intensity/severity)—via affective and cognitive centers in the brain—and illness behavior.

Patients with IBS have a higher prevalence of comorbid affective disorders, personality disturbances, and psychiatric illnesses compared with normal populations, all of which up-regulates symptom experience and behavior. Therefore, more frequent and severe psychological difficulties are found among patients who frequently seek medical care for more severe symptoms. Psychological tests fail to identify a specific pattern of psychological symptoms or traits that are unique to any of the FGIDs, including IBS.

One explanation of the link between psychological stress and symptom experience and behavior relates to the high incidence of abuse history (up to 50%) among women in GI referral practices, particularly for those with functional diagnoses. Abuse history is associated with more severe symptoms, poorer daily function, greater psychological distress, and poorer health outcome. This may be mediated through CNS pathways that amplify the pain experience or the patient's perceived ability to cope with it.

Since both physiologic and psychological factors contribute to symptoms and illness, a biopsychosocial model of illness and disease is helpful in explaining patients' clinical symptoms and behavior (Fig. 109.1). Environmental stress, thoughts, and emotions can have various influences on aspects of gut physiologic mechanisms of action, the symptom experience, health behavior, and outcome. A biopsychosocial approach addressing all of these factors is necessary for establishing more comprehensive and effective diagnosis and treatment of patients with IBS.

FIGURE 109.1. Schematic representation of the biopsychosocial model (see text for details.) (From Drossman DA. Gastrointestinal illness and the biopsychosocial model [Presidential Address]. *Psychosom Med* 1998;60:258–267, with permission.)

DIAGNOSIS

CLINICAL SYMPTOMS

Abdominal pain associated with a change in the consistency or frequency of stools and relieved with defecation is the hallmark of IBS. The abdominal pain often is poorly localized and may be migratory and varying in nature. It often occurs after a meal, during psychological stress, or at the time of menses. Associated symptoms can include bloating or a sensation of distention, presence of mucus in the stool, urgency, and a feeling of incomplete evacuation. IBS can be diarrhea predominant, constipation predominant, or a combination of both at varying times. Symptoms that awaken the patient from sleep, the onset of symptoms at an older age, or the presence of GI bleeding, weight loss, or fever suggest a diagnosis other than IBS and may require further evaluation. It should be noted that IBS can coexist with other GI diseases (inflammatory bowel disease). A positive diagnosis of IBS is based on identifying unequivocal symptoms suggestive of the disorder using symptom-based criteria (Rome, Manning) and a modest effort to exclude other diseases.

DIAGNOSTIC STRATEGY

The initial evaluation involves limited diagnostic screening tests, including blood tests, stool tests, and sigmoidoscopy. Additional studies depend on the patients' history and dominant symptom. Examples of testing include the lactose hydrogen breath test in a patient with diarrhea-predominant symptoms or plain abdominal radiography during an acute episode for a patient with pain, gas, or bloating as the primary symptom. If the initial screening evaluation gives normal results, the physician should withhold further diagnostic studies and begin treatment with a follow-up visit within 4 to 6 weeks. Other factors must be considered in planning a diagnostic strategy, including the duration and severity of symptoms, age at onset, family history of colon cancer, change over time (getting worse or better), previous diagnostic evaluations, and psychosocial status. Good clinical judgment based on a thorough history and physical examination can help minimize unneeded investigative studies.

SPECIFIC DIAGNOSTIC TESTING

The initial evaluation should include a complete blood count, sedimentation rate, serum chemistries, evaluation of the stool for ova, parasites and blood, and sigmoidoscopy. Colonoscopy or barium enema with sigmoidoscopy is recommended if the patient is older than 50 years. The presence of the following signs should raise the suspicion of other diagnosis (Table 109.3) and may lead to further studies: history of weight loss, onset of symptoms in an older patient, nocturnal awakening, family history of carcinoma or inflammatory bowel disease, fever, abnormal physical finding (abdominal mass, hepatomegaly), abnormal laboratory result (occult blood in stool, anemia, leukocytosis, elevated sedimentation rate, abnormal chemistries).

If any of the initial tests show abnormal results or if a first therapeutic trial fails, further investigative studies may be necessary. Those patients with constipation as their predominant symptom should undergo colonic function tests, such as colonic transit time and anorectal manometry (see [Chapter 100](#)). Patients with mainly diarrhea may require stool tests (volume, electrolytes, fat, white count), small-bowel evaluation (small-bowel follow-through radiography and endoscopy with duodenal aspirate and biopsy), breath tests to exclude bacterial overgrowth, and colonic biopsies to exclude collagenous/lymphocytic colitis (see [Chapter 111](#)). Additional small-bowel radiographic studies should be considered for patients with bloating and pain, to exclude partial obstruction.

TREATMENT STRATEGY

PHYSICIAN–PATIENT RELATIONSHIP

Once a diagnosis of IBS has been established, the physician's confidence in the diagnosis should be conveyed to the patient along with reassurance and education about the condition and its consequences. An effective physician–patient relationship is the basis for any treatment program. This relationship is achieved through adhering to the following recommended guidelines. First, the physician must conduct a nonjudgmental, patient-centered interview to identify his or her symptoms, fears, and concerns; exacerbating factors; and psychosocial contributions. Second, the physician should clearly explain the disorder, including its pathophysiologic characteristics, natural history, chronic nature, and the role of environmental stress and psychosocial factors on the symptoms. Third, attention must be paid to the patient's beliefs and expectations, making efforts to integrate them realistically into a plan of care that helps the patient better control symptoms. This plan includes developing strategies that address symptoms, cognition, and modes of behavior. Finally, it is essential to provide continuity of care while setting limits on the frequency of clinical visits and the extent of additional testing. A specific treatment strategy is based on the nature (diarrhea, constipation, pain/bloating) and severity (mild, moderate, severe) of the symptoms.

TREATMENT APPROACH BASED ON SEVERITY

The severity of IBS is determined by the intensity and constancy of the symptoms, the nature of the physiologic disturbances (diarrhea or constipation), the degree of psychosocial difficulties, and the frequency of health care use. Most patients with IBS do not see physicians for their symptoms. The majority (about 70%) of the patients who do see physicians have mild and infrequent symptoms associated with little disability and no overt psychological difficulties. These patients often are seen in primary care and usually require only reassurance, education, and dietary or lifestyle changes. Patients with moderate symptoms (about 25% of those who see physicians) experience more intense and frequent symptoms that occasionally interfere with daily activities (missing work) and may be associated with psychological distress. These patients may require pharmacologic and/or behavioral treatments. Only a small proportion of IBS patients (about 5%) have severe symptoms. They experience more constant abdominal pain, often in the context of psychological difficulties (depression) that chronically interfere with daily functioning. They frequently use health care services and may undergo extensive testing. These patients usually are referred to tertiary centers and often need psychopharmacologic (antidepressants) and/or psychological (cognitive-behavioral) treatment. Patients with the most refractory symptoms should be referred to specialized functional GI disorders or pain treatment centers.

SPECIAL TREATMENTS

Dietary Modifications

Identifying offending dietary substances and making dietary modifications can be helpful with some patients. Food items that may be associated with IBS symptom exacerbation include lactose (in lactose intolerant individuals), caffeine, fatty foods, alcohol, gas producing foods (e.g., cabbage, beans), sorbitol (>10 gm/day) and other offending food items that aggravate GI motility. Recommendations for dietary changes should usually also involve life style changes and encouragement for health promoting behaviors.

Pharmacotherapy

Most patients with IBS require no prescribed medications. Medications are best used intermittently or for short-term periods, mainly during exacerbations, and only as part of a complete management plan. Placebo effects may occur in as many as 70% of patients and should be considered when assessing the benefit of any drug treatment. Nevertheless, individual symptoms may respond to specific agents. The use of medication directed at the gut depends on the dominant symptom (pain, diarrhea, or constipation). When pain and bloating are the main symptoms, such anticholinergic agents as dicyclomine hydrochloride or hyoscyamine sulfate can be used, preferably before meals for postprandial pain. Other antispasmodics, such as octylonium, cimetropine, mebeverine, or peppermint oil, are not available in the United States. There are a few new medications, currently in clinical trials, that are directed at minimizing gut sensitivity. They include serotonin receptor antagonists and the kappa opioid antagonist fedotozine. In more severe or refractory cases, low doses of antidepressants should be considered. They often are used for their neuromodulatory and analgesic properties as well as for their psychotropic effects. Tricyclic agents, such as desipramine (50 to 150 mg) or amitriptyline (25 to 100 mg), have been studied best and appear to be effective. However, serotonin re-uptake inhibitors, such as fluoxetine or paroxetine, may be preferred for older patients or those with associated constipation because of their less prominent anticholinergic effects.

When diarrhea is the primary symptom, antidiarrhea agents, such as loperamide (4 to 8 mg per day), may help diminish urgency, stool frequency, and soiling and increase stool consistency. For patients with constipation, increasing dietary fiber (25 g per day) may be effective. If this solution is not sufficient, osmotic laxatives, such as milk of magnesia, sorbitol, or lactose, may be added. Stimulant laxatives (senna phenolphthalein) should be avoided on a long-term basis. The use of promotility agents, such as cisapride, also has been suggested for patients with colonic inertia but may be helpful only for those with milder symptoms.

Psychological Treatments

Referral for psychological treatment usually is recommended for patients with disabling symptoms or associated psychiatric disorders (major depression). Several psychological treatments have been used in patients with IBS, including cognitive-behavioral therapy, dynamic psychotherapy, hypnotherapy, and relaxation training (arousal reduction). There are several well-designed studies that suggest their beneficial effect. Psychological treatments appear to be superior to conventional medical treatment in minimizing psychological distress, improving coping, and reducing bowel symptoms. No one specific treatment was found to be superior. The most important aspect of treatment is the patient's acceptance of the need for treatment and the motivation to engage in it. A physician's willingness to address both biologic and psychological aspects of the illness and to develop an effective therapeutic relationship (adopting a biopsychosocial approach) with patients can contribute significantly to the success of treatment.

CHAPTER 110: DISORDERS OF DIGESTION AND ABSORPTION

DENNIS J. AHNEN

[Normal Nutrient Assimilation](#)
[Disorders of Digestion and Absorption](#)

The human gastrointestinal tract is extraordinarily well adapted for efficient digestion and absorption of nutrients; more than 90% of ingested and endogenously secreted fat, protein, and carbohydrate is digested and absorbed. Disorders at any level of this process, however, can cause nutritional deficiency.

NORMAL NUTRIENT ASSIMILATION

Normal nutrient digestion and absorption is a highly coordinated process. For the major nutrients, digestion, absorption, and metabolism can be considered to occur in four phases: hydrolysis in the intestinal lumen, hydrolysis at the enterocyte brush border, transport from the lumen into the enterocyte, and intracellular processing and secretion from the enterocyte into the portal or lymphatic circulation.

FAT ASSIMILATION

Dietary fat consists predominantly of triglycerides, phospholipids, and cholesterol. Although fat intake varies widely worldwide (15% to 50% of total caloric intake), the average American diet consists of roughly 42% fat, containing about 100 g of triglycerides, 2 to 8 g of phospholipids, and 0.2 to 0.5 g of cholesterol per day. In addition to ingested fats, about 9 g per day of phospholipid and 1 to 2 g per day of cholesterol are secreted into the intestinal lumen each day (mostly from bile). Overall, more than 95% of ingested and secreted lipid is digested and absorbed, predominantly in the proximal jejunum.

Triglycerides are composed of three fatty acids linked by ester bonds to glycerol. Considerable variability exists in the relative amounts of the saturated fatty acids (palmitic and steric) versus the unsaturated fatty acids (oleic and linoleic) in the diet. Certain essential fatty acids cannot be adequately synthesized by humans and must be ingested and absorbed. Phospholipid structure is similar to that of triglycerides, with one of the hydroxyl groups of glycerol linked to one of several polar head groups (choline, serine, ethanolamine) instead of a fatty acid. Cholesterol has a multiringed sterol nucleus; it is the most abundant sterol in human tissue and is the precursor of other steroid hormones and bile acids.

Dietary fats are not soluble in water and spontaneously form lipid aggregates. Triglycerides tend to aggregate into lipid droplets. Phospholipids are amphipathic molecules that have a propensity to aggregate into phospholipid bilayers, with their polar head groups on the outside and their hydrophobic fatty acids in the interior. These aggregates form the structural bridges between water-soluble proteins and nonpolar lipids, such as in the phospholipid bilayer of biologic membranes. Other water-insoluble nutrients, such as cholesterol and fat-soluble vitamins, are sequestered in the hydrophobic interior of triglyceride and phospholipid aggregates.

Triglyceride Digestion and Absorption

The overall process of triglyceride digestion and absorption is depicted in [Fig. 110.1](#). Lipolysis of ingested triglycerides is initiated in the stomach by the action of gastric lipase, an acidic lipase (pH optimum of 3 to 6) that preferentially hydrolyzes medium-chain triglycerides. Gastric lipase may be particularly important for neonatal digestion of milk fat, which is rich in medium-chain triglycerides. The bulk of intraluminal lipolysis in the adult is mediated by pancreatic lipase. Bile acids can displace pancreatic lipase from the lipid droplet, and another pancreatic protein, colipase, is required to restore lipase activity in the presence of bile acids. The lipase–colipase complex acts on the first and third positions of triglycerides, yielding b-monoglyceride and two free fatty acids ([Fig. 110.1](#)).

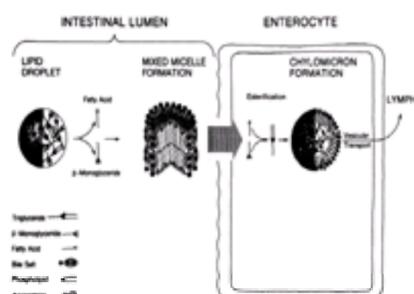

FIGURE 110.1. Digestion and absorption of triglycerides. Triglycerides are ingested as lipid droplets (shown in partial cross section) and hydrolyzed by lipase in the intestinal lumen to fatty acids and b-monoglycerides. Fatty acids and b-monoglycerides are solubilized by bile acid micelles (shown in partial cross section) and absorbed from micellar solution by passive and carrier-mediated transport systems. In the enterocyte, they are re-esterified to triglycerides; incorporated into chylomicrons (shown in partial cross section), which are secreted by exocytosis; and cleared by the intestinal lymphatics.

The products of triglyceride hydrolysis (fatty acids and b-monoglyceride) are solubilized within the intestinal lumen in combination with secreted bile acids to form mixed micelles. Bile acids are amphipathic, with their hydrophobic and hydrophilic regions clustered at different ends of the molecule. As a result, they can form aggregates, with their hydrophilic domains (solid circles in [Fig. 110.1](#)) oriented on the external surface and their hydrophobic domains on the interior surface. Fatty acids and b-monoglycerides are also amphipathic and become oriented within the micelle with their hydrophobic regions clustered in the interior of the mixed micelle. The bile acid micelle increases the solubility of fatty acids and b-monoglycerides by a factor of 100 to 1,000, thus increasing the delivery of the lipolytic products through the aqueous environment of the intestinal lumen to the enterocyte brush border.

At the enterocyte brush border, fatty acids and b-monoglycerides are released from the micelle to diffuse through the adjacent microvillar membrane. Transport through the microvillar lipid bilayer traditionally has been thought to be by passive diffusion, but more recent data suggest that it also may be facilitated by a fatty acid-binding protein in the microvillar membrane. Once taken up by the enterocyte, fatty acid and b-monoglyceride transport to the endoplasmic reticulum is mediated by the intestinal fatty acid-binding protein. The mechanism for transport of other glycerides and lipids is not certain, but it may require a separate fatty acid-binding protein. Within the cytosol, fatty acids are acylated to fatty acid acyl coenzyme A (CoA). Re-esterification of b-monoglycerides with fatty acid acyl-CoA to form triglycerides is mediated by acyltransferases on the inner surface of the endoplasmic reticulum.

The re-esterified triglycerides become incorporated into another type of lipid aggregate, the chylomicron ([Fig. 110.1](#)), which consists of a central lipid droplet composed predominantly of triglycerides plus small amounts of cholesterol esters and free cholesterol. The droplet is coated with a monolayer of phospholipids that are oriented with their polar head groups to the exterior and their hydrophobic domains to the interior. Several apoproteins (apoA-I, apoA-IV, and apoB-48) also are incorporated into the phospholipid monolayer. These amphipathic apoproteins are synthesized by the enterocyte and become associated with the chylomicron surface within the endoplasmic reticulum and Golgi apparatus. Apoprotein function is not fully understood, but apoA-I is a cofactor for the plasma cholesterol esterification enzyme lecithin-cholesterol acyltransferase, apoA-IV has been shown to be a satiety factor in rats, and apoB-48 appears to be required for coordinated intestinal triglyceride transport. Chylomicrons are packaged into membrane-bound transport vesicles in the Golgi apparatus, transported to the basolateral membrane, secreted by exocytosis into the lamina propria, and selectively taken up into lymphatics.

Phospholipid Digestion and Absorption

Phospholipid digestion and absorption is similar to those of triglycerides. Within the intestinal lumen, phospholipids are hydrolyzed by phospholipase A₂, a 14-kd enzyme secreted by the pancreas as a proenzyme. Trypsin-mediated cleavage of seven N-terminal amino acids results in enzyme activation. Phospholipase A₂ requires both bile salts and calcium for activity. Phospholipase A₂ hydrolyzes the fatty acid at position 2 of phospholipids to form lysophospholipids, which are then solubilized in mixed micelles and taken up into the enterocyte by both passive diffusion and facilitated transport. Intracellularly, lysophospholipids can be re-esterified to phospholipids or degraded by lysolecithinase. Phospholipid assimilation, like that of triglycerides, is more than 90% efficient in the proximal small bowel.

Cholesterol Digestion and Absorption

Cholesterol plays an important role as a component of biologic membranes (modulates fluidity) and as a substrate for steroid hormone and bile acid synthesis. Free cholesterol is the predominant sterol in the diet and in biliary secretions. The small amount of cholesterol ester in the intestinal lumen is hydrolyzed to free cholesterol by pancreatic cholesterol esterase. This enzyme has an absolute requirement for trihydroxy bile acids and is capable of hydrolyzing triglycerides, phospholipids, and esters of vitamins A, D₃, and E. Free cholesterol is solubilized in bile acid micelles; then cholesterol is transported across the jejunal brush border by an energy-requiring process that, in all likelihood, is facilitated by a specific carrier protein. Most of the absorbed cholesterol is re-esterified in the endoplasmic reticulum. Both free cholesterol and cholesterol esters are incorporated into chylomicrons for secretion. Only about half of dietary cholesterol is absorbed into the enterocyte, and its absorption depends critically on the presence of bile acids.

Fat-Soluble Vitamin Assimilation

The fat-soluble vitamins (A, D, E, K) are hydrophobic molecules that are absorbed in a manner similar to that of lipids. Their absorption depends critically on bile acid solubilization. Vitamin A (retinol) is ingested primarily as the provitamin beta carotene, which is solubilized in mixed micelles and passively absorbed from micellar solution. Beta carotene is cleaved intracellularly to two molecules of retinol. Retinol is esterified, incorporated into chylomicrons, secreted, and cleared by the lymphatics. Vitamin A is stored exclusively in hepatic lipocytes as retinol ester.

Most vitamin D is synthesized endogenously in the skin, but it undergoes significant enterohepatic circulation. As a result, substantial vitamin D deficiency can occur in the context of fat malabsorption. Vitamin D is stored in the liver and in peripheral tissues. A portion of vitamin E (alpha tocopherol) is ingested as an ester. The ester is mostly hydrolyzed to alpha tocopherol in the intestinal lumen by nonspecific pancreatic lipase. Absorption of vitamin E is similar to that of vitamin D, with little re-esterification before secretion in chylomicrons.

Vitamin K₁ (phyloquinone) is ingested with food, and vitamin K₂ (menadione) is derived from bacterial sources. Vitamin K₁ appears to be absorbed by active transport, whereas vitamin K₂ is absorbed passively. Both vitamins are secreted largely unchanged into chylomicrons. There is little tissue storage and rapid turnover of the total body pool of vitamin K.

CARBOHYDRATE DIGESTION AND ABSORPTION

The average American diet contains about 250 g of carbohydrates, which accounts for about 45% of daily caloric intake. About half of ingested carbohydrate consists of starch. Two-thirds of ingested starch is amylopectin, a large (10⁶ kd) glucose polymer containing both a₁₋₄- and a₁₋₆-linked glucose molecules, and one-third is amylose, a smaller (100 kd) a₁₋₄-linked glucose polymer. The disaccharides sucrose and lactose constitute about 15% of ingested carbohydrates, and the mushroom disaccharide trehalose is a small component of the diet. Monosaccharides (glucose, galactose, fructose, sorbitol, maltodextrins) are being ingested in increasing amounts in processed and dietetic foods and in soft drinks and now compose up to 10% of ingested carbohydrate. The remainder of dietary carbohydrate (about 10 gm per day) consists of undigestible fiber (cellulose, hemicellulose, gums, and pectins). Although these fibers are not digested in the small intestine, they can be fermented by colonic bacteria. The overall process of carbohydrate digestion and absorption is depicted in [Fig. 110.2](#).

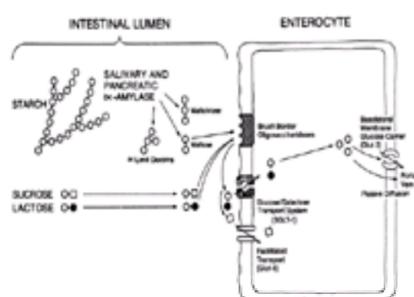

FIGURE 110.2. Digestion and absorption of carbohydrates. Carbohydrates are ingested predominantly as starches and the disaccharides sucrose and lactose. Starches are hydrolyzed by amylases in the intestinal lumen to oligosaccharides (maltose, maltotriose, α -limit dextrins). The oligosaccharides as well as sucrose and lactose are hydrolyzed to monosaccharides by brush-border oligosaccharidases. Glucose and galactose are absorbed by the same active transport process (upward arrow), whereas fructose is absorbed by facilitated diffusion, a passive (downward arrow) process. Monosaccharides are passively secreted into the lamina propria by two mechanisms (simple diffusion and a carrier-mediated process) and cleared by the portal circulation. m, glucose; §, galactose; o, fructose.

Both salivary and pancreatic amylase enzymes are capable of cleaving the internal a₁₋₄-linked glucose bonds of starch. Salivary amylase activity ordinarily is short-lived, because it is not active at the acidic pH of the stomach. The bulk of ingested starch is hydrolyzed by pancreatic amylase to oligosaccharides. The end products of amylase action are a₁₋₄-linked glucose polymers (maltose and maltotriose) as well as a series of α -limit dextrins containing both a₁₋₄ and a₁₋₆ linkages ([Fig. 110.2](#) and [Table 110.1](#)). Sucrose, lactose, and the oligosaccharide products of intraluminal starch hydrolysis are further hydrolyzed to their component monosaccharides by a series of oligosaccharidases of the jejunal brush border ([Fig. 110.2](#) and [Table 110.1](#)). Through the combined action of these enzymes, luminal oligosaccharides are hydrolyzed to glucose and smaller amounts of galactose and fructose.

Substrate	Enzyme	Products
Maltose, Maltotriose, α_{1-4} -linked glucose oligosaccharides	Maltase	Glucose
Sucrose	Sucrase- α -dextrinase	Glucose and fructose
α -limit dextrins (α_{1-4} link)	Sucrase- α -dextrinase	Glucose
α -limit dextrins (α_{1-4} link)	Sucrase- α -dextrinase	Glucose
Lactose	Lactase	Glucose and galactose
Trehalose	Trehalase	Glucose

TABLE 110.1. OLIGOSACCHARIDASES OF THE INTESTINAL BRUSH BORDER

Monosaccharides are transported across the enterocyte by members of two distinct families of transporters, the secondary active sodium/glucose co-transporter SGLT-1 and the facilitated glucose transporters Glut-5 and Glut-2. Glucose and galactose entry across the microvillar membrane is mediated by SGLT-1 and driven by the $\text{Na}^+, \text{K}^+, \text{-ATPase}$ -generated sodium gradient across the apical cell membrane (Fig. 110.3). Fructose enters the cells by facilitated transport that is probably mediated by the Glut-5 transporter. Ingestion of large amounts of fructose found in some soft drinks can overwhelm this transport system and result in osmotic diarrhea. Similarly, sorbitol, which is widely used in dietetic foods, is poorly absorbed by the normal intestinal tract and also can induce osmotic diarrhea. Once inside the cell, the sugars can be used by the enterocyte as an energy source, but most are secreted across the basolateral membrane into the interstitial space. The bulk of the secreted glucose exits by a sodium-independent facilitated transport system (Glut-2), and a smaller fraction (up to 25%) diffuses passively down its concentration gradient through the basolateral membrane. Glucose passes to the portal circulation by passive diffusion. The intestinal assimilation of dietary starch and sucrose is efficient, with nearly 100% assimilation within the jejunum. The efficiency of lactose assimilation varies considerably among different populations (see “Lactase Deficiency”).

FIGURE 110.3. Glucose and galactose transport across the enterocyte. Glucose and galactose are actively cotransported with sodium across the enterocyte brush border by the transport protein SGLT-1. A homotetramer of four SGLT-1 subunits of protein forms the functional cotransporter. Sodium passes down the concentration gradient generated by the sodium–potassium ATPase pump located on the basolateral membrane of the enterocyte and glucose or galactose is cotransported on a 1:1 molar ratio with sodium.

PROTEIN DIGESTION AND ABSORPTION

The average American diet consists of 70 to 100 g per day of protein (about 10% of total caloric intake). In addition, 20 to 30 g per day of endogenous protein is secreted into the intestinal lumen through biliary, pancreatic, and intestinal secretions. Proteins are composed of α -amino acids linked by peptide bonds. There are 20 common amino acids found in protein. Of these, eight essential amino acids (Table 110.2) must come from dietary sources, because they cannot be synthesized by human cells. The overall scheme of protein digestion is shown in Fig. 110.4, Fig. 110.5 and 110.6.

- Leucine
- Isoleucine
- Lysine

TABLE 110.2. ESSENTIAL AMINO ACIDS

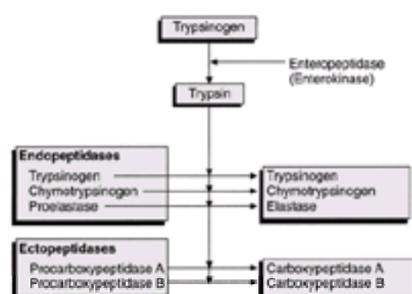

FIGURE 110.4. Activation of the pancreatic protease proenzymes in the intestinal lumen. Trypsinogen is cleaved to the active protease trypsin by the microvillar membrane enteropeptidase. Trypsin can then mediate the proteolytic activation of additional trypsinogen as well as the other proenzymes.

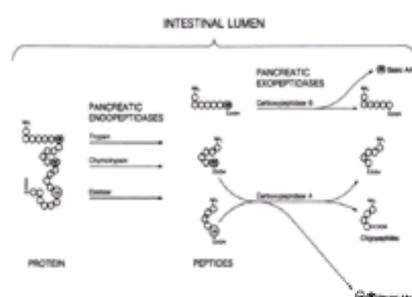

FIGURE 110.5. Intraluminal digestion of proteins by pancreatic proteases. Although protein digestion is initiated in the stomach, most proteolysis is mediated by the

sequential action of pancreatic endopeptidases (trypsin, chymotrypsin, elastase) and exopeptidases (carboxypeptidases A and B). The endopeptidases cleave internal peptide bonds. Each of the pancreatic endopeptidases has a different specificity; thus, a series of oligopeptides results from their action. The carboxypeptidases can then cleave the carboxy-terminal amino acid from the oligopeptides. Trypsin preferentially cleaves peptide bonds on the carboxyl side of basic amino acids, resulting in small peptides with basic carboxy-terminal amino acids. These peptides serve as substrates for carboxypeptidase B, which cleaves the basic carboxy-terminal amino acid from the peptide. Chymotrypsin preferentially cleaves peptide bonds adjacent to aromatic neutral amino acids, and elastase preferentially cleaves bonds adjacent to aliphatic neutral amino acids. The peptides created by chymotrypsin and elastase are then subject to cleavage by carboxypeptidase A, to release the neutral carboxy-terminal amino acid. The products of pancreatic proteolysis therefore are free amino acids and oligopeptides.

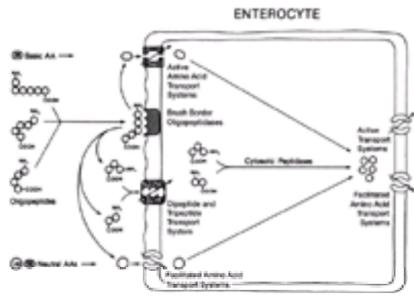

FIGURE 110.6. Brush-border digestion and absorption of proteins. The oligopeptides that are produced by pancreatic protease digestion are further hydrolyzed to free amino acids, dipeptides, and tripeptides by oligopeptidases of the enterocyte brush border. At least seven different sodium-dependent active transport systems (upward arrows) and two facilitated transport systems (downward arrows) of the brush border are responsible for amino acid absorption, and a separate active transport system mediates the absorption of dipeptides and tripeptides (upward arrow). Absorbed oligopeptides are further hydrolyzed to amino acids by a series of cytosolic peptidases. Amino acids are secreted into the lamina propria by both active and facilitated amino acid transport systems of the basolateral membrane and cleared by the portal circulation.

Protein digestion is initiated in the stomach by the action of a group of enzymes, the pepsinogens, that are secreted by chief cells as inactive precursors. At acidic pH, pepsinogens are converted to pepsins by autocatalytic cleavage. The extent of gastric proteolysis depends on many factors, including the rate of gastric emptying, the gastric pH, and the type of protein digested. Gastric proteolysis undoubtedly increases the efficiency of protein digestion, but gastric function is not essential for normal protein digestion.

The bulk of intraluminal proteolysis is mediated by pancreatic proteases through a highly ordered series of events. The pancreas secretes both endopeptidases (trypsin, chymotrypsin, elastase), which are capable of cleaving internal peptide bonds, and carboxypeptidases (carboxypeptidase A and B), which in turn are capable of cleaving the carboxy-terminal amino acid from peptides. All these pancreatic proteases are synthesized and secreted as inactive precursors. Within the small-bowel lumen, trypsinogen is hydrolyzed (by removal of the N-terminal hexapeptide) to the active protease trypsin by enteropeptidase (enterokinase). Enterokinase is a protease that is released from the intestinal brush border by bile acids. Trypsin is then capable of cleaving additional molecules of trypsinogen to trypsin, as well as the other inactive enzymes to their active counterparts (Fig. 110.4). Dietary proteins are initially cleaved by the pancreatic endopeptidases, each of which has a different substrate specificity (Fig. 110.5). The resultant peptides are the preferred substrates for the pancreatic carboxypeptidases. The end products of this ordered sequence of intraluminal proteolysis are basic and neutral amino acids (40%) and a series of oligopeptides (60%).

The oligopeptide products of pancreatic proteases are hydrolyzed further by a series of brush-border oligopeptidases (Fig. 110.5), which remove the amino-terminal amino acid from oligopeptides. A comparable series of brush-border carboxypeptidases can cleave the carboxy-terminal amino acid from oligopeptides, and a family of endopeptidases are capable of cleaving internal peptide bonds of oligopeptides. The final products of the brush-border oligopeptidases are free amino acids, dipeptides, and tripeptides.

The jejunal brush border contains a series of amino acid transporters with different or overlapping specificities. At least six sodium-dependent secondary active transporters for α -amino acids, one active transporter for taurine (a β -amino acid), and three sodium-independent facilitated transporters can mediate amino acid uptake across the microvillar membrane (Table 110.3). System B is thought to be the major apical transport system for neutral amino acids, whereas the X/AG and imino systems are thought to be critical for acidic and proline-containing amino acid transport, respectively. The relative importance of the other transport systems for neutral and basic amino acids is not yet known.

Transport System	Location (Apical/Basolateral)	Substrates	Sodium Dependence
B	Apical	Neutral amino acids	Yes
B ⁺	Apical	Neutral and basic amino acids	Yes
Imino	Apical	Imino acids (proline, hydroxyproline)	Yes
β	Apical	β -amino acid (taurine)	Yes
X ^{+/0}	Apical	Acidic amino acids	Yes
B ⁺	Apical	Neutral and basic amino acids	No
L	Both	Large hydrophobic neutral amino acids	No
Y	Both	Basic amino acids	No
A	Basolateral	Neutral amino acids	Yes
AGC	Basolateral	Three and four-carbon neutral amino acids (alanine, serine, cysteine)	Yes
ac	Basolateral	Three and four-carbon neutral amino acids	No

TABLE 110.3. AMINO ACID TRANSPORTERS OF THE ENTEROCYTE APICAL AND BASOLATERAL MEMBRANE

Many amino acids are more efficiently absorbed as constituents of di- and tripeptides than as single amino acids. One active transport system thus far has been characterized for dipeptides and tripeptides. Dipeptides and tripeptides containing compact amino acids (proline, hydroxyproline, glycine) are the optimal substrates for this sodium-dependent active transport process. Undoubtedly, additional transport systems for amino acids and oligopeptides will be identified.

Absorbed di- and tripeptides are hydrolyzed almost completely to amino acids by a series of cytosolic oligopeptidases that are entirely different from those in the brush border. The three best characterized of these enzymes are cytoplasmic dipeptidase, which hydrolyzes neutral dipeptides; cytosolic prolidase, which specifically hydrolyzes dipeptides containing proline or hydroxyproline; and cytosolic tripeptidase, which has strong affinity for tripeptides containing an amino-terminal proline.

About 10% of absorbed amino acids are used by the enterocyte for protein synthesis, with glutamine being preferentially used as a source of energy. The remainder of absorbed amino acids are transported across the basolateral membrane by several amino acid transport systems (three facilitated and two active transport systems have been described; see Table 110.3). Overall protein assimilation is efficient. More than 95% of dietary and endogenous proteins within the intestinal lumen are absorbed by the proximal and middle small bowel.

ASSIMILATION OF FOLATE AND OTHER WATER-SOLUBLE VITAMINS

Most dietary folates are polyglutamic acid conjugates of folic acid. Hydrolysis of the polyglutaminated folate probably is mediated by a specific brush-border hydrolase that deconjugates the polyglutamate to monoglutaminated folate. The monoglutamyl product is absorbed by an energy-dependent transport process. Relatively little is known about the absorption of the other water-soluble vitamins. Animal studies suggest that there are active transport mechanisms for ascorbic acid, biotin, inositol, nicotinic acid, and thiamine. Para-aminobenzoic acid and pyridoxine appear to enter the cell by simple diffusion, whereas choline and riboflavin are absorbed by carrier-mediated facilitated diffusion.

IRON ABSORPTION

Normally, 1 or 2 mg of iron is absorbed daily. Heme iron, which is found in animal protein, is about six times more efficiently absorbed than the non-heme iron of grains and cereals. Most heme iron is absorbed as an intact metalloporphyrin by gastric and intestinal epithelial cells. The iron is released from heme after absorption by oxidative cleavage mediated by heme oxygenase. In contrast, absorption of nonheme iron depends on several intraluminal factors. Iron is poorly absorbed from ferric salts unless it is reduced, because ferric iron is insoluble in aqueous solution above pH 3. In addition, a number of dietary factors can either increase or decrease nonheme iron solubility in the gut. Organic anions, such as phosphate, phytate, and phosphoproteins, can bind iron and render it insoluble, whereas some amino acids, such as histidine and lysine, complex with iron and make it more soluble. Nonheme iron is absorbed most efficiently in the duodenum, where it is taken up by a carrier-mediated transport process. Once in the cell, iron is either bound to ferritin or transferred to plasma bound to transferrin. The iron–transferrin complex is taken up by the hepatocyte by receptor-mediated endocytosis. The efficiency of iron absorption is enhanced when body iron stores are depleted and diminished when body iron stores rise. The mechanism of regulation is not known, but when the efficiency of iron absorption improves, the absorption of other metals, such as zinc, nickel, manganese, cobalt, and lead, also improves.

SPECIALIZED ILEAL ABSORPTIVE MECHANISMS

Cobalamin (Vitamin B₁₂)

Cobalamin is produced by bacteria and absorbed by animals after ingestion of contaminated foods or after production by the intestinal microflora in ruminants. In humans most dietary cobalamin comes from meat, milk, egg products, and dietary supplements. Cobalamin always is bound tightly to proteins and undergoes a series of protein transfers during its absorption. In ingested tissues it is bound to intracellular enzymes (methylmalonyl-CoA mutase and methyltetrahydrofolate-homocysteine transferase). It is released from these enzymes by gastric proteases and transferred to a family of glycoproteins called R proteins. Both intrinsic factor and R proteins are secreted into gastric juice. Pancreatic proteases subsequently hydrolyze the R protein, freeing cobalamin to bind to intrinsic factor. The cobalamin–intrinsic factor complex is not absorbed in the proximal small bowel but binds to specific receptors on the brush border of the distal ileum. This binding is calcium dependent and requires a neutral pH. The mechanism of uptake and transcellular transport of cobalamin is not clear, but intrinsic factor does not appear to be transported across the enterocyte. Before secretion into the lamina propria, cobalamin is transferred to yet another carrier protein, transcobalamin II. Intestinal malabsorption of cobalamin thus can result from gastric disease that interferes with intrinsic factor secretion, pancreatic insufficiency with failure to release intrinsic factor from R proteins, ileal disease or dysfunction (Crohn's disease, radiation injury, tropical sprue), or bacterial overgrowth (see "Bacterial Overgrowth").

Bile Acids

About 10% of bile acids are absorbed by passive diffusion in the proximal small intestine. The remainder reaches the terminal ileum, where it is absorbed by the sequential action of two secondary active transport systems (conjugated bile acid–anion cotransport across the brush border and bile acid–anion countertransport across the basolateral membrane). Ileal bile acid absorption normally is very efficient—more than 90% of secreted bile acids are reabsorbed into the portal circulation to be extracted by the liver and resecreted into the bile. If bile acids are not absorbed at the terminal ileum, they may enter the colon, where they induce electrolyte and water secretion. Severe bile acid malabsorption, which cannot be compensated for by increased hepatic bile acid synthesis, leads to a decrease in biliary bile acid secretion below the critical concentration necessary to produce mixed micelles, with resultant malabsorption of lipids and fat-soluble vitamins.

Bile acid malabsorption can be assessed by direct measurement of fecal bile acids or fecal excretion of radiolabeled conjugated bile acids, but these assays are cumbersome and not commonly available. Measurements of selenium-75-homocholeic acid taurine (⁷⁵SHCAT) or [¹⁴C]glycocholate or [¹⁴C]taurocholate are more widely used to detect bile acid malabsorption. Plasma levels of 7α-hydroxy-4-cholestene-3-one and lathosterol plasma levels have been shown to reflect bile acid production rate in the liver. Since hepatic synthesis is highly correlated with intestinal loss of bile acids, these plasma sterol measurements may become more convenient ways to measure bile acid malabsorption.

DISORDERS OF DIGESTION AND ABSORPTION

CLINICAL FEATURES OF MALABSORPTION

The dominant symptoms of malabsorption depend on whether there is a generalized defect in nutrient assimilation or a defect in the assimilation of a specific nutrient, such as lactose. A simplified approach to patients suspected of having generalized malabsorption is shown in [Fig. 110.7](#). In generalized malabsorption, the major symptoms result from the loss of calories into the stool (weight loss), an increase in stool volume (diarrhea), colonic fermentation of unabsorbed carbohydrates (abdominal bloating, distention, and flatulence), and deficiency of dietary nutrients (malnutrition). Patients with generalized malabsorption may experience weight loss despite a good and sometimes increasing appetite. They also may have anorexia and lessen their dietary intake because of such symptoms as bloating, cramping, and diarrhea after meals. Abdominal discomfort is common, but significant abdominal pain is unusual and should suggest alternative or additional diagnoses. Nongastrointestinal symptoms, such as short stature or infertility, can be the initial manifestations of chronic subclinical malabsorption.

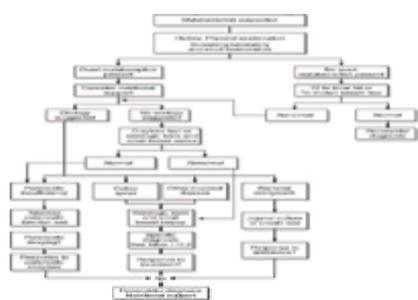

FIGURE 110.7. Approach to the patient with suspected generalized malabsorption. See text for details of specific diagnostic tests and treatment.

If diarrhea is defined strictly as increased stool volume (>200 mL), almost all patients with generalized malabsorption have diarrhea. The diarrhea results from a combination of osmotic and secretory factors (see [Chapter 99](#)). The increased stool volume may or may not be associated with liquid stools, however. Some patients with significant steatorrhea continue to have formed, albeit bulky, stools. Oil or undigested food particles may be seen in the stool. Usually, the stool is pale, yellow, spongelike and difficult to flush down the toilet.

Carbohydrates that are not absorbed in the small bowel can be fermented by colonic bacteria. The resultant gases (predominantly hydrogen and carbon dioxide) contribute to the symptoms of abdominal distention, bloating, and flatulence. The short-chain acids produced by carbohydrate fermentation also can contribute to the osmotic load in the colon and inhibit colonic water absorption.

Deficiency of specific dietary nutrients may be superimposed on the symptoms of generalized malabsorption or may be the initial abnormality. Weakness and lethargy are among the most typical early symptoms of generalized malabsorption and usually are caused by anemia, dehydration, hypokalemia, and hypomagnesemia. Deficiency of iron, folate, or cobalamin can result in anemia. Excessive bruising or bleeding (vitamin K deficiency), paresthesia or tetany (hypocalcemia or hypomagnesemia), and pathologic fractures due to osteoporosis or osteomalacia (calcium and protein deficiency) are the common initial manifestations of specific dietary deficiencies. On clinical examination, pallor, muscle wasting, and hair loss often are present. Follicular hyperkeratosis, chelosis, and glossitis are common signs of nutritional deficits. The abdomen may have a doughy consistency, because of dilated, fluid-filled loops of small intestine. Peripheral edema develops as the result of hypoalbuminemia, and there may be clubbing of the nails or evidence of peripheral neuropathy.

Laboratory test results vary depending on the severity and type of malabsorption. In generalized malabsorption, the stool is usually semiformal or watery and has a high volume. It may appear greasy, and its consistency ranges from watery to putty-like. Anemia is common and may be microcytic, normocytic, or macrocytic, depending on the underlying deficiency. The prothrombin time may be prolonged as the result of vitamin K deficiency. Profound electrolyte depletion, with hyponatremia, hypokalemia, hypochloremia, and metabolic acidosis, may develop with severe disease. Decreased levels of serum calcium, magnesium, zinc, and phosphorus are common. Hypoalbuminemia and hypocholesterolemia are typical in moderate to severe disease. Malabsorption of specific nutrients results in a narrower clinical spectrum than generalized malabsorption. Lactose malabsorption, for example, causes osmotic diarrhea, but it is not associated with the weight loss and malnutrition seen with generalized malabsorption.

DIAGNOSTIC TESTS OF MALABSORPTION

Screening Tests

The serum levels of carotene, cholesterol, and albumin are routinely low in the context of significant malabsorption. Tests for these nutrients therefore can be used as a simple screening battery; however, none of them are specific for malabsorption. Carotene, a fat-soluble vitamin A precursor, is not stored in significant quantity in the body; its serum level depends on recent dietary intake. The level declines in cases of fat malabsorption and is low in people eating low-fat diets. Serum cholesterol and albumin are sensitive tests of generalized malabsorption, but both nutrient levels are diminished in liver disease. Similarly, anemia with signs of low iron, folate, or cobalamin can occur in the context of malabsorption but more commonly are due to other causes. Measurement of stool pH and total reducing substances is useful to screen for carbohydrate malabsorption. All these tests may support the clinical suspicion of generalized malabsorption, though more specific tests are used to establish the diagnosis.

Quantitative Fecal Fat

The quantitation of fat in a 72-hour collection of stool has been the standard for the detection of steatorrhea. To obtain the best results, the patient should ingest a diet containing 70 to 100 g of fat for at least 3 days before collection of the stool. All stool specimens for the subsequent 3 days are collected and mixed, and an aliquot is analyzed for fat content. Most laboratories that measure fecal fat use the titrimetric method of Van de Kamer, but near infrared reflectance analysis may have better reproducibility. Normally, more than 95% of the dietary fat intake is absorbed. Stool fat in excess of 6 g per day is considered abnormal. Falsely elevated results can be obtained from patients taking mineral oil, castor oil, or the fat substitute Olestra.

Quantitative fecal fat determinations are difficult to complete, and collections of stool are unpleasant for both the patient and the staff. Usually, the samples are sent to outside laboratories for analysis, delaying the availability of results. As a result, many other diagnostic tests for steatorrhea have been developed. The stool steatocrit can be measured in an aliquot of acidified, homogenized stool, to estimate the percentage of fat in the specimen. This method is reported to have reasonably high sensitivity (87%) and specificity (97%) for steatorrhea.

Qualitative Stool Fat by Light Microscopy

Sudan III staining of a freshly obtained stool specimen can confirm immediately a clinical impression of severe steatorrhea. To carry out the test, a small sample of stool is mixed with two drops of water, two drops of 95% ethyl alcohol, and several drops of Sudan III stain. Light microscopic examination shows the presence of the yellow to yellow-orange refractile fat globules. This direct Sudan stain identifies neutral fats in the stool, such as those found with pancreatic insufficiency. To detect fatty acids and fat soaps, the stool is mixed with several drops of Sudan III stain and several drops of glacial acetic acid and heated before examination. There are fewer than 100 tiny fat globules in each high-power field of normal stool; the globules are more numerous and larger in steatorrhea. Test results are false-positive for people taking mineral oil, castor oil, or the fat substitute Olestra. The test correlates well (>85%) with the presence of severe steatorrhea (>15 g) but has low sensitivity for mild to moderate disease.

[¹⁴C]Triolein Breath Test

In the [¹⁴C]triolein breath test, the carbon 14–radiolabeled triglyceride triolein is taken orally with a fat meal. Each hour for 6 to 8 hours, a sample of the patient's exhaled breath is analyzed for the ¹⁴C-labeled carbon dioxide (¹⁴CO₂). Normally, the lipids are absorbed and subsequently metabolized, releasing ¹⁴CO₂. Fat malabsorption results in blunted ¹⁴CO₂ production. There is considerable variability in the literature concerning the clinical value of this test. The most favorable reports suggest that it has 85% to 90% sensitivity and specificity for significant steatorrhea.

D-Xylose Test

Once generalized malabsorption is established, the D-xylose test is of value in localizing the site of malabsorption. D-Xylose is a five-carbon sugar that is absorbed intact in the jejunum by passive diffusion. D-Xylose absorption is typically normal in luminal causes of maldigestion, such as pancreatic or bile acid deficiency, but is diminished in diffuse mucosal diseases. Normal subjects given an oral dose of 25 g of D-xylose excrete 4.5 g of the xylose in the urine within 5 hours, and the 2-hour blood level is more than 30 mg per deciliter. An abnormal D-xylose test has about 80% sensitivity and specificity for detecting mucosal dysfunction. False-positive test results may occur with renal disease, delayed gastric emptying, ascites (increased volume of distribution of xylose), and bacterial overgrowth (intraluminal bacterial use of xylose).

Small-intestinal Radiographs

Radiologic evaluation of the small intestine sometimes is useful in distinguishing between luminal and mucosal causes of generalized malabsorption. The presence of pancreatic calcifications suggests the possibility of pancreatic insufficiency. The small-intestinal mucosal pattern is usually normal in pancreatic or biliary causes of malabsorption, whereas it is frequently abnormal in mucosal diseases. The pattern of mucosal abnormality also can suggest the type of mucosal disease. Dilated small intestine (>3 cm in caliber) with variable mucosal fold thickening (>3 mm) typically is seen in celiac and tropical sprue, short bowel syndrome, and bacterial overgrowth. Markedly thickened mucosal folds with or without dilatation are seen in malabsorptive disorders associated with infiltration of the intestinal wall with fluid (blood, lymph, edema) or cells (tumor, inflammation). The thickened folds may be straight and regular, as in lymphangiectasia, abetalipoproteinemia, or amyloidosis, or irregular and distorted, as in Whipple's disease, lymphoma, or Crohn's disease.

Small-intestinal Biopsy

In mucosal causes of malabsorption, small-intestinal biopsy may establish a specific diagnosis or show a pattern that is seen in several disorders (villous atrophy). Biopsy specimens may be obtained either with a suction instrument or at the time of endoscopy. The endoscopic appearance of scalloped duodenal folds or loss of duodenal folds suggests the diagnosis of villous atrophy. Once the biopsy specimens are obtained, they should be oriented before fixation, to ensure optimal interpretation ([Fig. 110.8](#)).

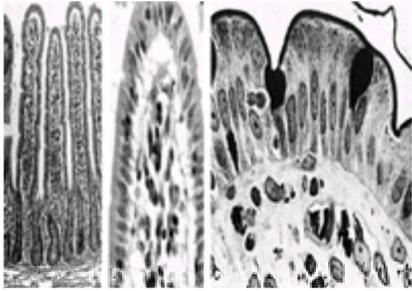

FIGURE 110.8. Histologic appearance of normal jejunum. **A:** The villi are long and slender, and the villus/crypt length ratio is 4:1. Scattered cells are present in the lamina propria. **B:** The enterocytes are columnar with basal nuclei. A few intraepithelial lymphocytes (dark round nuclei) are present. **C:** Electron microscopy of columnar enterocytes with scattered goblet cells (black-stained mucus) and a uniform microvillus surface. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

Tests for Intestinal Bacterial Overgrowth and Specific Nutrient Malabsorption

Although other tests for intestinal bacterial overgrowth are simpler, jejunal cultures remain a standard for documenting small-intestinal bacterial overgrowth. In this test, a nasogastric tube is passed into the proximal jejunum. Several samples of jejunal secretions should be obtained for aerobic and anaerobic cultures. A culture result showing more than 10^5 aerobic organisms per milliliter or any anaerobic growth is considered abnormal (10^3 to 10^5 organisms per milliliter is suggestive of abnormality).

The D- ^{14}C xylose test measures the release of $^{14}\text{CO}_2$ after ingestion of 1 g of D-xylose containing a trace amount of D- ^{14}C xylose (see [Chapter 129](#)). Bacterial fermentation of D- ^{14}C xylose in the small intestine results in a prompt increase in $^{14}\text{CO}_2$ in the breath. The test has 90% to 95% sensitivity and specificity for small-intestinal bacterial overgrowth.

Several breath hydrogen tests have been developed on the principle that most hydrogen in the breath comes from fermentation of undigested carbohydrates by intestinal bacteria (see [Chapter 100](#)). The bile acid breath test measures $^{14}\text{CO}_2$ in the breath after oral administration of choly- L- ^{14}C glycine and can be used to detect either bile acid malabsorption or bacterial overgrowth. If the radiolabeled bile acid is not absorbed normally in the ileum or is deconjugated by bacteria in the small intestine, the ^{14}C glycine is fermented to $^{14}\text{CO}_2$, which is measured in the exhaled breath. All breath hydrogen tests have the limitation that 10% and 25% of normal subjects do not have enough hydrogen-producing bacteria in the intestine to cause fermentation. Cobalamin absorption classically is measured with a dual-labeled Schilling test. Increased serum homocysteine and/or methylmalonic acid levels are a relatively sensitive screening test for cobalamin deficiency.

MALDIGESTIVE SYNDROMES

Exocrine Pancreatic Insufficiency

The two most common causes of exocrine pancreatic insufficiency in adults are chronic pancreatitis (see [Chapter 117](#)) and pancreatic carcinoma (see [Chapter 118](#)); in children, the most common cause is cystic fibrosis. Regardless of the source, pancreatic insufficiency can result in severe malabsorption, with fecal fat excretion of more than 35 g per day.

The diagnosis of exocrine pancreatic insufficiency is suggested by the presence of significant steatorrhea together with normal D-xylose absorption or normal small-intestinal radiographs. The diagnosis is supported by radiologic evidence of pancreatic disease (calcification) and endocrine pancreatic insufficiency. Pancreatic secretory testing is the best means of directly evaluating pancreatic function (see [Chapter 117](#)). In clinical practice, the diagnosis of exocrine pancreatic insufficiency often rests on indirect tests, such as the bentiromide test (PABA) and the pancreolauryl tests, which measure urine, plasma, or breath levels of the pancreatic hydrolytic products of orally administered substrates. Fecal levels of chymotrypsin or elastase levels also are diminished in patients with pancreatic insufficiency. Often the diagnosis is established by clear improvement in malabsorption in response to a trial of pancreatic enzyme replacement.

Bile Acid Deficiency

Solubilization of fatty acids requires bile acids; thus, moderate steatorrhea can develop in disorders that cause deficient bile acid delivery to the intestinal lumen (bile duct obstruction, intrahepatic cholestasis). In ileal disease or resection, failure of bile acid reabsorption leads to depletion of the bile acid pool. Inherited defects in ileal bile acid transport have been identified, and ileal bile acid absorption is particularly sensitive to the effects of radiation. These partial defects in bile acid absorption more commonly cause diarrhea, as a result of the effects of unabsorbed bile acids on colonic fluid secretion, than frank malabsorption. In states of bile acid deficiency, the symptoms of malabsorption often are overshadowed by other symptoms of the underlying disease (obstructive jaundice, active Crohn's disease of the ileum). Specific defects in ileal bile acid uptake can be measured with a bile acid breath test.

Bile acid depletion can improve with treatment of the underlying disease (i.e., glucocorticoids for ileal Crohn's disease), but the defect often is fixed (ileal resection). Bile acid diarrhea improves with binding resins, such as cholestyramine, but they can worsen bile acid depletion and its associated steatorrhea. Therapy for steatorrhea is directed at improving fat absorption, supplementing fat-soluble vitamins, and minimizing symptoms. Vitamin B₁₂ and bile acid malabsorption typically co-exist with ileal disease.

MALABSORPTIVE SYNDROMES

Celiac Sprue

Until recently celiac sprue (gluten-sensitive enteropathy, nontropical sprue) was thought to be a relatively uncommon disorder characterized by chronic diarrhea and overt generalized malabsorption. Recognition of cases with milder clinical expression, wider use of endoscopic biopsy of the duodenum, and, in particular, immunologic screening methods have changed that view dramatically. Screening studies have suggested that celiac sprue may be very common, affecting as many as one in 200 individuals. The prevalence of celiac sprue is higher in patients with selective IgA deficiency (up to 10%) and Down's syndrome (up to 16%).

Celiac sprue is thought to be an immune disorder in genetically predisposed individuals that produces injury to the small-intestinal mucosa and is triggered by the gliadin fraction of gluten. Gliadin is a protein constituent of wheat, barley, rye, and perhaps oats. Genetic factors are important in the pathogenesis of celiac sprue. About 10% of first-degree relatives of patients with celiac sprue also have the disease, and concordance of disease in identical twins has been reported. Genetic susceptibility to celiac disease is likely multigenic. Linkage with the HLA-DQ2 and/or -DQ8 gene loci account for part of the genetic predisposition, but a non-HLA locus on the short arm of chromosome 6 and other loci also appear to be involved.

An autoimmune response to gliadin-related peptides is suggested as a mechanism of injury in celiac disease by both histologic and immunologic features of the disease. The small-intestinal lamina propria is infiltrated heavily with lymphocytes and plasma cells, some of which have been shown to be capable of producing antigliadin antibodies, and there is an increased number of g/d T-cell receptor–positive intraepithelial lymphocytes. The presence of circulating antibodies to gliadin and a variety of autoantibodies (antireticulin, anti-endomysial, anti-tissue transglutaminase) suggests that humoral immunity also plays a part in the response.

Celiac sprue causes varying degrees of diffuse injury to enterocytes, resulting in sloughing of cells from the villi and compensatory crypt hyperplasia. On histologic examination, the total thickness of the mucosa is normal ([Fig. 110.9](#)); the villi are atrophic, however, and the crypts are elongated. The surface epithelium, which is normally columnar, appears cuboidal, and there is a loss of the normal basal polarity of the enterocyte nuclei. The crypts are hyperplastic and hyperproliferative. The lamina propria has higher than normal numbers of plasma cells and lymphocytes and more intraepithelial lymphocytes. Electron microscopy shows shortened and

sparse microvilli and loss of tight junctions. Enzymatic analyses confirm a decrease in the concentration of digestive hydrolases in the mucosa. These abnormalities result in both fewer numbers and impaired functional capacity of absorptive cells.

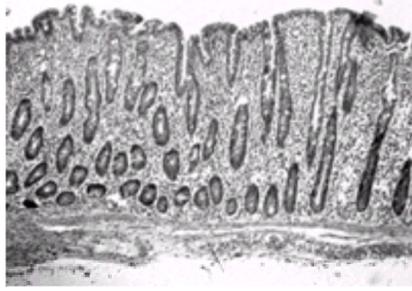

FIGURE 110.9. Histologic appearance of the jejunum in a patient with celiac sprue. Villi are absent (total villous atrophy). The crypts are hyperplastic. The lamina propria is infiltrated with mononuclear cells. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

The length of intestine affected in celiac sprue varies and correlates with the severity of symptoms, but the degree of involvement diminishes from proximal to distal sites. Thus, malabsorption of nutrients that normally are absorbed in the proximal small intestine (fat, protein, carbohydrate, iron, calcium, vitamin D) is more common than malabsorption of bile acids or cobalamin.

Clinical Findings and Diagnosis

The clinical features of celiac sprue vary widely, and spontaneous exacerbations and remissions of symptoms occur. Celiac sprue that manifests during childhood may go into remission during adolescence, only to recur in adulthood. The symptoms, signs, and laboratory data in celiac sprue span the entire spectrum described earlier for generalized malabsorption. The clinical manifestations of celiac sprue may be as subtle as short stature or as severe as malabsorption with dehydration, emaciation, and adrenocortical insufficiency. Nongastrointestinal symptoms may predominate ([Table 110.4](#)).

- Short stature
- Delayed puberty
- Oligomenorrhea
- Infertility
- Iron-deficiency anemia
- Osteomalacia or osteoporosis
- Hypoalbuminemia
- Depression
- Ataxia
- Arthritis

TABLE 110.4. EXTRAINTESTINAL MANIFESTATIONS OF CELIAC DISEASE

Several clinical features suggest the diagnosis of celiac sprue. A family history of the disorder is helpful. The spontaneous remission seen in adolescence is not observed in other causes of malabsorption. Dermatitis herpetiformis, a pruritic, papulovesicular rash typically present over the elbows, knees, and buttocks, develops in 10% to 25% of patients with celiac sprue. Almost all (85% to 90%) patients with dermatitis herpetiformis have abnormal small-bowel biopsy results, but the intestinal involvement can be patchy, and the disease is often mild and asymptomatic.

The diagnosis of classic celiac sprue rests on findings of mucosal malabsorption, small-intestinal biopsy results showing villous atrophy, and resolution of the disorder after gluten withdrawal. The malabsorption may be generalized, with steatorrhea, or more selective (iron, folate, vitamin D deficiency). The D-xylose test shows abnormal results in about 70% of patients, and a small-intestinal series typically shows dilatation of the small intestine and various degrees of thickening of the mucosal folds. Villous atrophy is seen in other diseases ([Table 110.5](#)), but celiac sprue is the most common cause of total villous atrophy. The presence of circulating antigliadin, anti-endomysial, or antitransglutaminase antibodies supports but does not establish the diagnosis. Evidence of a prompt clinical response and histologic signs of improvement in the small bowel with institution of a strict gluten-free diet confirm the diagnosis.

Normal	Villous height ratio 3 or 1; columnar epithelial cells, scattered mononuclear cells in the lamina propria (Fig. 110.8)
Disorders in which small intestinal biopsy is diagnostic	
Whipple's disease	Distention of cells, PAS-positive macrophages in the lamina propria, lactin's or lactoferrin (microscopically) (Fig. 110.15)
Hyperparathyroidism	Partial villous atrophy, loss of plasma cells and lymphocyte infiltrate in lamina propria, sandstone bodies (lymphoid hyperplasia)
Abetalipoproteinemia	Intensification of villi with lipid droplets (Fig. 110.12)
Ameloidosis	Amorphous deposits in the mucosa and submucosa
Disorders in which small intestinal biopsy may be diagnostic	
Celiac sprue	Macronuclear cause of total villous atrophy, crypt hyperplasia, lymphocytic infiltration of lamina propria (Fig. 110.9)
Intestinal lymphangiectasia	Dilated proliferation in the lamina propria
Intestinal lymphoma	Infiltration of lamina propria and displacement of crypts with malignant lymphocytes
Quincke's edema	Flourishing villi, normal crypts
Parvovirus infections	Giant cells or cytoplasmic inclusions attached to epithelial cells, vesicles in crypts
Relapsing enteritis	Acute partial villous atrophy, no crypt hyperplasia, decreased mucus in crypts
Disorders in which the small intestinal biopsy result is abnormal but not diagnostic	
Tropical sprue	Partial villous atrophy, lymphocytic infiltration of lamina propria (Fig. 110.10)
Shigellosis, bacterial overgrowth	Partial villous atrophy and lymphocytic infiltration of lamina propria in a patchy distribution

TABLE 110.5. HISTOLOGIC CHARACTERISTICS OF THE SMALL INTESTINE

Serologic studies increasingly are being used to aid in the diagnosis of celiac sprue. The relative sensitivity and specificity of these tests from one laboratory are shown in [Table 110.6](#), but these results vary among laboratories. For screening of low-risk populations, the anti-endomysial antibody test has slightly better performance characteristics but is more expensive than the IgA antigliadin test. A negative result on either test suggests an alternative diagnosis. In subjects with a high or moderate probability of having the disease, the anti-endomysial test is preferred because of its higher specificity. The IgG anti-gliadin test is used only in subjects with selective IgA deficiency. Serologic screening of asymptomatic subjects is not recommended at present, because clinical benefit has not been established and any potential benefit requires adherence to a difficult dietary regimen.

Antibody	Prev	Sens	Spec	PPV
IgA antiendomysial	<1%	85-95%	91-100%	95-100%
IgA anti gliadin	<1%	80-90%	85-95%	12%
IgG anti gliadin	7%	75-85%	75-90%	2%

Prev, prevalence in the general population; Sens, sensitivity; Spec, specificity; PPV, positive predictive value in a general population at low risk for celiac disease.
 Kelley CP. Use of serum antibodies to diagnose celiac disease. In Rose BD, ed. *Up to Date in Medicine*. Up to Date in Medicine, Inc., 1999.

TABLE 110.6. RELATIVE PERFORMANCE CHARACTERISTICS OF SEROLOGIC TESTS FOR CELIAC SPRUE IN A GENERAL POPULATION

Some patients with celiac disease in childhood experience remission of disease later in life and can have normal jejunal mucosa and few or no symptoms while on a gluten-containing diet. Such individuals are said to have latent celiac disease and are at risk of recurrent symptoms. Patients who have never had a biopsy result suggestive of celiac disease but who have characteristic immunologic abnormalities are said to have potential celiac disease.

Optimal Management

The therapy for celiac sprue includes nutritional repletion and strict gluten withdrawal. Gluten withdrawal may not be simple to achieve, because gluten-containing grains are ubiquitous in processed foods. The patient must be both well informed and highly motivated to achieve strict gluten withdrawal. The clinical response to gluten avoidance correlates with the length of intestine involved. Improvement in symptoms usually takes place within 1 to 2 weeks of initiation of therapy, but the histologic features may take several months to normalize. Less than 10% of patients with the diagnosis of celiac sprue fail to respond to a gluten-free diet (so-called refractory sprue). Some of these patients respond to a trial of prednisone. Relapse of symptoms after adequate gluten withdrawal is common and usually is caused by failure to maintain a strict gluten-free diet. If symptomatic recurrence persists despite adequate dietary control, the possibility of a secondary complication, such as intestinal lymphoma, should be considered.

Tropical Sprue

Tropical sprue is a syndrome of uncertain origin that results in progressive mucosal injury to the entire small intestine and probably represents more than a single entity. It should be suspected in residents of tropical regions with chronic diarrhea and malabsorption of at least two unrelated nutrients (xylose and vitamin B₁₂). The disorder may manifest within months of arriving in the tropics, after many years of tropical residence, or after return to a temperate climate from the tropics. Tropical sprue is not uniformly prevalent in the tropics; it is common in Haiti, the Dominican Republic, India, Indonesia, and Southeast Asia but rare in Jamaica, the Bahamas, and Africa.

One form of tropical sprue probably results from bacterial infection of the gastrointestinal tract. The data suggesting that tropical sprue is an infectious disease are the geographic distribution of its occurrence; the seasonal appearance of disease, peaking between April and June; the appearance of epidemics and focal outbreaks of the disease; the apparent declining incidence of the disease; the relatively rapid appearance of the disease in visitors to endemic areas; and the response of affected patients to antibiotic therapy. Enterotoxigenic coliform bacteria have been isolated in the proximal small intestine of patients with tropical sprue, but no specific strains have been found consistently. Chronic protozoal infection (*Cryptosporidium parvum*, *Isospora belli*, *Cyclospora cayentanensis*) also has been suggested as a cause of the syndrome. Nutritional factors are important in tropical sprue. There is a much lower incidence of the disease in tropical countries whose populations are generally well nourished (Puerto Rico). The rapid and often dramatic response to folate therapy highlights the importance of this nutritional element.

Pathogenesis

Tropical sprue can affect any or all regions of the small intestine, often in a patchy distribution. The small-intestinal mucosa shows partial to subtotal villous atrophy and infiltration of the lamina propria with a mixture of lymphocytes and plasma cells (Fig. 110.10). No histologic features completely distinguish tropical from celiac sprue, but total villous atrophy is much less common in tropical sprue.

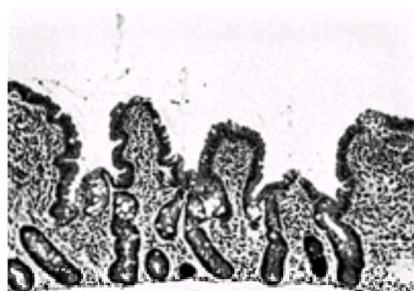

FIGURE 110.10. Histologic appearance of the jejunum in a patient with tropical sprue. The villi are shortened (partial villous atrophy). The crypts are mildly hyperplastic. (The villus/crypt ratio is 1:1.) The lamina propria is infiltrated with mononuclear cells. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

Clinical Findings and Diagnosis

Patients with tropical sprue usually suffer a progressive course that begins with fatigue and diarrhea and leads to abdominal distention and watery diarrhea. Late in the course of the disease, severe anemia (combinations of B₁₂, folate, and/or iron deficiency) and progressive malnutrition are noted. Although most of the features of tropical sprue are similar to those of celiac sprue, there are several distinctions. Megaloblastic anemia due to vitamin B₁₂ deficiency is much more common in tropical sprue, because the entire small intestine is affected. Abdominal pain also is more typical of tropical sprue (90%) than celiac sprue (30% to 50%). A pellagroid or eczematous rash over the ankles and wrists is characteristic of tropical sprue, but it is distinct from the dermatitis herpetiformis seen in celiac sprue.

The diagnosis of tropical sprue is based on the clinical syndrome of progressive malabsorption and malnutrition, an appropriate residence or travel history, evidence of malabsorption caused by mucosal disease; a typical small-intestinal biopsy result showing partial villous atrophy (Fig. 110.10); and an appropriate response to specific therapy. Because this disease occurs in the tropics, the differential diagnosis includes parasitic and tuberculous enteritis as well as inflammatory bowel disease, gluten-sensitive enteropathy, and the other causes of mucosal malabsorption (Table 110.5).

Optimal Management

Patients with early symptoms of tropical sprue respond within a few days to folate therapy. Patients with signs of disease lasting longer than 4 months should be treated with tetracycline, 500 mg four times daily for the first month and then 500 mg twice daily for 5 to 11 months, and folate, 0.5 mg per day for 6 to 12 months.

Failure to improve progressively on this therapy should prompt reevaluation of the diagnosis.

Whipple's Disease

Whipple's disease is a rare, chronic systemic bacterial infection that appears to strike predominantly white men. Many organs can be affected in Whipple's disease, but gastrointestinal involvement with generalized malabsorption is the most common clinical picture. A bacterial cause for Whipple's disease had long been suspected because of evidence of numerous, weakly gram-positive bacilli in many tissues, including enterocytes and macrophages of the intestinal lamina propria ([Fig. 110.11](#)) and by the clinical response to antibiotics. The organism responsible for Whipple's disease (*Tropheryma whipellii*) was originally identified by a polymerase chain reaction-based assay and later cultured in human phagocytes in vitro.

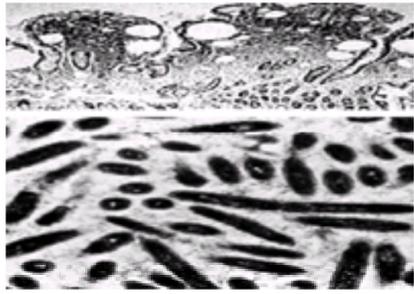

FIGURE 110.11. Histologic appearance of the small intestine in a patient with Whipple's disease. **A:** The villi are widened by the infiltration of periodic acid-Schiff-positive macrophages. **B:** Electron microscopic appearance of the bacteria (*Tropheryma whipellii*) seen in Whipple's disease. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

The intestinal features of Whipple's disease may be patchy, but they are typically most severe in the proximal small intestine. Clubbing of the villi and periodic acid-Schiff (PAS)-positive macrophages in the lamina propria are seen in intestinal biopsy specimens ([Fig. 110.11](#)). Similar PAS-positive macrophages may infiltrate other organs, including the remainder of the gastrointestinal tract, mesenteric and peripheral lymph nodes, heart, brain, lung, spleen, liver, and pancreas.

Clinical Findings and Diagnosis

Although involvement of the small intestine with resultant progressive malabsorption is the usual reason that patients with Whipple's disease seek medical attention, it is the extraintestinal symptoms that suggest the specific diagnosis. The most common extraintestinal features of Whipple's disease are arthritis and arthralgia. The joint symptoms may predate the development of diarrhea and malabsorption by many years. Low-grade fever and lymphadenopathy are typical, and murmurs of aortic or mitral insufficiency are found in about 25% of patients. Central nervous system involvement can cause a host of neurologic abnormalities (personality changes, dementia, visual disturbances, hypothalamic symptoms, meningoencephalitis, spastic paresis, encephalopathy, posterior column disease).

The diagnosis of Whipple's disease is based on the clinical picture of generalized malabsorption with prominent extraintestinal manifestations and positive results of small-intestinal biopsy. Steatorrhea occurs in more than 90% of patients, and decreased D-xylose absorption is found in 75%. Because the disease primarily involves the proximal small intestine, vitamin B₁₂ or bile acid malabsorption is uncommon. Radiographic studies show irregular thickening of the duodenal and jejunal folds with dilatation of the jejunal loops. Small-intestinal biopsy specimens show blunting of the villi and PAS-positive macrophages in the lamina propria ([Fig. 110.11](#)). The diagnosis is confirmed by microscopic evidence of characteristic bacteria within enterocytes or macrophages.

Optimal Management

A typical regimen for treatment of Whipple's disease is 1.2 million units procaine penicillin and 1 g streptomycin daily for 10 days, followed by trimethoprim-sulfamethoxazole, one double-strength tablet twice daily, or tetracycline, 1 g per day for 1 year. With treatment, a sense of well-being and improved appetite usually return within a few weeks, and the malabsorption is corrected within the first few months. A second biopsy of the small intestine shows clearing of the bacteria from the enterocytes, but the PAS-positive macrophages may persist for several years. Whipple's disease may relapse after therapy, without significant gastrointestinal involvement. Neurologic symptoms are the most difficult to treat; they may or may not respond to antibiotic therapy.

Abetalipoproteinemia

Abetalipoproteinemia results from a genetic defect in triglyceride transport and secretion. It is a rare autosomal recessive disorder that has a high prevalence among Mediterranean Jews. In at least some families, the disease appears to be caused by a mutation in a microsomal triglyceride transport protein. The disease results in a failure of b-lipoprotein (chylomicrons and very low density lipoprotein) assembly. The resultant impairment in chylomicron secretion from the enterocyte leads to triglyceride accumulation within the enterocyte and mild fat and fat-soluble vitamin malabsorption in infancy. Characteristically, small-intestinal biopsy shows normal villous architecture, but the enterocytes are filled with lipid droplets ([Fig. 111.12](#)). Neurologic symptoms develop late in the course of the disease, and the typical acanthocytic red blood cells appear later still. Markedly low serum triglyceride (<10 mg per deciliter) and cholesterol (<50 mg per deciliter) levels are noted frequently. No effective therapy exists for the extraintestinal manifestations; however, nutrition may be improved with the use of a low-fat diet supplemented with fat-soluble vitamins and medium-chain triglycerides.

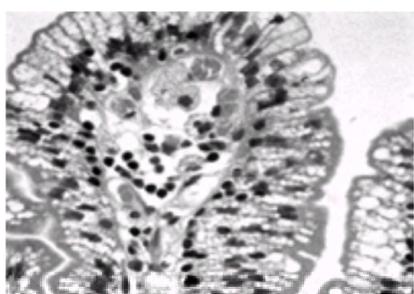

FIGURE 110.12. Histologic appearance of small intestine in a patient with abetalipoproteinemia. The villous architecture is normal. The enterocytes are columnar, but they are filled with lipid droplets. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

Parasitic Nematode and Cestode Diseases

Giardia lamblia can cause diarrhea through several intraluminal effects, including bile salt deconjugation and uptake by the parasite, promotion of bacterial overgrowth, and inhibition of enterocyte lactase and other hydrolases. The presence of generalized malabsorption, however, is closely related to the organism's ability

to induce enteropathy. Giardial enteropathy occasionally is seen in immunocompetent subjects, but it is a common source of villous atrophy and mild to moderate fat malabsorption in immunodeficient subjects, particularly those with common variable immunodeficiency or the acquired immunodeficiency syndrome. The mechanism of giardial enteropathy is not known. The diagnosis of giardiasis can be made by examination of the stool or duodenal aspirate by wet preparation.

Infestation with *Cryptosporidium* protozoa or *Isospora belli* usually leads to an acute diarrheal illness (see [Chapter 321](#)) that sometimes is associated with generalized malabsorption. As with giardiasis, immunodeficient subjects are at higher risk of primary, persistent, and recurrent coccidiosis. The protozoa may be seen on stool examination, but the diagnosis usually is made by small-intestinal biopsy. Small-intestinal biopsy in these cases shows evidence of partial villous atrophy with a mixed eosinophilic, lymphocytic, and polymorphonuclear infiltrate in the lamina propria. Cryptosporidia may take the form of basophilic bodies along the microvillus border. Various forms of *Isospora* may be evident within epithelial cells. Strongyloidiasis and capillariasis also can cause generalized malabsorption. *Diphyllobothrium latum* can provoke vitamin B₁₂ malabsorption, and *Ascaris lumbricoides* can bring about vitamin A malabsorption.

Immunodeficiency States and Malabsorption

About 10% of patients with selective IgA deficiency or common variable immunodeficiency syndrome have diarrhea and steatorrhea. The latter patients often have long histories of recurrent sinopulmonary infections before the onset of diarrhea and malabsorption. Often, malabsorption is caused by giardiasis, but other chronic infections can elicit similar symptoms. The diagnosis of malabsorption is established in the usual manner, but stool cultures and examination for ova and parasites establish the correct diagnosis. Small-intestinal radiographs may show nodular lymphoid hyperplasia ([Fig. 110.13](#)). The small-intestinal biopsy sample is characterized by villous atrophy and cellular infiltration of the lamina propria, but the appearance is distinguished from those of other conditions by the absence of plasma cells in the lamina propria and the presence of *Giardia lamblia* trophozoites adherent to the luminal mucosa. Nodular lymphoid hyperplasia also may be found on histologic examination ([Fig. 110.14](#)). Diarrhea and malabsorption usually resolve with therapy of the enteric infection.

FIGURE 110.13. Loop of small intestine showing nodular lymphoid hyperplasia in a patient with hypogammaglobulinemia and generalized malabsorption. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

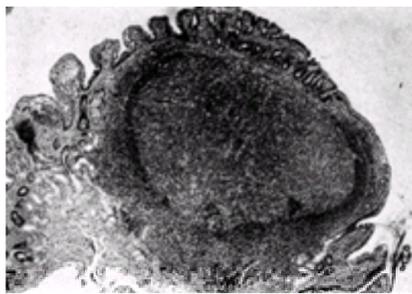

FIGURE 110.14. Histologic appearance of nodular lymphoid hyperplasia of the small intestine. The mucosa overlying the lymphoid nodule is flattened. (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

Diarrhea with or without malabsorption occurs frequently in the context of the acquired immunodeficiency syndrome and contributes to the progressive weight loss and cachexia seen in this disease. A specific treatable infectious agent should be sought—the most common are *Cryptosporidium* species, *G. lamblia*, *I. belli*, *Mycobacterium avium-intracellulare*, and cytomegalovirus. Often, however, a specific agent that accounts for the diarrhea is not found. Secondary lactase deficiency and bile acid and cobalamin malabsorption are particularly common in this context and can respond to specific therapy. Symptomatic antidiarrheal therapy also can be effective.

Small-intestinal Resection

The end result of a small-intestinal resection on nutrient assimilation depends on the length and site of the resection and the functional capacity of the remaining bowel. In general, resections that leave more than half of the jejunum intact do not result in significant malabsorption, but larger resections are associated with varying degrees of malabsorption. Even small resections of critical sites within the small intestine can provoke specific deficiencies, however. Patients with resections that include the duodenum and proximal jejunum have a high incidence of iron and calcium deficiency, whereas resections of the distal ileum are associated with vitamin B₁₂ and bile acid malabsorption. Any resection that includes the ileocecal valve is associated with a greater risk of postoperative diarrhea, because it shortens the duration of nutrient retention in the small intestine and may allow bacterial overgrowth due to the retrograde spread of colonic bacteria. Not surprisingly, the capacity of the residual small intestine to absorb nutrients is an important factor in the clinical consequences of small-intestinal resection. Resection is followed by adaptation of the small-intestinal remnant, which may lead to diminishment of the severity of malabsorption over time. The mechanism of adaptation is unknown, though trophic hormones, luminal nutrients, and neural factors have been proposed as important elements. Adaptation appears to occur more readily in children than adults.

Clinical Findings and Diagnosis

Usually, it is not difficult to make the diagnosis of malabsorption stemming from small-intestinal resection, because the symptoms begin immediately after surgery. The clinical picture ranges from isolated nutrient deficiencies to generalized malabsorption and malnutrition. Resections of less than 100 cm of ileum typically are associated with modest (20% to 50%) declines in bile salt absorption. Although these declines lead to increased loss of bile salts into the colon, enhanced hepatic synthesis of bile salts is capable of maintaining the bile acid pool size, thereby preventing fat malabsorption. The presence of excessive amounts of bile salts in the colon, however, produces increased colonic water secretion and diarrhea. With larger resections of the ileum (>100 cm), more extensive bile salt malabsorption can provoke bile salt depletion and steatorrhea.

Optimal Management

Parenteral nutrition should be instituted routinely after major small-intestinal resections. Enteral feeding can be resumed quickly if the length of resection is moderate. If the resection is extensive, however, it is prudent to initiate enteral feeding slowly, with several small feedings containing little fat. The amount of fat in the diet should be increased progressively to tolerance. Once the diet is stabilized, the severity of malabsorption can be assessed and nutritional therapy instituted as outlined

in the section on nutritional management of generalized malabsorption.

Moderate bile acid malabsorption (small ileal resection) and the diarrhea it produces can be treated effectively with cholestyramine, though such treatment can make the diarrhea associated with fat malabsorption (large ileal resection) worse. After a large small-intestinal resection, some patients have marked gastric or intestinal hypersecretion, which can cause both diarrhea and malabsorption. Treatment with an H₂ receptor antagonist or a proton pump inhibitor may result in prompt improvements in some patients, and the somatostatin analog octreotide has been effective in others. Bacterial overgrowth can complicate small-intestinal resection, particularly if the ileocecal valve is resected; this problem can be improved substantially by administering courses of broad-spectrum antibiotics. If adequate nutrition cannot be maintained orally, long-term home parenteral nutrition must be considered.

Protein-Losing Enteropathy

Protein-losing enteropathy is a syndrome characterized by loss of protein with or without loss of lipids and lymphocytes (lymph) into the gastrointestinal tract ([Table 110.7](#)). The syndrome can be caused by a variety of disorders, including mesenteric lymphatic obstruction, with loss of lymph into the gut lumen, and mucosal disorders that result in the exudation of protein-rich secretions into the lumen. Increased fecal protein loss often occurs in patients with HIV-related conditions, regardless of the presence opportunistic infections. Protein loss into the gut can cause hypoproteinemia, which can lead to edema, and the lymph loss may provoke immunodeficiency.

Mechanism of Action	Diseases
Lymphatic obstruction Mechanical	Lymphangiectasia, retroperitoneal fibrosis, lymphoma, Whipple's disease
Elevated lymphatic pressure	Constrictive pericarditis, pulmonary stenosis, superior vena caval obstruction
Exudative protein loss Neoplastic	Gastric, colonic, esophageal, and small-intestinal cancer, familial polyposis, Gardner's syndrome, juvenile polyposis
Ulcerative	Inflammatory bowel disease, gastritis, infectious enteritis, radiation enteritis
Nonmalignant, nonulcerative	Hypertrophic gastropathy, allergic gastroenteropathy, celiac sprue, tropical sprue

TABLE 110.7. DISORDERS CAUSING PROTEIN-LOSING ENTEROPATHY

The diagnosis of protein-losing enteropathy can be made by measuring the appearance of parenterally administered radiolabeled albumin in the stool or, more simply, by the α_1 -antitrypsin clearance test. Normally, α_1 -antitrypsin is not secreted into the small intestine, but it is present if there is substantial intestinal protein loss. Because α_1 -antitrypsin is degraded in the stomach, this test is not useful for the diagnosis of hypertrophic gastropathy or other gastric conditions causing protein loss.

Lymphangiectasia can stem from a primary developmental abnormality or from obstruction of the enteric lymphatics by retroperitoneal fibrosis, pancreatitis, lymphoma, or Whipple's disease. The syndrome is characterized by loss of lipid and protein-rich lymph into the intestinal lumen, with resultant hypocholesterolemia, hypoalbuminemia, edema, chylous effusions, and diarrhea. In addition to nutrients, immunoglobulins and lymphocytes are also lost into the gut; this results in lymphocytopenia, decreased serum immunoglobulins, and, in many cases, cutaneous anergy. The diagnosis is supported by documentation of protein loss into the gut and small-intestinal biopsy results showing evidence of broad villi with dilatation of the mucosal and submucosal lymphatics ([Fig. 110.15](#)). Severe right-sided congestive heart failure, particularly that caused by constrictive pericarditis, can resemble lymphangiectasia in its clinical manifestations. Dilated lymphatics may be present on small-intestinal biopsy but the two disorders are distinguishable by the cardiac findings.

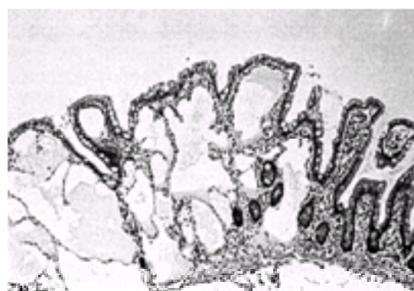

FIGURE 110.15. Lymphangiectasia of the small intestine. Markedly dilated lymphatics are present in the lamina propria, causing widening of the villi. The patchy nature of the lesion can be seen. (The villi at right are normal.) (From Misiewicz JJ, Bartram CI, Cotton PB, et al., eds. *Slide atlas of gastroenterology*. London: Gower Medical Publishing, 1985, with permission.)

Neoplastic and ulcerative diseases of the gut can provoke exudative protein loss into the small intestine ([Table 110.7](#)). Occasionally, hypoalbuminemia and edema are the dominant abnormalities in these disorders. Hypertrophic gastritis is the most common gastric cause of protein-losing enteropathy. Allergic gastroenteropathy is discussed in [Chapter 114](#).

Optimal Management

Therapy for protein-losing enteropathy depends on the causative disorder. If the underlying cause is not correctable, dietary therapy is useful. With lymphatic obstruction, the combination of low-fat diet and medium-chain triglycerides results in a decrease in lymphatic flow and may moderately lessen the protein loss.

Small-intestinal Lymphoma and a Heavy Chain Disease

Lymphoma of the small intestine can cause malabsorption by diffuse infiltration of the lamina propria and submucosa. The normal mucosa is replaced progressively, and mucosal ulceration as well as lymphatic obstruction may occur. The association of malabsorption and intestinal lymphoma is particularly common in a heavy chain disease, an unusual disorder of B lymphocytes that initially appears to be infectious but subsequently progresses to intestinal lymphoma. These disorders are characterized by progressive symptoms of diarrhea and malabsorption with prominent abdominal pain. Small-intestinal radiographs show nodular, irregular thickening of the mucosa in advanced disease. The small-intestinal biopsy result differs from that of celiac or tropical sprue in that there is no crypt hyperplasia and the lamina propria is infiltrated with a monomorphic population of lymphocytes. The malignant nature of the lymphocytic infiltrate may not be obvious at first. Thus, a full-thickness biopsy is sometimes necessary to make the diagnosis. Specific therapy for lymphomas and a heavy chain disease is discussed in detail in [Chapter 233](#), [Chapter 234](#) and [Chapter 235](#), but nutritional support is occasionally necessary for the associated malabsorption.

DISORDERS WITH COMBINED MALDIGESTIVE AND MALABSORPTIVE FEATURES

Bacterial Overgrowth

Relatively few ($<10^3$ organisms per milliliter) bacteria can be found within the lumen of the normal small intestine. Bacterial growth is prevented by the hostile acid environment of the stomach as well as by the rapid transit of intestinal contents. Furthermore, colonic bacteria are prevented from refluxing into the small intestine by the ileocecal valve. Accordingly, achlorhydria, small-intestinal strictures, blind loops, large fistulas, ileal resections, and motility disorders can result in the proliferation of bacteria within the small intestine.

Intestinal bacterial overgrowth can cause diarrhea and malabsorption through a combination of intraluminal and mucosal effects. Anaerobic bacteria produce folate but consume both vitamin B₁₂ and D-xylose (bacterial overgrowth is one nonmucosal source of an abnormal D-xylose test result). Certain bacteria have the capacity to deconjugate bile salts, and anaerobic bacteria can ferment carbohydrates with the resultant production of gas (carbon dioxide and hydrogen) and short-chain organic acids. In addition to their effects on intraluminal nutrient digestion and solubilization, bacteria can have a direct toxic effect on the enterocyte. Small-intestinal biopsies in patients with bacterial overgrowth may uncover partial villous atrophy in a patchy distribution.

Clinical Findings and Diagnosis

The clinical features of bacterial overgrowth are those seen with any disorder of generalized malabsorption. Weight loss, diarrhea, anemia, and fat-soluble vitamin deficiency are the most common clinical findings. The anemia seen in bacterial overgrowth usually stems from vitamin B₁₂ deficiency (bacterial utilization); folate deficiency is uncommon, because bacteria can produce folate. The malabsorptive symptoms often are overshadowed by the underlying cause of the bacterial overgrowth. Bacterial overgrowth should be considered in patients with diarrhea or malabsorption in the context of possible intestinal stasis, such as postoperative partial intestinal obstruction, Crohn's disease, intestinal pseudo-obstruction, or autonomic neuropathy. The diagnosis of bacterial overgrowth can be made by small-intestinal culture or by the D-[¹⁴C]xylose breath test.

Optimal Management

Anatomic causes of bacterial overgrowth usually must be treated surgically. If surgical correction is not feasible, antibiotic therapy is appropriate. If jejunal cultures have been taken, the choice of antibiotics is dictated by the results of the cultures. Broad-spectrum, nonabsorbable antibiotics are appealing, but they have not been tested widely for this disorder (rifaximin has been shown to be effective in European trials). An absorbable broad-spectrum antibiotic, such as tetracycline or chloramphenicol, is also a reasonable first choice. Because of the importance of anaerobic bacteria, metronidazole is a useful alternative. Antibiotics typically are taken for a period of 7 to 10 days (250 to 500 mg tetracycline four times a day, 50 mg chloramphenicol per kilogram per day in four divided doses, or 250 mg metronidazole three times a day). Frequently, a single 7- to 10-day course of therapy can result in several months of improvement. Some patients may experience a shorter duration of response, requiring longer or cyclic therapy for improvement, and some patients may not respond or may become resistant to the effects of antibiotics over time. If malabsorption cannot be corrected, nutritional supplementation may be required.

Zollinger–Ellison Syndrome

Diarrhea is a prominent symptom in about 30% of patients with gastrinoma (see [Chapter 107](#)). Steatorrhea is less common (5%), but it can result from inactivation of pancreatic lipase and protonation of fatty acids, making them less soluble in bile salt micelles (below pH 6); precipitation of bile acids (below pH 5); and injury to the small-intestinal mucosa. Symptoms respond promptly to successful acid suppression.

Crohn's Disease

Crohn's disease of the small intestine (regional enteritis) is a common cause of malnutrition, owing to inadequate oral intake, increased gastrointestinal losses, and malabsorption. Crohn's disease can provoke malabsorption by direct mucosal inflammation and injury, enteric fistulas, bacterial overgrowth, and loss of functional absorptive surface due to disease and/or intestinal resection. The terminal ileum is the most common site of disease, and, for this reason, selective bile acid or vitamin B₁₂ malabsorption may be evident (see [Chapter 111](#)).

Radiation Enteritis

Radiation therapy to the small intestine can cause generalized malabsorption through direct injury to the mucosa and bacterial overgrowth of the small intestine. The risk of radiation enteritis increases with the dose of radiation (>50 Gy) and with the concomitant presence of atherosclerotic vascular disease or fixation of the intestine (previous laparotomy).

Acute radiation injury results in suppression of cell proliferation in the intestinal crypts, which can lead to ulceration of the mucosa. Months to years after completion of radiation therapy, progressive obliterative enteritis may appear, causing a progressive ischemic injury that can lead to generalized malabsorption. The terminal ileum is particularly prone to direct radiation injury; thus, bile acid and cobalamin malabsorption is typical. Ischemic injury also can result in fibrosis, strictures, and fistulas that predispose to bacterial overgrowth of the small intestine.

Malabsorption induced by radiation injury may take the form of specific lactose, bile acid, or cobalamin malabsorption with resultant diarrhea and/or anemia or severe generalized malabsorption and malnutrition. The diagnosis can be missed because symptoms of weight loss and diarrhea may be attributed to the disease for which the radiation was given. An abnormal D-xylose test or a small-intestinal radiograph establishes the mucosal nature of the disease. The small-intestinal series may show irregular thickening of the mucosal folds, particularly of the ileum. With more severe injury, there may be strictures and enteroenteric fistulas. These radiologic features can be difficult to differentiate from those found in Crohn's disease or invasion of the intestine by cancer. Often, the coexistence of radiation proctitis helps clarify the cause of the small-intestinal disease. Ileal biopsy specimens obtained at colonoscopy may be diagnostic. Occasionally, laparotomy is required to establish the diagnosis.

No specific therapy for radiation enteritis exists, though there have been reports of benefit from glucocorticoids and sulfasalazine. Bacterial overgrowth stemming from discrete strictures and fistulas improves with resection, but intestinal resection is hazardous in this context because anastomotic leaks may result from ischemia. Treatment with broad-spectrum antibiotics may be useful for associated bacterial overgrowth. Lactose cobalamin and bile acid malabsorption respond to specific therapy. Nutritional management is critical in severe disease.

Amyloidosis

Significant small-intestinal involvement develops in about 70% of patients with systemic amyloidosis (see [Chapter 235](#)). The involvement is diffuse, with initial perivascular deposition of amyloid followed by muscular, neural, and submucosal infiltration. Malabsorption may result from ischemic injury and bacterial overgrowth. The diagnosis is established by rectal or small-intestinal biopsy. There is no specific therapy for amyloidosis of the small intestine. Antibiotics for documented bacterial overgrowth and nutritional support are the cornerstones of management.

Ischemia of the Small Intestine

Malabsorption is an uncommon complication of chronic ischemia of the small intestine, but it can result from either direct injury to the intestinal wall or bacterial overgrowth originating from an ischemic stricture.

MISCELLANEOUS DISORDERS

Generalized malabsorption may develop in diabetes mellitus either because of pancreatic insufficiency or because of bacterial overgrowth deriving from autonomic insufficiency and intestinal stasis. Thyrotoxicosis can cause a shortened gastrointestinal transit time and mild malabsorption, usually without significant malnutrition. Partial villous atrophy is evident on small-intestinal biopsy in both hypothyroidism and hypoparathyroidism. Some malignancies that do not directly involve the gastrointestinal tract have been associated with unexplained partial villous atrophy and malabsorption.

A variety of drugs can cause defects in nutrient absorption. Neomycin given orally in doses higher than 2 g per day can precipitate bile salts, resulting in poor micellar solubilization of fat. Sulfasalazine interferes with folate absorption. Cholestyramine binds bile salts in a dose-dependent manner, resulting in impaired micellar solubilization and modest malabsorption of fat. Colchicine can produce generalized malabsorption characterized by partial villous atrophy and infiltration of the lamina propria with lymphocytes. These features are reversible with discontinuation of the drug. Somatostatin and its analogs have provoked modest steatorrhea as the dose-limiting toxicity. Ethanol occasionally can lead to mild generalized malabsorption.

DISORDERS OF SPECIFIC NUTRIENT ASSIMILATION

Disorders of specific nutrient assimilation are caused by an isolated defect in an enzyme or transport system and are not associated with generalized malabsorption or malnutrition. The clinical features depend on the specific nutrient affected.

Lactase Deficiency

Lactase deficiency is the most common defect of nutrient assimilation in the world. Normally, lactase levels peak in the infant intestine just before delivery. In most populations, excluding those from northern Europe, lactase mRNA and protein levels fall significantly between the ages of 2 and 15 years (constitutional lactase deficiency). Transient secondary lactase deficiency typically develops after enteric infections, and a rare autosomal recessive form of hereditary lactase deficiency is associated with low levels of lactase even in the neonate.

Lactase deficiency results in a failure of lactose hydrolysis, with resultant malabsorption of the disaccharide. Unabsorbed lactose may cause osmotic diarrhea; furthermore, when it reaches the colon, it is fermented by colonic bacteria to form carbon dioxide, hydrogen, and short-chain fatty acids, producing abdominal bloating and flatulence. Typically, these symptoms begin within 1 to 2 hours after the ingestion of lactose. Because this disorder is so common, a trial of lactose withdrawal is used early in the workup of postprandial bloating, flatulence, and diarrhea. A specific diagnosis can be made with either a lactose tolerance test or a lactose hydrogen breath test. Although lactase levels can be measured directly in peroral jejunal mucosal biopsy specimens, this is not usually necessary.

Secondary lactase deficiency is seen routinely in diffuse mucosal disease of the small intestine, such as celiac or tropical sprue, or in acute enteritis caused by viral, bacterial, or parasitic infestation. Such deficiency may persist after the acute form of enteritis has resolved and should be suspected when diarrheal symptoms do not resolve after an episode of acute enteritis. Secondary lactase deficiency is very common (up to 70%) in HIV-infected patients and is particularly severe in those with advanced disease.

Therapy for primary and secondary lactase deficiency includes lactose withdrawal or replacement. High concentrations of lactose are present in milk, ice cream, cheese, and many desserts, sauces, and stuffings. Withdrawal of these foods alone may reduce dietary lactose below the level at which symptoms develop. Low-lactose milk is now widely available. In addition, lactase may be added to milk or ingested with meals.

Hereditary Sucrase-a-Dextrinase Deficiency

Congenital defects of sucrase-a-dextrinase are unusual; only about 100 cases have been well studied, but the incidence is particularly high among natives of Alaska and Greenland. One type of the disorder (about 20% of the total) results from a defect in synthesis of both sucrase and a-dextrinase, but the more common type is associated with selective absence of sucrase activity. The symptoms of sucrase-a-dextrinase deficiency begin in childhood, when sucrose-containing formulas or foods are ingested. The resultant osmotic diarrhea may lead to severe dehydration and malnutrition. Sucrase-a-dextrinase deficiency can be confirmed by an abnormal sucrose tolerance test result, an abnormal sucrose hydrogen breath test result, or a decreased enzyme level in a jejunal biopsy specimen. Patients with sucrase-a-dextrinase deficiency can be treated by simple withdrawal of sucrose-containing foods.

Glucose–Galactose Malabsorption

Glucose–galactose malabsorption is a rare autosomal recessive disorder caused by mutations in the sodium-dependent glucose and galactose cotransporter of the enterocyte brush border (SGLT-1). The failure of glucose and galactose uptake into the enterocyte results in osmotic diarrhea after ingestion of glucose or starch. The onset of diarrhea occurs when oral feeding is started, and diarrhea may lead to severe dehydration and even death if the cause is not recognized. A specific diagnosis can be established by an abnormal oral glucose tolerance test result combined with a normal D-xylose test result.

Fructose Malabsorption

A rare congenital form of fructose malabsorption has been described, but the biochemical basis of the disease is not yet known. It does not appear to be due to mutations in the Glut-5 fructose transporter of the intestinal brush border.

Genetic Amino Acid Transport Disorders

Hartnup's disease and cystinuria are genetic defects in amino acid transport (neutral amino acids and basic amino acids plus cystine, respectively) in the small intestine and proximal renal tubule. Lysinuric protein intolerance is a genetic defect in basic amino acid transport in all tissues. This defect causes postprandial hyperammonemia due to ornithine deficiency, which impairs the urea cycle. These disorders do not cause nutritional defects because the affected amino acids can be absorbed by other amino acid and peptide transporters.

Selective Bile Acid Malabsorption

Mutations in the ileal cobalamin receptor can cause a rare form of selective cobalamin malabsorption. This autosomal recessive disease typically appears in children (0 to 5 years of age); the symptoms are failure to thrive, infections, megaloblastic anemia, neuropathy, and mild generalized malabsorption. Similarly, mutations in the ileal bile salt transporter can cause leaks in the enterohepatic circulation, leading to severe chronic diarrhea and malabsorption in adults.

[Prognosis](#)

Inflammatory bowel disease (IBD) encompasses at least two forms of idiopathic intestinal inflammation: ulcerative colitis (UC) and Crohn's disease (CD). The latter is also called regional enteritis, regional ileitis, Crohn's ileitis, and granulomatous colitis. Although many other inflammatory disorders affect the gastrointestinal (GI) tract, they can be distinguished from UC and CD by the presence of a specific underlying etiologic agent or by the character and manifestations of the inflammatory activity. In contrast, the causes of the major forms of IBD are unknown.

In the absence of identifiable causative agents, UC and CD are defined empirically by their typical clinical, pathologic, endoscopic, radiologic, and laboratory features. Although these features usually allow the clinician to distinguish between UC and CD, the validity of this diagnostic distinction remains uncertain. UC and CD are at least partly distinct in their initial pathogenetic events, but they have many key pathophysiologic processes in common. Moreover, UC and CD each may encompass several variants, which are at least partially distinct. For example, patients with CD may manifest different complications (fistulas) and may express different inflammatory mediators, perhaps owing to underlying genetic differences between the two groups. Thus, patient subgroups defined by disease location, specific pathologic findings (the presence or absence of granulomas in patients with CD), or disease complications may reflect a multiplicity of diseases with some shared features.

Regardless of this uncertainty, the broad classification of IBD into UC and CD that has emerged from extensive clinical experience and investigation over more than 60 years serves as a useful framework for the evaluation and treatment of these patients. Nonetheless, in some patients it is impossible to distinguish with confidence UC from CD affecting the colon using any of the conventional diagnostic criteria; such cases are often labeled "indeterminate colitis."

EPIDEMIOLOGY

The incidence and prevalence of the major forms of IBD have been studied extensively in many populations ([Table 111.1](#)). These studies document a wide variation in incidence and prevalence rates and support the conclusion that both environmental and genetic factors contribute to the pathogenesis of UC and CD. The rates of UC and CD in men and women are essentially equivalent, but significant differences are found among different racial and ethnic groups. The highest prevalence rates are reported in non-Hispanic whites, with significantly lower rates in American black and Hispanic populations. Ashkenazi Jews have higher rates of IBD than do other populations in the same country, supporting the notion that genetic factors contribute to some of the epidemiologic variation.

Incidence (per 100,000)	1–10 (CD), 2–18 (UC)
Prevalence (per 100,000)	20–100 (CD), 40–100 (UC)
Race	White > black > Hispanic
Sex	M = F
Age at onset	Peak 15–25, second peak 50–80 (CD)
Ethnic	Jewish > non-Jewish
Smoking	Associated with CD, inversely associated with UC
Relapse association	Nonsteroidal anti-inflammatory drugs, oral contraceptives (CD), refined sugar?

CD, Crohn's disease; UC, ulcerative colitis.

TABLE 111.1. EPIDEMIOLOGIC FEATURES OF INFLAMMATORY BOWEL DISEASE

Higher rates of both UC and CD among first-degree relatives of patients have been observed consistently in different populations. In general, there appears to be a substantially greater probability that IBD will develop among siblings than among unrelated controls. In parents or children, the relative risk may be fivefold or greater. Enhanced risk in first-degree family members seems to be due to genetic rather than environmental factors. However, the increased risk does not conform to any simple mendelian pattern of inheritance, and even among first-degree relatives, the overall prevalence of IBD is generally below 10%.

Incidence and prevalence rates of IBD among inhabitants of different countries typically vary in proportion to socioeconomic development. A North–South gradient in rates has been noted, with especially high rates in Scandinavian and other northern European countries. In general, the incidence and prevalence rates of UC and CD vary in parallel among populations, but there are exceptions—for instance, UC is relatively common in Japan, but CD is rare. The prevalence of CD increased steadily (as much as sixfold) from the early 1960s through the 1980s in Western Europe and the United States, but the rates for UC remained essentially unchanged during this interval. The overall incidence and prevalence rates of the two disorders are roughly equivalent in these populations, with incidence rates for each ranging from 3 to 10 per 100,000 and prevalence rates ranging from 30 to 50 per 100,000.

Other epidemiologic associations may provide clues to pathogenesis. The incidence of UC is inversely associated with smoking, and clinical relapses have been related to cessation of smoking. Nonetheless, attempts to use nicotine for therapeutic intervention have provided equivocal results at best. In contrast, the incidence of CD parallels smoking. Oral contraceptive use may be associated with a higher risk of CD, and increased consumption of acetaminophen and other non-narcotic analgesics (nonsteroidal anti-inflammatory drugs), as well as simple sugars, may play a part in flare-ups of CD. Both UC and CD may manifest at virtually any age, from early childhood to the ninth decade. The onset is usually in the second and third decades, however, with a smaller increase in incidence in the fifth and sixth decades.

PATHOGENESIS

The precise cause or causes of UC and CD are unknown. Considerable evidence suggests that they result from an interaction between genetically determined host susceptibility and acquired environmental influences. Observations supporting the inference that genetically determined factors contribute to the development of IBD in humans include variations in the prevalence rates of the diseases among different populations, cosegregation of IBD with disorders thought to be genetically determined in some kindreds, and the higher risk of disease in first-degree relatives of a patient with UC or CD. The high degree of concordance of disease in monozygotic twin pairs in Sweden (as high as 67% when the proband has CD and 20% when the proband has UC, compared with 8% for nonidentical twins) provides especially compelling support for the central role of genetic factors.

Although genetic factors may predispose to UC and CD, the development of disease requires either cooperative interaction among more than one genetic locus or initiating "environmental" (most likely intestinal luminal) factors or both. The rate of disease in first-degree relatives of patients with IBD (generally 5% to 10%) is too low simply to reflect recessive inheritance of a single mendelian "disease gene," even with variable penetrance. Furthermore, the fact that the identical twin of a

patient does not uniformly show signs of IBD clearly implies that disease development does not solely reflect genetically defined host susceptibility.

Identification of disease-associated genes has not yet been confirmed, but several candidate genetic loci have been studied. Genome-wide screens using anonymous DNA markers scattered throughout all chromosomes have been carried out in members of kindreds multiply affected with IBD. Such screens permit identification of a region of the genome linked to a disease without previous bias as to the likely location of the genes. Application of these techniques has identified a putative susceptibility locus for CD, *IBD1*, in the pericentromeric region of chromosome 16 in some families from northwestern Europe and America, particularly Ashkenazi Jews. The locus is not linked with UC. Other loci on chromosomes 3, 7, and 12 have been linked to both UC and CD, suggesting that UC and CD share some, but not all, susceptibility genes; however, these associations require confirmation. Intensive efforts will be needed to identify the specific gene responsible for the linkage with CD on chromosome 16 and to determine whether the gene or genes identified in the multiply affected kindreds are similarly important in the great majority of patients with CD who have no family history of IBD.

Extensive attempts have been undertaken to find associations with major histocompatibility complex loci. A higher incidence of HLA-DR2 (and lower rate of DR4 and DRw6) among patients with UC and a higher incidence of haplotypes DR1 and DQw5 in patients with CD have been reported but require confirmation. The possibility of a genetically encoded aberration in immune response is also supported indirectly by the frequent finding of a distinctive form of antineutrophil cytoplasmic antibodies (ANCA) in the serum of patients with UC and 70% of their first-degree relatives and of anti-*Saccharomyces cerevisiae* antibodies (ASCAs) in the serum of 70% of patients with CD and some of their first-degree relatives. Although it is unlikely that ANCA have a direct role in the pathogenesis of UC, they may reflect genetically defined dysregulation of immunoglobulin production, as further indicated by the disproportionate infiltration of IgG-producing B lymphocytes in IBD tissue. In contrast, the finding of ASCAs in patients with CD may reflect an increase in intestinal permeability to luminal antigens, as is typical of this disorder.

Genes responsible for the expression of colonic mucin glycoproteins are also candidates for genetic contributors to IBD. Alterations in colonic mucin glycoproteins have been found consistently in patients with UC and unaffected identical twins of patients with UC, but not in patients with CD. It is unclear which structural genes are responsible for the altered glycoprotein profile (apoprotein genes or those responsible for glycosylation). Finally, altered levels of expression or biological activity of cytokines and other regulatory peptides in patients with IBD (see "Pathophysiology") may be the result of genetic variation (e.g., relative expression and activity of interleukin [IL]-1 and IL-1 receptor antagonist, alterations in the production of IL-2 by mucosal lymphocytes, and variations in the expression of IL-4 and IL-10).

Recently developed animal models of IBD support the notion that chronic intestinal inflammation can derive from the interaction of several genetic factors. Specifically, in various mouse models, alteration of several different murine genes has resulted in a form of IBD. For example, colitis has been found in mice made deficient in T lymphocytes bearing the α/β class of receptors as well as those made deficient in IL-2, the major histocompatibility complex class II molecules, the G protein $G_{i\alpha}$, *mdr1*, and intestinal trefoil factor, among others, by gene deletion techniques. In addition, generalized inflammation of the GI tract has been noted in IL-10-deficient mice and transforming growth factor β (TGF- β)-deficient mice as well as in HLA-B27 transgenic rats. These findings suggest that IBD in humans could be the consequence of alterations in one of a number of genes controlling the immune response. Alternatively, IBD could reflect a spectrum of disorders resulting from alterations of various genes, in each case leading to similar manifestations owing to shared common pathways of inflammation and tissue injury.

Several observations suggest that CD4⁺ lymphocytes are essential for the development of IBD. These observations include the direct demonstration of activated CD4⁺ lymphocytes in patients with IBD, the ability of therapeutic agents that modulate lymphocyte activation to ameliorate disease activity, and the apparent requirement for CD4⁺ T cells in murine models. Indeed, adoptive transfer of a subpopulation of CD4⁺ lymphocytes (CD45RB^{hi}CD4⁺) to SCID mice results in an IBD-like colitis in recipient mice. Moreover, prolonged remission of CD has been noted in a series of patients who underwent allogeneic bone marrow transplantation for treatment of coincidental leukemia. Genes encoding products that play a role in lymphocyte activation or down-regulation might contribute to a chronic immune response in IBD. Candidate genes are those that encode for aberrant antigen-presenting molecules, elements of the T-cell-receptor complex and its secondary signaling pathways, or cytokines that attenuate immune activation. Regardless of whether there is an intrinsic genetic alteration of the immune system, there is increasing evidence that CD is associated with a so-called TH1 response, in which CD4⁺ lymphocytes of this subtype predominate (see "Pathophysiology"). In contrast, UC may be characterized by a predominance of the TH2 T-lymphocyte subset.

Gene products necessary for sustaining epithelial integrity also may play a role in the pathogenesis of IBD. Genes whose products could control mucosal barrier function include structural elements of the epithelial cells themselves, epithelial products that form the overlying continuous viscoelastic mucous coat (mucin glycoproteins or trefoil factors), or cytokines/growth factors.

Much effort has been directed toward the identification of environmental factors that may play a causative role in IBD. The role of environmental factors is suggested by clinical improvement when patients with IBD are placed on bowel rest or an elemental diet and by experimental germ-free animal models. Several transmissible agents—including atypical mycobacteria, cell wall-deficient bacteria, and the measles virus—have been suggested as specific etiologic agents, but associations have been inconsistent. Bacterial products, rather than a specific species of bacteria, may be critical to the development of IBD. The bacterial flora produce a complex mixture of proinflammatory and chemotactic substances (e.g., formylated peptides), and injection of bacterial cell wall products into genetically susceptible animals can result in granulomatous enteritis with features similar to those of CD. Furthermore, the development of colitis in genetically altered mice (IL-2-deficient mice) appears to depend on the presence of intestinal flora, even if the flora do not contain bacteria that are pathogenic by conventional mechanisms of action. The therapeutic benefit of oral antibiotics and elemental diets in some patients with IBD may be due to reductions in luminal bacterial populations that contribute to intestinal inflammation. Bacterial flora, epithelial cell barrier function, and mucosal immune responses also may be modulated by other environmental agents. These include some medications (nonsteroidal anti-inflammatory agents may impair the mucosal barrier), smoking, and diet.

PATHOPHYSIOLOGY

Although the hypothesis previously outlined provides a framework for understanding the initiation of IBD, its major clinical manifestations depend on a series of immunologic and inflammatory events. Immunoregulatory molecules, cytokines in particular, play a major role in the up-regulation of lymphocytes, macrophages, and neutrophils and facilitate amplification of immune responses by enhancing the recruitment and activation of inflammatory cells. They are produced by and also may activate epithelial cells, endothelial cells, smooth-muscle cells, and fibroblasts. Indeed, the recognition of the close integration of the epithelium with the mucosal immune system has been an important recent development. The proinflammatory cytokines also mediate systemic manifestations of inflammation, such as fever and hepatic production of acute-phase reactants. Other important effects include the enhanced production of collagen and other extracellular matrix components by smooth muscle, thereby leading to fibrosis and stricture formation in CD.

Alterations in many cytokines have been found in association with IBD, including proinflammatory cytokines (synthesis and secretion of tumor necrosis factor [TNF- α], IL-1, and IL-6 in involved tissue), regulatory cytokines (IL-2 and interferon- γ), and a hematopoietic cytokine (granulocyte-macrophage colony-stimulating factor). Patients with IBD also may have a relative deficiency of down-regulatory cytokines, including IL-1 receptor antagonist (IL-1RA), a natural inhibitor of the cytokine IL-1, and IL-10, as well as relative insensitivity to IL-4. As noted earlier, there is increasing evidence that patients with CD have a predominance of TH1 lymphocytes in affected bowel. These CD4⁺ lymphocytes produce IL-2 and interferon- α , which activate macrophages to generate proinflammatory cytokines (TNF- α , IL-1, IL-6) and cytokines, which reinforce further T-lymphocyte activation, particularly IL-12 and IL-18. To date, there is less compelling evidence that in UC the cytokines produced by TH2 lymphocytes predominate (e.g., IL-5).

Among their many effects, cytokines facilitate the recruitment of acute inflammatory cells to sites of disease. Indeed, in recent years there has been increasing recognition of a family of cytokines, designated chemokines, that may be especially important in cell recruitment. Chemokines include IL-8 and related peptides that contribute to neutrophil recruitment and activation as well as monocyte chemoattractant protein 1, which may play a role in macrophage activation. Chemokine activities are augmented by other inflammatory mediators, both cytokines and noncytokines (TGF- β , leukotrienes, formylated peptides, and complement fragment C5a, in addition to IL-8, all of which attract and activate neutrophils). Redundancy in the effects of immune and inflammatory mediators has been found as a common feature of inflammation within the mucosa.

In addition to cytokines, neuropeptides may play an important role in regulating many of these same inflammatory responses and modulating the functional effects of cytokines and other mediators. Increased concentrations of some neuropeptides, such as substance P, somatostatin, and vasoactive intestinal polypeptide, are present in IBD tissues, and their receptors may be found on many cell populations. These peptides may substantially modulate lymphocyte activation and other mucosal inflammatory responses.

Collectively, chemotactic molecules and cytokines recruit neutrophils and other leukocytes to IBD-affected tissues through various mechanisms of action, including sequential events in which circulating leukocytes roll on the vascular endothelial surface, attach, and then migrate into the tissue. Several cytokines and other inflammatory mediators induce the expression of adhesion molecules on local endothelium and stimulate leukocyte activation, thereby enhancing these processes.

Key vascular adhesion molecules (e.g., E-selectin, which is necessary for neutrophil adhesion to endothelium) are expressed on intestinal endothelium in association with active IBD.

Recruitment of acute inflammatory cells leads to the production of additional key mediators of inflammation, with resulting amplification of these processes. These products include additional cytokines and chemokines as well as “nonspecific” mediators of inflammation. Among the latter, arachidonic acid metabolites (leukotrienes and prostaglandins) seem to be especially important. Leukotrienes are chemotactic; prostaglandins, along with other metabolites and some cytokines, promote intestinal electrolyte and fluid secretion, thereby contributing to diarrhea. Activation of inflammatory cells results in the production of reactive oxygen metabolites that may serve as the final common pathway of actual tissue damage. Although reactive oxygen metabolites may be produced by many cell populations, neutrophils and macrophages appear to be the major source.

In addition to their proinflammatory role, it seems as though cytokines and other regulatory peptides have a key role in the down-regulation of inflammation and the reestablishment of mucosal integrity and healing. Several cytokines appear to have potent anti-inflammatory effects that counterbalance the proinflammatory peptides. In addition to IL-1RA, which seems to act as a competitive inhibitor of IL-1, peptides with direct down-regulating properties include IL-10, IL-4, and TGF- β (though in some contexts the latter may augment inflammatory responses). Cytokines, especially TGF- β , and trefoil peptides may facilitate mucosal healing after ulceration. Insulin-like growth factors and some cytokines may promote healing through fibrosis, though these processes may lead to the formation of strictures.

PATHOLOGY

ULCERATIVE COLITIS

The inflammatory process in UC is confined to the mucosa and superficial submucosa of the colon and rectum. UC rarely spares the rectum, and the inflammatory process typically extends in a continuous manner proximally from the rectum. The length of proximal extension varies among patients, involving the entire colon (pancolitis or universal colitis) at onset in approximately one-third of patients.

The histopathologic features are characteristic but nonspecific and may be seen in other intestinal inflammatory conditions ([Fig. 111.1A](#)). They include the presence of significant numbers of neutrophils within the lamina propria and the crypts, where they form microabscesses. Depletion of goblet cell mucin is also common. In addition to neutrophil infiltration, many lymphocytes and other leukocyte populations are present. This mixed population of inflammatory and immune cells reflects the constituents of both an acute and a chronic inflammatory response. The presence of the features of chronic inflammation distinguish UC (and CD) from many other forms of intestinal inflammation, including most forms of infectious colitis. The absence of inflammation in the deeper layers of the bowel (except in the most severe form of the disease, designated fulminant colitis) is characteristic. In conjunction with severe inflammation and the coincident production of a complex mixture of inflammatory mediators (see earlier discussion), extensive superficial mucosal ulceration develops.

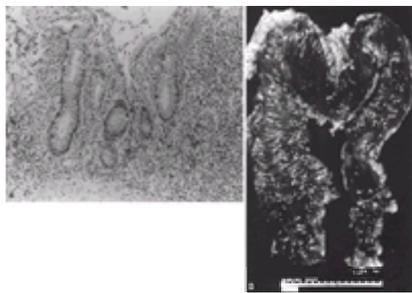

FIGURE 111.1. A: Histopathologic picture of acute ulcerative colitis. This photomicrograph shows some of the typical features of acute ulcerative colitis. Note the presence of microabscesses formed by collections of neutrophils within the lumen of the crypt. Also note the epithelial destruction and the intense, diffuse acute and chronic inflammatory infiltrate in the lamina propria. **B:** This surgical specimen exhibits the characteristic features of severe ulcerative colitis, with diffuse destruction of the mucosal surface and overlying mucopurulent exudate.

On the macroscopic level, as seen through the sigmoidoscope or colonoscope, mild inflammation is evidenced by mucosal edema and mild granularity, which contrasts with the smooth, glistening appearance of the normal mucosa. With more severe inflammation, diffuse friability (bleeding on contact) is apparent and may progress to become areas of broad superficial ulceration, frequently covered with a mucopurulent exudate ([Fig. 111.1B](#)). Areas of regenerative or residual inflammatory tissue may be apparent as pseudopolyps. In parallel with histopathologic findings, macroscopic involvement is diffuse, extending proximally to a varying degree, though the most severely affected mucosa is almost always present most distally. In especially severe disease, complete destruction of the mucosa is apparent; it may be accompanied by marked thinning of the deeper muscular layers in patients with fulminant colitis, when the colon is examined after colectomy.

CROHN'S DISEASE

CD is much more varied in its pathologic and clinical manifestations. Active disease is characterized by an infiltrate in which macrophages and lymphocytes predominate. The aggregation of macrophages into noncaseating granulomas is found in most patients, but this is not an invariable feature of the disease. In contrast to the continuous and diffuse inflammatory process found in UC, inflammation in CD can be patchy, and segmental involvement of different areas is typical.

Although the acute and chronic inflammatory infiltrate in the mucosa can resemble that found in UC, extension of the inflammatory process into the deeper layers of the bowel wall is a distinguishing feature, and transmural involvement is typical ([Fig. 111.2A](#)). Mucosal ulceration occurs frequently. The earliest mucosal lesions of CD are aphthoid ulcerations overlying Peyer's patches and areas of dense lymphoid infiltration. Perhaps as a further consequence of the transmural nature of the inflammatory process, more advanced ulcers are typically deep and linear, often serpiginous or fissure-like, in contrast to the broad superficial ulcers found in UC. Linear ulceration with intervening areas of intact mucosa, often heaped up due to infiltration with large numbers of immune and inflammatory cells, leads to a cobblestone appearance. Inflammation actually may extend through the serosa, frequently leading to adherence to adjacent intra-abdominal and pelvic structures. Pathologic anatomic connections, designated fistulas, may develop within these areas of inflammation, leading to various clinical syndromes depending on the involved sites. Thus, fistulas may communicate between different segments of the luminal GI tract (small intestine and colon, colon and stomach) or between the bowel and other organs (bladder and vagina). Fistulas also typically extend from the terminal ileum or distal colon to the skin, particularly in the perianal region. Microperforation or blind tracts (sinuses) stretching from the bowel lumen may become occluded, leading to abscess formation. Collagen deposition within the bowel wall is also common and may lead to stricture formation, which usually is not found in UC. Macroscopically, the bowel wall may be substantially thickened, though narrowed areas of fibrosis and stricture are also found ([Fig. 111.2B](#)). At surgery, mesenteric fat is often seen creeping over the bowel.

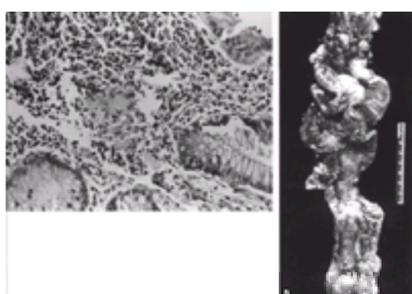

FIGURE 111.2. A: Histopathologic features of Crohn's disease. This photomicrograph exhibits some of the typical features of Crohn's disease, including a complex

chronic inflammatory infiltrate in the lamina propria that extends to deeper layers. Poorly formed noncaseating granulomas can be seen, though they are not uniformly present. (From Friedman LS, Graeme-Cook F, Schapiro RH. Inflammatory colitides. In: Boland CR, ed. *Colon, rectum, and anus*. Philadelphia: Current Medicine, 1996. [Feldman M, ed. *Gastroenterology image collection*, vol. 4.], with permission.) **B:** Surgical specimen of Crohn's ileitis shows some of the features typical of Crohn's disease, including marked thickening of the intestinal wall due to transmural inflammation and resulting luminal compromise. The mucosal surface itself has linear ulcerations, in contrast to the diffuse mucosal ulcerations typical of ulcerative colitis.

Although CD may affect any region of the GI tract, involvement of the terminal ileum or colon is most common. In about 30% of patients, disease is present only in the small intestine (usually the terminal ileum). In approximately 30% of cases, only the large bowel is affected, and in 40% the large bowel and small intestine are affected. In contrast to UC, CD involvement of the colon is usually segmental, and in many patients the rectum is spared. "Skip areas" are often present between regions of disease. In a few patients, however, Crohn's colitis may be diffuse, with rectal involvement, making its distinction from UC more difficult. Although it is less common, CD may involve more proximal areas of the GI tract entirely, including the mouth, esophagus, and stomach. Moreover, a distinctive form of focal microscopic gastritis has been found in a substantial proportion of patients with CD of the small intestine or colon or both. This type of gastritis is frequently asymptomatic.

CLINICAL FEATURES

ULCERATIVE COLITIS

The cardinal symptom of UC is bloody diarrhea. Because of irritability of the inflamed rectum, bowel movements are frequent but often small in volume. Symptoms can include fever, crampy lower abdominal pain, rectal pain, tenesmus, and rectal urgency. The severity of the inflammation and the resulting symptoms varies in part with the extent of colonic inflammation. When inflammation is confined to the rectum or rectosigmoid, blood is occasionally present only on the surface of the stool, and systemic symptoms are usually absent. With more extensive colonic inflammation, blood is typically mixed with the stool, and fatigue, fever, and weight loss are common.

Of patients with UC, approximately one-third have pancolonic disease at onset, slightly less than half have disease limited to the distal colon (proctosigmoiditis), and the rest have disease of intermediate extent (generally left-sided disease). Over time, left-sided disease develops in as many as 70% of patients, and 35% of those with proctosigmoiditis experience proximal extension of the disease process.

The activity of UC often is classified as mild, moderate, or severe on the basis of symptoms, physical findings, and laboratory abnormalities ([Table 111.2](#)). Disease activity during a first attack of UC is mild in more than 50% of patients. In most such cases, the disease is limited to the rectum or rectosigmoid and is characterized by mild diarrhea, often with rectal bleeding. Approximately 25% of patients have a moderately severe first attack of UC, characterized by up to six bloody bowel movements a day, abdominal pain, fatigue, and low-grade fever. In many cases, the onset of the attack is mild, and symptoms worsen gradually over days or weeks. Approximately 20% of patients experience more severe disease, characterized by frequent bouts of bloody diarrhea, profound fatigue, fever, tachycardia, weight loss, abdominal pain and tenderness (occasionally with rebound), anemia, and hypoalbuminemia. The outcome of an initial attack of UC usually correlates with the extent of disease and the severity of symptoms. More than 90% of patients with a mild initial attack achieve clinical remission with medical therapy (confirmed on sigmoidoscopy), whereas up to 25% of patients with a severe initial attack prove unresponsive to medication and may require colectomy.

Feature	Mild	Moderate	Severe or Fulminant
Bowel frequency per day	<4	4-6	>6
Rectal bleeding	Intermittent	Usual	Continuous and overt
Fever	No	Possibly	Yes
Pulse	Normal	May be >90/min	Often >90/min
Abdominal tenderness	Absent	Often present	Present with distention
Hematocrit (%)	Normal	>30	<25-30
Albumin	Normal	Normal	Reduced
Erythrocyte sedimentation rate (mm/hr)	<30	May be >30	>30

TABLE 111.2. SPECTRUM OF SEVERITY OF ULCERATIVE COLITIS

Typically, UC follows a chronic relapsing course characterized by intermittent acute attacks interspersed with periods of remission. Some patients (>5%), however, have no recurrence after an initial acute attack. In an even smaller percentage of cases, symptoms are chronic and continuous. Neither the severity of the first attack nor the extent of colonic inflammation at the time of diagnosis predicts the frequency of relapses. For patients younger than 50, the median time until relapse after resolution of the first attack is approximately 2 to 3 years; for older patients the median time to relapse is longer (see "Inflammatory Bowel Disease in the Elderly"). The severity of the first attack does correlate with the subsequent overall rate of colectomy, which may be as high as 50% within 2 years after a severe first attack of UC, compared with 10% or less during this interval for patients with initial signs of mild disease or proctitis. Overall, approximately 25% of patients ultimately require colectomy.

Local Complications

Patients with an initial severe acute attack of UC can experience various complications. Colonic perforation is more likely during the initial attack of UC than with subsequent attacks, because of the lack of colonic fibrosis and scarring at the outset. Perforation occurs most often in the sigmoid colon. Over time, strictures of the colon occasionally develop as a consequence of hypertrophy and thickening of the muscularis mucosa, particularly in patients with extensive colitis and continuous symptoms. Strictures may result in exacerbation of diarrhea and fecal incontinence or in symptoms of colonic obstruction. Distinguishing benign stricture formation from malignant stricture can be especially difficult.

The most serious complication of acute UC is toxic megacolon, in which the inflammatory process extends beyond the submucosa into the muscularis, leading to the inability of the colon to contract and subsequent colonic distention. Fever, tachycardia, anemia, and leukocytosis usually are present. Additional signs of toxicity often include dehydration, altered mental status, electrolyte disturbances, and hypotension. On physical examination, the abdomen is distended as a result of colonic dilatation, and there is often rebound tenderness over the colon; bowel sounds are hypoactive or absent. Although it is associated with pancolitis in most cases, toxic megacolon now and then also develops in the context of more limited disease and colitis stemming from other causes, including infectious colitis and Crohn's colitis. Risk factors for toxic megacolon in patients with severe colitis include the use of antimotility agents, such as anticholinergic drugs and narcotic analgesics; barium enema examination; colonoscopy; and hypokalemia. Plain radiographs of the abdomen are useful in establishing the diagnosis of toxic megacolon and in following the course of the disease. Colonic dilatation is usually maximal in the transverse colon or whichever segment of the colon is highest in the abdominal cavity when the patient is supine; the luminal diameter exceeds 6 cm. Colonoscopy and barium enema should be avoided when toxic megacolon is suspected on the basis of physical examination and plain abdominal radiographs.

Once toxic megacolon is recognized, aggressive medical therapy should be initiated. The patient should be given nothing by mouth, and a nasogastric tube should be put in place. Fluids and electrolytes, parenteral glucocorticoids, and, in many cases, intravenous broad-spectrum antibiotics are administered. Intravenous cyclosporine has been found to be beneficial in some patients with severe or fulminant UC (see "Immunosuppressive Agents"). If the patient's clinical symptoms do not improve and radiography shows no change in 24 to 48 hours, surgical intervention, generally a subtotal or total colectomy, is necessary. Patients with severe UC or toxic megacolon unresponsive to intravenous glucocorticoids sometimes have cytomegalovirus inclusion bodies on colonic mucosal biopsy specimens and respond to the withdrawal of glucocorticoids and treatment with intravenous ganciclovir. Surgery is mandatory after colonic perforation, which is associated with a mortality rate above 40%, compared with a mortality rate of 2% for patients with toxic megacolon operated on before perforation.

Ulcerative Colitis and Colon Cancer

Patients with long-standing UC have a markedly higher risk of colon cancer compared with the general population. The risk of colon cancer correlates with the extent of colitis and begins to rise in patients who have had pancolitis for 8 to 10 years and in those who have had left-sided colitis (not beyond the splenic flexure) for 15 years—and possibly sooner. The magnitude of the risk of colon cancer in patients with UC appears to vary, with average incidence rates of 0.5% to 1.0% per year for patients with pancolitis of at least 10 years' duration. The risk of cancer is greatest in patients who have UC early in life, because of the long period they are at risk. The average age at onset of colon cancer in patients with UC is in the fourth decade, compared with later middle age and old age in the general population.

Compared with colon cancer in the general population, colon cancer in patients with UC is more likely to be multicentric and submucosal. Methods used to screen the general population for colorectal cancer, such as examination of the stool for occult blood, do not apply to patients with UC, because of the high incidence of bleeding due to colitis. Therefore, surveillance colonoscopy is used to screen at-risk patients for colon cancer or dysplasia, a histologic lesion in which mucosal cells are marked by nuclear stratification, loss of nuclear polarity, and nuclear and cellular pleomorphism. Dysplasia may be classified as low grade, high grade, or indefinite, depending on the degree of cellular atypia. Dysplasia often precedes the development of invasive colon cancer and may be used as a marker to identify patients at high risk of harboring invasive cancer or experiencing it in the future. Indeed, up to 88% of colons resected for malignancy in UC are found to have associated dysplasia elsewhere in the specimen.

Invasive cancer is particularly likely when dysplasia arises in the vicinity of a suspicious lesion or mass (so-called dysplasia-associated lesion or mass); in such cases, there is at least a 40% chance that the lesion is a carcinoma. Similarly, there is a 40% chance that carcinoma is present in the colon when surveillance colonoscopy detects high-grade dysplasia. In addition, there is as much as a 20% chance that a colon contains carcinoma when surveillance colonoscopy shows low-grade dysplasia.

Although the association between dysplasia and UC is well established, the benefits of surveillance colonoscopy to detect dysplasia are still debated. The benefits of surveillance colonoscopy may be limited: 20% of cases of colon cancer develop in patients not found to have dysplasia on previous routine surveillance colonoscopy, interpretation of mild dysplasia is difficult in the context of active inflammatory disease, and a reduction in cancer mortality rate attributable to surveillance has been difficult to establish. Additional genetic markers of colon cancer, such as mutations of the p53 and *ras* genes, have been identified in some patients with UC and colonic dysplasia or cancer, but their role in the development of cancer in UC and their value in screening require more study.

The usual approach to surveillance is to perform colonoscopy every 1 to 2 years in patients with ulcerative pancolitis of at least 8 to 10 years' duration or of at least 15 years' duration in those with left-sided colitis. Generally four biopsy specimens are taken every 10 cm throughout the colon. Noninflamed areas, masses, strictures, and flat lesions, in particular, should be biopsied. High-grade dysplasia is an indication for colectomy, and experience suggests that low-grade dysplasia, if confirmed by a second pathologist, should also be an indication for colectomy. In a patient who is unwilling or unable to undergo repeated surveillance colonoscopy, prophylactic colectomy is an option in terms of lowering the risk of colon cancer.

CROHN'S DISEASE

Compared with UC, CD is more varied in its initial clinical symptoms and course, in part because of the diversity of anatomic involvement and in part because of the transmural nature of the inflammatory process. At first, approximately 40% of patients have disease involving the ileum and cecum, 30% have disease confined to the small intestine, and 30% have disease confined to the colon, with pancolitis in 30% of the latter patients and segmental or left-sided (distal to the splenic flexure) disease in 70%. Less often, CD involves the oral cavity, esophagus, stomach, or duodenum, though there is increasing appreciation of the frequent presence of asymptomatic gastric inflammation.

Patients with CD most often initially experience the triad of diarrhea, abdominal pain, and weight loss. The onset of disease can be insidious, and the mean duration of symptoms is more than 12 months before patients seek medical evaluation. In patients with colonic disease, diarrhea is often small in volume and associated with rectal urgency and tenesmus. In patients with disease confined to the small intestine, stool volume is larger ([Table 111.3](#)). In patients with severe terminal ileal inflammation or those who have undergone surgical resection of the terminal ileum, watery diarrhea may develop from stimulation of colonic fluid and electrolyte secretion by bile salts unabsorbed in the terminal ileum; steatorrhea ultimately may result from frank bile salt deficiency. Steatorrhea also may result from bacterial overgrowth, with deconjugation of bile salts as a consequence of strictures in the small intestine. Additionally, diarrhea may stem from fistulas between intestinal segments.

Intestinal inflammation (prostaglandin E₂, cytokines)
Bacterial overgrowth
Bile salt malabsorption
Lactose intolerance
Fistulas
Short bowel syndrome (previous intestinal resection)

TABLE 111.3. PATHOGENESIS OF DIARRHEA IN CROHN'S DISEASE

Patients with ileocolonic CD often have crampy right-lower quadrant pain after eating, an effect of partial intermittent obstruction of the ileum. Associated symptoms include abdominal distention, nausea, and vomiting. Weight loss may result from diffuse intestinal inflammation, malabsorption, or decreased intake of food because of anorexia or abdominal pain. Colonic CD is associated with rectal bleeding and perianal involvement more often than small-intestinal CD. Patients with gastroduodenal CD may have early symptoms of epigastric pain suggestive of a duodenal ulcer or postprandial vomiting due to duodenal stenosis.

On physical examination, patients with active or long-standing CD will often appear pale and ill, sometimes with evidence of weight loss and muscle wasting. The abdomen is often tender, with evidence of thickened bowel loops, a thickened mesentery, or an abscess on palpation, most often in the right-lower quadrant. Perianal involvement is characterized by inflammation, induration, and fistulous openings. Laboratory findings may include anemia resulting from chronic disease, blood loss, or deficiencies in iron, folate, or vitamin B₁₂. The white blood cell count often is mildly elevated and may be markedly elevated in patients with an intra-abdominal abscess. Thrombocytosis also may develop in the context of active disease. It is more likely that the erythrocyte sedimentation rate will be high in colonic disease than in ileal disease, but it also can be normal. Hypoalbuminemia reflects severe disease and malnutrition.

Because of the varied clinical features of CD, no single parameter reflects disease activity in every case. For clinical studies, several numeric systems have been devised for assessing disease severity and response to therapy ([Table 111.4](#)). Ancillary measures of intestinal inflammatory activity include the erythrocyte sedimentation rate and acute-phase reactants in serum, such as C-reactive protein or orosomucoid levels.

Variables	Weighting Factor
Number of liquid or soft stools in past 7 days	2
Abdominal pain (0 = none; 1 = mild; 2 = moderate; 3 = severe)	5
General well-being (0 = well; 1 = slightly unwell; 2 = poor; 3 = very poor; 4 = terrible)	7
Number of complications (arthritis, iritis, uveitis, fever >100°F, aphthous stomatitis, erythema nodosum, pyoderma gangrenosum, fissure, fistula, abscess)	20
Taking opiates/antimotil for diarrhea (0 = no; 1 = yes)	30
Abdominal mass (0 = none; 2 = questionable; 5 = definite)	10
Decrease in hematocrit from normal	6
Percentage below standard weight	1

* The total is obtained by summing the products of the grade of each variable and its weighting factor. A score <150 signifies remission; a score >450 signifies severe disease.

TABLE 111.4. CROHN'S DISEASE ACTIVITY INDEX (CAI) FORMULATED BY THE NATIONAL COOPERATIVE CROHN'S DISEASE STUDY GROUP³

Complications

Patients with CD can experience a variety of intestinal complications; depending on the predominant complication, the pattern of disease in an individual case is designated as *inflammatory*, *fistulizing*, or *stricturing*. A mixed clinical picture of these types also is relatively common. Fistulas develop in 20% to 40% of patients with CD. Fistulas are usually enteroenteric or enterocutaneous and occasionally enterovesical or enterovaginal, resulting from extension of the inflammatory process through the intestinal wall into an adjacent organ or the skin. The terminal ileum is involved most often and may be associated with fistulas extending to other loops of small intestine or to the sigmoid colon. Most enteroenteric fistulas in patients with CD are small in diameter and may represent incidental findings on barium contrast studies, but occasionally fistulas are large enough to cause diarrhea, malabsorption, or weight loss. Abdominal pain typically stems from active Crohn's inflammation rather than the presence of a fistula. Enterocutaneous fistulas may cause particular problems and frequently are the result of anastomotic leaks after surgical resection for active disease. Rectovaginal fistulas usually develop in the context of active rectal CD and may lead to a foul vaginal discharge or, now and then, the passage of gas or stool through the vagina. Enterovesical fistulas from diseased ileum or sigmoid to the bladder may produce pneumaturia and recurrent polymicrobial urinary tract infections.

From time to time, free intestinal perforation can occur in CD, but it is less common than in UC because of the characteristic thickening of the bowel wall due to transmural inflammation. Abscesses, which develop in up to 20% of patients with CD, often arise from the terminal ileum and may form between loops of intestine, in the mesentery, or between the intestine and peritoneum. They may also extend into the iliopsoas and retroperitoneal regions, resulting in hip or back pain. Rarely, hepatic or splenic abscesses develop, and, in the postoperative period, anastomotic leaks can lead to intra-abdominal abscesses. Patients with intra-abdominal abscess show signs of fever and abdominal pain and may have a tender abdominal mass on examination as well as leukocytosis with a "shift to the left".

Intestinal obstruction may complicate the course of CD, particularly of the small intestine, in up to 30% of cases; it results from thickening of the intestinal wall by the inflammatory infiltrate, muscular hyperplasia, fibrosis from previous inflammation, or adhesions. Symptoms include crampy midabdominal pain and diarrhea that worsens after meals and improves with fasting. Occasionally, prolonged episodes of severe pain are accompanied by nausea and vomiting.

Perianal disease, seen in approximately 25% of patients with CD, stems from ulceration of the anal canal, with subsequent formation of perirectal abscesses or fistulas. Fistulous openings are usually in the perianal skin, but they also can be in the scrotum, vulva, or groin. Initial symptoms include drainage of serous or mucoid material, redness, induration, and pain that is typically worsened by defecation, sitting, or walking. Sometimes deep perirectal abscesses are evidenced by fever in the absence of localizing symptoms.

Several complications in patients with CD result from intestinal malabsorption due to ileal inflammation or previous ileal resection. Cholesterol gallstones form with increased frequency because of a decrease in the size of the bile salt pool as a result of malabsorption of bile salts. The frequency of calcium oxalate kidney stones is also higher in patients with CD compared with the general population. Calcium oxalate stones are thought to form when fatty acids, normally absorbed in the terminal ileum, reach the colon owing to small-intestinal disease or resection and bind calcium, permitting oxalate, bound to sodium as sodium oxalate, to be absorbed in the colon. Hydronephrosis may develop in patients with CD as a consequence of obstruction of the right ureter by an inflammatory mass surrounding the terminal ileum.

As in UC, the incidence of colon cancer is higher in patients with Crohn's colitis than in the general population. The risk increases with the duration and extent of disease—in patients with extensive Crohn's colitis it is 20 times that of the general population. Surveillance colonoscopy has been recommended for patients with extensive Crohn's colitis, but it has not been evaluated in prospective trials. The risk of adenocarcinoma of the small intestine is also higher in patients with CD of the small intestine. Cancers usually arise in areas of active inflammation, but as many as a third may develop in noninflamed segments. Surgically bypassed loops of small intestine once were thought to be particularly susceptible to developing cancer, but this apparent association reflects the long duration of CD in patients who underwent intestinal bypass many years ago, when that operation was a standard surgical approach to small-intestinal CD.

SPECIAL PATIENT GROUPS

INFLAMMATORY BOWEL DISEASE IN THE ELDERLY

Although IBD affects young adults primarily, epidemiologic studies have shown consistently that nearly 16% of patients with CD and 12% of those with UC are older than 60 at the time of diagnosis. Older patients with UC tend to have less extensive disease: most have proctitis or limited left-sided colonic inflammation. In contrast, ischemic colitis, a major diagnostic consideration in an elderly patient with acute colitis, almost always spares the rectum. Bloody diarrhea is the typical first symptom, but constipation is a more common initial symptom in older patients than in younger patients. On average, the first attack of UC tends to be more severe in older than in younger patients and is more likely to lead to toxic megacolon and higher mortality rates. Nonetheless, after the initial attack, in most older patients UC follows a mild course with no impact on survival, presumably because the extent of colonic inflammation is limited. Although the risk of colon cancer increases with age in the general population, there is no additional risk in patients with late-onset UC, owing to the limited extent and short duration of disease.

Like younger patients, older patients with CD usually have abdominal pain, diarrhea, rectal bleeding, and weight loss. Older patients are more likely to have left-sided colonic or rectal involvement without associated small-intestinal disease. In fact, two-thirds of patients with isolated anorectal or distal colonic CD are older than 50 at the time of diagnosis. In the older age group, women are affected twice as often as men, and there is less likely to be a family history of IBD. The prognosis of CD in the elderly is also good; the disease generally has a mild course. Colonic CD tends to be more responsive to medical treatment than small-intestinal CD. Moreover, postoperative recurrence is less common in elderly patients than in younger patients. Relative mortality rates from CD or colon cancer related to CD among elderly patients do not exceed those of the general population, in contrast to younger patients, in whom the relative mortality rate is markedly higher.

INFLAMMATORY BOWEL DISEASE IN CHILDREN

In 15% of patients with UC and approximately 30% of patients with CD, the onset of illness is before age 20. In general, the clinical picture of UC in childhood resembles that of UC in adulthood. Although GI symptoms of CD are similar in children and adults, extraintestinal manifestations are more often found on initial examination in children than in adults. In addition, growth failure is a major initial complaint in 30% of children with CD. In children with long-standing disease, linear growth, bone development, and sexual maturation may be delayed markedly; such delays can antedate the onset of intestinal symptoms. Factors contributing to growth retardation include malnutrition due to poor oral intake as a result of anorexia and the avoidance of food, as well as malabsorption and increased caloric requirements stemming from extensive intestinal inflammation. Glucocorticoid therapy also can contribute to growth retardation.

PREGNANCY AND INFLAMMATORY BOWEL DISEASE

IBD often occurs in young adults in the peak of reproductive life. Fertility in women with UC appears to be normal, but some studies have suggested that fertility is impaired in women with CD. A decline in the birthrate among women with CD may relate to avoidance of sexual activity or pregnancy, emotional or cosmetic factors, or early menopause rather than a decreased rate of fertility per se. Among men with IBD, infertility sometimes results from reversible abnormalities in sperm number and function caused by the drug sulfasalazine. Most pregnancies in women with IBD lead to the delivery of healthy infants, and the incidence of spontaneous

abortions, stillbirths, prematurity, and congenital abnormalities is similar to that of the general population. Some studies have indicated that the incidence of fetal complications is slightly higher when the mother's disease is active during pregnancy.

The best predictor of the activity of IBD during pregnancy is the activity of disease at the onset of pregnancy. Patients in remission at the time of conception are likely to remain in remission during the course of pregnancy, and the relapse rate during the course of pregnancy is no greater than that in nonpregnant patients followed over the same time period. On the other hand, when the disease is active at the time of conception, it remains so throughout pregnancy in two-thirds of patients. Onset of IBD during pregnancy is no more severe than in nonpregnant women. When UC occurs for the first time or recurs during pregnancy, attacks are most likely to manifest during the first trimester or in the postpartum period. Diagnostic radiographic studies or endoscopy with sedation may be required for a pregnant patient with active IBD but are best avoided during the first trimester. The 5-aminosalicylates and glucocorticoids appear to be safe for use during pregnancy, but immunosuppressants and metronidazole, in general, should not be administered.

DIAGNOSIS

In most cases, the diagnosis of IBD can be strongly suspected on the basis of clinical symptoms of diarrhea, bloody diarrhea, abdominal pain, or perianal abscess. In some cases, fever, growth retardation, or an extraintestinal manifestation may be the first problem. In patients with diarrhea, stool cultures for enteric pathogens and examinations for ova and parasites should be carried out and may be repeated during an exacerbation of IBD, to exclude infectious enterocolitis. Various nonspecific markers of inflammation have been used to monitor disease activity, including the erythrocyte sedimentation rate, serum albumin level, serum C-reactive protein or orosomucoid levels, and presence of α_1 -antitrypsin in stool. In some patients with small-intestinal CD, features of malabsorption may require evaluation. Anemia can be caused by iron deficiency as a result of blood loss or, occasionally, duodenal inflammation and malabsorption of iron. Macrocytic anemia may stem from folate or, rarely, vitamin B₁₂ deficiency due to duodenal or terminal ileal inflammation, respectively. Other features of malabsorption include hypocalcemia and vitamin D deficiency, hypoalbuminemia, and frank steatorrhea due to bile salt deficiency. ANCAs are found in the serum of approximately 70% of patients with UC, and ASCAs are found in the serum of approximately 70% of patients with CD. These tests are not recommended for routine clinical practice, however, and are seldom needed to make a diagnosis. Liver function tests may be indicated to screen for primary sclerosing cholangitis and other liver diseases associated with IBD.

The principal techniques used to confirm the diagnosis of IBD are endoscopy (sigmoidoscopy and colonoscopy) and contrast radiography. They often are used in a complementary fashion, depending on the clinical question being addressed ([Table 111.5](#)). Endoscopy is useful in defining the extent of mucosal inflammation and detecting mild inflammation, and air-contrast radiography is appropriate for assessing colonic distensibility, detecting strictures, and defining fistulas. Barium enema, in particular, is contraindicated in patients with moderate or severe UC or Crohn's colitis because of the possibility of precipitating toxic megacolon.

Feature	Ulcerative Colitis	Crohn's Disease
Onset	Only in adult life	Common
Abdominal pain	Uncommon	Common
Diarrhea	Common	May be absent
Rectal bleeding	Very common	Occasional
Weight loss	Uncommon	Common
Signs of malabsorption	Uncommon	Common in small bowel Crohn's
Perianal disease	Rare	Common
Abdominal mass	Rare	Common
Intestinal complications	Rare	Common
Stenosis	Rare	Common
Fistulae	Rare	Common
Toxic megacolon	Occasional	Rare
Perforation	Uncommon	Uncommon
Risk of malignancy	Increased	Increased
Proctitis	Characteristic	May occur
Appendicitis and liver abscess	Rare	Common
Colonic appearance	Neat	Common
Polyps	Common	May occur
Rectal involvement	Universal	Not all cases of Crohn's colitis
Small intestine	Uncommon	Occasional in Crohn's
Small bowel	Uncommon	Common
Ulceration	Flatt, superficial	Deep, with ulcers
Stenosis	Rare	Common
Strictures of fistulae	Rare	Common
Rectal involvement	Universal ("backwash ileitis")	Not universal, nodular

TABLE 111.5. CLINICAL, ENDOSCOPIC, AND RADIOLOGIC FEATURES OF ULCERATIVE COLITIS AND CROHN'S DISEASE

In patients with colitis, colonoscopy is superior to barium enema in providing direct assessment of the extent and severity of inflammation. In addition, colonoscopy permits histologic examination of mucosal biopsy specimens. In UC, inflammation almost invariably begins in the rectum and extends proximally to a varying degree, without skip areas. Mild UC is characterized by loss of the fine vascular pattern seen in the normal colonic mucosa. Additional findings may include erythema, edema, and granularity, resulting from the uneven reflection of light from the irregular mucosal surface. Exudate or mucopus may be observed with more active disease, and the mucosa may exhibit friability (bleeding on contact). In more severe disease, mucosal bleeding is spontaneous, and ulcerations are evident. Colonoscopy should be avoided in patients with severe colitis or deep ulceration, because of the risk of toxic megacolon or colonic perforation.

The earliest manifestation of CD is aphthous ulcer with intervening areas of normal mucosa. In more severe disease, ulcers may be large and stellate or linear and, in some cases, long and serpiginous. Often a characteristic cobblestone appearance is noted. In contrast to UC, the rectum may or may not be involved in CD. Colonoscopy is particularly useful for evaluating strictures and mass lesions (permitting biopsy for diagnosis) and for conducting surveillance examinations for dysplasia. Benign strictures are usually concentric and smooth, and malignant strictures are more likely to be rigid, nodular, or eccentric. Occasionally, benign strictures can be dilated with a balloon passed through the colonoscope. Polypectomy may be performed through the colonoscope, but pseudopolyps are not premalignant and do not require excision.

In general, radiographic findings do not correlate with the activity of disease; some patients with markedly abnormal radiographic studies may be asymptomatic, and improvement in radiographic findings may lag behind clinical improvement. The diffuse ulceration of UC is seen clearly on air-contrast barium enema or the postevacuation film of a single-contrast barium enema. In early UC, the results of barium enema may be normal or show only limited distensibility, narrowing of the lumen, and shortening of the colon. The mucosa may appear slightly irregular or granular. In more severe UC, the mucosa may evidence coarse granularity and nodularity. "Collar button" ulcers that penetrate the mucosa and inflammatory polyps (pseudopolyps) may be present.

Severe rectal inflammation can result in enlargement of the presacral space. In approximately 15% to 20% of patients with pancolitis, inflammation extends into the terminal ileum as backwash ileitis, marked by mucosal irregularity, dilatation of the terminal ileum, and a deformed ileocecal valve. In chronic UC, the colon is shortened and has a tubular appearance owing to a loss of haustral markings ([Fig. 111.3](#)). A mass protruding into the lumen; a flattened, rigid area; or a stricture suggests the possibility of colon cancer, but radiologic methods fail to detect cancer in patients with UC in up to 15% of cases.

FIGURE 111.3. Barium enema of chronic ulcerative colitis. As a result of long-standing inflammatory disease, the colon becomes foreshortened with a loss of the characteristic haustral markings, leading to a tubular appearance of the colon. (From Friedman LS, Graeme-Cook F, Schapiro RH. Inflammatory colitides. In: Boland CR, ed. *Colon, rectum, and anus*. Philadelphia: Current Medicine, 1996. [Feldman M, ed. *Gastroenterology image collection*, vol. 4.], with permission.)

Early CD is identified on air-contrast barium enema as small, discrete (aphthous) ulcers. Aphthous ulcers also may be seen in various other conditions, including

shigellosis, amebiasis, and Behçet's syndrome. In more severe CD, barium enema or small-bowel radiographs may show ulcers that are larger and deeper and often stellate or linear with nodularity of the intervening mucosa (cobblestone appearance; [Fig. 111.4](#)). As a result of transmural inflammation and fibrosis, the bowel wall may lack distensibility, the lumen may be narrow, and frank strictures may be noted. Long segments of luminal narrowing stemming from circumferential inflammation and fibrosis may produce a characteristic string sign. Fistulas are studied better by radiography than by endoscopy ([Fig. 111.5](#)). Involvement of the stomach and duodenum, almost always seen in association with involvement of the jejunum or ileum, is marked by mucosal infiltration and stiffening, in some cases suggesting tumor.

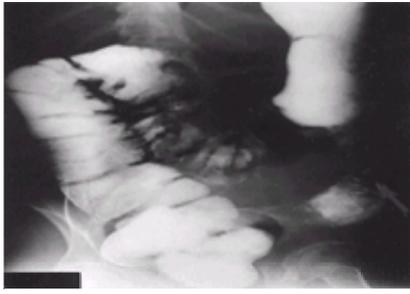

FIGURE 111.4. Barium enema showing features of Crohn's colitis. In contrast to ulcerative colitis, which affects the colon diffusely, Crohn's disease typically spares the rectum and exhibits segmental involvement.

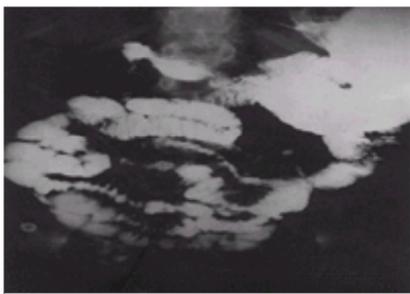

FIGURE 111.5. Upper gastrointestinal and small-bowel follow-through barium study in Crohn's disease, showing extensive involvement of the small intestine by Crohn's disease and obvious impairment of the lumen by inflammatory disease.

Computed tomography is particularly useful in the evaluation of patients with CD because of its ability to identify thickening of the bowel wall and abscesses ([Fig. 111.6](#)). This technique also may be used to direct percutaneous drainage of abscesses. In some centers, scanning with white blood cells labeled with indium In 111 is used to assess the extent and activity of disease on the basis of the homing of neutrophils to sites of active inflammation. Disease activity also can be estimated by quantitating radiolabeled neutrophils in stool. Although these techniques are sensitive for detecting intestinal inflammation, they are not specific for IBD, and white blood cell scanning is limited by relatively poor resolution.

FIGURE 111.6. Computed tomography scan in Crohn's disease shows a right-lower-quadrant inflammatory mass, which must be distinguished from frank abscess formation.

DIFFERENTIAL DIAGNOSIS

In the patient with onset or flare-up of IBD, the most challenging problem often is to distinguish IBD from acute infectious colitis caused by various enteric pathogens ([Table 111.6](#)). *Yersinia* ileitis can mimic acute appendicitis or Crohn's ileitis but is cured readily by antibiotic therapy. Many bacterial pathogens, most notably campylobacter and salmonella, can provoke illness resembling UC. Diarrhea caused by infectious agents rarely continues beyond a few weeks, and stool cultures for bacterial pathogens, testing for *Clostridium difficile* toxin, and, in some cases, examination for ova and parasites as well as serologic tests for amebiasis identify most cases of acute infectious colitis. Occasionally, the onset of IBD actually follows a bacterial illness or viral gastroenteritis. Histologic examination of rectal biopsy specimens obtained by sigmoidoscopy on initial evaluation helps distinguish acute self-limited colitis from idiopathic IBD; only the latter is associated with abnormal crypt architecture.

Infectious colitis
Campylobacter
Shigella
Salmonella
Clostridium difficile
E. coli O157:H7
Amebiasis
Hirschsprung disease
Giardiasis
Chlamydia
Eggs/Parasitology/Immunology
Yersinia enterocolitica
Histoplasmosis
Aeromonas
Ischemic colitis
Dissecting aortic aneurysm
Carcinoma
Lymphoma
Radiation enteritis
Carcinoid syndrome
Eosinophilic enteritis
Vasculitis
Behçet's syndrome
Drugs (e.g., monoteroidal anti-inflammatory drugs, oral contraceptives)
Erythema nodosum
E. coli, Shigella, Yersinia

TABLE 111.6. DIFFERENTIAL DIAGNOSIS OF INFLAMMATORY BOWEL DISEASE

In patients with prolonged diarrhea, the diagnosis of giardiasis must be considered. Intestinal tuberculosis, which usually involves the cecum and ileum, must be distinguished from CD in patients from endemic areas; pulmonary tuberculosis may be absent. Intestinal stenosis and draining fistulas sometimes can be caused by chronic fungal infections, such as blastomycosis, as well as actinomycosis. In homosexual men who practice anal intercourse, several pathogens can cause proctitis that resembles ulcerative proctitis, including chlamydia, lymphogranuloma, herpesvirus, cytomegalovirus, syphilis, and gonorrhea. In human immunodeficiency virus–infected patients, diarrhea and abdominal pain may be prompted by various opportunistic infections, including those caused by cytomegalovirus, *Mycobacterium avium* complex, *Cryptosporidium*, *Microsporidium*, and *Isospora*.

Additional diagnostic considerations vary with the patient's age and the clinical picture. In the elderly, ischemic colitis must be considered. In contrast to UC, ischemic colitis spares the rectum because of extensive collateral circulation and usually resolves spontaneously within days to weeks. Distinguishing Crohn's colitis from diverticulitis may be challenging. Both diseases can be accompanied by abdominal pain, fever, diarrhea, and rectal bleeding. In general, attacks of diverticulitis are acute, in contrast to the chronic course of IBD. In elderly patients, a syndrome of segmental colitis, characterized by patchy mucosal erythema and hemorrhage involving a segment of colon containing diverticula, may be confused with IBD. Diversion colitis in a segment of colon that has been bypassed surgically can mimic CD (the condition for which the bypass may have been performed originally) and can be triggered by a deficiency of intraluminal short-chain fatty acids as a result of interruption of the fecal stream. Microscopic colitis, either lymphocytic or collagenous colitis, typically takes the form of chronic watery diarrhea in middle-aged women. In contrast to IBD, the colonic mucosa looks normal on endoscopy, and histologic features are diagnostic. Radiation proctitis usually results from pelvic irradiation and is marked by mucosal friability, ulcerations, atrophy, and telangiectases. Colitis caused by a variety of drugs, such as nonsteroidal anti-inflammatory drugs, gold, estrogen, and allopurinol, sometimes mimics or exacerbates IBD. Ulcerative jejuno- ileitis is a rare complication of celiac disease that can lead to abdominal pain, diarrhea, and malabsorption and may mimic CD.

Hemorrhoids or anal fissures are a possibility in patients with mild UC and initial symptoms of rectal bleeding. Irritable bowel syndrome, characterized by crampy lower abdominal pain, diarrhea, constipation, or alternating diarrhea and constipation, may be considered in a young person with mild CD, but bleeding and signs of inflammation are absent, and radiographic and endoscopic studies are invariably normal in this condition. Occasionally, intestinal lymphoma can produce symptoms similar to those of CD, including fever, abdominal pain, diarrhea, and weight loss. Radiographic and endoscopic features are also similar, and, in such cases, definitive diagnosis depends on intestinal biopsy.

VARIANT FORMS OF INFLAMMATORY BOWEL DISEASE

LYMPHOCYTIC AND COLLAGENOUS COLITIS (MICROSCOPIC COLITIS)

In addition to the major forms of IBD, over the past two decades other forms of nonspecific inflammatory disorders affecting the intestinal tract have been recognized. The pathogenetic relationship of these disorders to UC and CD remains unclear. In general, the inflammatory processes and resulting symptoms are of modest severity in these variant forms of IBD. They include lymphocytic colitis (also called microscopic and minimal change colitis) and collagenous colitis. Although these initially were described as distinct inflammatory conditions on the basis of pathologic changes on mucosal biopsies, their differences probably reflect a spectrum of findings that can be present in the context of a single disease.

Patients with lymphocytic or collagenous colitis experience mild, often watery diarrhea. Blood is found only rarely in the stools. Both entities are characterized by microscopic inflammatory changes in the absence of macroscopic abnormalities on endoscopic or radiologic examination. Some patients with microscopic colitis have crypt abscesses on mucosal biopsy, but more typically a modest increase in lamina propria lymphocyte populations is the dominant histopathologic finding. The mucosa of patients with collagenous colitis exhibits marked expansion (to 10 μ or more) of the basement membrane beneath the colonic surface epithelium, presumably composed predominantly of collagen. The inflammation or the deposition of collagen may be continuous through the colon or patchy. Whether the deposition of collagen is a secondary consequence of mild lymphocytic inflammation or a primary alteration is unknown. Similarly, the role of the collagen in the pathogenesis of diarrhea is uncertain. Changes usually occur within the right colon, so colonoscopic examination for mucosal biopsy may be necessary to document the disease.

These subtle forms of colonic inflammation sometimes respond to symptomatic treatment with an antidiarrheal agent (loperamide or diphenoxylate) or to sulfasalazine or other 5-aminosalicylic acid (5-ASA) compounds. The therapeutic responses suggest that these disorders share at least some pathophysiologic properties with the major forms of IBD, especially UC. This impression is reinforced by the observation that these patients exhibit some of the same immune-associated markers present in patients with UC, such as circulating ANCAs. Preliminary observations suggest that patients with lymphocytic or collagenous colitis respond to treatment with bismuth subsalicylate, two tablets by mouth four times a day for 8 weeks. In most cases, lymphocytic colitis resolves spontaneously within 3 years. In severe refractory cases, diversion of the fecal stream has resulted in cessation of diarrhea and reversion of the collagen layer.

DIVERSION COLITIS AND POUCHITIS

Two distinctive forms of intestinal inflammation can develop after certain surgical procedures. Diversion colitis is found in the defunctionalized segments of the bowel after exclusion from the path of flow of luminal contents. The mucosa in these bypassed segments can appear quite friable and even ulcerated, owing to broad, typically superficial inflammation. Patients may void small-volume, possibly bloody stools frequently. Diarrhea can be accompanied by abdominal pain and systemic signs of inflammation, including anorexia and fever. This lesion can result from depriving the surface epithelial cells within the affected segment of their primary metabolic fuel (glutamine for the small-intestinal epithelium and short-chain fatty acids for the colonic epithelium), which they normally derive directly from the lumen. Compromise of the mucosal barrier can lead to penetration of luminal proinflammatory substances and result in mucosal inflammation. Efforts to treat diversion colitis with short-chain fatty acids have yielded mixed results. Occasionally, patients respond to nonspecific anti-inflammatory agents, such as glucocorticoids, though reestablishing continuity of the colon or resecting the affected segments are the most effective approaches, when feasible.

With the increasing use of procedures in which a neorectum is created from the ileum after total colectomy (ileal pouch–anal anastomosis or ileoanal pull-through) in patients with UC or familial polyposis, the development of idiopathic inflammation in the pouch has become a well-recognized complication. Pouchitis is more common in patients with a history of UC than in those with a history of polyposis, suggesting that a predisposition to intestinal inflammation also contributes to this disorder. In these patients, biopsy of the pouch mucosa is essential to exclude the possibility of underlying CD, which can be mistaken for UC before colectomy. The mucosa is typically friable and exhibits diffuse, nonspecific inflammation on biopsy; the presence of granulomas indicates CD. Patients experience rectal urgency and frequent bowel movements. Fever and other constitutional symptoms may accompany local manifestations. Treatment is empiric. Some patients respond to the antibiotics metronidazole or ciprofloxacin. Alternatively, patients can be treated with topical or oral 5-ASA or glucocorticoids. In the most refractory cases, takedown of the pouch and conversion to conventional ileostomy may be necessary.

EXTRAIESTINAL MANIFESTATIONS

Both UC and CD are associated with various extraintestinal manifestations. The most common extraintestinal manifestation of IBD, occurring in 25% of cases, is arthritis, usually in the form of migratory pain or painful swelling involving the knees, hips, ankles, elbows, and wrists. Symptoms involving fewer than five joints (pauciarticular) tend to be acute and self-limited and correlate with relapses of IBD and the presence of other extraintestinal manifestations. Control of bowel inflammation generally results in dramatic improvement in arthritis. A second pattern of peripheral arthritis is characterized by involvement of five or more joints (polyarticular), persistence of symptoms for months to years independent of the activity of IBD, and an association with uveitis. Deformity of joints is uncommon. A similar type of arthritis is seen in association with various enteric infections.

A less common type of arthritis seen in patients with IBD is sacroiliitis with or without ankylosing spondylitis; the incidence of this condition is 30-fold higher in patients with UC than in the general population. In 80% of patients, the human leukocyte antigen HLA-B27 is present. Ankylosing spondylitis tends to pursue a relentlessly progressive course; the activity of arthritis does not parallel that of bowel disease. Patients experience lower back pain, morning stiffness, and a stooped posture. Characteristic radiographic changes include squaring of the vertebrae, straightening of the spine (resulting in the so-called “bamboo spine”), and blurring and patchy sclerosis of the margins of the sacroiliac joints. Frank ankylosing spondylitis is uncommon; a more limited process affecting the sacroiliac joints is often evident.

Hepatic complications of IBD include fatty liver, primary sclerosing cholangitis, chronic hepatitis, and cirrhosis. Fatty liver develops in approximately 50% of hospitalized patients with IBD and may relate to weight loss and malnutrition. Up to 20% of patients with IBD have asymptomatic elevations of the serum alkaline phosphatase level, and frank primary sclerosing cholangitis is found in 1% to 4% of patients with UC (but a much smaller percentage of those with CD). Early biliary

ductal changes may be confined to intrahepatic bile ducts (formerly termed pericholangitis) and can be confirmed only by liver biopsy. Ultimately, progressive periductal fibrosis develops. In more advanced cases, the serum bilirubin level may be elevated, and gross changes may be seen on endoscopic retrograde cholangiopancreatography. Findings include strictures and focal dilatations of the intrahepatic and extrahepatic biliary tree, suggestive of sclerosing cholangitis. Approximately 75% of patients with primary sclerosing cholangitis have associated IBD. Primary sclerosing cholangitis pursues a course independent of the activity of colitis and may even have its onset after colectomy for UC. Patients may have symptoms of fever, right-upper-quadrant pain, and jaundice stemming from episodes of bacterial cholangitis. Dominant strictures may be seen at the bifurcation of the common bile duct, and cholangiocarcinoma develops at this site in up to 10% of cases. In advanced cases, there may be secondary biliary cirrhosis and portal hypertension.

Dermal complications of IBD, seen in approximately 15% of patients, include erythema nodosum, pyoderma gangrenosum, and, in rare instances, Sweet's syndrome (neutrophilic dermatosis). Erythema nodosum, most common in children with CD, is characterized by raised, tender nodules, usually over the anterior surface of the tibia. The course of erythema nodosum parallels that of bowel disease and improves with resolution of bowel disease. Approximately one-third to one-half of patients with pyoderma gangrenosum have IBD (more often UC than CD), but pyoderma gangrenosum occurs in fewer than 5% of patients with IBD. The typical lesion is an expanding discrete ulcer on the leg with a necrotic base. The ulcer may become large and deep, resulting in destruction of surrounding soft tissue. Lesions usually develop during an attack of acute colitis, but their subsequent activity can be independent of that of bowel disease. Pyoderma gangrenosum usually improves with control of bowel disease.

The principal ocular complications of IBD, seen in less than 5% of cases, are episcleritis and uveitis. Episcleritis takes the form of scleral injection and burning and generally responds to treatment with topical glucocorticoids. Uveitis, or iritis, is an inflammatory lesion of the anterior chamber of the eye, with initial symptoms of eye pain, photophobia, blurred vision, and conjunctival injection. Because vision can be impaired, it is important to make an immediate diagnosis by slit-lamp examination, so that therapy with topical glucocorticoids and atropine can be initiated.

The risk of thromboembolic events, including deep venous thrombosis and pulmonary embolism, is higher in patients with UC and CD. In as many as 50% of patients with IBD and venous thrombosis, activated protein C resistance, due to factor V Leiden mutation, can be detected. Other factors that contribute to a thromboembolic tendency include activation of clotting factors, such as factor VIII and fibrinogen; decreased levels of antithrombin III; and thrombocytosis. The risk of amyloidosis, particularly involving the kidney, is higher in patients with CD and may result in renal insufficiency. Low bone mineral density is common at diagnosis in patients with CD but not UC, and long-term therapy with corticosteroids also may contribute to osteopenia. Rare pulmonary complications of IBD include pulmonary infiltrates with eosinophilia, bronchiolitis obliterans with organizing pneumonia, necrobiotic pulmonary nodules, serositis, glomerulonephritis, and myelodysplastic syndromes. Aphthous stomatitis is common in both UC and CD.

MEDICAL THERAPY

SUPPORTIVE MEASURES

Antidiarrheal agents, such as loperamide or diphenoxylate, may be used in patients with mild symptoms of IBD to reduce the frequency of bowel movements and to relieve rectal urgency. In patients with moderate or severe colitis, antidiarrheal agents must be used with particular caution because they predispose to the development of toxic megacolon. Anticholinergic agents, such as tincture of belladonna, dicyclomine hydrochloride, or propantheline bromide, may minimize abdominal cramps and rectal urgency, particularly when administered before meals to lessen peristalsis. These drugs are contraindicated in patients with severe colitis. Narcotics are best avoided because of the risk of dependency.

In patients with severe IBD requiring hospitalization, repletion of fluids and electrolytes is essential, and blood transfusions may be required for patients with profound anemia. Some patients with refractory chronic anemia respond to treatment with recombinant human erythropoietin. Those patients with anorexia or malnutrition may benefit from supplementation of oral intake with defined-formula diets. Parenteral nutrition may be required, for instance, for patients with chronic small-intestinal obstruction not amenable to surgical resection, a previous massive small-bowel resection and insufficient remaining small intestine, or severe, uncontrollable diarrhea.

Specific deficiencies of iron, calcium, magnesium, zinc, vitamin D, vitamin K, and vitamin B₁₂ may require correction. Specific therapy may be indicated for extraintestinal manifestations of IBD, as discussed in the chapters describing those entities. If possible, nonsteroidal anti-inflammatory drugs, which can exacerbate IBD, should be avoided. The value of elemental diets consisting of amino acids, monosaccharides, essential fatty acids, vitamins, and minerals as primary therapy for IBD is the subject of controversy. Experience suggests that such elemental diets limit the activity of CD and achieve remission nearly as often as glucocorticoids but that remission is unlikely to be sustained. Moreover, most patients find these diets unpalatable and monotonous.

As for any chronic illness, particularly one that manifests in the prime of life, education and emotional support are crucial to successful management. Patients should be encouraged to learn about their illness and to participate fully in therapeutic decision making. Stress and psychosomatic factors do not cause IBD but may exacerbate it. A sympathetic physician committed to long-term care is vital. In the United States, the Crohn's and Colitis Foundation of America is an excellent source of information and support for patients. There is no specific curative drug treatment for IBD. Because of the multiplicity of drugs (each with limitations) as well as the variability of disease among patients with IBD, therapy must be individualized ([Table 111.7](#)).

Clinical Problems	Options
Proctitis and distal colitis	Topical 5-aminosalicylic acid Topical hydrocortisone
Mild to moderate	Oral sulfasalazine Oral 5-aminosalicylic acid Oral prednisone Oral prednisone or 5-aminosalicylic acid (for hospitalized) or hydrocortisone
Severe	Hydrocortisone (for hospitalized) or prednisone
Refractory disease or high corticosteroid requirements	Addition of 6-mercaptopurine or azathioprine to standard therapy
Maintenance of remission	Oral sulfasalazine Oral 5-aminosalicylic acid
Mild to moderate	Oral sulfasalazine Oral 5-aminosalicylic acid Oral prednisone Oral prednisone or 5-aminosalicylic acid
Severe	Hydrocortisone (for hospitalized) or prednisone
Refractory disease	Oral prednisone Oral 6-mercaptopurine or azathioprine
Maintenance of remission	Addition of 6-mercaptopurine or azathioprine to standard therapy
Refractory disease, high corticosteroid requirements, or relapses	Addition of 6-mercaptopurine or azathioprine to standard therapy
Maintenance of remission	Oral 5-aminosalicylic acid Oral 6-mercaptopurine or azathioprine

TABLE 111.7. APPROACH TO THE TREATMENT OF INFLAMMATORY BOWEL DISEASE

5-AMINOSALICYLATES

The original 5-aminosalicylate, sulfasalazine (Azulfidine), remains a useful first-line drug in the treatment of UC and Crohn's colitis of mild to moderate severity. Sulfasalazine consists of 5-ASA (or mesalamine) linked by an azo bond to sulfapyridine. The 5-ASA is the active (therapeutic) component of the drug; sulfapyridine prevents proximal absorption and ensures delivery of 5-ASA to the colon. In the colon, bacteria split the azo bond to release 5-ASA, which exerts a topical action on inflamed colonic mucosa, presumably by inhibiting prostaglandin and leukotriene synthesis, inhibiting granulocyte chemotaxis and activation, and scavenging reactive oxygen metabolites. Much of the freed sulfapyridine is absorbed systemically, accounting for most of the toxicity of sulfasalazine.

Sulfasalazine (up to 1.5 g orally four times daily) induces remission of acute attacks of UC in up to 80% of cases. Once remission is achieved, continued maintenance therapy with doses of 500 mg four times daily or 1 g twice daily lowers the subsequent relapse rate by 50%. Sulfasalazine is also beneficial for active Crohn's colitis, but its efficacy in small intestinal, ileocecal, and perianal CD is less predictable. The role of sulfasalazine in maintaining remission in CD is uncertain; total daily doses as high as 3 to 4 g may prevent relapses or postsurgical recurrences of CD.

Up to half of patients taking sulfasalazine experience side effects; the most common are anorexia, nausea, vomiting, epigastric discomfort, and headache. These effects are dose related and are most likely to occur in patients who are slow acetylators of sulfapyridine on a genetic basis. Reversible decreases in sperm number and function are common in men taking sulfasalazine and, on isolated occasions, may result in infertility. Rare, idiosyncratic reactions to sulfasalazine include fever, rash, neutropenia, agranulocytosis, pancreatitis, hepatitis, pneumonitis, polyarteritis, pulmonary fibrosis, and lupus erythematosus. Most such side effects can be

attributed to the sulfapyridine component of sulfasalazine, which, in general, should not be reinstated after an idiosyncratic reaction. Folic acid (1 g per day taken orally) is often prescribed with sulfasalazine, which may limit the intestinal absorption of folate.

Because 5-ASA is the active component of sulfasalazine and because sulfapyridine accounts for most of the drug's toxicity, several alternative formulations of 5-ASA have been developed. Formulations of 5-ASA effective in the treatment of colonic IBD, and in some cases distal small-intestinal IBD, include enemas, suppositories, and various encapsulated and slow-release preparations (Table 111.8). Enemas or suppositories containing 5-ASA (or a related compound, 4-ASA) are beneficial in the treatment of distal UC confined to the rectum or rectosigmoid colon. Oral delayed-release preparations of 5-ASA (mesalamine) include Asacol, in which 5-ASA is coated with an acrylic resin that dissolves at an intraluminal pH greater than 6, and Pentasa, in which 5-ASA in the form of microgranules is coated with a semipermeable membrane of ethyl cellulose, permitting slow release of 5-ASA throughout the small intestine and colon. In another formulation, olsalazine (Dipentum), 5-ASA is linked to a second 5-ASA molecule instead of sulfapyridine, creating a dimer and permitting delivery of 5-ASA to the distal small intestine and colon.

Drug	Brand Name	Formulation	Initial Dose	Maintenance Dose	Comments
Mesalamine	Asacol	5-ASA coated with acrylic resin, released in alkaline pH (terminal ileum, colon)	100 mg q.d.	100 mg q.d.	May need to taper
Mesalamine	Pentasa	5-ASA microgranules coated with ethyl cellulose, slowly released throughout distal small intestine and colon	100 mg q.d.	100 mg q.d.	Numerous side effects (20% of patients, see text); often given with folic acid 1 mg q.d.
Olsalazine	Dipentum	5-ASA linked to 5-ASA, split for sulfapyridine in colon	100 mg q.d.	100 mg q.d.	Causes diarrhea in 20% of cases; may improve with slow induction and administration with food
Mesalamine	Asacol	5-ASA coated with acrylic resin, released in alkaline pH (terminal ileum, colon)	100 mg q.d.	100 mg q.d.	Effective in terminal ileitis as well as colitis
Mesalamine	Pentasa	5-ASA microgranules coated with ethyl cellulose, slowly released throughout distal small intestine and colon	100 mg q.d.	100 mg q.d.	Some efficacy in small bowel CD and UC

TABLE 111.8. 5-AMINOSALICYLATES

The various oral formulations of 5-ASA are associated with fewer side effects than sulfasalazine, though olsalazine may cause diarrhea in up to 20% of patients. Rare cases of acute pancreatitis and pericarditis as well as nephrotoxicity have been associated with the use of oral 5-ASA. In general, the 5-ASA compounds appear to be as effective as sulfasalazine in the treatment of ulcerative and Crohn's colitis and in the maintenance of remission of UC, and they are probably more effective than sulfasalazine in preventing relapses of CD, though they are more expensive. Because it is released in the small intestine, Pentasa may be useful in the treatment of small-intestinal CD, but other 5-ASA compounds, such as Asacol, can be administered to maintain remission in patients with ileitis at doses larger than 3 g per day. Because 5-ASA compounds are potentially nephrotoxic, renal function should be monitored in patients treated with these drugs.

GLUCOCORTICOIDS

Glucocorticoids are the most widely used agents in the treatment of moderate to severe UC or CD. These compounds can affect many factors contributing to inflammatory activity in IBD. Glucocorticoids are potent inhibitors of the release of arachidonic acid from cell membranes and of the inflammatory response. In addition, they inhibit the release of IL-1 and IL-2 from immune cells. They are available in oral, intravenous, and rectal formulations of varying potency and duration of action. Despite their effectiveness in suppressing severe IBD, there is no evidence that continued use of glucocorticoids after remission is achieved helps prevent relapse of the disease.

In patients with severe UC or CD, initial therapy consists of intravenous hydrocortisone (300 mg per day), solumedrol (60 mg per day), or the equivalent. Continuous infusion may be preferable to intermittent dosing. Once clinical remission is achieved, a tapering regimen of oral prednisone is instituted. Corticotropin (ACTH; 120 U per day) is as effective as 300 mg per day of intravenous hydrocortisone for the treatment of CD and UC and may be more effective than hydrocortisone in the few patients with a first attack or relapse of UC not previously treated with glucocorticoids. For patients with moderately severe disease, treatment can be initiated on an outpatient basis with oral prednisone (40 to 60 mg per day); once remission is achieved, the drug is tapered over 2 to 3 months. Although the ultimate goal is to discontinue glucocorticoids, some patients require long-term treatment with low-dose prednisone (10 to 15 mg per day) because of continued smoldering disease activity.

Numerous side effects complicate the use of glucocorticoids, including fluid retention, acne, glucose intolerance, adrenal suppression, a predisposition to severe infections, glaucoma, cataracts, peptic ulcer disease, hypertension, osteoporosis, emotional lability or frank psychiatric disorders, and Cushing's syndrome. Every attempt should be made to avoid prolonged use of glucocorticoids. In some cases, long-term alternate-day glucocorticoid therapy may be useful in suppressing disease activity with fewer side effects.

Topical hydrocortisone (hydrocortisone enemas or foam) commonly is used in the treatment of distal colitis. As the dose increases, however, so do systemic absorption and the frequency of adverse systemic side effects. Therefore, several topical glucocorticoid preparations with enhanced potency and diminished systemic bioavailability, such as budesonide, have been developed and are undergoing clinical trials. Although not yet generally available in the United States, budesonide undergoes extensive first-pass metabolism and has fewer systemic side effects than conventional glucocorticoids. Oral formulations of budesonide are also being studied.

IMMUNOSUPPRESSIVE AGENTS

The immunosuppressant azathioprine and its metabolite 6-mercaptopurine are used most often in conjunction with glucocorticoids in the treatment of CD and UC unresponsive to standard therapy alone (glucocorticoids, sulfasalazine). Their precise mechanism of action in IBD is uncertain, but they may have an inhibitory effect on T-cell production. Immunosuppressants are particularly useful in treating Crohn's fistulas, limiting or eliminating glucocorticoid requirements or preventing prompt relapse after a course of standard medical therapy or surgical resection. Although azathioprine and 6-mercaptopurine appear to prevent relapses of CD or UC in remission, long-term maintenance therapy with these drugs must be balanced against concerns about a possible higher risk of malignancy. As yet unconfirmed evidence suggests that there is no benefit to continuing these drugs if a patient taking one of them has been in remission for more than 4 years.

Azathioprine or 6-mercaptopurine is generally administered in an oral dose of 50 mg per day. The dose is increased gradually to a maximum of 1.5 mg per kilogram per day for 6-mercaptopurine or 2.0 mg per kilogram per day for azathioprine, as tolerated. There is usually a latent period of about 2 months and sometimes up to 6 months before a therapeutic effect is observed. Because of this delayed onset of benefit, these medications are not helpful in controlling acute disease activity and generally should not be used unless therapy for a year or more is contemplated. Adverse effects of both drugs include acute pancreatitis in approximately 3% and fever and rash in 2% of patients. Nausea is common, and diarrhea develops in some patients. Bone marrow suppression is uncommon with a standard dose of 50 mg per day but may be a problem at higher doses; peripheral blood counts should be monitored during therapy. Rare patients experience profound leukopenia within 7 to 14 days of starting these drugs because of a deficiency of the enzyme thiopurine methyltransferase, which results in increased intracellular accumulation of 6-thioguanine. Both drugs should be administered with great caution to patients receiving allopurinol, owing to competitive inhibition of the pathways responsible for their metabolism.

Cyclosporine, an immunosuppressant used to prevent rejection of transplanted organs, has been used with success in the treatment of refractory IBD. Cyclosporine has a more rapid onset of action than azathioprine or 6-mercaptopurine, and clinical benefit is often seen within 1 to 2 weeks. The most encouraging results have been reported in severe UC—intravenous cyclosporine (4 mg per kilogram per day) given by continuous infusion may result in a dramatic response, thereby preventing or at least delaying the urgent need for surgery. On the other hand, cyclosporine is unlikely to be useful for long-term management of IBD because of its expense and many side effects, including hypertension and renal dysfunction. Tacrolimus, a newer immunosuppressant with properties similar to those of cyclosporine, is also undergoing clinical evaluation in patients with IBD, but preliminary studies have not established its superiority to cyclosporine.

Methotrexate, a folic acid antagonist that interferes with the action of IL-1, has shown promise in the management of both UC and CD unresponsive to standard therapy. The most widely used regimen consists of intramuscular injections of 25 mg once a week for 12 weeks. Potential side effects include acute alveolitis in up to 10% of patients and hepatic fibrosis. In general, the use of such agents as cyclosporine and methotrexate should be confined to centers performing controlled trials of

novel agents to treat IBD.

Infliximab, an anti-TNF- α chimeric monoclonal antibody, was recently approved by the U.S. Food and Drug Administration for the treatment of moderate to severely active CD unresponsive to conventional therapy. The drug is given as a single infusion of 5 mg per kilogram over at least 2 hours. Additional doses at 2 and 6 weeks are recommended for patients with fistulizing disease, but reports of anaphylactoid reactions and lymphomas in rare patients treated with infliximab suggest that caution is required in using the drug, despite clinical remission rates of approximately 70%. In addition, a serum sickness–like illness has been reported in up to 25% of patients treated again after a prolonged interval following initial infusion. The drug is not recommended for use in children. Limited experience suggests that thalidomide, which also inhibits TNF, has beneficial effects in CD, but its use is closely restricted.

ANTIBIOTICS

Metronidazole is useful in the treatment of perineal CD, Crohn's colitis, and pouchitis. Its mechanism of action in IBD is unclear. The standard dose is 10 to 20 mg per kilogram per day (750 to 1,500 mg per day) in divided doses. Occasionally, there may be dramatic healing of perianal disease, rectovaginal fistulas, and complex perineal abscesses. Metronidazole may be especially effective in controlling Crohn's colitis, despite a lack of effect in UC. However, the use of metronidazole is limited by a high rate of often intolerable side effects, which are dose related; these include a metallic taste, furry tongue, GI upset, and disabling paresthesias. Moreover, there is a high relapse rate when the drug is discontinued, and the safety of long-term therapy with metronidazole, which may have carcinogenic potential, is uncertain. Other orally administered antibiotics, such as ciprofloxacin, may be helpful in the treatment of perineal CD and possibly Crohn's ileitis or UC. Broad-spectrum intravenous antibiotics often are administered to patients with severe or fulminant UC or toxic megacolon, but they are of unproven therapeutic benefit.

OTHER DRUGS UNDER INVESTIGATION

Numerous other agents have been reported to be effective in the treatment of IBD, at least anecdotally. Some have undergone limited clinical trials, but none is used routinely. Fish oil contains eicosapentanoic acid, which diverts the metabolism of arachidonic acid from leukotriene B₄ to leukotriene B₅ and has been reported to have a glucocorticoid-sparing effect in IBD. Specific inhibitors of 5-lipoxygenase, which catalyzes the formation of leukotriene B₄, have shown limited promise in preliminary studies, particularly in patients not taking sulfasalazine. Agents that bind to the leukotriene B₄ receptor have shown some benefit in IBD. A variety of agents that inhibit specific inflammatory mediators and cytokines are under study, including IL-10 and IL-11. An antisense oligonucleotide that inhibits expression of the intracellular adhesion molecule ICAM-1 has shown promise in a highly preliminary trial. Mycophenolate mofetil, a newer immunosuppressant, has had an effect in patients with CD who cannot tolerate azathioprine. Enemas containing sodium cromoglycate, a stabilizer of mast cell membranes, have been efficacious in distal UC. Hydroxychloroquine, which is thought to act by correcting a defect in the ability of antigen-bearing epithelial cells to stimulate suppressor T cells, occasionally results in remissions in UC. Superoxide dismutase, a scavenger of reactive oxygen metabolites, has shown some benefit in limited clinical trials. Nicorette gum and transdermal nicotine, evaluated because of an association between the cessation of tobacco use and the development of UC, have been of limited clinical benefit in patients with UC. In unresponsive perineal CD, hyperbaric oxygen has been reported to have efficacy.

STRATEGIES FOR OPTIMAL CARE

ULCERATIVE COLITIS

In patients with ulcerative proctitis or distal colitis, initial therapy with hydrocortisone or 5-ASA enemas is often effective. Alternatively, oral sulfasalazine, or another oral 5-aminosalicylate, may be administered in gradually increasing doses. Once clinical remission is achieved, the frequency of enemas can be decreased to every other day or every third day, or a lower (maintenance) dose of an oral 5-aminosalicylate can be given. Patients who do not respond to enemas or oral 5-aminosalicylates may require a trial of oral prednisone beginning at a dose of 40 mg per day.

For patients with more extensive colitis that is mild in activity, oral sulfasalazine (or another oral 5-aminosalicylate) can be tried, starting at a dose of 500 mg twice a day and increasing to 1 to 1.5 g four times a day over a week. Patients unresponsive to oral aminosalicylate may need a trial of oral prednisone at an initial dose of 20 to 60 mg per day. Patients with moderately severe disease probably should be given oral prednisone at the outset. Once clinical remission is achieved, the dose of oral prednisone can be tapered at a rate of 2.5 to 5 mg per day per week to 20 mg per day, at which point the rate of tapering may be slowed to 2.5 to 5 mg per day every other week. At some point, it is reasonable to start an oral aminosalicylate, which can be continued as maintenance therapy once the oral prednisone is discontinued.

Patients with severe UC require hospitalization and parenteral glucocorticoids. Dehydration and hypokalemia should be corrected, and the patient should be monitored for the development of toxic megacolon. Malnourished patients may need parenteral nutrition. Intravenous hydrocortisone (300 mg per day) or its equivalent should be administered. The value of intravenous broad-spectrum antibiotics in severe colitis is uncertain, but they should be considered for patients with clinical signs suggesting sepsis. Once the patient's clinical condition improves, intravenous glucocorticoids can be discontinued and oral prednisone begun.

In patients with UC that does not respond to oral aminosalicylates or glucocorticoids, therapy with immunosuppressive agents may be considered. For patients with mild to moderately severe disease, azathioprine or 6-mercaptopurine can be tried, but these agents may require several months for a response. In patients with severe UC, a trial of intravenous cyclosporine can be considered; if it is effective, clinical improvement should occur within a week. Patients unresponsive to aggressive medical therapy can be considered for colectomy (see "[Ulcerative Colitis](#)" below).

CROHN'S DISEASE

In patients with Crohn's colitis or ileocolitis of mild to moderate severity, oral sulfasalazine or an alternative 5-aminosalicylate should be tried, as described for UC. Patients unresponsive to an oral aminosalicylate or those with more severe disease should be started on oral prednisone (40 mg per day). If an intraabdominal abscess is present, broad-spectrum antibiotics should be administered, and the abscess should be drained. Because abdominal pain is often the predominant symptom in patients with CD, efforts should be undertaken to identify the basis of the pain; specifically, the possibility of intestinal obstruction caused by a fibrotic stricture should be explored and, if necessary, treated surgically or, if it is accessible, endoscopically. If diarrhea is the predominant symptom, additional explanations, such as a fistula or bacterial overgrowth, may need to be investigated. Antibiotics (metronidazole or ciprofloxacin) also may be effective as primary treatment for patients with disease of the large bowel and possibly the ileum.

Patients with severe CD often require hospitalization, intravenous hydration, and parenteral glucocorticoids. Patients unresponsive to corticosteroids alone may need immunosuppressive drugs as well. Surgical intervention should be considered when prolonged courses of high-dose glucocorticoids are needed or when a specific complication requiring surgical intervention is identified (see next section). For patients with perianal disease, a course of oral metronidazole or ciprofloxacin may be worthwhile. Treatment with infliximab can be considered for patients with refractory symptomatic fistulas. Nutritional repletion and supplementation may be necessary for the malnourished patient. In the patient with terminal ileal disease or a previous ileal resection, supplemental vitamin B₁₂ is often mandatory.

SURGICAL THERAPY

ULCERATIVE COLITIS

Up to 25% of patients with extensive UC ultimately require colectomy. The most common indication for surgery is the failure of medical therapy to control colonic inflammation. In most cases, intractability manifests as chronic diarrhea severe enough to impair the patient's quality of life. In some cases, surgery is considered when it is not possible to wean the patient from high-dose glucocorticoids. In children, intractability manifests primarily as growth failure. Additional indications include the failure of extraintestinal manifestations of colitis to respond to medical management and the finding of dysplasia or carcinoma on colonoscopy. Emergency colectomy may be necessary for toxic megacolon or severe fulminant colitis. Rarely, severe hemorrhage is an indication for emergency colectomy.

The standard operation for UC is proctocolectomy with a Brooke ileostomy, which may be performed in one or two stages. A two-stage procedure is generally favored for patients who are severely ill (e.g., those with toxic megacolon). Advantages of proctocolectomy and ileostomy are that the procedure is curative and associated with excellent technical and functional results. Disadvantages are the need for an ostomy with an appliance and the risk of impaired sexual function in men.

An alternative to standard proctocolectomy and ileostomy is ileal pouch–anal anastomosis, in which the colon is removed, but the muscularis of the rectum is left in place after dissection of the rectal mucosa and submucosa. A pouch constructed from the terminal ileum is sewn to the dentate line at the anorectal junction. A temporary diverting loop ileostomy is commonly created to protect the ileal pouch–anal anastomosis until it heals. The major advantage of the ileal pouch–anal anastomosis is that it maintains bowel continuity. Initially, patients have numerous bowel movements and frequent fecal incontinence, which improves gradually over 12 months. Additional potential complications include the formation of an abscess in the ileal pouch and pouchitis, a syndrome characterized by diarrhea, rectal bleeding, malaise, and both endoscopic and histologic evidence of inflammation of the pouch. In some cases, pouchitis is responsive to oral antibiotics, such as metronidazole (250 to 500 mg three times a day for 7 to 10 days). Approximately 2% of patients require excision of the ileal reservoir and placement of a permanent ileostomy.

CROHN'S DISEASE

Ultimately, most patients with CD undergo surgery for the disease. Although surgical resection is not curative, intractability and failure of medical therapy often result in the need for surgery in CD. Additional indications are intestinal obstruction, symptomatic fistulas, abscesses, toxic dilatation, perforation, and cancer.

In patients with small-intestinal CD, the most common surgical procedure is segmental resection for intestinal obstruction or fistula. Only grossly involved bowel is resected, because resection of intestine that is macroscopically normal but microscopically abnormal does not lessen the frequency of recurrence. In fact, the frequency of ileal recurrence after resection for ileitis or ileocolitis is approximately 50% after 10 years. The site of recurrent disease is almost invariably proximal to the anastomosis. In a patient operated on for acute appendicitis but found instead to have acute ileitis, ileal resection should not be performed, because of the likelihood that acute ileitis will be self-limited; however, appendectomy should be performed so that diagnostic confusion is avoided in the future.

To preserve bowel length and lower the chance that short bowel syndrome will result from repeated intestinal resections, stricturoplasty is often carried out for patients with an intestinal obstruction caused by a fibrotic stricture in the absence of substantial inflammation. The technique involves making a longitudinal incision of the stricture, followed by transverse closure. Segmental or total resection of the colon is ultimately required in 50% of patients with Crohn's colitis. However, recurrence rates are as high as 75% 10 years after segmental resection. The rate of recurrence of the disease in the small intestine after total colectomy is approximately 25%. For patients with extensive rectal CD, total proctocolectomy with a Brooke ileostomy may be considered. An ileal pouch–anal anastomosis is inappropriate in the context of Crohn's colitis, because of the invariable recurrence of CD in the pouch.

PROGNOSIS

Both UC and CD are generally chronic, relapsing diseases, but in an individual case the course is unpredictable. For patients with a first attack of UC, the risk of relapse approaches 90% after 25 years of follow-up. However, at any point in time, half of all patients with UC are in remission. Colectomy is ultimately required in 25% of patients. The mortality rate is slightly higher than that of the general population after the initial attack, reflecting patients with severe acute pancolitis. After that, the mortality rate is not increased, and more than 90% of patients lead full, productive lives.

At least 50% of patients with CD require surgery, and most of them experience a subsequent symptomatic recurrence; another surgical procedure is required in at least a third of the patients who undergo surgery. Intestinal obstruction is most likely to occur in patients with small-intestinal CD, and fistulas and abscesses are most likely in those with ileocolonic disease; the latter group has a higher risk of postsurgical recurrence than the former. Compared with the general population, life expectancy is slightly lower in patients with CD. Death rates are highest in the immediate postoperative period, and death tends to occur during the first 5 years after diagnosis. Although most patients lead active lives, the disease may be continually active and debilitating in 15% to 20% of cases.

CHAPTER 112: MESENTERIC VASCULAR DISEASES

JAMES C. STANLEY

[Mesenteric Macrovascular Circulation](#)
[Mesenteric Microcirculation](#)
[Splanchnic Ischemia](#)
[Splanchnic Artery Aneurysms](#)

Mesenteric vascular diseases are a heterogeneous group of clinically significant illnesses that have become recognized with increasing frequency due to the more common imaging of the intestinal circulation during study of vascular and nonvascular diseases of the abdomen. Considerable information exists regarding some of these diseases, whereas knowledge about others is anecdotal. It is important to recognize differences among the common ischemic diseases ([Table 112.1](#)) and common splanchnic aneurysms ([Table 112.2](#)).

	Acute Embolic Occlusion	Low-Flow States	Chronic Arteriosclerotic Occlusive Disease
Vessel pathology	Embolic occlusion of 200 to 300 μm diameter from CA and SMA, from dislodged aortic thrombus like to aortic bifurcation	Cardiac failure	Atherosclerotic arteriosclerosis causing critical stenosis of at least two of the three major splanchnic arteries. Usually involves critical stenosis of CA and SMA.
Gender ratio (M:F)	2:1	1.5:1	1:2
Clonal			
Pathogenesis	Mechanical occlusion between acute narrowing of abdominal aorta and a paucity of early physical findings	3 to 4 days history of vague abdominal pain, distention	Gradual but progressive development of peritoneal pain, bloating 2 to 4 h. Associated "small bowel syndrome" and weight loss
Diagnostic studies	Emergency angiography, operative diagnosis	Arteriography, occluded splanchnic arteries in subacute cases, mesenteric "thumb printing"	Lateral aortography
Treatment	Emergency SMA resection, chronic anticoagulation	Improve cardiac function, vasodilators (nitroglycerin) and fluids	Reperfusion or endarterectomy of CA and SMA
Mortality	Operative mortality 50% without mesenteric infarction, 10% with mesenteric infarction	Low, but 80% with mesenteric infarction	Operative mortality less than 10%

TABLE 112.1. MESENTERIC ISCHEMIC DISEASE

Aneurysm Location	Frequency in Splanchnic Circulation	Males/Females Ratio	Contributing Factors	Frequency of Ruptured Rupture	Site of Rupture	Mortality with Rupture
Splenic artery	3%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	75% distal aneurysms, 25% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Hepatic artery	2%	2:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Superior mesenteric artery	1.5%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Inferior mesenteric artery	0.5%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Renal artery	0.5%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Renal vein	0.5%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Abdominal aorta	1%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	
Thoracic aorta	1%	1:1	MMA degenerative arterial fibrodysplasia, atherosclerosis, portal hypertension, trauma, stress, pancreatitis with portal hypertension, pancreatitis	20% distal aneurysms, 80% infrarenal	Infrarenal with 20% fatal and suprarenal with 50% fatal	

TABLE 112.2. SPLANCHNIC ARTERY ANEURYSMS

MESENTERIC MACROVASCULAR CIRCULATION

Mesenteric blood flow is derived from the celiac, superior mesenteric, and inferior mesenteric arteries. The celiac artery arises from the aorta between the crura of the diaphragm. This vessel courses ventrally for nearly 2 cm, then divides into the common hepatic, left gastric, and splenic arteries. The superior mesenteric artery arises from the aorta behind the pancreas. Superior mesenteric artery blood flow averages 600 mL per minute, accounting for approximately 15% of the cardiac output. Blood flow increases by about 100% in the superior mesenteric artery after a solid meal. Clearly, the range of normal blood flow to the small intestine is great.

The first two branches of the superior mesenteric artery are the inferior pancreaticoduodenal and middle colic arteries. These vessels are the source for important collateral flow between the superior mesenteric artery and the celiac artery, as well as the inferior mesenteric artery. The inferior mesenteric artery arises from the aorta approximately 5 cm above its bifurcation. This vessel branches into the left colic artery and the superior rectal arteries.

MESENTERIC MICROCIRCULATION

The stomach's mucosa constitutes more than half of the gastric wall mass, has the most active metabolism, and receives about 75% of the resting gastric blood flow. The stomach's muscularis layer constitutes over one-third of the gastric wall mass but receives less than 25% of the resting gastric blood flow. Capillaries of the muscularis externa and muscularis mucosa exist in parallel, whereas capillaries of the submucosa and mucosa are arranged in series, so that blood must first pass through the submucosal plexus before entering the juxtaposed mucosal plexus.

The small intestine's three anatomical layers are dominated by the villi and microvilli of the mucosa. The villi's high capillary density facilitates exchange of large quantities of fluid between the blood and transporting surface. The mucosa of the small intestine receives over 50% of this organ's resting blood flow, whereas the muscularis externa, constituting half of the small intestine's mass, receives only 10% to 15% of the total blood flow. Serosal blood vessels must first pierce the muscularis externa before forming an extensive submucosal plexus. From this plexus, one group of arteries pierces the muscularis mucosa at the base of the villi to form a capillary network about the glands lining the mucosal crypts. A second group of arteries enters the base of the villi and provides extensive branches to the tip of the villi. The colon has a similar microcirculation, with more than 75% of its blood flow perfusing the mucosa.

Intramural collateral blood vessels are derived mostly from precapillary microvascular channels. Two-thirds of these collateral vessels originate from extramural marginal vessels; the rest arise from intramural vessels. The primary hemodynamic determinant of collateral flow is passive; modest vasodilatation in an ischemic bowel segment is the only active component. It is unlikely that consistent reflex vasoconstriction or vasodilatation occurs in the vessels of adjacent nonischemic bowel, as was thought for some time.

SPLANCHNIC ISCHEMIA

MICROCIRCULATORY CONSEQUENCES OF INTESTINAL ISCHEMIA

Severe reductions in intestinal blood flow cause cellular hypoxia, accumulation of oxygen free radicals, elevation of portal venous pressure, adverse effects of digestive enzymes on the gut tissues themselves, and intraluminal bacterial proliferation. The entire cellular coverage of the villus may be destroyed before reperfusion takes place. Non-neutrophil-derived reactive oxygen metabolites cause further injury, with reperfusion of ischemic intestinal tissues. An early susceptibility to ischemic injury and invasion of the microcirculation by intestinal bacteria, evident by the presence of portal venous gas ([Fig. 112.1](#)), causes intestinal ischemia to be much more damaging than that affecting other tissues, such as skeletal or cardiac muscle.

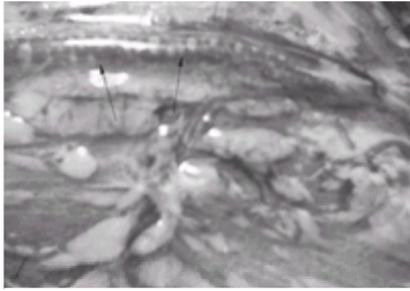

FIGURE 112.1. Portal venous air bubbles (*arrows*) associated with the invasion of a profoundly ischemic bowel wall by gas-forming bacteria. (From Wakefield TW, Stanley JC. The intestine. In: Zelenock GB, ed. *Clinical ischemic syndromes: mechanisms and consequences of tissue injury*. St. Louis: CV Mosby, 1990, with permission.)

The small intestine can sustain modest reductions in blood flow without ischemic injury, as long as there is no more than a 50% decrease in oxygen consumption. Drugs that influence mesenteric blood flow, such as glucagon, have major effects on intestinal motility. Agents that decrease intestinal motility may lessen oxygen needs of the gut and increase its tolerance to subcritical ischemia. Perhaps most important in this effect is the relaxation of the intestine's muscularis mucosa, with subsequent decreases in the resistance to blood flow from submucosal vessels to mucosal and villous vessels.

ACUTE EMBOLIC MESENTERIC VASCULAR OCCLUSION (TABLE 112.1)

The most catastrophic form of treatable intestinal ischemia is macroembolism involving the superior mesenteric artery. Such emboli have a cardiac origin in nearly 95% of patients. Most originate from atrial thrombi associated with arteriosclerotic heart disease and atrial fibrillation or from ventricular thrombi following myocardial infarction. Men are affected twice as often as women. Nearly 5% of all peripheral emboli involve the superior mesenteric artery. Half of these patients have had prior episodes of embolism of extraintestinal vessels, most often involving the femoral or popliteal arteries. Superior mesenteric artery emboli usually lodge beyond the origin of the inferior pancreaticoduodenal and middle colic arteries ([Fig. 112.2](#)). This effectively isolates the distal superior mesenteric arterial circulation and causes critical ischemia of the distal jejunum, entire ileum, and right colon.

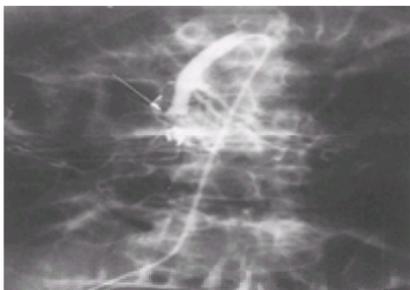

FIGURE 112.2. Superior mesenteric artery embolus (*arrow*) of cardiac origin, causing occlusion of this vessel beyond the inferior pancreaticoduodenal and middle colic arterial branches. (From Wakefield TW, Stanley JC. The intestine. In: Zelenock GB, ed. *Clinical ischemic syndromes: mechanisms and consequences of tissue injury*. St. Louis: CV Mosby, 1990, with permission.)

Patients experiencing acute superior mesenteric artery embolic occlusions usually present with intense unremitting midabdominal pain with nausea and vomiting. This may be accompanied by explosive diarrhea. Early physical examination is usually normal, without evidence of abdominal tenderness, rigidity, or mass lesions. The diagnosis should be suspected in the face of such a disparity in the severity of symptoms and the absence of physical findings.

Leukocytosis, hemoconcentration, and systemic acidosis often accompany embolic occlusion of the superior mesenteric artery. Bowel infarction may be accompanied by elevated levels of serum amylase, inorganic phosphates, creatinine phosphokinase, and alkaline phosphatase, but none of these are reliable biochemical markers of intestinal ischemia.

Early radiographic features of superior mesenteric artery embolism are usually minimal. Tissue invasion by gas-forming organisms, with evidence of mesenteric or portal venous gas on abdominal films, implies a grave prognosis. Computed tomography may document intravascular gas, as well as intestinal wall thickening accompanying gut infarction.

Patients suspected of acute superior mesenteric artery embolism should undergo emergency arteriographic study and operation. Arteriographic studies usually reveal a characteristic meniscus sign at the site of acute embolic occlusion. Revascularization of ischemic intestine is best performed by superior mesenteric artery embolectomy. Intestines appearing marginally viable at initial operation should be allowed to remain, with the intent of undertaking a second-look operation 24 to 36 hours later. Reperfusion of the intestine after embolectomy may cause sloughing of ischemic mucosa and massive gastrointestinal hemorrhage, a serious problem in patients who require anticoagulants to lessen further peripheral embolization.

Vasodilators have been advocated as a logical means of improving flow to noninfarcted, marginally viable intestine associated with acute mesenteric embolic occlusion, but no controlled studies exist to document the efficacy of such therapy. Papaverine requires intra-arterial administration and may be associated with tachyphylaxis if administered over prolonged periods of time. Glucagon is not associated with autoregulatory escape and when administered intravenously has the same effect as superior mesenteric artery catheter infusion. The usefulness of low molecular weight dextran has not been documented in clinical studies.

Aggressive diagnosis and prompt surgical therapy has lessened the mortality of superior mesenteric artery embolism from 95% with intestinal infarction to 60% without infarction.

Microembolization from aortic atherosclerotic material, diseased heart valves, prosthetic valves, or infective endocarditis may also cause acute intestinal ischemia. These minute emboli usually produce segmental intestinal infarctions. Clinical manifestations of microemboli are those of an acute abdomen and frequently lead to operations without suspicion of the underlying disease. Limited bowel resections are appropriate in these settings.

Other causes of acute mesenteric ischemia deserve mention. In particular, acute superior mesenteric artery thrombosis may present in a manner similar to that of embolic occlusion. In most instances of thrombosis, the underlying arteriosclerosis affects the proximal superior mesenteric artery, and the prodromata of intestinal angina may precede the thrombotic event. The entire midgut, including the proximal jejunum, becomes ischemic. Acute mesenteric thrombosis necessitates an urgent endarterectomy or bypass procedure; outcomes are less salutary than with operative interventions for embolism. Unfortunately, thrombolytic therapy and balloon angioplasty has little value in this setting because of attending hemorrhage from the reperfused intestine.

LOW-FLOW NONOCCLUSIVE MESENTERIC ISCHEMIA (TABLE 112.1)

The second most common lethal form of intestinal ischemia follows nonmechanical reductions in mesenteric blood flow. Patients at particular risk are those in cardiac failure. Men are affected 50% more often than women. Digitalis in this setting causes an increase in mesenteric vascular resistance, as will many vasopressors used

for the management of acute cardiac failure. Elderly patients who become hypovolemic from various illnesses, ranging from simple dehydration to sepsis, are also at high risk for nonocclusive mesenteric ischemia.

The most vulnerable portion of the intestine to low-flow ischemia is the colon's splenic flexure because of its watershed blood supply. However, the entire intestine may be affected by low flow. The incidence of nonocclusive intestinal ischemia remains ill defined, mainly because many patients have self-limited unreported sequelae, such as mild ischemic colitis.

Nonocclusive mesenteric ischemia is often manifest by a 3- or 4-day history of vague lower or midabdominal discomfort with distention, accompanied later by nausea and vomiting. The severity often becomes intense with transmural bowel infarction and peritoneal irritation. The latter is usually accompanied by leukocytosis. Biochemical evidence of intestinal infarction is an unreliable diagnostic finding. Plain radiographic studies may reveal bowel wall edema, and barium enema studies often reveal a "thumb-printing" pattern in the colon, indicative of submucosal hemorrhage and edema. Arteriographic studies in low-flow intestinal ischemia usually exhibit delayed arterial emptying and delayed venous filling, with a segmental or diffuse appearance of vasoconstriction. The latter is reversible with intra-arterial administration of papaverine or another vasodilator.

Treatment of low-flow nonocclusive mesenteric ischemia requires restoration of a normal hemodynamic state by appropriate administration of blood, colloids, and electrolyte fluids in conjunction with management of the patient's compromised cardiac status. Cardiac function may deteriorate further with additional intestinal ischemia, an event that may be lessened by the administration of various vasoactive drugs. Theoretically glucagon, which has inotropic and chronotropic actions, has the potential to improve cardiac function at the same time it produces splanchnic vasodilatation and reduces intestinal motor activity. Papaverine, administered directly into the superior mesenteric artery by a percutaneously inserted catheter, may also be used in these patients. The efficacy of these pharmacologic therapies has not been documented in controlled studies. Nevertheless, patients with low-flow nonocclusive intestinal ischemia appear to benefit when treated aggressively by these means. Operation should be undertaken only when transmural infarction is suspected and resection of the bowel appears necessary. The mortality of low-flow nonocclusive intestinal ischemia when intestinal infarction has occurred is 60%.

CHRONIC ARTERIOSCLEROTIC MESENTERIC VASCULAR OCCLUSIVE DISEASE (TABLE 112.1)

The most common form of chronic intestinal ischemia is due to splanchnic arteriosclerosis. The incidence in women is nearly twice that in men. Smoking is a prominent risk factor in these women, but lipid disorders, hypertension, diabetes mellitus, or premature menopause do not appear with frequencies great enough to explain this gender difference.

Arteriosclerotic stenoses typically affect the origins and proximal few centimeters of the three major intestinal arteries. Most of these stenoses represent coexisting spillover aortic arteriosclerosis. Total occlusion or a narrowing of more than 90% in both the celiac and superior mesenteric arteries affects more than 95% of patients with symptomatic splanchnic arteriosclerosis (Fig. 112.3). The inferior mesenteric artery, although involved with hemodynamically significant stenotic disease in nearly 50% of cases, tends to be the least likely of the three major splanchnic arteries to become occluded. Because of the usual efficiency of the collateral circulation, chronic single-vessel intestinal occlusive disease rarely causes gut ischemia.

FIGURE 112.3. Arteriosclerotic stenoses (arrows) of the proximal celiac and superior mesenteric arteries. (From Wakefield TW, Stanley JC. The intestine. In: Zelenock GB, ed. *Clinical ischemic syndromes: mechanisms and consequences of tissue injury*. St. Louis: CV Mosby, 1990, with permission.)

Clinical manifestations of splanchnic arteriosclerotic occlusive disease depend on the adequacy of the mesenteric collateral circulation. When the collateral blood supply is inadequate, intestinal angina occurs, manifest by midabdominal pain within 10 to 15 minutes of eating. This usually persists for 3 to 4 hours until the ingested food has completed its transit through the small intestine. The severity of intestinal angina usually progresses and is often associated with a 10- to 15-kg weight loss by the time it is diagnosed. Eating less food causes less pain, and weight loss occurs because of the reduced food intake, often referred to as "small-meal syndrome."

Transabdominal ultrasonography of the proximal intestinal arteries offers a noninvasive means of screening patients suspected of having chronic arteriosclerotic splanchnic artery occlusive disease. However, lateral aortography is necessary to confirm the presence of ostial obstructions of the major mesenteric arteries. There are no pathognomonic tests for chronic mesenteric ischemia.

Treatment of chronic intestinal ischemia due to arteriosclerotic disease necessitates revascularization of the intestines. Endarterectomy of the celiac and superior mesenteric arteries or bypass procedures involving these vessels are the most successful means of restoring normal blood flow to the intestines. The mortality of such surgery is less than 10%, and amelioration of symptoms occurs in over 90% of survivors. Experience with percutaneous balloon angioplasty has been limited; the procedure carries the risk of acute embolic infarction of the intestines.

SPLANCHNIC ARTERY ANEURYSMS (TABLE 112.2)

Splanchnic artery aneurysms are an unusual but important group of diseases. Nearly 22% of these aneurysms present as emergencies, including 8.5% that are fatal. The most commonly involved vessels, in decreasing order of frequency, include the splenic, hepatic, superior mesenteric, celiac, gastric-gastroepiploic, jejunal-ileal-colonic, pancreaticoduodenal-pancreatic, and gastroduodenal arteries (Fig. 112.4).

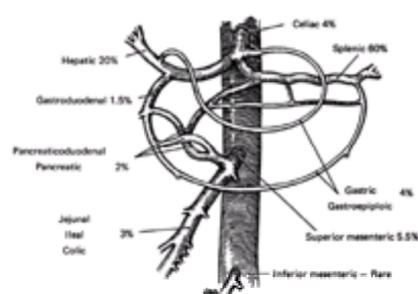

FIGURE 112.4. Distribution of splanchnic artery aneurysms. (From Stanley JC, Zelenock GB. Splanchnic artery aneurysms. In: Rutherford RB, ed. *Vascular surgery*, fourth ed. Philadelphia: WB Saunders, 1995, with permission.)

SPLENIC ARTERY ANEURYSMS

Aneurysms of the splenic artery account for more than 60% of splanchnic artery aneurysms. Their incidental recognition in 0.78% of abdominal arteriographic studies probably reflects their prevalence in the general population. Splenic artery aneurysms are usually saccular, occur at bifurcations, and are multiple in 20% of patients (Fig. 112.5).

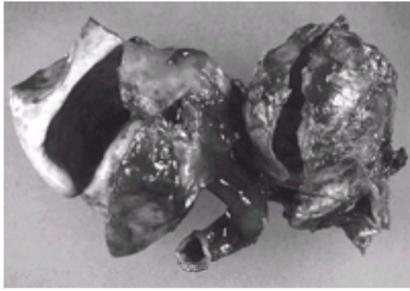

FIGURE 112.5. Splenic artery aneurysms are usually saccular and occur at branchings. (From Stanley JC, Zelenock GB. Splanchnic artery aneurysms. In: Rutherford RB, ed. *Vascular surgery*, fourth ed. Philadelphia: WB Saunders, 1995, with permission.)

Women are affected four times more often than men. Three distinct conditions are associated with these aneurysms: (a) arterial fibrodysplasia, (b) portal hypertension with splenomegaly, and (c) multiple pregnancies with 40% of the women exhibiting these lesions having completed six or more pregnancies. These aneurysms often exhibit arteriosclerotic changes; but arteriosclerosis is considered a secondary event, not a primary cause of these aneurysms. Trauma and inflammatory disease, such as chronic pancreatitis with pseudocyst erosion of the splenic artery, are less common but important causes of some aneurysms. Microaneurysms of the splenic artery, usually associated with connective tissue disorders, are of less clinical importance.

Most splenic artery aneurysms are asymptomatic. These aneurysms may be suspected with signet ring calcifications in the left upper quadrant on plain abdominal radiographs. However, diagnosis is usually the result of arteriography performed for some other disease. Ultrasonography, computed tomography, or magnetic resonance imaging may prove useful in the initial recognition of splenic artery aneurysms, but arteriography is usually necessary to confirm their presence.

Life-threatening rupture affects less than 2% of bland splenic artery aneurysms in nonpregnant women. Symptoms of a “double rupture” occur in 25% of such cases, with bleeding into the retrogastric area occurring first and frank intraperitoneal hemorrhage and shock developing later when the lesser space tamponade is lost. The contention that rupture is less likely to occur in calcified aneurysms, normotensive patients, or patients older than 60 years is not supported by clinical experience. Rupture has affected nearly 95% of aneurysms recognized during pregnancy; maternal mortality is 70% and fetal mortality 75% in this setting.

Operative intervention is easily justified for aneurysms in pregnant patients or women of childbearing age who might become pregnant, and for symptomatic aneurysms. Aneurysm size greater than 2.5 cm is a relative indication for surgical therapy.

Treatment consists of aneurysmectomy or ligation and exclusion of the aneurysm. Splenectomy may be necessary if the aneurysm is within the splenic parenchyma. The mortality rate for ruptured aneurysms in nonpregnant patients is 25%. Thus, on the basis of a 2% incidence of rupture with an accompanying 25% mortality rate, operative mortality must be less than 0.5% to justify elective surgical therapy. Catheter-directed occlusion of these aneurysms with thrombotic material is an available alternative therapy for high-risk patients.

HEPATIC ARTERY ANEURYSMS

Hepatic artery aneurysms account for 20% of all splanchnic artery aneurysms. Men are affected twice as often as women. These aneurysms are usually recognized during the sixth decade of life. Causes include atherosclerosis (32%), acquired medial degeneration (24%), trauma (22%), and infection associated with illicit drug use (10%). Traumatic pseudoaneurysms are increasingly recognized in contemporary times with the greater use of computed tomography to evaluate the injured patient. Periarteritis nodosa, cystic medial necrosis, and other arteriopathies are uncommon causes of these aneurysms. Most aneurysms of the hepatic artery are solitary, being fusiform when less than 2 cm in diameter and saccular when more than 2 cm in diameter. Hepatic artery aneurysms are extrahepatic in 80% of cases and intrahepatic 20% of the time.

Most hepatic artery aneurysms are asymptomatic. Symptoms, if present, characteristically include right upper quadrant and epigastric pain, which when severe is similar to that of pancreatitis. Large aneurysms uncommonly obstruct the biliary tract. Hepatic artery aneurysms are discovered most often during arteriographic evaluations of other gastrointestinal or abdominal diseases.

Rupture of a hepatic artery aneurysm causes bleeding into the peritoneal cavity and biliary tract with equal frequency. The latter results in hematuria with acute gastrointestinal bleeding and fever from cholangitis. Melena and chronic anemia are uncommon with this complication. Hepatic artery aneurysms rupture in less than 20% of cases. The mortality with rupture approaches 35%.

Aneurysms of the common hepatic artery are treated by aneurysmectomy or exclusion, often without arterial reconstruction. If the aneurysm is in the proper hepatic artery, blood flow to the liver should be restored after aneurysmectomy, preferably with an autologous vein graft. Simple ligation or percutaneous transcatheter obliteration of a hepatic artery aneurysm may also be appropriate in selected patients. Partial hepatectomy is rarely required but may be necessary to successfully treat hematuria due to intraparenchymal aneurysms.

SUPERIOR MESENTERIC ARTERY ANEURYSMS

Aneurysms of the superior mesenteric artery account for 5.5% of all splanchnic artery aneurysms. Men and women are affected equally. Infection accounts for nearly 50% of cases, occurring most often as a result of nonhemolytic streptococcal infection originating from left-sided bacterial endocarditis. Infection associated with illicit intravenous drug abuse is a second cause, increasing in frequency. Medial degeneration, atherosclerosis, and trauma are less common causes. Aneurysms in young patients are usually mycotic, whereas those in patients older than 50 years are most often noninfectious in origin.

Superior mesenteric artery aneurysms are usually recognized when vascular calcifications are identified on radiographs of the abdomen or arteriograms performed for unrelated diseases. Epigastric pain is not uncommon. Symptoms of intestinal angina may accompany nonmycotic lesions, in which aneurysmal dissection or thrombus has compromised intestinal blood flow. The reported frequency of rupture is low, but thromboembolic complications of these aneurysms is relatively high, and most lesions should be treated operatively. Mortality is 50% with rupture. Aneurysmectomy with formal arterial reconstruction is preferred in most cases. However, simple ligation of vessels entering and exiting the aneurysm has been successful in about 30% of reported cases. The operative mortality rate in treating superior mesenteric artery aneurysms is less than 15%.

CELIAC ARTERY ANEURYSMS

Celiac artery aneurysms represent 4% of splanchnic artery aneurysms. Most exhibit medial degeneration. There is no gender predilection. Celiac artery aneurysms are usually asymptomatic or cause vague abdominal discomfort. The rupture rate approaches 13%, with a mortality of 50%. Treatment usually consists of aneurysmectomy and arterial reconstruction. Celiac artery ligation may be done in selected cases if circulation to the liver is adequately maintained through collateral

vessels. More than 90% of operations for celiac artery aneurysms are successful.

GASTRIC AND GASTROEPIPLOIC ARTERY ANEURYSMS

Aneurysms of the gastric and gastroepiploic arteries account for 4% of all splanchnic artery aneurysms. Gastric artery aneurysms are ten times more common than gastroepiploic artery aneurysms. Men are three times more likely to be affected than women. These aneurysms are usually acquired, most as a result of medial degeneration or as a consequence of periarterial inflammation. They often present as vascular emergencies without prior symptoms. Rupture occurred in more than 90% of reported cases, with 70% causing serious gastrointestinal bleeding and the rest caused life-threatening intraperitoneal hemorrhage. Nearly 70% of patients with rupture die from this complication.

Ligation of aneurysmal vessels with or without aneurysm excision is appropriate for extragastric lesions. Intramural lesions should be excised with the involved portion of the stomach.

JEJUNAL, ILEAL, AND COLONIC ARTERY ANEURYSMS

Aneurysms affecting the intestinal branches of the superior and inferior mesenteric arteries account for 3% of all splanchnic artery aneurysms. Men and women are affected equally. These aneurysms are recognized most often in the seventh decade of life. Ninety percent of these aneurysms are solitary, except for microvascular aneurysms associated with connective tissue disorders. Congenital or acquired medial defects cause most of these lesions. Certain aneurysms represent the sequelae of an endarteritis from septic cardiac emboli.

Most mesenteric artery branch aneurysms are incidental findings during exploratory surgery for intestinal or intraperitoneal bleeding. Seventy percent of these aneurysms cause abdominal pain or bleeding, and some may represent as a tender abdominal mass. Arteriography is necessary to establish a preoperative diagnosis.

The risk of rupture is 30% and the reported mortality with rupture is 20%. Treatment of these small aneurysms usually consists of ligation or aneurysmectomy for extraintestinal aneurysms, and bowel resection for intramural aneurysms.

PANCREATODUODENAL, PANCREATIC, AND GASTRODUODENAL ARTERY ANEURYSMS

Pancreatic and pancreaticoduodenal artery aneurysms account for 2% of all splanchnic artery aneurysms. Gastroduodenal artery aneurysms represent an additional 1.5% of these lesions. These aneurysms are among the most hazardous of all splanchnic artery aneurysms. Men are affected four times more often than women. The most common cause is periarterial inflammation, which usually occurs as a consequence of pancreatitis with vascular necrosis or vessel erosion by an adjacent pseudocyst (Fig. 112.6). Most patients with these aneurysms have epigastric pain and discomfort. This may reflect the fact that about 60% of gastroduodenal and 30% of pancreaticoduodenal artery aneurysms are complications of pancreatitis. Asymptomatic aneurysms of these vessels are unusual.

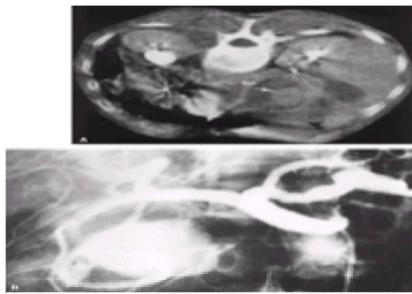

FIGURE 112.6. Gastroduodenal artery aneurysm in a patient with alcoholic-related pancreatitis and pseudocyst erosion of the artery. **A:** CT scan. **B:** Arteriography. (From Eckhauser FE, Stanley JC, Zelenock GB, et al. Gastroduodenal and pancreaticoduodenal artery aneurysms: a complication of pancreatitis causing spontaneous gastro-intestinal hemorrhage. *Surgery* 1980;88:335–344, with permission.)

Aneurysmal rupture of gastroduodenal and pancreaticoduodenal aneurysms occurs in 75% of inflammatory lesions and 50% of noninflammatory lesions. Bleeding into the biliary or pancreatic ductal system may also occur. Endoscopy, ultrasonography, computed tomography, and magnetic resonance imaging often contribute to the diagnosis, but arteriography is essential to confirm the presence of these lesions. Mortality with rupture approaches 50%.

Operative intervention with aneurysmectomy is justified in all reasonable-risk patients. Aneurysms embedded within the pancreas are best treated by suture–ligation of entering and exiting vessels from within the aneurysm. Eventual extirpation of the diseased pancreas may be necessary. Transcatheter embolization may temporarily control acute bleeding from some of these aneurysms but is associated with a high rate of rebleeding and abscess formation.

CHAPTER 113: GASTROINTESTINAL INFECTIONS

C. M. THORPE AND ANDREW G. PLAUT

[Workup and Laboratory Evaluation of Patients With Acute Diarrhea](#)
[Pathogenesis of Acute Enteric Infections](#)
[Common Acute Bowel Infections](#)
[Miscellaneous Intestinal Infections](#)

From ancient times to today, infections of the gastrointestinal (GI) tract occur throughout the world. GI infections are more common and have a higher impact in developing countries, among children, and in persons with protein-calorie malnutrition or immunodeficiency. These illnesses are clinically challenging because they are caused by a variety of microbes that have many mechanisms for causing disease, and the severity of infection can range from trivial discomfort to severe or even fatal illness. The care of patients with GI infections calls for careful attention to supportive measures, such as fluid and electrolyte replacement, as well as an informed decision regarding the risks and benefits of specific antimicrobial therapies.

Our understanding of how to prevent and treat GI infections is well advanced, but the causative organisms are highly persistent, and outbreaks and sporadic incidents remain among the most common events seen in medical practice. Although GI infections are usually associated with diarrhea, recent clinical observations and research have identified newer agents that are important in causing nondiarrheal illness. One example is *Helicobacter pylori*, a gram-negative spiral rod that can colonize the gastric mucosa and is associated with peptic ulcer disease and possibly gastric malignancy. Furthermore, the clinical spectrum of some diarrhea-causing agents has been redefined in the era of immunosuppression due to HIV infection or due to drugs used in organ transplantation.

This chapter provides a guide for evaluating patients with GI infection, reviews some of the pathogenic mechanisms of these organisms, and highlights some specific infectious agents that cause predominantly diarrheal disease. The distinction between *colonization* and *infection* is important, as a normal, abundant, and varied GI microflora is found in everyone. Many of these microorganisms harmlessly colonize mucosal sites, but only a few species, under circumstances not always clear, cause clinically apparent illnesses that we refer to as infections.

WORKUP AND LABORATORY EVALUATION OF PATIENTS WITH ACUTE DIARRHEA

In patients with infectious diarrhea the primary objectives are to relieve symptoms and limit fluid loss from diarrhea and vomiting (see also [Chapter 99](#)). Many patients treated with supportive measures alone will recover spontaneously. The identification and drug eradication of the causative agent may be secondary objectives. In general, extensive efforts to identify the cause of illness are justified only when the infection is severe or protracted, if it affects many individuals in an obvious outbreak, or if specific antimicrobial therapy is being planned for a given patient. An aggressive diagnostic approach may, however, be justified if the host is very young, debilitated, or immunocompromised.

Evaluation begins with a careful history to clearly establish the context of the illness. Where has the patient been working and traveling? Are others ill? Were foods possibly contaminated? Is the patient malnourished, aged, very young, immunocompromised, or less likely to spontaneously clear an infection than would a normal person? Have there been social practices such as receptive anal intercourse that may encourage acquisition of unusual infections? Is the infected person already on antimicrobial therapy for other reasons (suggesting antibiotic-associated diarrhea)?

Once the setting of the infection is established, the clinician should determine which intestinal organ is most involved. GI infections dominated by vomiting suggest the presence of preformed toxins, although any invasive bacterium or virus can trigger central vomiting centers. Pain has much localizing value: if periumbilical, infection or distention of the small intestine with fluid or gas is likely, while infraumbilical pain on either side suggests colonic involvement. Painful evacuation (tenesmus) occurs with anorectal inflammation that causes high-frequency but low-volume bowel movements containing mainly mucus, sometimes blood, but little stool. High-volume diarrhea suggests that the infection is interrupting the normal balance of gut secretion and absorption, which is typical for infections caused by the protozoan *Giardia lamblia*, certain toxin-producing bacteria such as *Vibrio cholerae*, and certain strains of *Escherichia coli*. Despite their severity, secretory diarrheas are not typically associated with stool blood or mucus because enterotoxins usually do not induce inflammation or tissue destruction. In contrast, stools containing blood and mucus are more likely with enteroinvasive agents such as *Shigella* species or *Entamoeba histolytica*, and these are also more likely to cause fever and generalized symptoms. Common microbial causes of acute diarrhea and common clinical presentations are summarized in [Table 113.1](#).

Secretory: High-volume watery diarrhea, noninflammatory, dehydrating, few fecal leukocytes
Vibrio cholerae
Toxicogenic *E. coli* (ETEC strains)
Giardia lamblia
Viruses

Inflammatory: Low-volume diarrhea, mucus and blood, many fecal leukocytes
Shigella species
Certain *E. coli* (EIEC and STEC strains)
Entamoeba histolytica (not many leukocytes)
Clostridium difficile
Campylobacter jejuni
Salmonella species

Mixed or variable type:
Yersinia enterocolitica
Cryptosporidium

Focal gastroenteritis:
Clostridium parvifringens
Bacillus cereus
Staphylococcus aureus

Traveler's diarrhea:
Toxicogenic *E. coli* (ETEC strains)
Invasive *E. coli* (EIEC strains)
Shigella species
Salmonella species
Giardia lamblia
Viruses

TABLE 113.1. MICROBIAL CAUSES OF ACUTE DIARRHEA

Efforts to identify the specific cause of a gut infection are most productive in the inflammatory-type diarrheas. Laboratory evaluation should begin with an examination for gross or occult fecal blood and fecal neutrophils, which suggest invasive infection. Stool cultures should be obtained for outpatients and for those inpatients admitted to the hospital with a community-acquired diarrhea, and specimens should be tested for *Salmonella* species, *Shigella* species, *Campylobacter* species, and Shiga toxin-producing *E. coli* (STEC). However, culture yields for these pathogens are too low to warrant such culture studies on patients who develop diarrhea after 3 days in the hospital. GI infections beginning in hospital are much more likely to be due to nosocomial causes, e.g., *Clostridium difficile*. In the United States, routine culture for *Yersinia* species, *Aeromonas* species, and other less common bacterial pathogens is not recommended except in selected cases. Culture for *Neisseria gonorrhoeae* or specific testing for *Chlamydia trachomatis* are appropriate in those patients with diarrhea who engage in receptive anal intercourse. If there is a history of anal intercourse, and rectal pain or mucoid discharge is a clinical feature, culture for herpes simplex virus may also be helpful. Prior antibiotic use should prompt a search for *C. difficile* toxin in the stool. Parasites can also cause diarrhea, of which the three most common are *G. lamblia*, *E. histolytica*, and *Cryptosporidium parvum*. Stool examination for ova and parasites should be done when diarrhea occurs in the following epidemiologic and clinical situations: (a) patients who engage in anal intercourse, (b) patients who have recently traveled to parasite-endemic areas; and (c) patients with rectal pain or itching, severe tenesmus, persistent diarrhea, or chronic diarrhea with weight loss.

Sigmoidoscopy can be valuable in patients with bloody stools; features of acute proctitis such as rectal pain, tenesmus, and bloody discharge; a history of anal surgery or insertive anal intercourse; or recent antibiotic use (to exclude pseudomembranous colitis). The examination should be conducted without preliminary bowel cleansing or laxatives, and with limited insufflation of air to reduce the risk of perforation. Cultures and smears from specific lesions can be of great value in identifying the cause of the infection and guiding therapy. Practical considerations in the evaluation of acute diarrhea are summarized in [Table 113.2](#).

Stool volume is more important than frequency; replace solutes and water.
 Use antidiarrheal drugs sparingly in management of inflammatory diarrhea.
 Amebiasis, *Campylobacter*, and *Escherichia coli* diarrhea may mimic ulcerative colitis.
 Ask patients of both sexes about specific sexual practices.
 Location of abdominal pain often identifies the major organ involved.
 Sigmoidoscopy can injure or perforate the inflamed colon.
 Barium x-ray examinations of the inflamed colon may worsen the illness.
 Some protozoan parasites (amebae, giardia) do not cause peripheral eosinophilia.
 Counsel travelers about diarrhea before departure.
 Bacterial overgrowth syndromes are easily overlooked.
 Older people get colon cancer. Gross or occult fecal blood persisting after gut infections requires careful follow-up.

TABLE 113.2. PRACTICAL CONSIDERATIONS IN THE CARE OF PATIENTS WITH ACUTE DIARRHEA

PATHOGENESIS OF ACUTE ENTERIC INFECTIONS

Entry of microorganisms into the gut has one of three outcomes: immediate expulsion, colonization, or clinically apparent infection. Expulsion is most likely and occurs when microbes cannot withstand natural barriers. Gastric acidity, bile acids, intestinal motility, competition from established microbes, and the secretory immune system of the small and large bowel all promote rapid removal of gut microbes. Colonization occurs when organisms multiply after first binding to specific host cells; by definition, colonizing organisms do not provoke a significant inflammatory response. These bacteria constitute the normal gut flora but can cause infection if they become enteroinvasive or if they are translocated to other tissues, such as the peritoneal cavity, biliary tree, and urinary tract.

Despite their clinical importance, true enteric infections are the least likely outcome of bacterial or parasite entry into the gut. The risk of infection can be enhanced in patients whose gut defensive systems are compromised or those on drugs that modify the normal gut microflora. When infection occurs, microbes or microbial products can produce direct tissue injury or stimulate host inflammatory and/or metabolic events, resulting in clinical illness. The depth of tissue penetration of enteric pathogens is summarized in [Table 113.3](#). It should be noted, however, that some pathogens do not fit neatly into a single category. For example, STEC can cause tissue damage without invading. During the infectious process, the microorganism can undergo changes that allow enhancement of virulence, illustrating how well infectious agents have adapted to their hosts. These findings also indicate that the study of infectious bacteria in a laboratory setting may not identify critical virulence attributes that are induced during infections in a natural host, although such information is essential for understanding pathogenesis and for vaccine development.

No entry strictly necessary (preformed toxin)
Staphylococcus aureus
Bacillus cereus
 Enterocyte binding, trivial cell injury
Vibrio cholerae
 Toxigenic *E. coli*
 Mild injury to intestinal epithelium
Giardia lamblia
Cryptosporidium
 Invasion of intestinal epithelium with cell injury or death
Shigella species
 Most *Salmonella* species
Campylobacter jejuni
Yersinia enterocolitica
 Enteroinvasive *E. coli*
Clostridium difficile
Entamoeba histolytica
 Probably most viral agents
 Passage through superficial epithelial cells to deeper tissues
 Rotavirus (via M cells to lymphoid follicles)
Salmonella typhi (to regional lymphoid tissue and blood)
Mycobacterium avium complex (to lamina propria macrophages)

TABLE 113.3. DEPTH OF TISSUE PENETRATION OF ENTERIC PATHOGENS

Enteric pathogens have developed many strategies to disrupt normal functioning of the GI tract. Some pathogens are capable of binding to and damaging enterocytes without invasion. Some produce toxins that affect host cells. Some pathogens are capable of invading through intestinal epithelium to deeper tissues of the intestine or regional lymph nodes. Examples of pathogens that are known to enter and multiply within intestinal epithelial cells include *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter*. In contrast, *Vibrio cholerae* is an infectious agent that binds noninvasively to the enterocyte and produces potent enterotoxins without causing significant tissue destruction but markedly altering intestinal function.

Bacterial toxins are a heterogeneous group of proteins that can be encoded by bacterial chromosomal DNA, plasmids, or chromosomally integrated bacteriophage. Toxin production is carefully regulated by the pathogen. Some known regulators of bacterial toxin synthesis include environmental pH, osmolality, and temperature, but often more subtle and less understood environmental features also may change toxin synthesis. Toxin synthesis is often coordinated with other virulence determinants in the same organism. For example, in *V. cholerae*, synthesis of cholera toxin is coregulated with formation of an essential intestinal colonization factor, the toxin-coregulated pilus. Simultaneous expression of multiple virulence determinants in bacteria is thought to reflect a coordinated response to host factors.

Enterotoxins cause intestinal secretion and diarrhea by stimulating adenylate cyclase–cyclic adenosine monophosphate (cAMP), the guanylate cyclase–cyclic guanosine monophosphate (GMP) system, or other less well-defined signaling pathways. For example, *V. cholerae* enterotoxin is a protein that initiates several intracellular biochemical steps leading to an increase in cyclic AMP, which in turn inhibits the coupled influx of Na⁺ and Cl⁻ across the brush border of the enterocyte in the small intestine. Cholera toxin also stimulates Cl⁻ secretion by gut crypt cells. This combined oversecretion and underabsorption by the small intestine results in volume accumulation in the gut, with high-volume diarrhea that characterizes this disease. In its most severe form known, as cholera gravis, patients can pass liters of “rice water” stool in a day, resulting in severe dehydration. Thus clinical cholera, a profound and sometimes fatal illness, is the result of a toxin that does not directly kill intestinal cells.

Some bacterial products are cytotoxins that damage the intestinal mucosa by inducing disturbances in cell protein synthesis or by igniting acute inflammation that leads to necrosis and ulceration. For instance, when injected into rodent intestine, *C. difficile* enters cells and toxin A disrupts the actin cytoskeleton, leading to fluid secretion, mucosal damage, and intestinal inflammation. Although some toxins are shown to cause damage in vitro, proof that they mediate disease in vivo has been verified for only certain well-studied pathogens. Therefore, many details of how cytotoxins injure gut tissue remain uncertain.

Finally, some GI pathogens do not invade host cells or produce pathogenic toxins, but they clearly cause diarrhea. Examples of such infectious agents are *G. lamblia* and enteropathogenic *E. coli*.

COMMON ACUTE BOWEL INFECTIONS

In the industrialized world, one-third of carefully evaluated cases of acute diarrhea can be ascribed to known bacterial agents, and the number of such identifiable agents is increasing. In developing countries and warm climates, bacterial agents are responsible for more than half of diarrhea cases. In all countries combined, enteroinvasive agents such as *Shigella*, *Salmonella*, and *Campylobacter jejuni* are responsible for diarrhea in about 15% of patients, but other microbial agents can dominate in particular seasons of the year, or in outbreaks and other special circumstances. These agents include *Yersinia enterocolitica*, *Aeromonas* species, *Plesiomonas shigelloides*, STEC, *V. cholerae*, and noncholera vibrios.

The three protozoan parasites most commonly associated with diarrheal disease are *G. lamblia*, *E. histolytica*, and *Cryptosporidium parvum*. Other parasitic agents are also important in certain settings and include *Blastocystis hominis*, *Dientamoeba fragilis*, and *Strongyloides stercoralis*. A newly recognized coccidian organism, *Cyclospora cayatanensis*, may also be associated with diarrhea in both immunocompetent and immunocompromised patients.

Viral pathogens are important causes of diarrhea in the United States in all ages. Rotavirus, a double-stranded RNA virus, is one of the most important causes of sporadic and epidemic gastroenteritis in children under 2 years old. Calciviruses, a group of single-stranded RNA viruses usually named for the location where first

isolated, are an important cause of epidemic outbreaks among older children and adults. Norwalk virus is the best known example of the calicivirus family and is thought to be responsible for 40% of viral gastroenteritis outbreaks in the United States. Less commonly, enteric adenoviruses and astroviruses have been associated with gastroenteritis. At least a third of viral gastroenteritis cases in the United States are thought to be caused by as-yet-undescribed agents.

SALMONELLOSIS

Salmonella species are major causes of enteric infection worldwide. In the United States, they account for 5% to 10% of acute infectious diarrheas, and more than 40,000 cases of nontyphoidal salmonellosis are reported annually. Only 1% to 5% of cases are actually reported, indicating that the number of *Salmonella* infections is likely to be 800,000 to 4 million per year. About 500 persons die annually from conditions related to acute salmonellosis in the United States. *Salmonella* taxonomy has changed in the past several decades, primarily due to new information about molecular genetic relationships. There are two species of *Salmonella*: *S. enterica* (whose multiple subspecies and serovars are distinguished by somatic and flagellar antigen serology) and *S. bongori*. Most human pathogens are included in the subspecies of *S. enterica* subsp. *enterica* and more than 2,000 named serotypes of *Salmonella* can cause human disease. The nomenclature of the species *S. enterica* is confusing because the serotypes that constitute this species are referred to by serotype designation. For example, *S. enterica* subsp. *enterica* serovar *heidelberg* is referred to as simply *S. heidelberg*. *S. enterica* subsp. *enterica* serovar *typhi*, or *S. typhi*, is the cause of typhoid fever, a systemic illness of great importance worldwide but uncommon in the United States. *S. typhi* affects about 500 individuals annually in the United States, and even in these cases the majority are imported by travelers from areas where this organism is endemic. Nontyphoidal *S. enterica* serovars are of greater importance in the United States; approximately half of all isolates identified are either *Salmonella typhimurium* or *Salmonella enteritidis*.

Salmonella enterica strains have a reservoir in domestic and farm animals including poultry, cattle, and pigs, and thus find their way into human foods. Poultry and eggs are particularly troublesome, and in the United States, an estimated 0.01% of eggs with intact shells contain salmonellae, and many chickens sold are contaminated. Outbreaks of *Salmonella* infection from contaminated food continue to occur as in a recent U.S. outbreak of *S. enteritidis* traced to a commercial ice cream manufacturer. About 1 in 1,000 Americans and 15 in 1,000 persons in developing countries are asymptomatic carriers of *Salmonella* species.

Nontyphoidal *Salmonella* gastroenteritis begins with chills, headache, nausea, and vomiting 6 to 48 hours after exposure, soon followed by abdominal pain and diarrhea. Occasionally, respiratory symptoms such as cough will prompt patients to describe their illness as an "intestinal flu." This tissue-invasive pathogen causes fever in about half of patients. Although salmonellosis involves the ileum and colon only in its early phases, a severe, prolonged colitis may develop that can only be distinguished from shigellosis, *campylobacter* infection, and other nonbacterial colitides by stool culture. The ability of *S. typhimurium* and *Salmonella choleraesuis* to bind to and invade mammalian cells *in vitro* requires the synthesis of several bacterial proteins, and genetically engineered mutants having deletions of any one of these proteins cannot invade. These proteins appear to be induced by carbohydrate or protein components on host epithelial cells, suggesting that *Salmonella* species are able to sense and respond to the *in vivo* environment. Once they enter the blood, salmonellae can reach and invade any tissue, and thus may cause a variety of infections including endocarditis, cholecystitis, splenic abscess, meningitis, and septic arthritis.

Conditions predisposing to salmonellosis include the postgastrectomy state, hypochlorhydria, altered intestinal motility, prior antibiotic administration, sickle cell anemia, chronic liver disease, and immunodeficiency that accompanies neoplastic diseases and AIDS. Thus, already in 1987, recurrent *Salmonella* bacteremia was included in the U.S. Centers for Disease Control and Prevention (CDC) case definition of AIDS. Diagnosis of nontyphoidal salmonellosis is made by finding this easily cultured pathogen in stool or blood. Uncomplicated disease in adults usually resolves spontaneously and warrants only symptomatic and supportive therapy ([Table 113.4](#)).

<i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i>
Ciprofloxacin 500 mg PO q 12h × 3 d or norfloxacin 400 mg PO q12h × 3 d
Traveler's diarrhea, unknown organism
Ciprofloxacin 500 mg PO q12h × 3 d or norfloxacin 400 mg PO q12h × 3 d
<i>Entamoeba histolytica</i> (asymptomatic cyst passer)
Paromomycin 500 mg PO t.i.d. × 7 d or iodoquinol 650 mg PO t.i.d. × 20 d or diloxanide furate 500 mg PO t.i.d. × 10 d or metronidazole 750 mg PO t.i.d. × 10 d
<i>Entamoeba histolytica</i> (acute, dysenteric)
Metronidazole 750 mg PO t.i.d. × 10 d or tinidazole 1 g PO q12h × 3 d or ornidazole 500 mg PO q12h × 5 d, each followed by either iodoquinol 650 mg PO t.i.d. × 20 d or paromomycin 500 mg PO t.i.d. × 7 d
<i>Giardia</i>
Metronidazole 250 mg PO t.i.d. × 5 d or tinidazole 2 g PO × 1 dose
<i>Clostridium difficile</i>
Metronidazole 250 mg PO q.i.d. (or 500 mg PO t.i.d.) × 7–10 d or vancomycin 125 mg PO q.i.d. × 7–10 d

* Specific antibiotic regimens are revised frequently.

TABLE 113.4. ANTIMICROBIAL TREATMENT FOR ENTERIC INFECTIONS^a

In immunocompetent patients, antimicrobial treatment of *Salmonella* gastroenteritis does not substantially improve the symptoms or outcome, and it may prolong the excretion of the organisms. This can contribute to the maintenance and extent of the environmental reservoir of antibiotic-resistant salmonellae. In contrast, antimicrobial therapy in the immunocompromised or debilitated host can be of critical importance. AIDS patients often have high relapse rates after treatment of *Salmonella* bacteremia. Consequently, aggressive therapy (several weeks of parenteral antibiotics followed by oral therapy totalling 6 to 8 weeks) is recommended. Prophylaxis with antimicrobial therapy should be considered following treatment because even after aggressive therapy, relapses can occur in patients with AIDS. *Salmonella* strains that are resistant to quinolones have recently been identified, possibly due to the use of antimicrobial therapy and feed supplementation in food animals. Because of multidrug resistance of nontyphoidal salmonellae, seriously ill patients or those with complex infections such as endocarditis may require treatment with a third-generation cephalosporin even before antimicrobial susceptibilities are determined. Fecal excretion of salmonellae may occur for 6 to 8 weeks after the patient recovers, but some patients become chronic carriers. Control of human salmonellosis will eventually require reduction of salmonellae in foods from animal sources.

S. typhi causes typhoid fever and is not strictly an intestinal diarrheal disease. Humans are the only natural hosts and acquire the illness by fecal–oral contamination, often from a chronic carrier. Since there is no known animal reservoir, typhoid fever occurs under conditions of poor sanitation, and the marked decline in cases in the United States can be attributed to public health measures, not specific eradication of the agent by antimicrobials. Typhoid fever consists of fever, chills, sweats, headache, and abdominal pain beginning about 5 to 14 days after exposure, and it may last for weeks if untreated. Constipation, not diarrhea, typifies the early stage of the disease. A characteristic rash ("rose spots") may be found, predominantly on the trunk. In the second week there is a threat of GI hemorrhage and perforation due to infection of lymphoid follicles throughout the lower bowel. Diarrhea at this stage is common. Although the gut is the site of entry, the illness quickly involves other organs. The case fatality rate is about 2% in the United States and much higher (12% to 30%) in developing countries, where typhoid fever is made more severe by compromised host defenses and poor nutrition. Diagnosis is by culture of *S. typhi* or *S. paratyphi* from blood, bone marrow, or stool.

Chloramphenicol resistance and a high relapse rate have prompted the use of amoxicillin and trimethoprim–sulfamethoxazole as alternative oral therapies, although multidrug resistance of *S. typhi* has emerged as a problem in many endemic areas, such as the Indian subcontinent, Southeast Asia, and Africa. For critically ill patients or patients from areas where multidrug resistance is a problem, initiating therapy with agents active against potentially multidrug-resistant *S. typhi* should be considered while sensitivity testing is undertaken. The best choices are ciprofloxacin or ceftriaxone. Chronic colonization of the biliary system by salmonellae is a source of infection for others and occurs in about 1% of patients recovering from typhoid fever.

Safe and immunogenic vaccines to prevent typhoid fever are available, but efficacy is not 100%. Immunity requires both cell-mediated and humoral responses. Several commercial vaccines are currently available for travelers to endemic areas, including a live attenuated oral vaccine and a parenteral polysaccharide vaccine. These vaccines are ineffective against infections by nontyphoid salmonellae.

SHIGELLOSIS

Shigella species account for 2% to 3% of acute diarrheal diseases in the United States and are most prevalent in children and the poor. There is no animal reservoir; humans are the only known host. Illness is usually acquired by direct fecal–oral contact or fecal contamination of food, accounting for the disease's association with poor sanitation and crowding, and the recognition that shigellosis could be easily transmitted by anal–oral sex. One factor that favors transmission and explains the

occasional food- or water-borne outbreaks is the low number of organisms needed for infection.

The genus *Shigella* consists of four species: *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*. The first three have various serotypes. *S. sonnei* causes the mildest illness and is the commonest species infecting otherwise healthy people in the United States, but an increase in *S. flexneri* infections among adult U.S. males has been linked to anal–oral transmission in homosexuals. *S. flexneri* is predominant in Mexico, South America, and most other tropical countries. In the past 30 years, major pandemics of *S. dysenteriae* have occurred on multiple subcontinents, including Central America, Southeast Asia, and Central and East Africa. Shigellosis is a common cause of dysentery, the general term describing diarrhea consisting of low-volume stools containing blood, mucus, and fecal leukocytes. Fever is found in about half of patients, and febrile seizures in children are possible. Shigellae have their principal effects on the colon. The mucosal inflammatory response is intense as the shigellae penetrate, divide in, and lyse epithelial cells. Tenesmus is common and may lead to rectal prolapse in severely ill children who have many painful evacuations. On sigmoidoscopy the colorectum is very red, edematous, typically ulcerated, and coated with patchy mucus, and the degree of inflammation leaves little doubt as to why crampy pain and low-volume diarrhea, often with bloody stools, are the typical manifestations. However, in some patients shigellosis results in watery, nonbloody diarrhea. Though more commonly seen with infections by other agents, these milder symptoms may occur in shigellosis. Hemolytic-uremic syndrome and postinfectious arthritis have been described. Definitive diagnosis is made by culture of stool or fecal mucus, and swabs of rectal mucosa can also give positive results. Culture of fresh samples or immediate inoculation of plates or transport media is necessary, as shigellae do not survive well at room temperature.

Shigella dysenteriae produces a potent polypeptide toxin (Shiga toxin) that has cytotoxic and enterotoxic properties *in vitro*. Shiga toxin, which is closely related in structure to enterotoxins of *E. coli*, probably participates in the cell lysis typical of this infection, and its enterotoxic properties also contribute to the secretory component of the illness.

Shigellosis is usually self-limited, but antibiotics may shorten both the course of diarrhea and the duration of pathogen excretion in stool. Although resolving cases do not require antimicrobial drugs, these agents may be lifesaving in severe cases, and treatment may interrupt person-to-person transmission. The fluoroquinolones are the treatment of choice for adults. Vaccine development for shigellosis has not yet been successful, but the use of recombinant microbiologic techniques to identify the most antigenic or virulent attributes of shigella may in time lead to successful vaccines.

CAMPYLOBACTER INFECTION

Infections due to *Campylobacter* species were long thought to be uncommon, but through improved methods of stool culture they are now recognized as the cause of 10% to 15% of cases of acute diarrhea in the United States. Groups at high risk for infection include infants and young adults. *Campylobacter*, like *Salmonella*, has a large animal reservoir and can be cultured from healthy cattle, sheep, swine, poultry, and domestic animals. Human infection is typically acquired by the eating of contaminated poultry, reminiscent of the transmission of *Salmonella*, but outbreaks have also been traced to consumption of raw milk or untreated river or stream water. Two species—*C. jejuni* and *C. coli*—account for almost all clinical isolates in most series. A third species, *C. fetus*, tends to be associated with chronic infections in gay men or immunocompromised hosts.

The typical illness begins with abdominal cramps and diarrhea 2 to 4 days after exposure. Anorexia and malaise are also typical, and some patients have bloody diarrhea. As with nearly all bacterial pathogens, not every encounter with *Campylobacter* causes illness. In one volunteer challenge study, only 18% of healthy subjects became ill, usually within 3 days, but 70% of all subjects excreted large numbers of the organism in the stool. The incidence of clinical illness was higher with larger oral inocula (although as few as 500 to 800 organisms can cause illness), and attack rates rose when organisms were given with food or drugs that reduce gastric acidity.

Campylobacter enteritis has many systemic features, and the early phases of the illness have an influenza-like character. Fever occurs in about half of patients and may precede diarrhea, attesting to the tissue-invasive and inflammatory nature of this infection. The pain of *Campylobacter* enteritis may be intense and easily confused with a surgical abdomen. The jejunum and ileum are the main sites of infection, but the colon is involved in some patients. Fecal leukocytes and blood in the diarrheal stool are common. A reactive arthritis 10 to 14 days after the onset of illness has been described, a cause of Reiter's syndrome. An association between *Campylobacter* infection and the Guillain–Barre(c) syndrome, an acute inflammatory demyelinating polyradiculoneuropathy, has now been clearly documented. This serious sequel of otherwise typical *Campylobacter* enteritis is thought to occur due to molecular mimicry of host antigens by the infecting microorganism.

Campylobacter enteritis is among the forms of infectious gastroenteritis most easily confused with idiopathic ulcerative colitis, and corticosteroids may aggravate symptoms of *Campylobacter* infection and promote tissue injury. *Campylobacter* enteritis also mimics ulcerative colitis by its slow resolution, as diarrhea sometimes lasts 2 weeks. In most patients, systemic symptoms are usually much relieved before diarrhea stops. Diagnosis is made by stool culture, but *Campylobacter* species are relatively fastidious organisms requiring specialized media and other conditions for growth. Despite such technical obstacles, this organism should be sought routinely in patients with recent onset of bloody stools to avoid confusion with other forms of colitis. Properly collected and cultured specimens should yield the organism in 90% of typical cases but less common *Campylobacter* species may be overlooked using these methods. A specific search for major *Campylobacter* species is now the practice in most large laboratories.

Therapy involves the usual attention to fluid and electrolyte replacement and supportive measures. Antimicrobial agents shorten clinical illness and decrease the duration of fecal excretion, but since their routine use may encourage the emergence of resistant organisms, only severe, prolonged, or complicated illness should be treated with antibiotic therapy. Resistance to fluoroquinolones requires a single mutation in the DNA gyrase gene, and there has been a dramatic worldwide increase in resistance to fluoroquinolones. The organism is usually susceptible to the macrolide family to which resistance emerges less rapidly. For these reasons, macrolide antibiotics are the preferred agents for *Campylobacter* infections.

AMEBIASIS

Entamoeba histolytica is the protozoan parasite that causes amebiasis. In the subtropics and tropics, asymptomatic carriage of *E. histolytica* cysts is common (up to 80% in some populations), but asymptomatic carriage in the United States is relatively uncommon. The majority of cases of symptomatic amebiasis in the United States are imported by travelers from endemic areas, with less than 5% of cases occurring through fecal contamination in nursing homes, day care centers, and through anal–oral sexual encounters. Humans can harbor nonpathogenic amebae that are morphologically indistinguishable from *E. histolytica*; these nonpathogenic amebae, termed *Entamoeba dispar*, do not invade tissue and do not need treatment. *E. histolytica* and *E. dispar* can be distinguished by techniques such as polymerase chain reaction (PCR) and isoenzyme analysis, but these methods are not presently available for routine diagnostic use.

E. histolytica infection is acquired by fecal–oral transmission of cysts or trophozoites excreted by patients who are ill with the disease. Cysts can survive outside the human host for up to 10 days; once ingested, they excyst to become trophozoites, a poorly understood process essential for disease to occur. *E. histolytica* trophozoites are invasive and preferentially attack the colonic mucosa to cause focal necrosis and ulcerations. Lesions are more abundant in the cecum and ascending colon than elsewhere. Although it is uncertain as to how this organism lyses cells and causes the necrotizing ulcerations responsible for the clinical illness, increased expression and secretion of cysteine-type proteinases correlate with the virulence of different strains of *E. histolytica*. Although pathogenic strains can activate the alternative complement pathway, their trophozoites are resistant to killing by complement and can survive in the bloodstream to subsequently invade the liver. The ability of this parasite to cause tissue damage is a complex interaction of host and microbial factors.

Amebiasis has several clinical patterns of infection, including acute amebic dysentery, nondysenteric amebiasis, and the asymptomatic carrier state. Amebae can also disseminate from the bowel to produce extraintestinal infection, including liver and brain abscess as well as infection of serosal surfaces such as pleura, peritoneum, and pericardium. Acute amebic dysentery is characterized by severe abdominal cramps, chills, fever, and liquid bowel movements containing bloody mucus. Fecal leukocytes are present, but numbers are less than in the invasive bacterial diarrheas. The disease can be fulminant and extensive, involving the entire colon with widespread hemorrhagic ulceration. Perforation may occur in severe disease.

Sigmoidoscopy, which should always be performed with great caution and without cleansing of the colon, shows intense inflammation. The classically described oval ulcers with undermined edges and intervening normal mucosa are only seen in some patients. Mucosal ulcers in amebiasis contain numerous trophozoites, and microscopic examination of fresh scrapings held near 37°C is useful. Amebic trophozoites are about four times the diameter of an erythrocyte and when kept warm have slow, unidirectional movement along pseudopods.

Stool examination for trophozoites of *E. histolytica* is an art acquired with practice and patience; overdiagnosis is common because coexistent nonpathogenic amebae, erythrocytes, and cell debris can be confusing. Searching for trophozoites in stool mucus is often fruitful, as they originate in colonic ulcers teeming with organisms. Immunologic diagnostic tests are now being developed; for example, the Enzymeaba test is based on stool examination for histolysin, the major cysteine proteinase of

E. histolytica. This test has 87.5% sensitivity and 100% specificity for infection. Another assay based on the use of monoclonal antibodies to detect galactose-specific adhesin (present only on pathogenic strains of *E. histolytica*) has 97% sensitivity and 100% specificity. These tests are not widely available.

As with *Campylobacter* enteritis, it is important to differentiate acute amebic colitis from idiopathic ulcerative colitis, as corticosteroids can greatly aggravate amebiasis and convert it to a fulminant illness. Severe amebiasis may be indistinguishable from the acute toxic dilatation that complicates inflammatory bowel disease, so proper diagnosis may avoid the disaster of an unwarranted emergency colectomy. Nondysenteric intestinal amebiasis is a milder illness characterized by frequent watery or soft stools. Chronic amebic infection creates amebomas, lesions that must be differentiated from other chronic inflammatory and neoplastic diseases of the colon. Amebic liver abscess is characterized by fever, right upper quadrant pain, and the presence of spherical cavities in the liver that can be detected by various hepatic imaging techniques. These are not true abscesses but rather pockets of necrotic debris from which thick brown fluid can be aspirated. Diagnosis is confirmed by serologic testing, which is generally available in large medical centers or in public health laboratories.

Treatment of amebiasis varies with the clinical syndrome. Acute amebic dysentery should be treated with an antitrophozoite agent, such as metronidazole, tinidazole, or ornidazole, followed by diloxanide furoate, iodoquinol, or paromomycin (compounds active against cysts). Treatment of asymptomatic cysts is optional for patients who live in endemic areas. For those in nonendemic areas, cyst treatment with diloxanide furoate, paromomycin, or iodoquinol is recommended. Invasive disease, such as liver abscess, is treated with metronidazole followed by a luminal agent.

GIARDIASIS

Giardia lamblia is the most common protozoal infection of the intestinal tract worldwide. Prevalence varies from 2% to 5% in industrialized countries to 20% to 30% in the developing world. Giardiasis is endemic in the United States as either acute diarrhea or a chronic illness, usually acquired by consuming water contaminated with the feces of humans or domestic or wild animals. Drinking apparently clear water from streams or wells in mountainous areas is a common source of this microbe, and patients should be asked about recent hiking or camping trips. Transmission of giardiasis is common in day care centers and institutions for the mentally ill and retarded, and among homosexual men. The major clinical importance is in young children and the immunocompromised, but healthy persons may have severe illness caused by this protozoan parasite.

Patterns of clinical giardiasis are diverse, ranging from asymptomatic carriage to severe chronic diarrhea, malabsorption, and growth retardation in children. The acute illness, which often is falsely attributed to a number of bacterial causes, is characterized by periumbilical abdominal cramps, nausea and vomiting, and watery diarrhea that may lead to significant fluid depletion. The means by which *G. lamblia* causes high-volume diarrhea is unknown. Diarrhea is very occasionally absent in the acute infection. Many cases are short-lived and spontaneously clear without therapy. However, giardiasis often becomes a chronic intestinal infection and then can present in several ways: a nonspecific chronic diarrheal syndrome not associated with other significant symptoms, or a postinfectious malabsorptive syndrome characterized by abdominal distress, gas, bloating, and general malaise, without much diarrhea. As many as 50% of asymptomatic patients have biochemical evidence of carbohydrate, fat, and micronutrient malabsorption, and giardiasis has been reported as one of the causes of protein-losing enteropathy. Allergic and inflammatory phenomena, including urticaria and arthralgias, have also been described in association with giardiasis.

Diagnosis is made by finding trophozoites or cysts in stool or in intestinal fluid or tissue. However, stool examination for trophozoites or cysts is positive in only one-third to one-half of confirmed cases. Because *Giardia* organisms have a predilection for the proximal small intestine, the agent can also be recovered from duodenal or proximal jejunal aspirates. This is accomplished by tube or at endoscopy, or by a novel string test in which the free end of a thread is taped to the patient's cheek while the remainder is coiled into a swallowed gelatin capsule; when retrieved and examined microscopically, it may contain many adherent trophozoites. Alternatively, a small intestinal biopsy with examination of both the adherent mucus and the mucosal tissue may reveal the trophozoites.

Several drugs are effective in the treatment of giardiasis, including metronidazole, tinidazole, and quinacrine, but only metronidazole is readily available in the United States. Other less effective options include furazolidine (used in metronidazole failures) and paromomycin (for use in pregnancy).

VIRAL DIARRHEA

Viral diarrhea is a common cause of acute infectious diarrhea in the United States in both children and adults. The typical illness is characterized by fever, nausea, vomiting, cramps, and watery diarrhea. Although technically an invasive diarrheal disorder, the diarrhea is not inflammatory, so polymorphonuclear leukocytes and blood are often not found in stool. Frank bloody diarrhea should direct attention to bacterial or protozoan agents. The two most common and well-documented viral agents causing diarrhea are the rotaviruses and the calciviruses. Other less commonly identified viruses include enteric adenoviruses, astroviruses, and non-group A rotaviruses. Although there are few comprehensive community surveys, the incidence of rotavirus diarrhea alone is an estimated 3.5 million cases per year in the United States. Nearly everyone in the United States has had either symptomatic or asymptomatic rotavirus exposure during childhood.

Rotaviruses (named for their wheel-like appearance on electron microscopy) are among the RNA-reovirus group and cause enteric illness in children up to 2 years of age. In North America, rotavirus disease is most common in the winter, whereas infections in the tropics occur throughout the year. Symptomatic infection has an incubation period of 1 to 3 days, after which there is a sudden onset of vomiting lasting for 3 days and watery diarrhea lasting for 3 to 8 days. Fever and abdominal pain are common. Rotavirus can cause a delay in gastric emptying, making vomiting worse. While there are few sequelae of infection, inadequate fluid replacement in young children can result in severe dehydration and even death. Presumptive diagnosis can be confirmed serologically by finding viral antigens in the stool with a solid-phase ELISA assay. An effective live oral vaccine has been licensed in the United States and is administered in three doses with other childhood vaccines. The use of the vaccine has been restricted recently because of a high incidence of intersusception.

Norwalk and Norwalk-like diarrhea are caused by a heterogeneous group of viruses classified as calciviruses. They have been named for the location of recognized outbreaks (e.g., Snow Mountain virus or Montgomery County virus). These agents have not been cultured, but Norwalk and several other related Norwalk-like virus illnesses can be confirmed by a rise in serum antibody titer or by the detection of viral antigen in stool specimens. Oral vaccines for Norwalk virus are in early development.

Spread of Norwalk viruses may occur by person-to-person transmission, but more often through the ingestion of contaminated water or foods such as shellfish and salads. Infections occur at all ages, although adults typically have a milder illness than do children. This may be the result of partial immunity (most children have detectable antibody by age 10), which can attenuate the degree of disability from these ubiquitous viruses. Diarrhea in Norwalk disease is accompanied by abdominal pain, nausea, poor appetite, myalgias, and low fever lasting 1 to 4 days. There are no significant long-term sequelae.

Treatment of viral diarrhea requires adequate fluid and electrolyte replacement and supportive care. No specific drug therapy is known to be of benefit.

ESCHERICHIA COLI INFECTIONS

Escherichia coli is a normal component of the intestinal microflora in all normal people. Pathogenic *E. coli* organisms have acquired the potential to cause disease by uptake of DNA that encodes for virulence factors, and in this way differ from nonpathogenic strains. Currently, six categories of *E. coli* can be distinguished by epidemiologic, clinical, and pathogenic mechanisms: enterotoxigenic (ETEC), enteropathogenic (EPEC), enteroinvasive (EIEC), Shiga toxin-producing *E. coli* (STEC), enteroaggregative (EAggEC), and diffuse adherent (DAEC).

ETEC strains cause infant diarrhea in tropical and developing countries and diarrhea among travelers but are relatively uncommon in the United States. These organisms have fimbriae by which they attach to enterocytes of the small intestine. They cause diarrhea by liberating a heat-stable or heat-labile toxin, or both. Labile toxin is closely related in structure and biologic effects to the toxin of *V. cholerae*.

EPEC strains cause diarrhea in humans, but they have not been shown to be toxigenic or capable of invading epithelial cells. Unlike most other diarrheogenic *E. coli*, EPEC strains have a characteristic interaction with epithelial cells that can be demonstrated by electron microscopy. EPEC organisms adhere very closely to the surface of enterocytes and alter the cell by destroying the microvilli and causing rearrangement of the cell's cytoskeleton. These cell changes are called *attaching and effacing lesions*. The ability of EPEC to cause these lesions is encoded by plasmid-associated genes as well as a 35-kb chromosomal DNA insertion known as a pathogenicity island. Illness due to EPEC occurs in infants but can sporadically affect adults in outbreaks. Diarrhea is watery with little blood.

EIEC strains cause enteroinvasive intestinal infection similar to that of *Shigella* species. Both *Shigella* and EIEC organisms have 120- to 140-Md plasmids that encode genes that allow these bacteria to invade and spread intercellularly. The illness caused by EIEC organisms is centered in the colon and can be similar to *Shigella*

dysentery, with fever, cramps, and low-volume, bloody, frequent stools. As is the case with *Shigella*, however, diarrhea can be watery.

STECs, also called “enterohemorrhagic *E. coli*” or “EHECs,” are important pathogens in the developed world. STEC organisms can asymptotically colonize the gut, cause a mild watery diarrhea, or cause severe hemorrhagic colitis. Although STEC organisms are noninvasive, they have acquired the ability to synthesize Shiga toxins structurally related to that elaborated by *Shigella dysenteriae*. The genes encoding these toxins are carried on lysogenic bacteriophage in STEC organisms. Like EPEC, most STEC strains can also form attaching and effacing lesions. Infection has been food-borne in several large outbreaks in the United States, and this illness has major clinical and commercial importance. In one outbreak in the United States, more than 500 children and adults were stricken with STEC infection by eating contaminated hamburger meat in fast-food restaurants. An outbreak in Georgia was traced to a children's pool in a water park. STEC organisms have often been isolated from diarrheal outbreaks in day care centers, nursing homes, and schools. Of great clinical importance, STEC strains have been implicated in 63% to 92% of patients with the hemolytic-uremic syndrome, a serious sequela of STEC infection due to the systemic effects of Shiga toxins. While the appearance of these agents in outbreaks rather than individual cases is a distinguishing feature, the illness can be confused with idiopathic ulcerative colitis. One of the STEC serotypes, O157:H7, does not ferment sorbitol and can be readily distinguished from other *E. coli* strains on sorbitol-enriched MacConkey plates as colorless colonies. Laboratories that use this single criterion for STEC screening will identify only this serotype. However, it has been recognized that many other serotypes can also cause infection, so the best screening tests for STEC infection are not based on sorbitol fermentation but rely on identification of Shiga toxins in the stool by enzyme-linked immunosorbent assay.

DAEC and EAggEC are distinguished by their patterns of adherence to epithelial cells. DAEC are recovered more frequently from stools of children with diarrhea than those without, but data implicating these agents in diarrheal disease are inconclusive. EAggEC organisms are pathogenic, and at least some strains can secrete a heat-stable enterotoxin (East1) and a heat-labile protein that is immunologically similar to hemolysin. EaggEC have recently been shown to be associated with diarrhea in patients with HIV.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis is an inflammatory lesion of the colon that usually occurs in a setting of oral or parenteral antibiotic use, but it may also be seen during cancer chemotherapy, in patients infected with HIV, and occasionally in the absence of other risk factors. The illness can range from a mild to intense inflammation of the colon caused by one or more toxins of the responsible agent, *Clostridium difficile*, a strictly anaerobic, gram-positive bacterium.

Uncomplicated diarrhea is a common side effect of antibiotics themselves; for example, ampicillin and clindamycin cause self-limited diarrhea in up to 25% of patients. These drug side effects are relieved when drugs are stopped, distinguishing them from the disease caused by *C. difficile*. Pseudomembranous colitis begins during the period of antibiotic use or may start up to 4 weeks after the drug has been discontinued. The illness is characterized by diarrhea, fever, abdominal pain, and fecal leukocytosis; frank bleeding is unusual. Adults are more susceptible than children, and the occasional patient with *C. difficile* colitis will develop severe or fulminant disease. When fulminant, *C. difficile* colitis can be complicated by hypotension, very elevated peripheral leukocytosis, abdominal distention, toxic megacolon ([Fig. 113.1](#)) and even colonic perforation, but diarrhea may be minor or even absent. Sigmoidoscopy shows scattered or confluent pale yellow plaques extending proximally from the most distal rectum on an edematous and erythematous mucosa ([Figure 113.2](#)). An adherent pseudomembrane consisting of large amounts of mucus and cellular debris may obscure the underlying plaques. Often there is a poor correlation between the sigmoidoscopic and clinical findings, both of which are highly variable. Contrast radiography can aggravate the inflammation and should be avoided if the clinical setting and sigmoidoscopy are consistent with the diagnosis. These patients do not need colonoscopy for diagnosis, and this more invasive procedure is best avoided.

FIGURE 113.1. Toxic megacolon in a patient with *C. difficile* colitis. (Courtesy of Dr. Robert R. Paul.)

FIGURE 113.2. Sigmoidoscopic appearance of pseudomembranes in a patient with *C. difficile* colitis. (Courtesy of Dr. Sharon B. Turissini.)

The clinical terms pseudomembranous colitis, antibiotic-associated colitis, and *C. difficile* colitis are interchangeable. Antimicrobials probably trigger the illness by changing the enteric flora to allow entry or overgrowth of *C. difficile*. This organism is absent from stools of normal individuals in North America but appears in about 20% of patients who have diarrhea while receiving antimicrobial therapy, and in 95% of patients with pseudomembranous colitis. All antimicrobial drugs—particularly ones with activity against enteric bacteria—have been implicated in pseudomembranous colitis, but broad-spectrum penicillins and cephalosporins are most commonly implicated. Tetracycline and metronidazole are rarely involved.

People colonized by *C. difficile* may pass heat-resistant spores that represent a risk for patient-to-patient transmission by personnel in the hospital setting; these may be extremely difficult to control. For this reason, enteric precautions are essential in managing hospitalized patients with *C. difficile*. These precautions include private rooms, dedicated toilet facilities, and careful attention to handwashing by hospital personnel.

C. difficile produces two high molecular weight cytotoxins, A and B. Toxin A causes mucosal damage, intestinal inflammation, and fluid secretion in animal models and is a neutrophil chemoattractant in humans. Toxin B is not known to be enteropathogenic *in vivo*. The toxic effects of toxin A are mediated through damage to the cellular cytoskeleton after binding to an enterocyte receptor.

The A toxin causes actinomorphous (sunlike) rounding in cell culture and is blocked by specific antitoxin. This test is time consuming but has a sensitivity of 94% to 100% and a specificity of 99%. Alternatively, *C. difficile* infection can be confirmed by demonstrating toxin B in stool filtrate. Several rapid immunoassays for *C. difficile* antigens or toxins are available. The stool cytotoxin test remains the gold standard, but the commercial immunoassays are faster and cheaper and provide reasonable sensitivity and specificity.

Prompt cessation of antimicrobials should be considered, if possible. Patients with mild diarrhea may require no additional treatment, but oral metronidazole and oral

vancomycin are effective in treating more severe or persistent infections. Although the pharmacokinetics of oral vancomycin make it an ideal treatment of *C. difficile* colitis, its clinical overuse has resulted in the development of resistance in other organisms, e.g., the enterococci. Thus, metronidazole, which is much less expensive but usually effective, is the initial treatment of choice. Oral bacitracin is also active against *C. difficile*, but it is expensive and has been associated with a high relapse rate. Antiperistaltic agents should be avoided because they worsen the clinical disease.

Up to 20% of patients relapse within 3 weeks after an initial course of therapy. Management of relapse with metronidazole or vancomycin may be unnecessary if the relapse is not clinically severe, but a second course is advised for more severe or persistent diarrhea. Additional relapses are notoriously treatment-resistant. To treat persistent relapsing infection, rifampin, cholestyramine to bind toxins, treatments with the yeast *Saccharomyces boulardii*, and even fecal enema bacteriotherapy have been tried, but no generally acceptable therapy for recurrent infection has been described.

TRAVELER'S DIARRHEA

Traveler's diarrhea is a category of acute diarrheal illnesses typically contracted within a week of travel to a foreign country. These ailments are caused by bacterial, viral, or protozoal pathogens. Visitors to Latin America, Asia, the Middle East, and Africa are most often affected. More than 30 million people travel annually from an industrialized to a developing country, and of these 50% can expect to experience an episode of acute diarrhea. This illness is usually self-limited but often modifies the traveler's agenda.

Traveler's diarrhea usually begins 3 to 6 days after arrival in a foreign country and is accompanied by nausea, malaise, and vomiting. Fever occurs in about half of patients. About 20% of patients have fever or bloody stools, suggesting infection with an invasive organism. Patients are usually much improved in 72 hours, although symptoms may persist in some patients for more than a month.

The vast majority of these cases are infectious, and the specific agent involved is highly dependent on the country visited, the nature of the travel, and the foods consumed. Toxigenic *E. coli* (ETEC strains) cause up to 40% of cases, and *Shigella*, *Salmonella*, viruses, and *G. lamblia* are each implicated in about 5% to 10% of cases. *E. histolytica*, *C. jejuni*, *Cryptosporidium*, and *Aeromonas* are responsible in certain countries. Viruses such as rotavirus and the Norwalk family of viruses are responsible for up to 10% of cases. New enteropathogens continue to be discovered, and sometimes one need not travel at all to become exposed; that is, it is sufficient that one's food has traveled. An example of this phenomenon is the coccidian parasite *Cyclospora cayatenensis*, first described as a disease of travelers in the 1980s but now recognized as a pathogen that can be acquired by the eating of fresh fruits and vegetables imported from endemic areas.

Travelers become ill by eating leafy vegetables, poorly stored meat and seafood, dairy products, and water (or ice) that is fecally contaminated. Foods cooked at high temperature, beverages made with boiled water, and soda in tightly capped bottles are usually safe. The consumption of eggs, custard, mayonnaise, and milk- or cream-based sauces while traveling in many parts of the world should be avoided, and hot foods cooked in a cloud of steam at roadside may be the safest to eat. Contrary to popular belief, the grand and majestic hotels in the developing world do not have uniformly high standards of sanitation, but they do provide comfortable accommodations for the short period of recovery.

Treatment of traveler's diarrhea primarily involves fluid and electrolyte replacement. Even in the tropics most adults do not become rapidly dehydrated, so hypotonic solutions containing glucose taken with salted crackers, or salty soups combined with fruit juices and complex carbohydrates such as rice, potatoes, or bread (which promote active glucose–sodium cotransport), can usually meet fluid and salt requirements. Oral rehydration therapy with standardized, prepackaged mixtures of salts and carbohydrates in water is recommended for children with mild or moderate dehydration, and can be purchased at almost any pharmacy in the world. Many patients require no therapy beyond compounds that reduce stool frequency. Oral bismuth subsalicylate may reduce stool frequency by 50%, and loperamide by 80%, although such drugs should not be used in patients with fever or dysentery (bloody stools) because they may exacerbate invasive bacterial infections. Antimicrobial therapy is recommended for illness that is moderate or severe, including abdominal pain or cramps, fever or dysentery, or prolonged symptoms. Fluoroquinolones are the antibiotics of choice for adults, and usually a short course (3 days or less) is sufficient. Antibiotic therapy reduces the duration of diarrhea from an average of 3 days to less than 1 day. The combination of loperamide and an antimicrobial drug is particularly effective, reducing symptoms while eradicating the organism.

The role of chemoprophylaxis in preventing traveler's diarrhea remains controversial. The primary prophylaxis for traveler's diarrhea should be avoidance of food that may be fecally contaminated. For most travelers, chemoprophylaxis is unnecessary, expensive, and carries the risk of side effects. Furthermore, in this era of increasingly resistant microbes, widespread use of prophylactic antimicrobials must also be weighed against concerns about increasing antimicrobial resistance in enteric pathogens abroad. For travelers to high-risk areas who have underlying illness or cannot use food and water precautions, prophylaxis with bismuth subsalicylate, fluoroquinolones, trimethoprim–sulfamethoxazole, or doxycycline may be considered. Prophylaxis should begin on the first day in the country and should continue for 2 days after returning. Prophylaxis longer than 3 weeks is not advisable because of the cost, potential drug toxicity, and interference with the development of natural defense mechanisms against these infections.

INFECTIOUS PROCTITIS AND PROCTOCOLITIS

Infectious causes of proctitis should be considered in any patient with a history of anal intercourse. Proctitis implies sigmoidoscopic evidence of inflammation limited to the rectum and is often associated with constipation, tenesmus, rectal bleeding, and perirectal pain. Sexually transmitted microorganisms causing this illness include *N. gonorrhoeae*, *C. trachomatis*, herpes simplex virus, and *Treponema pallidum*. Proctocolitis suggests inflammation extending beyond the rectum, and in those patients diarrhea may accompany symptoms of proctitis. The most common infectious agents causing proctocolitis extending above the rectum are *S. flexneri*, *C. difficile*, *C. jejuni*, *C. trachomatis*, and *E. histolytica*.

AIDS

Gastrointestinal pathogens are common in HIV-infected patients and may affect any organ. Patients may have no symptoms, or they may be quite ill or sometimes debilitated from these infections. Diarrhea is common in those infected with HIV: it occurs in 30% to 60% of North American and European patients with clinical AIDS and in 90% of patients in developing countries. Many microorganisms cause acute, treatable illness, only some of which are classified as opportunistic pathogens, and they are acquired by anal–oral sexual practices. Homosexuals or bisexuals who have AIDS are more likely to have diarrhea with an enteric pathogen than are heterosexuals or intravenous drug users with HIV. The finding of an enteric pathogen, however, does not necessarily imply that symptoms can be ascribed to that particular organism, since similar enteric pathogens can be identified in up to half of asymptomatic patients. Multiple coinfections are common in AIDS patients.

As always, evaluation should begin with a careful history to help focus diagnostic efforts. Stools should be cultured for bacterial pathogens, assayed for *C. difficile* toxin, and examined for parasites. More extensive workup by endoscopy and biopsy is often required. Empirical treatment may be justified; for example, patients with symptoms of esophagitis, particularly if accompanied by oral thrush, may receive treatment with fluconazole for presumptive candidiasis, reserving more invasive investigation for refractory cases. The subject of AIDS is also covered in [Chapter 98](#), [Chapter 114](#) and [Chapter 343](#).

FOOD POISONING SYNDROMES

The term *food poisoning* describes the nausea, vomiting, abdominal cramps, chills, fever, and diarrhea that quickly follow consumption of food contaminated with bacteria or their toxins, or with toxic chemicals. Food poisoning should be considered when the illness starts within hours after ingestion of a meal, and if others eating the same foods or in the same locale are also affected. A specific diagnosis in the individual patient is usually not made, nor is a search justified, as uneventful recovery is the rule. In large outbreaks, public health authorities may deem it necessary to identify a source.

The pathogenic mechanism of microbial food poisoning involves ingestion of preformed bacterial toxin or the ingestion of an organism that then rapidly produces toxin *in vivo*. *Staphylococcus aureus* and *Bacillus cereus* are examples of organisms that can grow in food and make such toxins. Symptoms typically begin 1 to 6 hours after food ingestion. Vomiting and diarrhea are the hallmarks of staphylococcal food poisoning, whereas nausea and vomiting alone characterize *B. cereus* toxin ingestion. However, *B. cereus* also can cause long-acting food poisoning 8 to 16 hours after food ingestion, this form characterized by diarrhea and cramping abdominal pain. Another common cause of the 8- to 16-hour food poisoning syndrome is *Clostridium perfringens* type A, an organism that elaborates a potent enterotoxin capable of changing small intestinal solute and water transport. The abdominal cramps and diarrhea of *C. perfringens* disease usually is impossible to distinguish from other gut infections.

In all but extremely ill, elderly, or debilitated patients, treatment of microbial food poisoning syndromes is best limited to symptomatic treatment because these illnesses are usually relieved within 24 hours. Dominant vomiting in these diseases may result in hypochloremic alkalosis and consequent hypokalemia, both of which

are of clinical importance.

MISCELLANEOUS INTESTINAL INFECTIONS

SMALL INTESTINAL BACTERIAL OVERGROWTH SYNDROME (BLIND-LOOP SYNDROME)

The normal proximal small intestine is sparsely populated by bacteria (usually less than 10^3 per milliliter), consisting of a mixture of aerobes and anaerobes. However, these numbers may soar to 10^7 per milliliter to 10^9 per milliliter if intestinal motility or other gut clearance mechanisms are abnormal. This condition, known as bacterial overgrowth syndrome, stasis syndrome, blind-loop syndrome, or stagnant-loop syndrome, leads to malabsorption of dietary fat and fat-soluble vitamins and can result in weight loss, steatorrhea, macrocytic anemia, vitamin deficiency syndromes, and chronic diarrhea. Recognition of this group of disorders is important because treatment to correct the stasis or eradicate the responsible microorganisms is highly effective; however, these syndromes are commonly overlooked.

Clinical malnutrition due to bacterial overgrowth was first recognized in elderly patients with jejunal diverticula, but since then it has been found in any condition involving stasis in the small intestine. Such stasis occurs behind strictures or adjacent to fistulae due to inflammation such as Crohn's enteritis, in postirradiation states, and in neoplasms such as ovarian malignancies that secondarily involve the gut mesentery. Bacterial overgrowth is also found in postsurgical patients with inadequate emptying of reconstructed loops (such as the afferent loop of the Billroth II gastrectomy), in gastric achlorhydria, or in intrinsic motility disorders such as scleroderma of the small intestine, diabetes mellitus, and chronic pseudo-obstruction. Malabsorption is directly attributable to the type and number of bacteria in the upper gut, and these are largely anaerobes. Bacteria interfere by competing directly for nutrients such as vitamin B₁₂, which they can remove from intrinsic factor or other cobalamin binders en route from the stomach to the receptor sites in the terminal ileum. Perhaps of more direct importance, bacteria in the upper gut can modify or partially degrade bile acids, which renders them ineffective for the absorption of dietary triglycerides and fat-soluble vitamins. Bacterial deconjugation or dehydroxylation of bile acids changes their solubility and micelle-forming properties, which are needed for the absorption of dietary lipids. Bacterial overgrowth can also cause focal damage to the enteric mucosa, perhaps contributing to the malabsorption problem.

The main nutritional consequences are weight loss and macrocytic anemia, and the patient may have chronic diarrhea. However, diarrhea is often absent despite flagrant bacterial overgrowth, perhaps explaining why these disorders are clinically overlooked. Workup of patients suspected of having bacterial overgrowth or stagnant-loop syndromes should include contrast roentgenography of the small intestine to define the abnormal anatomy and to assess motility and clearance of gut contents. The diagnosis is firmly established by finding large numbers of bacteria in aspirated jejunal contents of the malnourished patient. Specific arrangements should be made with the bacteriology laboratory for quantitation and anaerobic growth of the aspirated sample. Diagnostic breath tests have also been developed; these include hydrogen breath analysis after ingestion of lactulose or glucose, or measurement of expired ¹⁴C₂ after ingestion of ¹⁴C-xylose or ¹⁴C-bile acids. These tests have significant false-positive and false-negative results. The breath hydrogen or ¹⁴C₂ response after antibiotic therapy may be used to judge the efficacy of treatment. Vitamin B₁₂ deficiency can be documented by measuring the serum vitamin B₁₂ level and by doing a Schilling test. In the blind-loop syndrome, serum vitamin B₁₂ is abnormal in both stage I (oral vitamin B₁₂ alone) and stage II (oral vitamin B₁₂ with intrinsic factor) tests.

Experienced clinicians often treat stasis syndromes without documenting bacterial overgrowth if the clinical circumstances strongly suggest the diagnosis. The basis of treatment is eradication of the overgrowing bacteria and caloric and vitamin replacement if nutritional depletion is severe. Specific therapy should include broad-spectrum antibiotic therapy with metronidazole, ampicillin, tetracycline, or clindamycin. The diet may be augmented by medium-chain triglycerides whose absorption is not dependent on bile acids. A gratifying weight gain of 5 to 15 kg is not unusual with proper treatment of a severely malnourished patient. A single course of antibiotic therapy often results in a prolonged remission, although repeated courses of antibiotics may be required. Correction of the anatomical disorder leading to overgrowth is not usually necessary but should be considered in the appropriate patient if antibiotic and other forms of therapy are ineffective.

TROPICAL SPRUE

Tropical sprue is a malabsorptive disorder of unknown cause that is endemic in the tropics, particularly southern India, Southeast Asia, and the Caribbean; it is rare in Africa. It occurs both in the indigenous population and in visitors from temperate climates. Tropical sprue can develop in visitors as soon as 2 weeks after their arrival, although a lengthy stay of months to years is more the rule. Occasionally, the illness appears several months after the visitor has been home. This illness should not be confused with nontropical sprue (celiac disease), a sensitivity to ingested gluten for which treatment is entirely different.

Chronic illness is usually preceded by an episode of acute infectious diarrhea that never fully resolves. The epidemiologic and clinical features, coupled with the response to antibiotic therapy, support the view that tropical sprue is one of several postinfectious malabsorption states whose full range of causes has not been identified. The differential diagnosis includes chronic bacterial or parasitic infections (chronic giardiasis, cryptosporidiosis, *S. stercoralis* infection) and neoplasms (mainly primary intestinal lymphoma). HIV should be in the differential diagnosis until serologically excluded.

The full tropical sprue syndrome is characterized by chronic diarrhea, folic acid deficiency, vitamin B₁₂ deficiency, malabsorption of various nutrients, megaloblastic anemia, edema, and hypoalbuminemia. Tropical sprue should be suspected in any person who has lived in the tropics, complains of diarrhea and weight loss, and has evidence of folic acid deficiency. Jejunal biopsy shows blunting (not usually absence) of the villi and infiltration of the lamina propria with lymphocytes and plasma cells.

Treatment consists of folic acid, vitamin B₁₂ replacement, and tetracycline. The prognosis is good, although therapy for several months may be necessary.

WHIPPLE'S DISEASE

This rare intestinal illness, largely confined to white males of European ancestry, is characterized by malabsorption and systemic illness. Bacteria in gut tissues were observed by electron microscopy many years ago but only recently were identified by polymerase chain reaction amplification of the microbial 16S ribosomal RNA in patient tissues. This revealed a gram-positive actinomycete unrelated to any known genus, now named *Tropheryma whippelii*. Details on the clinical manifestations of Whipple's disease are found in [Chapter 110](#).

Lymphoid cells comprise approximately 25% of the cells in the intestinal mucosa, thus representing a major component of the immune system. The intestinal immune system is organized in three interconnecting cellular compartments: Peyer's patches and lymphoid follicles, lamina propria lymphoid cells, and intraepithelial lymphoid cells (Fig. 114.1). The cell compartments are segregated by differences in physical location and structure and by the types and functions of the cells within them. The antigenic challenge to the mucosal immune system is enormous. Intestinal lymphoid cells are in a constant state of response to these antigens, as evidenced by the large numbers of plasma cells present continuously in the mucosa and by studies of germ-free animals in which the intestinal immune system is poorly developed.

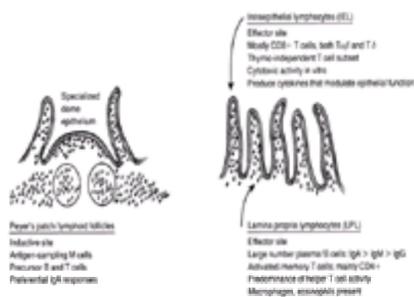

FIGURE 114.1. Important features of the major compartments of the intestinal immune system

PEYER'S PATCHES AND LYMPHOID FOLLICLES

Peyer's patches are organized lymphoid aggregates with follicles that extend from the epithelial layer down into the lamina propria and sometimes to the submucosa. Similar, smaller structures, many with but a single follicle, are dispersed throughout the human intestine. Peyer's patches and related lymphoid follicles lack afferent lymphatics. Instead, they have a specialized epithelium containing M cells that actively phagocytose and pinocytose antigenic materials in the intestinal lumen and deliver them to lymphoid cells below. Peyer's patches serve as sites of induction of immune responses, containing B-cell and T-cell precursors as well as antigen-presenting cells, but they are deficient in mature effector cells such as plasma cells or cytotoxic T cells, probably because differentiating B and T cells leave Peyer's patches after being stimulated there. The route of antigen exposure is critical. Peyer's patch cells respond almost exclusively to antigens delivered from the intestinal lumen. Peyer's patches and related follicles are a preferential site for the induction of IgA responses, which is the major immunoglobulin at mucosal surfaces.

Lymphocytes induced in the Peyer's patch and intestinal follicles leave these structures through efferent lymphatics that drain into mesenteric lymph nodes, where further division and maturation occur. From there, they travel by the thoracic duct into the circulation and are dispersed widely in the body. However, they tend to selectively accumulate or "home" to the intestine and other mucosal sites through the interaction of integrin receptors on lymphocytes that bind to ligands on the endothelial cells in the mucosa.

LAMINA PROPRIA LYMPHOCYTES

The intestinal lamina propria contains an abundance of B cells, plasma cells, T cells, and macrophages, as well as a lesser number of other cells, such as eosinophils and mast cells. Approximately 70% to 90% of the plasma cells in the intestine produce IgA, 5% to 15% produce IgM, and only 3% to 5% produce IgG, with IgE and IgD plasma cells occurring infrequently. Plasma cells are terminally differentiated, end-stage cells whose estimated half-life is about 5 days, indicating that their repopulation must be dynamic and continuous. Approximately two-thirds of lamina propria T cells have the CD4⁺ helper or inducer phenotype, and one-third have the CD8⁺ suppressor or cytotoxic phenotype, similar to that found in peripheral blood. Macrophages make up about 10% of lamina propria isolates, and mast cells constitute 1% to 3%. Mast cells are abundant in the lamina propria of the intestine and are present in the deeper layers of the bowel wall. At least two types of mast cells exist: the mucosal mast cell, which predominates in the lamina propria, and the connective tissue mast cell, which predominates in the deeper intestinal wall. The two types respond differently to various agonists and inhibitors—an observation of potential clinical importance. For example, mucosal mast cells are not inhibited by disodium cromoglycate. Eosinophils are a normal constituent in humans, but neutrophils are not. Natural killer cells and function seem to be deficient in the intestinal lamina propria, although precursors of lymphokine-activated killer cells are well represented. Lamina propria T cells differ from peripheral T cells in activation requirements and intracellular signaling pathways. They have surface markers of activated memory cells but proliferate poorly when stimulated in culture. They do produce cytokines *in vitro* but do not actively produce cytokines *in situ*, perhaps due to the influence of regulatory cells. The mechanism of this paradox of activated but hyporesponsive cells has yet to be elucidated.

INTRAEPITHELIAL LYMPHOCYTES

The third compartment of the intestinal immune system is represented by lymphocytes that are physically located within the epithelial layer, averaging 1 lymphocyte per 6 to 20 epithelial cells. The cellular composition of this compartment is quite different from that of the Peyer's patch or the lamina propria. The predominant cell type is the T cell, most of which bear the CD8 marker.

A variety of T-cell types are represented, including both $\alpha\beta$ and $\gamma\delta$ T-cell receptor-bearing cells. The latter is a major population in some species but represents only 5% to 7% of intraepithelial lymphocytes (IELs) in humans. These and some other IEL T cells appear to be generated directly in the gut epithelium rather than in the thymus, as are conventional T cells. The role of such thymic-independent IELs in health or disease is unclear. Unlike lamina propria cells, IELs have full cytotoxic capabilities, including natural killer, antibody-dependent cellular cytotoxicity, and T-cell cytotoxicity, but the exact role of such cells in mucosal defense is unknown. Because IELs increase in number after roundworm infestations, one hypothesis is that they may have a cytotoxic function directed primarily at parasites. IELs are increased in experimental graft-versus-host disease, prompting the suggestion that an increase in IELs may be a marker for cell-mediated immune responses in the intestine. There is some evidence that IELs may defend the epithelium against viral infections by secreting interferon or other cytokines, or perhaps by direct cytotoxicity for virally infected epithelial cells. Although we know very little about their precise function in gut-associated lymphoid tissue, IELs are in a site that would expose them to a great variety of antigenic stimuli and have the potential to participate in host defense and possibly mediate diseases. IELs are increased in number in some intestinal diseases, including celiac disease, dermatitis herpetiformis, and tropical sprue, but their role in these diseases is unknown.

ROLE OF THE EPITHELIUM

The epithelium is being increasingly recognized as an active participant in mucosal immune responses. Epithelial cells are in direct contact with IELs and in close apposition to lamina propria lymphocytes. Important interactions, or “cross-talk,” between epithelial cells and mucosal lymphocytes appear to occur through the secretion and response to various cytokines. The barrier function of the epithelial layer is mediated in large part by tight junctions between enterocytes. Exposure of epithelium to interferon- γ (IFN- γ), a cytokine known to be produced by IEL, diminishes tight-junction resistance and reduces barrier function. At the same time, IFN- γ up-regulates class II major histocompatibility complex (MHC) molecules on enterocytes. Increased class II MHC expression on intestinal epithelium is common at sites of chronic intestinal inflammation in humans. The role of epithelial cell class II MHC molecules *in vivo* is unclear, but epithelial cells can present foreign antigen to primed T cells *in vitro*; such presentation has stimulated suppressor rather than helper cells. Epithelial cells actively produce many cytokines, some of which influence immune responses. These include interleukin-8 (IL-8), a chemokine for neutrophils and lymphocytes, which is secreted rapidly during invasion of epithelial cells by bacteria. Epithelial cells produce transforming growth factor- β (TGF- β) and IL-6, both cytokines that promote IgA responses. TGF- β is also a potent inhibitor of many lymphocyte functions; its local secretion may be an important mechanism limiting inflammation in the normal gut.

SECRETORY IgA AND ITS TRANSPORT SYSTEM

The epithelium plays a crucial role in the transport of IgA into the gut lumen. Most plasma cells at mucosal sites produce IgA. IgA is produced as a monomer of 150-kd plus a dimer of 320 kd. IgA dimer is covalently coupled to a 15-kd protein known as J chain before secretion from plasma cells. Dimeric IgA, but not monomeric IgA, is able to bind to the polymeric immunoglobulin receptor (pIgR, also known as secretory component), a 70-kd receptor molecule produced by and present on the surface membrane of gut epithelial cells. J chain appears to be required for this binding to occur. After binding, the dimeric IgA-pIgR complex is endocytosed in a coated pit type of vesicle, transported to the apical membrane by a microtubule-dependent process, and released into the lumen (Fig. 114.2). Polymeric IgM is transported in a similar manner. In addition to transporting IgA into the lumen, pIgR confers to IgA a resistance to proteolysis. Once released into the lumen, secretory IgA has antiviral, antitoxin, and antibacterial functions, primarily by decreasing the ability of such cells or substances to bind or adhere to mucosa.

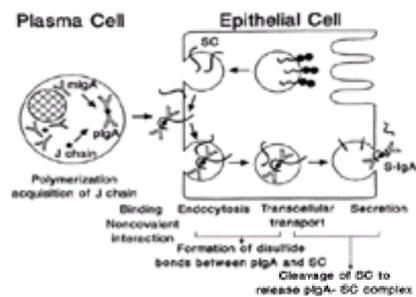

FIGURE 114.2. Model of the selective transport of J-chain-containing polymeric IgA (pIgA) through an epithelial cell. mIgA, monomeric IgA; SC, secretory component. (From Mestecky J, McGhee JR, Elson CO. Intestinal IgA system. *Immunol Allergy Clin North Am* 1988;3:356, with permission.)

The liver can actively transport IgA into bile; this transport also is mediated by pIgR. In some species, particularly rodents, pIgR is present on hepatocytes, and most IgA enters the intestine by this route. In humans, pIgR is present on bile ductular cells but not on hepatocytes, and this is not a major pathway of IgA transport. Because the same mechanism can transport immune complexes of IgA bound to antigen, this system may serve as an excretory route for the clearance of intestinal antigens out of the body. In humans, bile ductular cells, in addition to expressing pIgR on their surface membrane, express HLA-DR antigens. The transport of immune complexes and the expression of HLA-DR antigens by these ductular cells may be important in certain diseases, such as primary biliary cirrhosis and chronic graft-versus-host disease, in which there is a progressive destruction of bile ductular cells of apparent immune origin.

REGULATION OF THE RESPONSE TO ANTIGENS IN THE INTESTINE

Development of immunity to an antigen after an intestinal exposure is a well-known phenomenon that has been documented repeatedly after natural infections in humans and oral immunization regimens in experimental animals. “Natural” antibodies, such as the hemagglutinins, are examples of immunization at an intestinal surface. However, such exposure can also result in a state of specific systemic unresponsiveness, called *oral tolerance*. The factors that determine which result predominates are not understood, but presumably the answer lies in complex regulatory cell interactions within the intestinal immune system. Oral tolerance has been demonstrated in animals after feeding them a variety of different antigens, and it has also been demonstrated in humans. Feeding of autoantigens to experimental animals to induce oral tolerance ameliorates autoimmune diseases, and trials are under way to determine whether this may be an effective and nontoxic form of therapy for humans with autoimmune disorders.

CHRONIC ATROPHIC GASTRITIS

Chronic atrophic gastritis is a nonerosive inflammation of the gastric mucosa. Although a variety of upper abdominal complaints, such as dyspepsia, upper abdominal pain or fullness, nausea, and vomiting, have been attributed to chronic atrophic gastritis, this histologic lesion is common in the general population, most of whom are asymptomatic. Care must be used in attributing symptoms to this lesion, but it is likely that some patients' symptoms do result from chronic gastritis. The diagnosis is made by gastric biopsy, which shows a mononuclear infiltrate in the gastric mucosa associated with a variable loss of gastric glands; intestinal metaplasia is commonly associated with the gastritis. The final stage is gastric atrophy, in which the gastric glands have all but disappeared; at this stage, there are usually few inflammatory cells. Multiple gastric biopsies are preferable for diagnosis because the inflammation can be focal. Diagnosis based on x-ray films or solely on the endoscopic appearance is not reliable.

Chronic atrophic gastritis has been divided into two types, depending on which part of the stomach is involved and on the presence or absence of antibodies to parietal cells. In type A gastritis, inflammation affects the body and fundus of the stomach, but the antrum is spared. Serum anti-parietal cell antibodies and hypergastrinemia are common. Gastric acid secretion is usually low or absent. Patients with type A gastritis have an increased incidence of concomitant autoimmune disorders such as Hashimoto's thyroiditis, hypothyroidism, Graves' disease, insulin-dependent diabetes mellitus, Addison's disease, hypoparathyroidism, and vitiligo. The cause of the gastric lesion appears to be autoimmune damage to gastric parietal cells in the body and fundus of the stomach. The major autoantigens recognized by parietal cell antibodies are the a and b subunits of H⁺, K⁺-ATPase, the gastric proton pump responsible for acid secretion, which is localized on the cannicular (luminal) surface of the parietal cell. A subset of patients with type A gastritis develop *pernicious anemia* with absolute achlorhydria, an absence of intrinsic factor, and vitamin B₁₂ malabsorption. The clinical features of these patients are those of vitamin B₁₂ deficiency, including anemia, glossitis, neuropathy, memory impairment, and depression. There are usually few or no gastrointestinal symptoms. In addition to serum anti-parietal cell antibodies, anti-intrinsic factor antibodies are common. The diagnosis is made by establishing the presence of achlorhydria, a low vitamin B₁₂ level, an abnormal Schilling test result, and serum antibodies to intrinsic factor. Treatment consists of monthly vitamin B₁₂ injections, 100 μ g IM or daily cobalamin 1 mg PO.

In type B gastritis, inflammation affects the antrum and the body of the stomach; antibodies to parietal cells are not found. Serum gastrin levels are generally normal, although gastric acid secretion is often reduced. There is no association with autoimmune disorders, as is seen in type A gastritis. Instead, most cases are due to infections of the gastric mucosa with *Helicobacter pylori*. (see [Chapter 107](#)). Gastrointestinal symptoms are more common than in type A gastritis. The incidence of chronic type B gastritis increases with age and is also strongly associated with duodenal ulcer, gastric ulcer, gastric polyps, and gastric cancer. Because type B gastritis is much more prevalent than type A gastritis, it is numerically more important as a precursor lesion for gastric ulcer and cancer.

CELIAC SPRUE

Celiac sprue is a disease characterized by an abnormal small-bowel mucosa and malabsorption due to a reaction to dietary gluten proteins, which responds to a

withdrawal of wheat and other gluten-containing grains from the diet. This disorder has a variety of names, including celiac disease, nontropical sprue, idiopathic steatorrhea, adult celiac disease, and gluten-sensitive enteropathy, all of which describe the same disorder. The prevalence of this disorder in the population is unknown because individuals may have the lesion without any symptoms. The pathology, clinical features, and treatment are discussed in [Chapter 110](#).

When normal-appearing jejunal mucosa of celiac patients is exposed to gliadin, there ensues a rapid infiltration with inflammatory cells, damage and shedding of mature epithelial cells, compensatory proliferation of crypt cells, and an increased turnover of the epithelium. Crypt cells have poorly developed microvillus membranes, and they secrete rather than absorb fluids and electrolytes. The preponderance of crypt cells and deficiency of villus cells in the mucosa accounts for the deficient microvillus enzymes, poor nutrient absorption, net fluid secretion, and diarrhea of these patients. The exact pathogenesis of this abnormal response to gliadin is unknown. One theory postulates a missing intestinal peptidase and toxic damage by inadequately digested gliadin peptides, but there is little support for this idea. An immunologic pathogenesis is best supported by the evidence. An increase in IELs, particularly of bd T cells, is a characteristic feature of active celiac sprue. There is also an increase in lymphocytes, particularly CD4^+ T cells, and plasma cells in the lamina propria. Several immunologic abnormalities occur in celiac patients, including increased serum and mucosal antibodies to gliadin and increased serum antibodies to nongliadin antigens. Antibodies to certain autoantigens, such as connective tissue reticulin (endomysium), nuclear antigens, thyroid and parietal cells, also occur in these patients ([Table 114.1](#)). Although serum IgG anti-gliadin is more frequently elevated than IgA anti-gliadin, serum IgA anti-gliadin appears to be disease-specific and has been used as a screening test for celiac sprue. Serum antibodies to gliadin and to endomysium can be useful adjuncts for the diagnosis and follow-up of celiac sprue and are now available through commercial laboratories. Gliadin exposure has been shown to stimulate the release of cytokines by intestinal T cells of patients, indicating the presence of sensitized T cells in situ. The smallest gliadin peptide able to trigger the disease (ten amino acids long) is also the smallest size able to trigger sensitized T cells in vitro when presented in association with class II MHC antigens such as HLA-DR. The autoantigen recognized by antiendomysium has been identified as tissue transglutaminase. This enzyme may form a complex with glutamine-rich gliadin peptides, and the resulting complex may be the actual target of immune attack. Celiac sprue is strongly associated with class II HLA DR genes; 95% of patients carry two alleles (DQB1*0201 and DQA1*0501) that encode a specific DQ2 glycoprotein. This association implies that interactions between this HLA-DQ2 product and CD4^+ T cells are important in disease pathogenesis. Both B cells and T cells probably play a role in disease pathogenesis, in concert with a genetically determined susceptibility encoded at least in part by genes in the MHC.

Antibody	Sensitivity (%)	Specificity (%)
IgG anti-gliadin	90-100	60-90
IgA anti-gliadin	50-90	90-100
IgA anti-reticulin	25-50	98-100
IgA anti-endomysium	91-100	92-100

TABLE 114.1. SERUM ANTIBODIES USEFUL IN SCREENING FOR CELIAC DISEASE

The prognosis for most patients who are correctly diagnosed and appropriately treated is excellent. However, there are some serious complications that can develop in a minority of patients. Adult patients with celiac sprue have a higher incidence of primary small-bowel lymphoma and carcinoma than the population at large. Unexplained worsening of symptoms with abdominal pain, bleeding, or weight loss suggests this complication. It is unclear as to whether malignancy is less common in those adhering to a strict gluten-free diet, but it would seem best for the physician to assume so.

Ulcerative ileojejunitis may complicate celiac sprue; the major symptoms are abdominal pain, diarrhea, and intestinal bleeding. Intestinal obstruction or perforation not uncommonly complicates the course. Treatment with corticosteroids and immunosuppressives has been unsuccessful.

Refractory sprue is a rare occurrence in which patients no longer respond to gluten withdrawal, even though they did initially. Some of these patients may respond to treatment with corticosteroids or immunosuppressive drugs, such as azathioprine, but others pursue a relentlessly downhill course.

Collagenous sprue may represent a subset of refractory sprue; in this condition, collagen is deposited in the lamina propria beneath the epithelium, but the lesion otherwise is typical of celiac sprue. However, patients generally do not respond to gluten withdrawal or to other treatments, and their prognosis is poor.

Dermatitis herpetiformis is a skin disease that is closely linked to celiac sprue. It is an intensely itchy, chronic, usually papulovesicular eruption that occurs twice as often in males as in females and has a peak incidence in the second to fourth decades. Skin lesions tend to occur suddenly and are usually symmetrically distributed on the extensor surfaces, such as the knees and elbows, but also at other sites such as the scapula, sacrum, face, and scalp. It may occur in clusters, which explains its name but nongrouped lesions are also common. Mucous membrane lesions are uncommon. Healed lesions are often hyperpigmented and scarred. Intestinal biopsy reveals that most patients with dermatitis herpetiformis have a partial villus atrophy, similar to that seen in celiac patients, although the lesions tend to be patchy and less severe, and there are rarely any intestinal symptoms associated. Patients have an equally high incidence of the HLA-B8 DR3 haplotype, as do patients with celiac sprue. The intestinal and skin lesions respond to withdrawal of gluten from the diet.

The diagnosis is achieved by the characteristic clinical appearance and by biopsy. Histologically, the lesion is characterized by subepidermal vesicles due to neutrophil and eosinophil infiltration. Direct immunofluorescence reveals granular pockets of IgA1 at dermal papillary tips of involved and uninvolved skin. Complement components such as C3 are frequently found in the same areas as the IgA. These IgA1 deposits are possibly involved in the immunopathogenesis of the skin lesions, but the exact mechanism is unknown. The disease runs a long course, with spontaneous exacerbations and remissions. Rapid symptomatic relief of acute flares can be achieved with treatment with dapson or sulfapyridine. The optimal long-term treatment is a gluten-free diet, which has been shown to greatly or completely alleviate the skin lesions and decrease the IgA deposits in the skin, although the response can be delayed for 6 months or longer. The gluten-free diet also improves the intestinal lesions and theoretically reduces the risk of intestinal lymphoma, an occurrence that has been reported in patients with dermatitis herpetiformis.

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease are discussed in [Chapter 111](#).

COLLAGENOUS COLITIS/LYMPHOCYTIC COLITIS

Collagenous colitis is a clinicopathologic syndrome characterized by watery diarrhea and crampy abdominal pain, with a distinctive pathologic lesion consisting of a subepithelial collagen band, prominent chronic inflammatory cells in the lamina propria and epithelium, and damage of surface epithelium ([Fig. 114.3](#)). It afflicts middle-aged to elderly women predominantly, but it occurs sporadically in younger women and in men. Its pathogenesis is unknown but presumably represents an autoimmune process. There are significant associations with autoimmune thyroid disease and with enteropathic arthritis as well as sporadic associations with a variety of immune-mediated disorders. The colon mucosa appears normal to the endoscopist. Diagnosis requires colon biopsy; multiple biopsies should be taken proximal to the rectosigmoid regardless of endoscopic appearance because the lesion can be patchy. In some patients, a similar lesion can occur in the small bowel as well. A related condition, *lymphocytic colitis*, has only the increased chronic inflammation in lamina propria and epithelium but similar symptoms. Treatment is with antidiarrheal medications and a trial of sulfasalazine. Some cases may require a course of prednisone. A 2-month course of bismuth has been reported to benefit some patients.

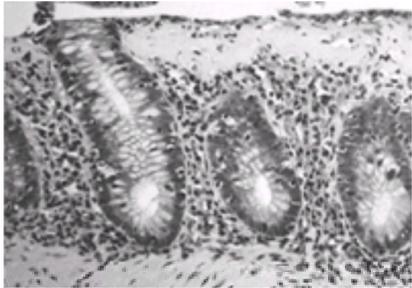

FIGURE 114.3. Features of collagenous colitis illustrated here include marked damage of surface epithelium (flattening), prominent subepithelial collagen band, numerous intraepithelial lymphocytes, and increased chronic inflammatory cells in the lamina propria. H&E, original mag $\times 3,200$. (From Lazenby AJ, Giardello FM. Collagenous and lymphocytic colitis. *Semin Colon Rectal Surg* 1993;4:84, with permission.)

INTESTINAL ALLERGY

Adverse reactions to foods are commonly reported by patients. There are multiple possible mechanisms for such reactions, only one of which is allergy. Food allergy or hypersensitivity has been defined as an immunologic reaction, usually IgE-mediated, resulting from the ingestion of food or a food additive. Allergic reactions to food are most common in infancy and early childhood, occur only in certain individuals, may be triggered by the ingestion of a small amount of the food, and are unrelated to any physiologic effect of the food or food additive. Symptoms tend to resolve with age despite continued exposure or reexposure to the offending food antigen and despite continued IgE reactivity to it, as evidenced by positive immediate skin test responses. The mechanisms for the remission of symptoms with age is unknown, but they probably account for the relative infrequency of allergic reactions to food antigens in adults. The clinical features of allergic reactions to foods are diverse, and the major manifestations often are outside the intestine, such as urticaria, tinnitus, serous otitis, asthma, and anaphylaxis. However, symptoms limited to the intestine, such as nausea, vomiting, diarrhea, and intestinal cramping, can also occur within a few hours of food ingestion. The pathogenesis of IgE-mediated food reactions is the same as that for other forms of allergy. The cross-linking of IgE molecules on the surface of mast cells by the allergen stimulates the release of potent mast cell mediators that cause vasodilatation and vasopermeability, stimulation of mucus production, smooth-muscle contraction, stimulation of pain fibers, and attraction of inflammatory cells. Patients may have noticed an association between the ingestion of a particular food and the acute onset of their symptoms, in which case the diagnosis is obvious. If the patient has not made any such association and particularly if the symptoms are chronic, the diagnosis relies on dietary manipulations in which various foods or food groups are removed from the diet. If the patient improves, the relevant foods are added back to the diet to determine whether the symptoms are reliably reproduced. If so, this indicates only that the patient is having an adverse reaction to food and not that the reaction is necessarily IgE-mediated. Demonstration of the latter requires some measure of the presence of IgE antibody specific for the food antigen by skin testing *in vivo* or by a number of *in vitro* assays. In selected instances, double-blind food challenges may be necessary to establish the diagnosis; this is the most rigorous but also the most cumbersome and least practical method of diagnosis. Biopsy of the intestine is only useful to exclude other diseases as a cause of symptoms. Pathologic analysis shows only edema of the mucosa, or the result is normal. When an adverse reaction to food is established, the differential diagnosis includes other forms of immunologic reaction (non-IgE-mediated), food poisoning, food idiosyncrasy, and pharmacologic and metabolic food reactions. Treatment consists mainly of avoidance of the food allergen.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis is an illness characterized by peripheral eosinophilia, infiltration of some part of the intestine with eosinophils, and gastrointestinal symptoms. Three clinical patterns have been identified, depending on which layer of the bowel wall is predominantly affected. The most common is mucosal involvement with variable degrees of malabsorption, intestinal blood loss, iron deficiency anemia, and hypoproteinemia secondary to protein-losing enteropathy. Symptoms are usually intermittent and include nausea, vomiting, diarrhea, and abdominal pain. A history of atopy and food intolerance is often obtained. Stools frequently contain occult blood and Charcot-Leyden crystals, a distinctive-appearing breakdown product of eosinophils. Eosinophilic infiltration is found readily on endoscopic biopsies. The diagnosis is based on the biopsy, the clinical history, and the eosinophilia. The differential diagnosis includes intestinal lymphoma, polyarteritis nodosa, regional enteritis, hypereosinophilic syndrome, and intestinal parasites; other causes of malabsorption and of protein-losing enteropathy may need to be considered in selected cases.

The second type of clinical presentation is one in which the deeper muscle layers are predominantly involved. The resulting thickening and rigidity of stomach or small bowel results in symptoms of gastric or small-bowel obstruction, such as nausea, vomiting, and crampy abdominal pain. In most patients, the process is limited to the antrum and pylorus. An allergic history and a history of food intolerance is common. The differential diagnosis includes infiltrating gastric carcinoma or lymphoma, Crohn's disease, polyarteritis, and eosinophilic granuloma. The diagnosis usually requires a full-thickness biopsy.

The third and least common presentation is predominant serosal involvement and eosinophilic ascites. The diagnosis is made by laparotomy by demonstration of a thickened serosa with eosinophilic infiltration. Although this and the other clinical patterns of the disease can occur alone, they not uncommonly overlap.

The pathogenesis of eosinophilic gastroenteritis is not well understood. Immunologic reactions to foods are postulated to account for about one-half of these patients. The treatment proceeds as for any allergic reaction to foods: identification and avoidance of the food responsible. The cause of the disease in the other one-half is unclear, but corticosteroid therapy seems beneficial for most patients.

IMMUNODEFICIENCY DISEASES

SEVERE COMBINED IMMUNODEFICIENCY

Severe combined immunodeficiency is a disease of infancy, and patients usually do not survive past 2 years of age unless they receive a bone marrow transplant or are given replacement therapy. They can have chronic diarrhea and malabsorption, which are usually of infectious origin, and candidiasis. These patients are extremely prone to infections, including enteric infections with *Salmonella*, *Shigella*, or enteropathogenic *Escherichia coli*. However, respiratory infections are always the greater clinical problem and the one to which the patient ultimately succumbs. Small bowel biopsy shows the absence of plasma cells, edema, blunted villi, crypt hyperplasia, a mononuclear infiltrate of the lamina propria, and periodic acid-Schill (PAS)-positive macrophages reminiscent of those seen in Whipple's disease. The defect is thought to be at the level of the bone marrow stem cell ([Table 114.2](#)), and the treatment usually is bone marrow transplantation.

Disease	Chromosome Site	Gene Product Encoded
X-linked agammaglobulinemia	Xq21.2-22	Btk, B-cell tyrosine kinase
Severe combined immunodeficiency		
X-linked	Xq13	Interleukin-2 receptor γ chain
Autosomal recessive	—	Adenosine deaminase, nucleoside phosphorylase
Hyper-IgM syndrome, X-linked	Xq26	CD40 ligand
Wiskott-Aldrich syndrome	Xp11, 23	Wiskott-Aldrich protein

TABLE 114.2. GENE MUTATIONS CAUSING SELECTED IMMUNODEFICIENCIES

X-LINKED AGAMMAGLOBULINEMIA (BRUTON'S)

Individuals with X-linked agammaglobulinemia show the early onset of recurrent bacterial infections associated with low or absent serum and secretory immunoglobulins, an absence of circulating B cells, and an absence of plasma cells in the gut or lymphoid tissues. Although the patients have recurrent respiratory infections with bacteria such as staphylococci, streptococci, and *Haemophilus influenzae*, these patients generally do not have clinically apparent gastrointestinal tract disease. They may rarely have chronic diarrhea, malabsorption, or bacterial overgrowth of the small intestine, and they occasionally may have infection with *Giardia* or rotavirus. The reasons for the relative absence of intestinal problems in this group are unclear.

COMMON VARIABLE HYPOGAMMAGLOBULINEMIA

Common variable hypogammaglobulinemia (CVH) is a heterogeneous group of disorders characterized by hypogammaglobulinemia, impaired ability to produce antibodies after challenge, and an increased incidence of infections. The age at onset, the clinical symptoms, and the pattern of immunologic deficiency are variable. The diagnosis requires an abnormally low level of two or more immunoglobulin isotypes. The T-cell defects may or may not be associated. Most patients have recurrent infections of the upper and lower respiratory tract with highly virulent encapsulated bacterial pathogens. Patients with CVH have a very high incidence of gastrointestinal abnormalities, including diarrhea in 60% and malabsorption in approximately 10% to 20%. Disaccharidase deficiency and protein-losing enteropathy also occur. Small-bowel biopsy shows markedly reduced numbers of plasma cells, and a variable number of patients have partial or complete villus atrophy which does not respond to gluten-free diet. Chronic infection with *Giardia lamblia* can occur in these patients and may be associated with a striking nodular lymphoid hyperplasia, which is evident on barium x-ray studies or endoscopy. CVH is frequently associated with atrophic gastritis, achlorhydria, and, in some cases, pernicious anemia. The latter is differentiated from classic pernicious anemia by an earlier age of onset, the absence of plasma cells from the gastric lamina propria, and the absence of antibodies to parietal cells or to intrinsic factor. Patients also have increased incidence of collagen vascular diseases and malignancy, especially reticuloendothelial neoplasms, although there is no increased incidence of primary lymphoma of the intestine. A subset of patients, perhaps 4% to 8%, can develop a segmental colitis resembling inflammatory bowel disease. Therapy is directed at treating various infections as they occur and employs chronic administration of intravenous g-globulins.

SELECTIVE IgA DEFICIENCY

Selective IgA deficiency is the most common immunodeficiency state of humans; it affects 1 of 500 to 3,000 persons in the general population. It is characterized by a deficient serum IgA level (<0.05 mg per milliliter) with normal or even elevated IgG or IgM levels. The continued production of secretory IgA in some patients and a compensatory increase in secretory IgM in others may explain why most patients with selective IgA deficiency remain well. The clinical syndrome is that of recurrent bronchopulmonary infection. Some of these symptomatic patients have a concomitant IgG subclass deficiency. Chronic infection with *G. lamblia* and nodular lymphoid hyperplasia are uncommon. There is an association of IgA deficiency with celiac sprue; such patients are clinically indistinguishable from other patients with celiac sprue and respond well to a gluten-free diet. This association may reflect a common genetic background; both conditions are associated with an increased frequency of HLA-B8. There is also an association between selective IgA deficiency and atrophic gastritis, pernicious anemia, and with other autoimmune diseases.

THYMIC APLASIA

Thymic aplasia (DiGeorge's syndrome) is a rare, congenital disorder with multiple abnormalities of structures derived from the embryonic third and fourth pharyngeal pouches, including facial abnormalities, congenital heart disease, and hypoplasia of the parathyroid and the thymus. The clinical features are dominated by hypocalcemia, congenital heart disease, and in those who survive the neonatal period, an increased susceptibility to infection. Gastrointestinal problems include chronic candidiasis, diarrhea, and malabsorption. Histologic examination of a small-bowel biopsy frequently yields abnormal results, revealing partial villus atrophy, crypt hyperplasia, and abnormal PAS-positive macrophages. The T-cell functions are markedly impaired; B-cell function is frequently normal, perhaps because of some residual helper T-cell activity. Treatment is largely supportive, but transplantation of a normal thymus can be helpful.

INTESTINAL LYMPHANGIECTASIA

Abnormalities of intestinal lymphatics in these patients result in protein-losing enteropathy, hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. The major clinical symptoms are diarrhea and edema, which begin in the first to third decades. Severe diarrhea with steatorrhea occurs in approximately 20% of patients. Chylous effusions occur in approximately 50%. A small intestinal biopsy shows dilated intestinal lymphatics, although these may occur only in a patchy fashion. The patients have reduced levels of serum immunoglobulins and reduced cellular immune responses, both of which result from excessive loss of immunoglobulin and lymphocytes into the intestinal lumen. The cause of the lymphatic abnormality is unknown. Similar intestinal lymphangiectasia can occur secondary to other diseases such as Whipple's disease, lymphomas, inflammatory states, congestive heart failure, and constrictive pericarditis. Patients have an increased incidence of tuberculosis but otherwise fare remarkably well against other types of pathogens. Treatment of the secondary lymphangiectasia is directed to the primary disease. A low-fat diet improves serum protein and lymphocyte levels in approximately half of patients.

AIDS

CD4⁺ helper T cells, the major target of HIV, are markedly depleted in the gut epithelium and lamina propria, as they are in other lymphoid tissues. This mucosal CD4 cell depletion is likely to have as profound an effect on mucosal immunity as it has on systemic immunity and to be a major factor in the large number of intestinal infections that occur in these patients. The damage done to the intestinal mucosa by the infections can result in malabsorption and malnutrition, which further reduce immune function, leading to chronic wasting and death.

Gastrointestinal symptoms are common in AIDS. The initial infection with HIV may be associated with a viral-like syndrome, including anorexia, nausea, vomiting, and diarrhea. Diarrhea is often prominent in patients after the disease is well established and may represent the major clinical problem. The diarrhea is frequently caused by infection with any of a variety of opportunistic protozoal, viral, bacterial, or fungal pathogens. The diagnosis of such infections is accomplished by stool culture, examination of the stools for ova and parasites, and gastrointestinal biopsy. The most common agents are *Entamoeba histolytica*, *G. lamblia*, cytomegalovirus, herpes simplex, *Candida*, *Salmonella typhimurium*, *Mycobacterium avium complex*, and *Cryptosporidium*.

Although diarrhea usually results from infection with one or more of the pathogens previously described, diarrhea occurs in some patients in the absence of any identifiable infection. This diarrhea is frequently accompanied by steatorrhea, weight loss, and malnutrition. Intestinal biopsies are abnormal; jejunal biopsies show partial villus atrophy, crypt hyperplasia, and increased numbers of IELs. Rectal biopsies indicate focal crypt epithelial cell degeneration (i.e., apoptosis) and frequently show viral inclusions. The cause of this AIDS-associated enteropathy is unknown, but viral infection and local autoimmune reactions have been proposed. Treatment is supportive, with particular attention paid to correction of nutritional deficits.

AIDS patients can develop Kaposi's sarcoma, an angioproliferative disorder thought to be of endothelial cell origin. The gastrointestinal tract is involved in about one-half of patients, almost always in association with oral or skin lesions. The flat to nodular vascular lesions are usually submucosal but sometimes extend into the mucosa and become ulcerated. Intestinal bleeding may occur. Most patients succumb to infection rather than to the tumor itself. Treatment with chemotherapy can relieve symptoms but has not been shown to enhance survival.

CHAPTER 115: UPPER GASTROINTESTINAL NEOPLASMS

ANIL K. RUSTGI

[Cancer of the Esophagus](#)
[Esophageal Adenocarcinoma](#)
[Benign Esophageal Tumors](#)
[Summary and Future Directions](#)

This chapter encompasses the salient features of the common benign and malignant esophageal, gastric, and small intestinal neoplasms. Upper gastrointestinal (GI) neoplasms are common in the United States but are even more so worldwide.

CANCER OF THE ESOPHAGUS

SQUAMOUS CELL CARCINOMA

Esophageal squamous cell carcinoma is the most common esophageal malignancy worldwide, although there is great geographic variation. Worldwide incidence is 2.5 to 5.0 for men and 1.5 to 2.5 for women per 100,000 population. However, high incidence areas, which include China, India, Iran, regions around the Caspian Sea, and South Africa, have rates exceeding 100 per 100,000 population. In the United States, African Americans have a four- to fivefold increased risk compared to white Americans. There is also an increase with each decade of life after age 40. It is a cancer that is more common in men than women regardless of ethnicity and age.

ETIOLOGIC FACTORS AND PREDISPOSING CONDITIONS

The geographic variation in esophageal squamous cell carcinoma strongly hints at the contribution of environmental factors or the interplay of environmental and acquired genetic factors. Tobacco and alcohol are the greatest risk factors for esophageal squamous cell carcinoma in North America and Western Europe. While often patients may have excessive intake of tobacco and alcohol together, studies have established that tobacco and alcohol act independently as risk factors. At the same time, there is a large increase in risk with patients who consume both tobacco and alcohol, with the amount and duration of use as critical parameters.

Vitamin and trace mineral deficiencies are crucial as risk factors. Vitamins A, C, and E demonstrate antioxidant effects. Certain trace elements, such as selenium, molybdenum, and zinc, show an inverse association with mortality from esophageal cancer mortality in high-incidence areas. Achalasia is a predisposing risk factor as there is a 5% prevalence of patients with achalasia of long-standing duration that ultimately develop esophageal squamous cell carcinoma. The interval from symptomatic achalasia to esophageal cancer is about 20 years, although the relative risk is unclear.

Patients with head and neck squamous cell carcinoma are at an increased risk for the development of esophageal cancer, which probably reflects the fact that patients with both cancers use tobacco and alcohol. Synchronous or metachronous esophageal cancers may develop at an annual rate of approximately 5% in patients with head and neck squamous cell cancer. A genetic predisposition to esophageal cancer is rare but is noteworthy in the condition of tylosis palmaris, an autosomal dominant disorder that involves hyperkeratosis of palms and soles. Such patients are predisposed to esophageal squamous cell carcinoma and oropharyngeal leukoplakia, especially by age 45. Other factors implicated in the pathogenesis of esophageal squamous cell cancer include chronic lye ingestion, exposure to ionizing radiation, celiac sprue, human papillomavirus infection, Plummer–Vinson syndrome, esophageal diverticula, and hot maté drinking.

PATHOLOGIC FACTORS

Early esophageal cancer, while not usual in the United States, may be superficial and manifest as an ulcer, plaque, or small polypoid lesion. Discrimination between early cancer and contiguous normal squamous mucosa may be enhanced by employing vital staining dyes such as toluidine blue or Lugol's iodine solution, which stain normal mucosa only. Advanced esophageal squamous cell cancers are invariably fungating, ulcerated, and sometimes annular. Submucosal invasion may produce nodules that are friable and may cause strictures. The vast majority of squamous cell cancers are found in the proximal to mid-esophagus.

PATHOGENESIS

The progression from normal squamous mucosa to epithelial dysplasia and eventually to cancer is the hallmark of esophageal squamous cell cancer. However, dysplasia may or may not be present at the time of pathologic analysis. Tobacco tars and cigarette smoke contain various chemical carcinogens, such as aromatic amines, *N*-nitroso compounds, and polycyclic aromatic hydrocarbons. In addition, alcohol may contain constituents that are directly or indirectly carcinogenic. Ethanol itself may facilitate the absorption of other carcinogens. Exposure of the squamous mucosa to high concentrations of combinations of carcinogens over a long period of time likely results in mucosal injury. Genetic alterations may accrue as a result, predisposing to malignant transformation. Frequent genetic alterations include cyclin D₁ oncogene amplification and *p53* tumor suppressor gene mutation. Animal models have been helpful to elucidate underlying molecular mechanisms. In this context, rats that are administered nitrosoamines can develop esophageal papillomas and squamous cancer. Transgenic mice with overexpression of the cyclin D₁ oncogene targeted specifically to the oral–esophageal epithelium develop severe dysplasia, a precursor to cancer.

CLINICAL FEATURES AND NATURAL HISTORY

Early esophageal squamous cell carcinoma may or may not be associated with symptoms. Growth of cancer is manifest by dysphagia as well as odynophagia. Nausea, vomiting, and hematemesis may result. Anorexia and weight loss may ensue from malnourishment. Mediastinal involvement by the cancer is suggested by retrosternal pain or radiation of pain to the back. Other symptoms may include cough, hoarseness, and bone pain. Cough may be the result of aspiration pneumonia or, rarely, tracheoesophageal fistula. Hoarseness is due to recurrent laryngeal nerve involvement. Skeletal metastases may cause bone pain. Esophageal cancer usually presents in an advanced stage. Unfortunately, about 75% of untreated patients succumb to disease within a year. The average survival of untreated patients with advanced cancer is approximately 9.5 months.

DIAGNOSIS

Evaluation involves by establishment of tissue diagnosis followed by staging and therapeutic planning. Initial diagnostic tests usually entail barium swallow supplemented with a tablet and flexible fiberoptic endoscopy. Staging involves computed tomography (CT) scan, endoscopic ultrasonography, and radionuclide bone scan. Bronchoscopy should be considered if tracheal invasion is suspected.

Barium swallow x-rays are useful in the evaluation of dysphagia. The radiologic appearance of early esophageal cancer may consist of a granular mucosal appearance with ulcerations. A polypoid, infiltrative, or ulcerative appearance can be the distinguishing features of advanced esophageal cancer. However, ultimately the accurate diagnosis of esophageal cancer requires endoscopy with biopsy/cytology. Multiple biopsies will increase the diagnostic yield in up to 96% of cases.

High-incidence areas, such as northern China, merit endoscopic screening in the general population. Screening in high-risk areas of China has been effective; 5-year survival was nearly 90% after operative resection for cancer cases detected. However, general screening in the United States is not feasible for esophageal squamous cell carcinoma given the lack of cost-effectiveness. Screening should be undertaken in patients with tylosis, achalasia, and head and neck cancer, perhaps every 1 to 2 years.

After diagnosis is established, staging of the cancer is necessary in order to optimize treatment options and management ([Table 115.1](#)). CT of the chest and abdomen is useful for lymph node, pulmonary and hepatic involvement. Endoscopic ultrasonography is particularly helpful in assessing depth of esophageal invasion and local lymph node involvement. Bone scan may be necessary to rule out bone metastasis.

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
Lymph Node (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
Distant Metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

TABLE 115.1. TNM STAGING SYSTEM FOR CANCER OF THE ESOPHAGUS

TREATMENT

Advanced esophageal cancer makes curative surgical resection difficult, if not impossible. Although nearly 60% of patients may be surgically explored, only two-thirds of such patients undergo resection. Thus, a total of 40% of patients will require palliative therapy. Overall, 1- and 5-year survival rates are approximately 18% and 5%, respectively.

Curative surgical resection remains the key for esophageal cancer. Surgical approaches include transthoracic esophagectomy, transhiatal esophagectomy, and, to a lesser extent, en-bloc resection for cancers of the distal esophagus and the cardia. An additional consideration is selection of esophageal replacement with stomach, colon, or jejunum.

Surgery alone may be curative in more than 60% of diseases in patients with T1 or T2 (N0 M0) lesions. For patients with locally advanced disease and good performance status, many expert centers recommend neoadjuvant chemotherapy and radiation therapy followed by surgical resection. Neoadjuvant chemotherapy or radiation therapy alone does not appear to yield any survival advantages, and combination neoadjuvant therapy requires further evaluation.

Advanced disease often dictates palliative approaches with simultaneous meticulous attention to nutrition and analgesia support. Palliative measures include external-beam radiation therapy, brachytherapy, endoscopic dilatation with insertion of expandable metal stents, endoscopic laser treatment, and photodynamic therapy.

Key prognostic factors include performance status, presence or absence of aneuploidy, and cyclin D₁ oncogene amplification; aneuploidy and cyclin D₁ gene amplification are poor prognostic parameters. Ultimately, selection of patients for neoadjuvant therapy will be influenced by identification of key clinical and biologic parameters.

ESOPHAGEAL ADENOCARCINOMA

Barrett's esophagus is an important precursor to esophageal adenocarcinoma. In addition, many adenocarcinomas of the gastric cardia may arise in short segments of Barrett's metaplasia. The incidence of esophageal adenocarcinoma, as well as adenocarcinoma of the gastric cardia, has increased at a rate of 4% to 10% annually over the past decade.

EPIDEMIOLOGIC FACTORS

The annual age-adjusted incidence rates of adenocarcinoma of the esophagus and gastric cardia in white men is 1.3 and 2.8 per 100,000, respectively, and is more common than in women. The incidence increases with each decade after age 40. The incidence of adenocarcinoma arising in Barrett's esophagus varies but may approach 500 cases per 100,000. This figure corresponds to nearly a 125-fold increased risk when compared to the general population in the United States. The prevalence of adenocarcinoma at the time of initial diagnosis of Barrett's esophagus is approximately 8%. The reason for the rapid increase in incidence of these two cancers is unknown but may be attributable to the rise in Barrett's esophagus and gastroesophageal reflux disease, and possible increasing eradication of *Helicobacter pylori* infection.

ETIOLOGIC FACTORS AND PREDISPOSING CONDITIONS

Barrett's esophagus encompasses metaplastic change from normal esophageal squamous epithelium to intestinalized columnar epithelium. As a premalignant condition, it is the most important risk factor for esophageal adenocarcinoma. It is conceivable that cigarette smoking and alcohol may be important once Barrett's esophagus has developed, but this is not established. Patients with Barrett's esophagus are identified at an average age of 55 years. It typically affects whites, a feature shared with esophageal adenocarcinoma. Chronic gastroesophageal reflux disease plays a role in the development and progression of Barrett's esophagus, but clearly other factors are important. Patients with cystic fibrosis and scleroderma may be at increased risk for Barrett's esophagus.

PATHOLOGIC FACTORS

Barrett's esophagus is distinguished by an intestinal columnar epithelium. A salient feature is the presence of goblet cells that can be histologically confirmed with Alcian blue stain. Various intestinal markers, such as villin and sucrase-isomaltase, among others, have been found to be increased in Barrett's esophagus. Barrett's metaplasia can progress to dysplasia, either low grade or high grade, which is the immediate precursor to carcinoma in situ and carcinoma. Esophageal adenocarcinoma is more likely to arise in long-segment Barrett's esophagus (more than 3 cm above the gastroesophageal junction) than in short-segment Barrett's esophagus (less than 3 cm), although the latter is definitely documented. Esophageal adenocarcinoma may have different stages of differentiation and grow longitudinally to the proximal esophagus and/or the proximal esophagus, thereby making classification of this cancer and gastroesophageal junctional adenocarcinoma difficult.

PATHOGENESIS

The transition of Barrett's metaplasia to adenocarcinoma involves progression through low-grade dysplasia, high-grade dysplasia, and carcinoma in situ. While gastroesophageal reflux may play a role, suppression of acid secretion does not ameliorate the progression of disease. Some investigators advocate the notion that bile reflux may be contributory, as demonstrated in a rodent model of esophagojejunostomy. The molecular mechanisms underlying the sequence of changes in Barrett's esophagus are being elucidated. Seminal studies have demonstrated that abnormal DNA content, as reflected by aneuploidy measured through flow cytometry, is associated with dysplasia and adenocarcinoma. Additionally, *p53* tumor suppressor gene mutations, *p16* tumor suppressor gene alterations by virtue of mutation or promoter hypermethylation, and microsatellite DNA instability are all important genetic alterations.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Early esophageal adenocarcinoma may be silent or a consequence of gastroesophageal acid reflux disease and its complications, such as ulcers and stricture. Symptoms attributable to advanced esophageal adenocarcinoma include dysphagia, odynophagia, weight loss, chest pain, nausea, vomiting, cough, and GI bleeding.

Only a subset of Barrett's patients develop adenocarcinoma. Most esophageal adenocarcinomas have high-grade dysplasia in the surrounding mucosa. Patients with low-grade dysplasia may progress or regress at follow-up. However, patients with high-grade dysplasia who undergo esophagectomy may have foci of adenocarcinoma in nearly one-third of resected specimens. Esophageal adenocarcinoma can spread through the esophageal wall or metastasize to lymph nodes,

lungs, or liver, among other structures. The prognosis is poor without treatment in a manner reminiscent of that for esophageal squamous cell cancer.

DIAGNOSIS

The squamocolumnar junction is displaced proximally in Barrett's esophagus and encompasses the junction between the stratified squamous epithelium and specialized metaplasia. The mainstay of diagnosis is endoscopy with confirmation of Barrett's esophagus by histopathologic examination demonstrating the intestinal columnar epithelium with goblet cells. Barium swallow x-ray may be useful in assessing esophageal motility, but more importantly, if there is mucosal irregularity or stricture present. Also, since scleroderma may be complicated by Barrett's esophagus, barium swallow x-rays may be helpful. The development of early esophageal cancer may be manifest by superficial erosions, nodules, or plaques superimposed on Barrett's esophagus, and therefore the index of suspicion must be high to warrant directed biopsies. Progression of cancer is associated with polypoid mass, ulcerated mass, as well as stricture formation. The approaches to staging of esophageal adenocarcinoma are the same as that for esophageal squamous cell cancer with endoscopic ultrasonography and CT scan.

In contrast to screening for esophageal squamous cell cancer in the United States, screening for Barrett's esophagus is of paramount importance. While there remains controversy as to the appropriate frequency of endoscopic screening, certain principles nonetheless prevail. Barrett's metaplasia likely requires endoscopy every 3 years; Barrett's esophagus with low-grade dysplasia merits endoscopy every 6 months for a year and, if stable, annually thereafter; and finally, the finding of high-grade dysplasia requires repeat endoscopy in a month. If high-grade dysplasia is reconfirmed, then esophagectomy should be recommended when appropriate.

THERAPY

Since the 5-year survival for esophageal adenocarcinoma is less than 10%, early diagnosis is imperative; moreover, detection of dysplasia in Barrett's esophagus carries even greater importance. Adenocarcinoma necessitates surgical resection, assuming that the patient is an appropriate candidate and there is no distant metastatic disease. The entire Barrett's segment should also be removed, given the propensity for contiguous dysplastic lesions and synchronous cancers. Recently, the potential of multimodal therapy has been investigated. Neoadjuvant or preoperative therapy may have a beneficial role. For instance, when patients were randomized to receive 5-fluorouracil and cisplatin chemotherapy before surgery, median survival improved from 11 to 16 months compared to surgery alone. Significantly, 3-year survival was 32% in the chemotherapy and surgery arm versus surgery alone, where it was less than 10%. Radiation therapy alone, in the neoadjuvant or adjuvant setting, has not been demonstrated to be efficacious as of yet. Patients who cannot undergo surgical resection due to poor performance status or the coexistence of mitigating comorbid illnesses are candidates for palliative approaches as outlined for esophageal squamous cell cancer.

BENIGN ESOPHAGEAL TUMORS

Leiomyomas are the most common benign esophageal tumors. Men are affected more commonly than women. Typically solitary, leiomyomas are submucosal with smooth overlying mucosa and higher occurrence in the distal esophagus. Squamous cell papillomas are usually discovered incidentally. They are typically small, sessile, and polypoid. Histologically, they are characterized by a papillated appearance. Other benign tumors include granular cell tumor, fibrovascular polyps, hemangiomas, lymphangiomas, lipomas, and fibromas.

GASTRIC CANCER

The most common gastric cancer is adenocarcinoma, with lymphomas and leiomyosarcomas as less common types. Benign neoplasms are rare.

Epidemiologic Factors

While there is geographic variation in the incidence of gastric cancer worldwide, there is a greater incidence in developing nations. Individuals who emigrate from high-risk areas to low-risk or low-incidence areas keep the risk of their original country. This has been observed in people emigrating from South America to the United States or from Japan to Hawaii. The annual incidence of gastric cancer in the United States is 10.9 per 100,000 among men and 5.0 per 100,000 among women. This has been decreasing steadily from the 1930s when gastric cancer was more common, although gastroesophageal junctional cancers have been increasing recently.

Etiologic Factors and Predisposing Conditions

For decades the focus has been on the role of dietary factors. Diets rich in salt—especially fish, meats, and pickled foods—as well as carbohydrates appear to predispose to gastric cancer. *N*-Nitroso compounds can form in the stomach by nitrosation of ingested nitrates, which are common in diet. It is felt that salt is a cocarcinogen.

Apart from dietary factors, there are a number of conditions that predispose to gastric cancer ([Table 115.2](#)). These include pernicious anemia, the stomach remnant S/P subtotal gastrectomy for benign disease, Ménétrier's hypertrophic gastropathy, chronic atrophic gastritis with intestinal metaplasia, gastric adenomatous polyp, and chronic gastric ulcer. In particular, the intestinal type of gastric cancer is often associated with chronic atrophic gastritis and intestinal metaplasia. It has also been demonstrated that in high-incidence areas of gastric cancer, superficial gastritis occurs early in childhood, and this likely progresses to chronic atrophic gastritis with intestinal metaplasia by adulthood. The discovery that *H. pylori* causes gastritis led to the supposition that *H. pylori* was related to gastric carcinogenesis. This was substantiated by studies in which individuals who were seropositive for *H. pylori* infection had a much higher incidence of gastric cancer than seronegative individuals. This risk was determined to be a three- to sixfold increase for patients with *H. pylori* infection. It also was found that families from developing nations who were of low socioeconomic status and lived under crowded conditions had higher *H. pylori* infection rates, especially during childhood.

Nonfamilial:
Chronic gastritis, especially chronic atrophic gastritis
Intestinal metaplasia
Gastric adenomatous polyp
Postgastrectomy stump
Gastric epithelial dysplasia
Ménétrier's disease
Chronic peptic ulcer
Familial:
Family history of gastric cancer
Hereditary nonpolyposis colorectal cancer type II
Blood group A

TABLE 115.2. CONDITIONS THAT PREDISPOSE TO GASTRIC ADENOCARCINOMA

Pathologic Factors

Adenocarcinoma accounts for nearly 95% of all gastric cancers; the remainder are lymphomas (see later section) and sarcomas. Depth of invasion is a key prognostic factor for gastric adenocarcinoma. In this context, when limited to mucosa or submucosa, there is a favorable prognosis. Grossly, gastric adenocarcinomas may be either fungating or polypoid masses or, alternatively, ulcerating. Importantly, these tumors may infiltrate adjacent structures. Other types of gastric adenocarcinomas requiring attention are linitis plastica and the superficial type. The linitis plastica lesion, found in up to 10% of gastric adenocarcinomas, is due to an infiltrating tumor comprising anaplastic cells that evoke a desmoplastic response. Since spread is throughout the stomach, the result is a nondistensible stomach that can be appreciated radiographically and endoscopically. Unfortunately, metastasis is common. In contrast, superficial tumors are limited to the mucosa and spread laterally, thereby making resection more plausible.

While there are several histologic classifications of gastric adenocarcinoma, the Lauren classification is the most commonly accepted. It divides gastric

adenocarcinoma into the following: (a) an *intestinal* (because it resembles intestinal carcinoma), well-differentiated type; and (b) a *diffuse*, infiltrating, poorly differentiated type that carries a worse prognosis. The intestinal type was noted to be more prevalent among male individuals, among older individuals, and in the setting of intestinal metaplasia, whereas the diffuse type occurred more commonly in younger individuals. The most common type in populations with a high incidence of gastric cancer, such as that seen in developing countries, was intestinal. In addition, the intestinal type is typically a fungating or polypoid mass, and is associated with *H. pylori* infection. The worldwide decline in gastric cancer suggests that the intestinal type of gastric cancer, which accounts for the majority of gastric tumors, results mainly from environmental causes. In contrast, diffuse-type gastric cancer, with its proclivity for younger individuals, its association with blood group A, and its similar incidence in high- and low-risk areas, most likely is controlled to a larger extent by genetic factors than by environmental factors. Nearly 50% of gastric adenocarcinomas are in the gastric antrum or pylorus, and the remainder are found more proximally. Recently, there has been a dramatic increase in these cancers in the cardia and the gastroesophageal junction, although not in association with *H. pylori* infection.

Pathogenesis

The mechanism by which *H. pylori* predisposes to gastric cancer has not yet been elucidated. However, several mechanisms have been postulated. *H. pylori* bacteria harbor several virulence factors, especially urease, which produces ammonia. These factors damage the gastric mucosa that is exacerbated by the host immune response to the infection. Prolonged infection with *H. pylori* results in insidious destruction of the gastric mucosa leading to atrophic gastritis, with the subsequent development of intestinal metaplasia. It is likely that ingested nitrites that are converted to nitrates augment abnormal cellular proliferation. Independently, *H. pylori* infection may also contribute to abnormal cell proliferation, thereby leading to DNA damage. Among the key genetic alterations in gastric carcinogenesis are abnormalities in growth factors (e.g., transforming growth factor α , K-sam), the *p53* tumor suppressor gene, and the phenomenon of microsatellite DNA instability.

Animal models have proved to be useful in recapitulating gastric cancer. A high rate of induction of gastric adenocarcinoma was first accomplished in rats with the nitrosamine *N*-methyl-*N*-nitro-*N'*-nitrosoguanidine (MNNG). Since then, *N*-methyl-*N*-nitrosourea (MNU) has been infused into the mouse glandular stomach and yielded gastric adenocarcinoma. Recently, transgenic mouse models have been developed in which transforming growth factor–overexpressing transgenic mice develop a hypertrophic gastropathy resembling Me(c)ne(c)trier's disease. Additionally, with *Helicobacter* inoculation into *p53*-deficient mice, there is acceleration of gastritis.

Clinical Features and Natural History

Gastric cancer in its earliest stages is usually not accompanied by symptoms. However, more typically, the cancer is either locally advanced or metastatic. The most common symptoms are weight loss, abdominal pain, nausea, anorexia, dysphagia, melena, early satiety, and ulcer-type pain. Gastric cancer has a poor prognosis if left untreated, and even intervention occurs when the disease is advanced. It can spread transmurally to local lymph nodes, and distantly to lungs, liver, and bone. Specialized instances include palpable supraclavicular lymph node (Virchow's node) and spread to ovaries (Krukenberg's tumor).

Diagnosis

The diagnosis of a luminal mass by upper GI radiography or fiberoptic endoscopy is straightforward. All suspicious lesions require biopsies for histopathologic analysis. Areas of abnormalities in the setting of intestinal metaplasia merit close scrutiny to detect early gastric cancer. Generally speaking, gastric ulcers should be biopsied as well. If benign, there will be chronic inflammation; however, atypia may be due to inflammation. The presence of malignant cells underscores the diagnosis of gastric cancer. Repeat biopsies may be necessary to resolve ambiguity. Benign gastric ulcers are much more common than gastric cancer arising in the ulcer. Ulcers may also arise from other causes, such as ethanol- or nonsteroidal anti-inflammatory drug–mediated injury.

It is important to distinguish masses or ulcers from submucosal lesions, such as leiomyomas or carcinoids, as biopsy may not be capable of diagnosing the submucosal lesions. Upon diagnosis of gastric cancer, other modalities should be employed to gauge penetration and extent of disease (Table 115.3). In this context, endoscopic ultrasonography can assess depth of invasion and CT scan can allow for determination for local and distant metastases. Apart from spread to lymph nodes, lungs, and liver, gastric adenocarcinoma can also metastasize to bone, thereby warranting bone scan under certain circumstances.

TABLE 115.3. STAGING OF GASTRIC CARCINOMA

A controversial topic in the United States is the use of screening for gastric cancer in patients with chronic atrophic gastritis or intestinal metaplasia. It is generally not done given the low incidence of disease in this population. However, patients who have under undergone gastric cancer surgery or who have dysplasia should be enrolled in screening and surveillance endoscopy. Since patients who have had a subtotal gastrectomy for benign ulcer disease are at increased risk for gastric cancer, they should be subjected to screening for gastric cancer, but only after 15 to 20 years has passed since the initial surgery. In contrast, screening endoscopy for gastric cancer in Japan is prevalent.

Treatment

The only chance for cure of gastric adenocarcinoma is surgical resection, but this is in the setting of disease being limited to the stomach. The vast majority of patients present with extension to lymph nodes and adjacent organs or spread to distant organs, thereby obviating the need for curative surgical resection. It should be noted that surgery for early gastric cancer carries a very favorable prognosis, approaching a 5-year survival of 80% to 90%. Recently, endoscopic mucosal resection has gained attention, especially in Japan.

The surgical approach for distal gastric adenocarcinoma involves subtotal gastrectomy and may be accompanied by extensive lymphadenectomy (the latter recommended by Japanese surgeons). If the gastric adenocarcinoma has invaded adjacent organs, removal of those organs may be required. Proximal tumors require total gastrectomy with distal pancreatectomy and splenectomy. Limited gastric surgery is pursued for excessive hemorrhage or obstruction. The 5-year survival rate in the United States is about 15% for all gastric cancers.

While GI tumors in general are not responsive to chemotherapy, gastric cancer may be sensitive. Partial response rates approaching 20% to 30% may be evident with single agents, such as doxorubicin, mitomycin C, and 5-fluorouracil. This may be increased with combinations of chemotherapeutic agents, without necessarily prolonging survival. Radiation therapy is largely ineffective and palliative. The results of combination chemotherapy and radiation require long-term study. Terminally ill patients may benefit from palliative measures such as laser treatment or prosthesis placement with the intent of maintaining lumen patency.

BENIGN GASTRIC NEOPLASMS

Recognition of benign gastric neoplasms is important to avoid unnecessary therapeutic interventions. Chief among this category are submucosal leiomyomas, which are typically in the middle to distal stomach. They may grow into the lumen with ulceration and bleeding. They can also grow into the serosa, leading to compression. On upper GI series radiographs, leiomyomas are smooth with an intramural filling defect. Endoscopic examination reveals overlying mucosa, and biopsies may not be

diagnostic. Bleeding leiomyomas should be surgically removed.

Gastric polyps may be predominantly either adenomatous or hyperplastic. Adenomas are usually found in middle-aged to elderly patients. They carry a low likelihood of becoming gastric cancer but can nonetheless progress to that stage through the intermediate dysplastic state. Gastric adenomas may be associated with familial adenomatous polyposis, an inherited syndrome with autosomal dominant mode of inheritance. In general, gastric adenomas are benign, but they may ulcerate and bleed. They may be suspected or inferred on upper GI radiography, but confirmation requires endoscopy. Whether sessile or pedunculated, polypectomy is predicated by size and bleeding.

Other benign gastric neoplasms include lipoma, carcinoid, neurofibroma, lymphangioma, and hamartoma.

GASTRIC LYMPHOMA

The stomach is the most common extranodal site for lymphoma and represents over half of all GI lymphomas ([Table 115.4](#)), typically non-Hodgkin's lymphoma. Gastric lymphoma may be associated with chronic atrophic gastritis and intestinal metaplasia. Although symptoms and signs are reminiscent of gastric adenocarcinoma, diagnosis of lymphoma is imperative because 5-year survival is much better, approaching 50%.

Low grade of mucosa-associated lymphoid tissue
Mediterranean lymphoma
Malignant lymphoma, centrocytic
Burkitt-like lymphoma
T-cell
EATL
Non-EATL

EATL, enteropathy-associated T-cell lymphoma.

TABLE 115.4. GASTROINTESTINAL LYMPHOMAS

Gastric lymphoma may present as an ulcer or ulcers, or as a submucosal lesion; endoscopic biopsy is critical. Apart from conventional histopathologic examination, immunoperoxidase staining of lymphoid markers is helpful. Treatment involves surgical resection, the extent of which is predicated on location of disease. Radiation therapy and chemotherapy are necessary (4,000 cGy to the upper abdomen and 2,000 cGy to the liver). Long-term survival approaches 80% when disease is limited to the stomach. Lymph node involvement requires combination chemotherapy and radiation therapy with careful attention to perforation and tumor lysis. However, disseminated disease merits particular focus on chemotherapy, with radiation therapy reserved for debulking large lesions.

An important gastric lymphoma subtype is mucosa-associated lymphoid tissue (MALT) lymphoma. MALT lymphoma is a low-grade B-cell lymphoma that is associated with chronic *H. pylori* infection. There have been reports of regression of MALT lymphoma with eradication of *H. pylori* infection, however, this should not supplant careful deliberation about radiation therapy and chemotherapy.

SMALL INTESTINAL CANCER

Malignancies in the small intestine are rare but primarily include adenocarcinomas, lymphomas, leiomyosarcomas, and carcinoids.

Adenocarcinoma

Nearly 50% of small intestinal malignancies are adenocarcinomas and predominantly occur in the duodenum and proximal jejunum. Predisposing conditions include familial adenomatous polyposis (especially around the ampulla of Vater in up to 12% of patients), hereditary nonpolyposis colorectal cancer type II, Crohn's disease, and celiac sprue. In familial adenomatous polyposis, small intestinal adenomas are usually proximal and, as indicated, in or around the ampulla of Vater, perhaps reflecting the potential synergy between a hyperproliferative mucosa and exposure to bile. Distal polyps in the jejunum and terminal ileum are unusual. Hereditary nonpolyposis colorectal cancer, another inherited form of colon cancer, can be associated with extracolonic cancers, especially endometrial, ovarian, gastric, renal, bladder, and pancreatic; recently, small intestinal adenocarcinoma as a manifestation has also been acknowledged. Adenocarcinoma complicating Crohn's disease can be difficult to diagnose due to underlying inflammation but should be suspected if stricture or obstruction is present. Nonetheless, it may be found incidentally. Celiac sprue can be complicated by malignancy, especially adenocarcinoma or lymphoma, apart from jejunal ulceration and stricture. For both Crohn's disease and celiac sprue, it is likely that adenocarcinoma of the small intestine could develop with long duration of disease.

If a patient is discovered to have small intestinal adenocarcinoma, it should be surgically resected. Unfortunately, chemotherapy and radiation therapy offer little promise. After resection, it would be prudent to survey with small-bowel follow-through x-ray film series or enteroclysis to monitor for potential recurrence. Small-bowel endoscopy, while advisable for any suspicious lesions or areas, is not necessarily feasible if the lesion is inaccessible to this approach.

Lymphoma

The small intestine is the second most common site (after stomach) for GI lymphomas, most of which are non-Hodgkin's type. Of these, nearly 60% are diffuse histiocytic lymphomas. The disease may be focal or diffuse. Typical symptoms are diarrhea, steatorrhea, and/or abdominal pain or obstruction. Lymphomas complicating celiac sprue are generally of the T-cell type. A variant of small intestinal lymphomas is Mediterranean lymphoma, which comprises malabsorption in association with a-chain protein in the serum. One should also be wary of small intestinal lymphomas in patients with AIDS.

When localized to the small intestine, lymphoma should be treated with radiation therapy at a dose of 3,500 to 4,000 cGy. The response is often excellent, with cure possible in up to 75% of patients. However, lymph node involvement decreases the response rate to radiation. Therefore, combination chemotherapy should be added involving such agents as cyclophosphamide, doxorubicin, vincristine, and prednisone. Surgical resection is helpful for obstructing or bleeding lesions. Undifferentiated as well as Burkitt's lymphomas require more aggressive combination therapy. The overall response of small intestinal lymphoma is contingent on histologic profile and stage, but survival ranges from 40% to 60% at 2 years.

Carcinoid Tumor

Carcinoid tumors may occur in the small intestine, especially in the terminal ileum and appendix. The syndrome is present in the face of liver metastasis. The details of carcinoid tumor and syndrome are discussed in [Chapter 118](#).

Other Neoplasms

Rare malignant small intestinal neoplasms include leiomyosarcomas and neurofibrosarcomas. Benign lesions include leiomyoma, lipoma, lymphoid hyperplasia, neurofibroma, and lymphangioma.

SUMMARY AND FUTURE DIRECTIONS

Esophageal, gastric, and small intestinal neoplasms, both benign and malignant, are important in the United States and worldwide from epidemiologic, diagnostic, and therapeutic perspectives. In particular, the progression from Barrett's esophagus to esophageal adenocarcinoma has received much attention in the United States.

Advances are being made through an understanding of underlying molecular mechanisms, through the employment of cell culture techniques and animal models, and through correlation of genetic and biochemical alterations with stage of disease. Ultimately, these will translate into improvements in chemoprevention with the focus on premalignant lesions, such as esophageal squamous dysplasia, Barrett's esophagus, and intestinal neoplasia. In addition, earlier diagnosis through molecular tools will lead to more meaningful therapeutic and survival outcomes for malignant esophageal and gastric neoplasms. Experimental therapeutics, notably the advent of gene therapy and the potential application of *H. pylori* immunization therapy, also offer hope.

CHAPTER 116: COLORECTAL NEOPLASIA

C. RICHARD BOLAND

[Colorectal Polyps](#)
[Colorectal Cancer](#)
[Familial Colorectal Cancer Syndromes](#)
[Other Familial Polyposes and Colorectal Cancer](#)

The epithelium of the colon and rectum is one of the most rapidly proliferating tissues in the body. The rapid cell turnover permits the large intestine to renew itself on a continuing basis to provide an effective interface between the host and the fecal stream. The regulation of epithelial cell proliferation, migration, and cell death is critical to the maintenance of the proper number of cells in each epithelial crypt. Cell division occurs at the bases of the crypts, and the daughter cells destined for maturation migrate up the crypt toward the surface, where they undergo apoptosis and are shed after 2 to 3 days. Neoplasia occurs as a result of clonal expansion of a cell that has undergone a genetic alteration that results in loss of normal growth control, which permits an inappropriate accumulation of cells. Benign neoplasia (in the colon and rectum this constitutes an adenoma) can grow larger, but it is incapable of invasion and metastasis. Malignant neoplasia—cancer—evolves from benign neoplasia through the stepwise acquisition of additional genetic alterations that ultimately permit malignant cellular behavior.

In this chapter, the term “colon” will be used to refer to the colorectum; issues of clinical significance to rectal lesions will be specified.

COLORECTAL POLYPS

DEFINITION

Colorectal polyps are any excrescences found in the colon or rectum, which does not imply any specific pathologic variety. However, the pathogenesis and natural history are dependent on the pathologic characteristics of the polyp. Adenomatous polyps and hyperplastic polyps make up the vast majority of what is found in the colorectum. Adenomas are the most common and important of these, as they are the precursors of cancer. There is a longer list of much less prevalent hamartomatous polyps, such as juvenile polyps. Submucosal lesions may have a polypoid appearance, but the behavior of these depends on what is beneath the colonic epithelium.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Adenomatous polyps increase in prevalence with advancing age and can be found in at least 40% of the population. Not every adenomatous polyp will necessarily increase in size, and only a small fraction of them progress to cancer. The tendency to develop adenomas has a strong familial component that probably reflects both genetic and environmental influences. The significance of adenomas is that they serve as markers of an increased risk of colorectal cancer, and their removal is associated with a significant reduction in that risk.

Hyperplastic polyps make up about 15% to 20% of colorectal polyps, and their incidence increases with age. Only rarely do they grow more than 1 cm in diameter, and they are not premalignant lesions. They occur predominantly in the distal colon and rectum; unlike adenomas, they are uncommon in the proximal colon.

Juvenile polyps are the principal variety in children, may occur in 1% to 2% of young children (under 10 years), and are quite rare in adults. Peutz–Jeghers polyps are a unique pathologic variety of hamartoma that is pathognomonic of the eponymous syndrome.

Other polypoid lesions of the colorectum include inflammatory polyps (which are a consequence of inflammation and repair, but are not neoplastic) and any submucosal lesion that elevates the normal overlying mucosa. The submucosal lesions include lipomas, lymphoid nodules, carcinoids, metastatic tumors from other organs, and many others.

ETIOLOGIC FACTORS AND PATHOGENESIS

An adenomatous polyp develops when both alleles of the adenomatous polyposis coli gene (*APC*) are inactivated in a colorectal epithelial cell. The first allele is usually lost by a point mutation that creates a premature stop codon in one allele, also called a “nonsense mutation,” which results in the synthesis of a truncated protein. The second allele is typically deleted from the nucleus by a poorly understood process that results in a loss of heterozygosity (LOH). The normal, or “wild-type,” APC protein regulates the intracellular concentration of b-catenin, which plays a role in mediating proliferation, migration up the crypt, and adhesion of the epithelial cell to other epithelial cells (Fig. 116.1). As the colorectal epithelial cell leaves the zone of proliferation and moves toward the surface of the epithelium, the APC protein expression is triggered, which leads to a fall in intracellular b-catenin, cessation of proliferation, initiation of the cell death program, and weakening of the intercellular adhesion apparatus. Loss of the two APC alleles permits b-catenin to remain at a high level, which provides a substantial growth advantage for that cell's progeny. This permits a clone of cells to grow at the top of the crypt that have intact intercellular adhesion characteristics; senescence and detachment of the cell do not occur. An adenomatous polyp is the result.

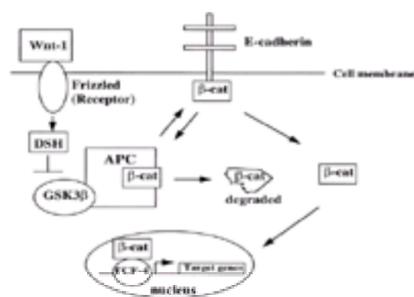

FIGURE 116.1. Regulation of b-catenin by the adenomatous polyposis coli gene (*APC*) in the colonic epithelial cell. Cellular proliferation and intercellular adhesion are controlled in part by b-catenin, which is regulated by *APC*. Not all of the members of this signaling pathway have been identified in the colon; it is likely similar to the WNT pathway of lower organisms, as indicated here. When b-catenin is present at a critical concentration in the cell, it binds to TCF-4, moves to the nucleus, and promotes the expression of proliferation-associated “target genes,” including *c-myc* and cyclin D. b-Catenin is also part of the intercellular adhesion complex, as indicated by E-cadherin in the figure. *Wnt-1* signaling through the “frizzled” receptor activates DSH, which then inhibits GSK3b, which is required for activation of *APC* and the subsequent degradation of b-catenin. Thus, Wnt signaling leads to cellular proliferation. When the epithelial cell matures and migrates to the top of the colonic crypt, this signaling pathway is turned off. The APC protein is expressed and phosphorylated by GSK3b and binds to b-catenin, leading to its degradation. Expression of the proliferation-associated target genes falls, mitosis is inhibited, and degradation of the E-cadherin complex permits the dying cell to detach from the crypt and fall into the colonic lumen. The absence of APC from the colonic epithelial cell permits unrestrained growth, and the intact intercellular adhesion promotes the formation of a tumor mass.

Some adenomas grow larger, some regress, and others do not change in size. At least one explanation for this variable behavior is that half of all adenomas acquire a mutation in codons 12 or 13 of the *K-ras-2* proto-oncogene, which further facilitates polyp growth. The *ras* gene mutations are most common in large, tubulovillous adenomas. Hyperplastic polyps have been much less extensively studied, but one model suggests that they are the result of *ras* mutations without concomitant *APC* mutations; these are not considered to be neoplasms or to be premalignant. A few colorectal polyps have features that are both adenomatous and hyperplastic, and

these should be expected to act like adenomas.

A critical event in the evolution of adenoma-to-carcinoma progression is the loss of both alleles of the *p53* tumor suppressor gene. This typically occurs first by the acquisition of a point mutation in an evolutionarily conserved portion of the *p53* gene, which alters the amino acid encoded (a missense mutation) and alters the function of the protein. As described previously for the *APC* gene, the genomic instability of the adenoma may eventually lead to loss (LOH) of the other, wild-type copy of *p53*. Loss of both *p53* alleles frequently mediates the transition from the benign adenoma to cancer. The tumor progression sequence and the putative genetic lesions that occur with each step are outlined schematically in [Fig. 116.2](#).

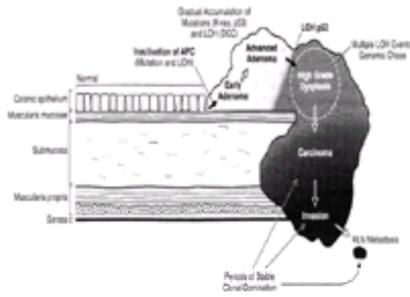

FIGURE 116.2. Tumor progression and genetic alterations in colorectal cancer development. This is a proposed model of the genetic events by which normal colorectal epithelium first enters into a neoplastic growth pathway (biallelic inactivation of the *APC* gene), undergoes additional growth in a variety of directions depending on the accumulated genetic events that might include *K-ras* mutations, *p53* mutations, or LOH at tumor suppressor gene loci, and the adenoma-to-carcinoma transition that occurs upon the inactivation of the *p53* gene (which will involve processes that inhibit the products of both *p53* alleles). (From Boland CR, Sato J, Appelman HD et al. Microallelotyping defines the sequence and tempo of allelic losses at tumour suppressor gene loci during colorectal cancer progression. *Nature Medicine* 1995;1:902–909, with permission.)

The pathogenesis of the juvenile polyp is unknown, but the identification of two tumor suppressor genes that are associated with juvenile polyposis coli (JPC; see below) suggests that this polyp represents a low-grade, poorly understood neoplasm. Inflammatory polyps are made up of non-neoplastic but disorganized tissue that results from cycles of epithelial damage and repair. These are seen in the setting of chronic inflammation, usually inflammatory bowel disease. Their principal importance is that inflammatory polyps are found in colons with increased malignant risk, and these polyps may grossly resemble an adenoma or cancer.

PATHOLOGIC FACTORS

Adenomatous polyps are defined by their size, their morphologic configuration, and their histopathologic features. The most important clinical issue is size. Polyps smaller than 6 mm are “diminutive,” polyps 6 to 9 mm are “small,” and those greater than 10 mm are considered large and clinically important. Polyps on a distinguishable stalk are considered pedunculated, which facilitates their complete removal colonoscopically, and those without a stalk are considered sessile. The histopathologic features of a polyp correlate generally with size and the accumulation of genetic abnormalities. Most small adenomatous polyps are tubular adenomas, characterized by a complex network of branching adenomatous glands. Larger adenomas are more likely to acquire a “villous” component, in which the adenomatous glands extend straight down from the surface to the center of the polyp, microscopically creating fingerlike projections. Tubulovillous (or villoglandular) adenomas have a combination of both.

Some polyps will develop a focus carcinoma completely surrounded by adenoma. If the malignant lesion does not invade the *muscularis mucosae* it is not considered invasive, and is usually termed carcinoma in situ or, simply, high-grade dysplasia. As a clinical issue, noninvasive cancer in the head of a polyp virtually never metastasizes.

Every adenoma is at least mildly dysplastic. All parts of the spectrum from mild dysplasia to carcinoma may be found in adenomatous polyps. The likelihood of encountering carcinoma increases directly in proportion to the size of the adenoma. The likelihood of finding carcinoma in diminutive or small adenomas is 1.3%. In adenomas 1 to 2 cm in size, 9.5% contain carcinoma; in adenomas greater than 2 cm, 46% have cancer. Villous features are more commonly seen in larger adenomas, and the presence of villous features, even in a small adenoma, increases the likelihood that cancer will be present.

Juvenile polyps are made up of a surface layer of normal-appearing colonic epithelium, which is elevated by an expansion of the underlying lamina propria. The interior of the polyp also is filled with dilated, mucous-filled glands, edema, and inflammatory cells. The coexistence of adenomatous epithelium should be carefully sought within juvenile polyps, since that is thought to be the source of the malignant potential.

Inflammatory polyps are also called pseudopolyps (really a misnomer because their morphology renders them true polyps). These lesions are covered with normal or inflamed epithelium, and are filled with inflammatory cells, edema, disorganized glands, vascular engorgement, and fibrosis of the lamina propria. The significance of these lesions is in distinguishing them from true neoplasms, which commonly occur in inflamed colons.

CLINICAL AND LABORATORY FINDINGS

Most colorectal polyps produce no symptoms. A few become large enough to obstruct the colon. This is extremely rare in the case of the adenoma, which is likely to become malignant before a benign lesion grows large enough to obstruct the colonic lumen. Benign polyps rarely bleed enough to produce anemia; however, they may produce a guaiac-positive stool if the polyp is large and located close to the rectum. Juvenile polyps may prolapse beyond the anus in children, or they may autoamputate and thus be passed in the stool.

There are no blood tests that detect the presence of any type of polyp in the colon. Colorectal polyps can only be detected by an imaging procedure (such as a radiologic test) or by direct visualization using endoscopy. The current best mode of diagnosis is colonoscopy and polypectomy followed by pathologic examination of the excised lesion. Novel approaches, such as “virtual colonoscopy,” are in development, which may provide a noninvasive, computerized tomographic method to screen for colorectal neoplasia. This would be particularly advantageous when the a priori likelihood of finding a significant lesion is relatively low.

OPTIMAL MANAGEMENT

Adenomatous polyps are common and are often found in the course of routine screening in asymptomatic patients (see next section on colorectal cancer). When encountered, they should be completely removed colonoscopically. A partial biopsy is not adequate management, as it can lead to an underestimation of the pathologic processes. Polyps can be removed by electrocautery using either biopsy forceps as a monopolar electrode (“hot biopsy”) or by snare cautery, which is most often employed to completely excise pedunculated lesions. Polyps containing only adenomatous tissue (with any grade of dysplasia) are adequately treated by total polypectomy. Even cancer in the head of a polyp is adequately treated if the margin of resection shows unambiguous excision of the cancer with an uninvolved excision margin. Surgical resection is not necessary in this case.

Many adenomatous polyps are discovered during flexible sigmoidoscopy. If a diminutive (less than 6 mm) polyp is encountered during sigmoidoscopy, the optimal management is controversial. The most careful approach would be to biopsy the polyp to exclude carcinoma or a villoglandular polyp (which would be unusual in such a small lesion). Diminutive adenomas and hyperplastic polyps are not associated with a significantly increased risk of finding clinically important neoplastic lesions in the proximal colon, and additional evaluation is not necessary. However, if larger polyps (greater than 5 mm), multiple polyps, or suspicious polyps containing ulceration or irregularities in shape are encountered, then the patient should undergo total colonoscopy. During colonoscopic examinations, optimal management would dictate removal of all polyps for pathologic analysis; however, the assiduous removal of every diminutive polyp during the performance of colonoscopy is time consuming and has not been demonstrated to improve the clinical outcome. Most pedunculated polyps can be totally removed colonoscopically. However, large (greater than 9 mm) sessile polyps should either be removed by an endoscopist with interventional expertise or may require surgery. Large polyps that are not

removed should undergo multiple biopsies to assist in making a decision about the need for surgical removal.

COLORECTAL CANCER

DEFINITION

Colorectal cancer is a malignant neoplasm of the colon that has developed through the multistep accumulation of critical mutations in growth-regulatory genes that permit invasion and metastasis to occur. Colorectal cancers usually (and probably always) evolve from pre-existing adenomas, although not necessarily from a polyp. The initial adenomatous lesion may have been small and flat. By the time a cancer is found clinically, the progenitor adenomatous tissue may no longer be present due to different rates of proliferation and the relative growth advantage of the malignant tissue.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Cancer of the large bowel (colon and rectum) is the most common neoplasm of the gastrointestinal (GI) tract and is the second most common cause of cancer-related mortality in the United States. Colorectal cancer occurs at some time in the lives of 5% to 6% of the population of the United States. The clinical importance of this disease is based both on the incidence of this disease and on the fact that early detection leads to a substantial improvement in outcome.

The incidence of colorectal cancer varies widely among nations. It is highest in industrialized countries, such as the United States, Western Europe, and Australia, and is much lower in developing countries. The principal exception to this rule is Japan, an industrialized nation with an incidence of colorectal cancer less than one-fourth that in the United States. It is of considerable interest that the incidence of colorectal cancer is increasing rapidly in Japan at the same time that other sweeping cultural changes have taken place. Within the high-risk regions, cancers of the colon and rectum are slightly more common in men than women, and the incidence rates are equal between blacks and whites. The most important risk factor in the United States is age. The incidence is very low before age 40, and the relative risk increases as an exponential function of age thereafter. The rates of colorectal cancer have been slowly increasing in the United States over the past four decades, although the mortality rate has fallen slightly, presumably due to earlier detection and improved management.

Frequent aspirin users have a relative risk of 0.6 (aspirin is protective) for colorectal cancer mortality, compared with nonusers. A similar degree of protection is conferred by other anti-inflammatory drugs, and this is thought to be accomplished by the inhibition of cyclooxygenase 2 (Cox-2) activity.

The age-adjusted relative risk for colorectal cancer among patients with one affected first-degree relative is 1.72. More than one affected first-degree relative increases the risk to 2.75, and the presence of an affected relative under the age of 45 increases the relative risk to 5.37. The existence of relatives with colorectal cancers occurring after age 60 do not add substantially to the familial risk. A similar degree of incremental risk is associated with first-degree relatives with adenomatous polyps, with additive risks when there are multiple or young relatives affected.

ETIOLOGIC FACTORS AND PATHOGENESIS

Although diets rich in fat and total calories have been implicated as a factor in the high incidence of colorectal cancer in the Western world, there are undoubtedly multiple factors that contribute to the pathogenesis of this disease. Per-capita ingestion of meat correlates with increased risk, whereas dietary fiber, the nondigested residue of complex plant carbohydrates, appears to protect against colorectal cancer. People in geographic locations with low levels of selenium in the soil have higher incidences of colorectal cancer, and selenium supplements may reduce mortality. However, excessive dietary selenium can be toxic, and routine supplementation is not recommended. Interventional trials that modify diets in patients who have already developed one or more adenomatous polyps have failed to reduce the recurrence rates of small adenomas, even when followed for up to 4 years. It may require decades of significant dietary modification to reduce the rates of new neoplasms.

The international differences observed in colorectal cancer incidence appear to be mediated in part by environmental, probably dietary, factors. Groups that migrate from low- to high-incidence regions experience a change in cancer incidence that gradually matches that in the new region.

Colorectal cancer develops through the multistep accumulation of genetic alterations—including point mutations and genetic deletions—as described above in the section on polyps. Whereas adenomas represent benign clonal expansions of colonic epithelium that have lost one level of growth control, carcinomas are clonal expansions that emerge from adenomas, in which there have been additional genetic modifications that permit invasion and metastasis. One genetic accident that can mediate adenoma-to-carcinoma conversion is biallelic inactivation of the *p53* gene. The likelihood of accumulating the critical combination of genes required for the malignant phenotype is low, and in spite of the underlying genomic instability in neoplastic tissue, this process requires many years (or even decades) and occurs in only a small proportion of all adenomas.

Although all cancers evolve through the accumulation of genetic alterations, not all cancers use the same pathway. All colorectal neoplasms are driven by genomic instability, which increases the mutational rate in the tissue. However, there are many ways to mutate the genome. About 85% of colorectal cancers have a type of genomic instability called *chromosomal instability*, which results in chromosomal deletion and numerous LOH events. These tumors are aneuploid, and have only one copy of both *APC* and *p53*; the single, remaining copies of these two genes in the tumors are mutated and inactive.

The 15% of colorectal cancers without chromosomal instability are diploid and have a form of hypermutability known as *microsatellite instability (MSI)*. MSI results from loss of the DNA mismatch repair (MMR) system, and short, repetitive DNA sequences are very prone to mutation during new DNA strand synthesis. There are about 10^5 of these simple repetitive “microsatellite” sequences in our genome, and most are in noncoding regions; those mutations are not thought to be biologically important. However, there are some microsatellite sequences in the coding regions of critical genes, such as the transforming growth factor (TGF) β_1 type II receptor (*TGF β_1 RII*), which is critical for inhibiting epithelial proliferation in the colon. Most tumors with MSI have a mutation in this sequence, which inactivates the gene and promotes growth. Several other genes with coding microsatellites are mutated in such tumors, including the insulin-like growth factor type 2 receptor (which is a component of the TGF- β signaling pathway), the apoptotic gene *BAX*, two of the DNA MMR genes themselves, *hMSH6* and *hMSH3*, the *E2F4* gene, and even *APC*.

The DNA MMR system consists of a complex of several proteins, as described below (see the section on hereditary nonpolyposis colorectal cancer). In about 80% to 90% of sporadic cancers with MSI, one of the DNA MMR genes, *hMLH1*, has undergone hypermethylation of its promoter, which silences the expression of the gene, resulting in loss of DNA MMR function and MSI. Abnormalities of gene methylation can be found throughout the non-neoplastic tissue in these colons, but the mechanism responsible is unknown.

CLINICAL FINDINGS

Early colorectal cancers, the ones that clinicians are most interested in finding, produce no symptoms whatsoever. Symptomatic colorectal neoplasia has two characteristic modes of presentation. The first of these is lower intestinal obstruction, which occurs when tumors (usually in the sigmoid colon or rectum) become large enough to obstruct the lumen. Second, tumor bleeding may result in hematochezia (most often with distal tumors) or iron deficiency anemia (more often noted with cancers in the cecum or ascending colon). The tendency for intestinal neoplasms to ooze blood has been exploited in the effort to detect asymptomatic cancers at an early stage. On physical examination, an abdominal mass or enlarged liver is found only in advanced disease. Occult bleeding can be detected by rectal examination. Rarely, colon cancers perforate spontaneously and present with an acute abdomen.

PATHOLOGIC FACTORS

Adenocarcinoma accounts for over 95% of malignancies of the colon and rectum. The prognosis in colorectal cancer is directly related to the penetration depth of the malignancy rather than to the total tumor bulk. Dukes initially categorized staging for rectal cancer, but this system has undergone repeated modification and adaptation to include colonic cancers as well. An internationally accepted classification and the historical precursors of colorectal cancer staging are outlined in [Table 116.1](#).

investment of resources.

Symptomatic Disease

If there are symptoms or signs suggestive of large intestinal disease, diagnostic colonoscopy (not just sigmoidoscopy) should be undertaken, regardless of the presence or absence of occult blood in the stool, since an FOBT is not sufficiently sensitive to exclude neoplasia. Flexible sigmoidoscopy is recommended as a screening test of the distal colon and rectum for asymptomatic individuals over age 50. Only two-thirds of colorectal neoplasms occur within the reach of this instrument, so it is inadequate as a solitary means to evaluate a patient with symptoms suggesting a neoplasm, with anemia, or with a positive FOBT.

Treatment of Colon Cancer

Some colorectal cancers, particularly those found in adenomatous polyps, can be excised colonoscopically. Most cancers require surgical resections. Principles of surgical therapy are based on the blood supply and lymphatic drainage of the colon. For most cancers, surgical excision with a 5-cm margin is the optimal therapy; however, this is based more on tradition than on data. Cancers of the cecum, ascending colon, and hepatic flexure are best treated with a right hemicolectomy and ileocolonic anastomosis. Cancers of the distal transverse colon, splenic flexure, or proximal descending colon may be treated by extended right hemicolectomies or segmental resections. Distal descending colon or sigmoid colon cancers are treated by a segmental resection ("low anterior resection") and primary colonic anastomosis. The treatment of colon cancers (above the level of the rectum) does not require a colostomy.

Treatment of Rectal Cancer

The treatment of rectal cancer is more complex than that of colorectal cancers and depends on its location in the rectum, the depth of invasion, and size. Rectal cancers in the proximal third of the rectum (more than 12 cm from the anus) can usually be resected with an operation that preserves the lower rectum and anus. Cancers in the mid-lower rectum (in the lowest 7 to 8 cm) may require a proctocolectomy, which necessitates abdominoperineal resection and a sigmoid colostomy. In order to avoid such radical surgery, local resection may be undertaken for rectal cancers when the tumor is small (less than 3 cm), polypoid, not fixed to submucosal tissues, and involves less than 25% of the circumference of the rectum. This approach may be chosen for patients with more advanced tumors who are at greater risk for surgical complications or who adamantly refuse to accept a colostomy.

Cancer in Adenomatous Polyps

Cancers that are confined to the head of a polyp and do not invade the stalk can be removed by colonoscopic polypectomy. When there is a clear margin of benign tissue between the cancer and the cut edge of the polyp, the incidence of recurrent disease is very low and the patient may be safely managed without a colonic resection. When a clear margin of benign tissue is not evident or when invasion occurs in a sessile lesion, colonic resection is indicated. In the rare instance when a poorly differentiated carcinoma occurs in a colonoscopically removed polyp, the outcome is less certain, and a formal cancer operation should be considered, depending on the clinical circumstances of the patient.

Follow-up of Colon Cancer

Patients who have had a cancer removed have a 5% likelihood of developing a metachronous tumor during the subsequent 10 years. The chance of recurrent neoplasia is twice as high in patients who have multiple synchronous lesions, either adenocarcinomas or adenomatous polyps. Patients who have had cancers removed should be reexamined with colonoscopy 6 to 12 months after the initial surgery. If new neoplastic lesions are encountered, these should be removed and the patients examined again in 1 year. If no new neoplastic lesions are encountered, the surveillance interval may be increased to 3 years indefinitely, except in cases where hereditary nonpolyposis colorectal cancer is suspected, as these require more frequent surveillance.

Adjuvant Postoperative Chemotherapy for Colon Cancer

Approximately 50% of all patients with large intestinal cancers undergo resection and have a long-term disease-free survival. The development of metastatic cancer remains a substantial threat in patients who have been told that their surgery was successful in terms of removing the primary tumor. Adjuvant therapy is the treatment of patients who have undergone successful resections with the intent of preventing tumor recurrences. Adjuvant therapy is not indicated in patients with stage I or II colon cancers [i.e., cancer limited to the wall of the colon (Dukes A or B1)] and is not associated with lymph node metastasis because the cancer-free survival rate after removal of these tumors is already better than 80% and chemotherapy does not significantly improve survival in this combined group. A modest but statistically insignificant improvement in 7-year disease-free survival from 71% to 79% has been reported for patients with stage II cancers.

Stage III cancer (i.e., with regional lymph node involvement) should be treated with adjuvant chemotherapy. The use of combined 5-fluorouracil (5-FU) and levamisole in patients with stage III cancers improves the 3.5-year disease-free survival from 47% to 63% and delays the time to recurrence. Adjuvant therapy requires the weekly administration of intravenous 5-FU for 1 year and a 3-day course of oral levamisole every 2 weeks. The toxicity may be unacceptable in some patients, and 30% are unable to complete the full year of treatment. Currently, the use of 5-FU and leucovorin has emerged as an alternative to 5-FU/levamisole, and a variety of regimens have been tested, all meeting similar results. No superiority in survival for either levamisole, leucovorin, or other drug in combination with 5-FU has been established; however, some of the leucovorin-containing regimens are of equal benefit but may be completed in only 6 months. Attempts have been made to improve outcome by portal venous infusion of chemotherapeutic agents to increase delivery to the liver, but this has not been shown to significantly decrease liver metastases to date.

Adjunctive Radiation Therapy for Rectal Cancer

Radiation therapy has a role as an adjunct to surgery for rectal cancer. Combined postoperative adjuvant therapy using 4,500 to 5,040 cGy plus a 5-FU-based chemotherapy regimen reduces recurrence rates in stage T3 and T4 (deeply invasive or regionally metastatic rectal cancer) by 34%. Many patients will find this regimen difficult to complete, but the benefits may be lifesaving. Chemoradiation may be used preoperatively to convert an apparently nonresectable tumor to one that can be surgically removed in some instances, and is increasingly being used in all rectal cancers.

Metastatic Colorectal Cancer

Intensive postoperative surveillance programs may detect an isolated focus of metastatic disease in the liver. Patients in whom additional metastases can be excluded should be offered surgical resection since medical therapies do not cure this disease. There are no successful modalities for treatment of widespread metastatic disease at this time. Chemotherapy (5-FU and other drugs) may produce partial tumor shrinkage in 15% to 25% of patients with advanced metastatic disease; however, no chemotherapeutic regimen has been proven to significantly prolong life in this disease. Chemotherapeutic regimens have played a palliative rather than curative role in metastatic disease. Hepatic artery infusions of chemotherapeutic agents have been used in numerous trials, but evidence from randomized controlled trials has yet to show a significant survival advantage for this therapy. Radiation therapy may provide symptomatic relief for some patients with localized metastatic lesions and may be used as a palliative measure.

FAMILIAL COLORECTAL CANCER SYNDROMES

FAMILIAL ADENOMATOUS POLYPOSIS

Familiality is a major issue in colorectal cancer, but only a small proportion of such cancers reflect inherited syndromes. The most easily recognized of these is familial adenomatous polyposis (FAP), which is an autosomal dominant disease characterized by the development of multiple adenomatous polyps, beginning in adolescence, followed by the appearance of carcinoma at a median age of about 40 to 45 years. This disease occurs in about 1 in 10,000 births, and it may occur as a "new mutation" in perhaps 25% to 30% of cases. Gardner's syndrome, most of Turcot's syndrome, and other eponymous variations of FAP are all attributable to germ line mutations in the same gene and highlight the phenotypic variation characteristic of this disease.

Etiologic Factors, Pathogenesis, and Disease Manifestations

Familial adenomatous polyposis is caused by a germ line mutation in the *APC* gene, located on chromosome 5q, as described above. Virtually all of the disease-causing mutations described create a prematurely truncated protein product of the *APC* gene. Every cell in the body carries this germ line mutation in FAP, and these cells are phenotypically normal. When the second, wild-type allele is mutated or lost from an individual colonic epithelial cell, it undergoes clonal expansion and evolves into an adenomatous polyp. This same process of biallelic inactivation occurs during the evolution of a sporadic adenoma as discussed above. However, in FAP, the likelihood is greater that many adenomas will develop early in life because the germ line lesion is present in every colonic cell from birth. Patients with FAP are at risk to develop small intestinal adenomas, fundic gland hyperplasia in the stomach, and extraintestinal manifestations including mandibular and cranial osteomas, dental abnormalities, fibromas, lipomas, epidermoid and sebaceous cysts, desmoid tumors, and pigmented lesions in the ocular fundus. FAP patients are at risk for periampullary adenomas and carcinoma. The phenotypic manifestations of the disease can, in part, be predicted based on the location of the mutation in the *APC* gene. Of particular interest, certain mutations occurring at the beginning (5' end) of the *APC* gene can produce a mild form of FAP called attenuated adenomatous polyposis coli (AAPC), or attenuated FAP, in which only a few polyps may develop, and the onset of adenomas and cancer is delayed by a decade or more compared with the classic forms of the disease. This is still FAP, but it is a mild form that is likely to be underdiagnosed.

One mutation in the *APC* gene does not inactivate the gene but creates a microsatellite tract, which is intrinsically unstable and is predisposed to developing another, inactivating mutation. This sequence variation, I1307K, is present in 6% of Ashkenazi Jews but is relatively weak in its expression as a cancer-predisposing gene. Individuals carrying I1307K may develop multiple colorectal adenomas, may have as much as a two- to threefold increase in cancer risk, and develop cancers approximately a decade earlier than usual.

Optimal Management of Fap

In FAP, screening sigmoidoscopy should be performed annually beginning in adolescence. The median age for first polyp is about age 16; the polyps occur diffusely, but the onset will be later in the attenuated forms of the disease. Considerable variation in phenotype may occur within families, presumably because of the presence of independently inherited “modifier” genes. A diagnostic blood test, the truncated protein test, is available for FAP based on the fact that the *APC* gene is mutated in a way that produces a prematurely truncated gene product in most cases. Each family will have its own unique mutation; unfortunately, only 60% to 70% of mutations will be detected with this test. If the test is positive in an index family member, it is extremely sensitive and specific to definitively rule the disease in or out in the relatives.

Treatment of FAP calls for either a total proctocolectomy or a subtotal colectomy with ileorectal or ileo-anal anastomosis in certain circumstances. Complete removal of all colorectal tissue is the most effective means of preventing the cancer; however, if the rectum is relatively free of polyps, a rectum-sparing operation in conjunction with an intensive program of proctoscopic follow-up may be elected as alternative, although less certain, management. The advantages of sparing the rectum are unfortunately associated with a 10% risk for the development of rectal cancer in spite of vigorous follow-up. Sulindac 300 to 400 mg per day can reduce the number of polyps in the colons and rectums of patients with FAP, but cancers have developed in spite of this treatment regimen. Patients who have undergone colectomies are still at risk for the development of malignant neoplasms in the periampullary region (10% to 15% of patients) and abdominal desmoid tumors (5% to 10% of patients). Patients with the I1307K permutation may not require surgery, and may be managed with frequent colonoscopy.

HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (OR LYNCH SYNDROME)

Hereditary nonpolyposis colorectal cancer (HNPCC) refers to familial colorectal cancer that is not FAP. In those instances in which a germ line mutation in one of the DNA MMR genes is linked to the disease, the term Lynch syndrome may be used. The clinical diagnosis of HNPCC can be confidently made (using the “Amsterdam criteria”) when there are three affected family members, one of whom is a first-degree relative of the other two, when one member has been affected by cancer prior to age 50. Some true Lynch syndrome kindreds fail to meet these criteria because of small family size or incomplete penetrance of the disease. The incidence of this disease is uncertain, but it accounts for about 3% to 4% of all colon cancers, and perhaps 1 in 500 births, making it a relatively common genetic disease. The key feature of the disease is an increased risk to develop cancer of specific organs—especially the colon and endometrium—at uncharacteristically early ages ([Table 116.2](#)).

Cancer Site	Lifetime Cancer Risk	Relative Risk	Median Age (y)
Any cancer by age 70	91% (men), 69% (women)	—	—
Colon or rectum	74% (men), 30% (women)	—	46
Endometrium	20-42% (by age 70)	—	46
Stomach	—	4.1	54
Ovaries	—	3.5	40
Small intestine	—	25	51
Hepatobiliary system	—	4.9	66
Kidney	—	3.2	66
Ureter	—	22	56
Kidney/ureter	—	75.3	—

TABLE 116.2. ESTIMATES OF CANCER RISK BY ORGAN SITE IN LYNCH SYNDROME

Etiologic Factors, Pathogenesis, and Disease Manifestations

Lynch syndrome is an autosomal dominant disease caused by a germ line mutation in one of the DNA MMR genes ([Fig. 116.3](#)). Mutations in any one of these genes cause the same syndrome ([Table 116.3](#)). Development of cancer occurs along a different pathway than occurs in most sporadic cancers or in FAP. Every cell in the body carries the germ line mutation in one allele of one DNA MMR gene. A genetic accident occurs in the matching allele in one cell, which then develops MSI. Neoplasia evolves as genes controlling growth accumulate inactivating mutations at microsatellite sequences.

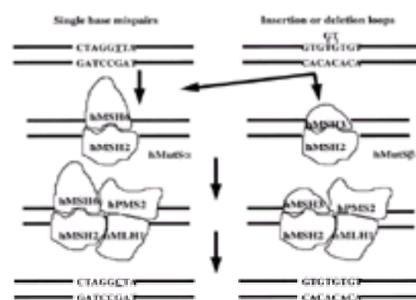

FIGURE 116.3. The DNA mismatch repair (MMR) system. The DNA MMR proteins work as a multimeric complex to repair base pair mismatches and heteroduplex loops that develop during new DNA synthesis. The hMSH2/hMSH6 protein complex binds to single-base mispairs, whereas the hMSH2/hMSH3 complex also can mediate the repair of insertion/deletion loops that sometimes form during the replication of a microsatellite sequence. The hMLH1/hPMS2 protein complex distinguishes the newly synthesized strand from the template strand and targets the mutant one for repair. Loss of any of these proteins results in loss of the DNA MMR function.

HNPCC Gene	Incidence/Proportion of Families
<i>hMSH2</i>	31%
<i>hMLH1</i>	33%
<i>hPMS1</i>	Rare (one family)
<i>hPMS2</i>	4%
<i>hMSH6</i>	Rare (a few families)
Undetermined loci	32%

HNPCC, hereditary nonpolyposis colorectal cancer.

TABLE 116.3. INCIDENCE OF GERM LINE MUTATIONS IN LYNCH SYNDROME.

Now that the disease can be confidently diagnosed, it is known that penetrance of the disease is incomplete; 91% of men and 69% of women with Lynch syndrome develop cancer during their lifetimes, and colon cancer develops in only 74% and 30% of men and women, respectively. Women have a 20% to 42% risk for endometrial cancer, depending on the registry, which is similar to the risk for colon cancer. In three separate registries, the incidence of colon cancer has been linear, and 1.6% per year from ages 25 to 75. In HNPCC, there are no phenotypic markers of disease; diffuse polyposis does not occur. Solitary adenomatous polyps may develop as early as the second decade, and the adenomas are unusually aggressive, rapidly evolving into villous adenomas or cancers. Colon cancer in this setting has an early onset (mean age 40 to 45 years, the same as in FAP), more than two-thirds of the cancers occur in the proximal colon, and multiple primary malignancies are common. There are additional risks for the early development of cancer in the stomach, small intestine, ureter, renal pelvis, brain, and other sites. Interestingly, there is no increased incidence of breast or lung cancers in HNPCC kindreds.

When the disease is suspected, the tumor can be assayed for MSI, which can be detected in paraffin-embedded, archival tumors that were removed decades earlier. The fact that 15% of sporadic tumors have MSI (most due to epigenetic silencing of the *hMLH1* gene) is a confounding factor. Immunohistochemistry may be useful to identify the mutant gene once MSI is found, and the germ line mutation in a DNA MMR gene may be found in blood samples by a variety of genetic tests. Currently, the mutant DNA MMR gene can be found in about half of HNPCC families. Some (less than 10%) of HNPCC tumors do not have MSI, which suggests that additional mechanisms for this disease remain to be discovered.

Optimal Management of Lynch Syndrome

In HNPCC, a full colonoscopic exam is required beginning at about age 25 (depending on the pattern of tumor development in the family), and this should be repeated every 1 to 2 years because of the aggressive pattern of tumor evolution in this disease. Diagnostic blood tests are being developed for HNPCC, but this is a more complex problem, since there are multiple genes that produce this syndrome. As in FAP, once the mutation is found in an individual family, it may be applied with confidence in those relatives. Patients with HNPCC are best treated with a subtotal colectomy and ileorectal anastomosis in order to limit the amount of residual colon at risk for cancer. Proctectomy is usually not necessary in the management of this syndrome, but annual proctoscopic surveillance is required after surgery. The endometrium represents a substantial cancer risk, and removal is recommended when childbearing is no longer an issue. The ovaries are at increased risk for cancer, and oophorectomy may be a reasonable step at the time of hysterectomy. The risk of cancer in the other organs is relatively low, and specific screening measures have not been recommended.

OTHER FAMILIAL POLYPOSES AND COLORECTAL CANCER [TABLE 116.4](#))

PEUTZ–JEGHERS SYNDROME

Peutz–Jeghers syndrome (PJS) is a rare, autosomal dominant disease inherited by a germ line mutation in a serine/threonine kinase located on chromosome 19p called *SKT11* or *LKB1*. The diagnosis can be made because of the dark pigmented macules around the mouth, digits, and elsewhere. Affected patients get characteristic PJ polyps throughout the GI tract that can cause obstruction or intussusception. The polyps, which themselves are benign hamartomas, have a diagnostic branching smooth-muscle component to them. Despite traditional opinions to the contrary, PJS patients have a lifetime risk of cancer of 48%, and these occur earlier than in the general population. Organs at risk for cancer include the GI tract, pancreas, breast, ovaries, and testes.

Polyposis Syndrome	Chromosome Location	Gene
Familial adenomatous polyposis, Gardner's syndrome, Turcot's syndrome	5q21	<i>APC</i>
Hereditary nonpolyposis colorectal cancer, or Lynch syndrome	2q16, 3p21, 2q22, 2p21, 2q16, 3p21	DNA mismatch repair genes: <i>hMSH2</i> , <i>hMLH1</i> , <i>hPMS1</i> , <i>hPMS2</i> , <i>hMSH6</i>
Peutz–Jeghers syndrome	19p13.3	<i>SKT11</i> (serine/threonine kinase)
Hereditary mixed polyposis syndrome	1q	<i>ARHGAP31</i>
Juvenile polyposis coli	10q23.3–2q11, 18q21.1	<i>PTEN</i> or <i>SMAD4</i>
Bannayan–Riley–Ruvalcaba syndrome, a variant of JPC	10q23	<i>PTEN</i>
Cowden's disease	10q23–21	<i>PTEN</i>

TABLE 116.4. POLYPOSIS SYNDROMES

JUVENILE POLYPOSIS COLI

Juvenile polyposis coli (JPC) is a rare, autosomal dominant disease caused by a germ line mutation in either the *SMAD4* gene on chromosome 18q or the *PTEN* gene on chromosome 10q. The diagnosis is made by finding ten or more juvenile polyps in an individual, followed by family analysis and testing for germ line mutations in *SMAD4* or *PTEN*. In JPC, the polyps are limited to the colon, but in some instances, generalized GI involvement with juvenile polyps may occur. In some cases, the polyps can be removed by repetitive endoscopic polypectomy; however, in other cases, polyp formation may be more extensive, complications such as chronic blood loss or protein-losing enteropathy may be present, and resection of segments of the large or small bowel may be required. Patients with JPC are at increased risk for cancer of the colon at an early age, presumably due to the evolution of adenomatous epithelium in the polyps.

A syndrome known as Bannayan–Riley–Ruvalcaba syndrome (and by several other names) is a rare variant of JPC, associated with characteristic macular pigmented lesions, macrocephaly, and other congenital anomalies, and linked to germ line mutations only in the *PTEN* gene.

COWDEN'S SYNDROME

Cowden's syndrome is a rare, autosomal dominant disease characterized by pathognomonic skin and tongue papules. About a third of these patients have multiple hamartomatous polyps of the intestine (including hyperplastic polyps, juvenile polyps, ganglioneuromas, and others). This disease has been linked to germ line mutations of the *PTEN* gene, as has JPC. Curiously, at least one family has been found with a *PTEN* mutation identical to one found in Bannayan–Riley–Ruvalcaba syndrome, even though these diseases are phenotypically distinct. Patients with Cowden's disease are not at increased risk for colon cancer, although the nature of the *PTEN* gene as a tumor suppressor gene is manifested in a risk for early-onset breast and thyroid cancers in affected patients.

CHAPTER 117: PANCREATITIS

JAMES H. GRENDALL

[Pancreatic Exocrine Function](#)
[Acute Pancreatitis](#)
[Chronic Pancreatitis](#)

PANCREATIC EXOCRINE FUNCTION

The exocrine pancreas is the master digestive gland of the body, secreting about 1 L of bicarbonate-rich, clear fluid into the small intestine every day. This fluid, pancreatic juice, contains the digestive enzymes necessary for the intraluminal hydrolysis of dietary macronutrients (protein, starch, fat, nucleic acids) and fat-soluble vitamin esters into smaller molecules that can either (a) be absorbed directly by enterocytes or (b) be acted upon further by constituents of bile or intestinal brush-border enzymes to permit absorption by the small intestine.

FUNCTIONAL ANATOMY

The pancreas lies deep within the abdominal cavity. In the adult, it is about 12 to 20 cm long and weighs 70 to 120 g. The head of the gland is apposed to the curvature of the duodenum, with the body and tail extending obliquely posterior to the stomach toward the gastric surface of the hilum of the spleen ([Fig. 117.1A](#)). Posteriorly the distal common bile duct enters the head of the pancreas and passes through the pancreatic parenchyma to reach the duodenal ampulla ([Fig. 117.1B](#)).

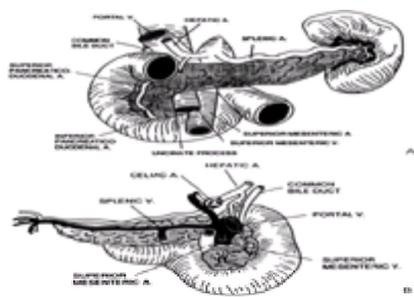

FIGURE 117.1. (A) Anterior and (B) posterior views of the pancreas and some surrounding structures. A, artery; B, body; H, head; T, tail; V, vein. (From Grendell JH. Embryology, anatomy, and anomalies of the pancreas. In: Haubrich WS, Schaffner, F, Berk JE, eds. *Bockus Gastroenterology*, fifth ed. Philadelphia: WB Saunders, 1995; 2815, with permission.)

The pancreas has a rich arterial blood supply derived from interconnected branches of both the celiac and superior mesenteric arteries (supplying the head and part of the body) and the splenic artery (supplying the rest of the body and tail). The venous drainage of the pancreas enters the hepatic portal venous system, emptying either directly into the portal vein or into the splenic vein.

Pancreatic lymphatics generally follow the course of the arteries and veins, with most lymphatic drainage entering the pancreaticosplenic lymph nodes and some the pancreaticoduodenal and pre-aortic nodes. Pancreatic lymphatics interconnect extensively with those of other nearby organs and retroperitoneal tissues.

The sympathetic and parasympathetic efferent innervation of the pancreas is supplied by the vagus and splanchnic nerves by way of the hepatic and celiac plexuses. The vagal (parasympathetic) efferent fibers pass through these plexuses but do not synapse until they reach the parasympathetic ganglia in the interlobular septa of the pancreas. The postganglionic fibers then supply the acini, ducts, and islets of Langerhans. Sympathetic nerves arise from the lateral gray matter of the thoracic spinal cord and pass through the greater splanchnic nerves to synapse in the celiac ganglia. The postganglionic fibers follow the distribution of the hepatic, splenic, and superior mesenteric arteries to innervate pancreatic blood vessels. Visceral afferent fibers (which appear to mediate pain) travel through the vagus nerves to the celiac ganglia and splanchnic nerves to reach the thoracic sympathetic chain and the spinal root ganglia.

HISTOLOGIC FACTORS

The pancreas is divided into lobules surrounded by connective tissue septa containing blood vessels, lymphatics, nerves, and exocrine secretory ducts. On microscopic examination, the parenchyma of the lobules consists mainly of the acini involved in exocrine secretion (more than 80% of the gland). Scattered among the acini are the islets of Langerhans (1% to 2% of the gland), which are responsible for pancreatic endocrine secretion.

Acinar cells are tall and pyramidal, situated on a basal lamina. They are highly specialized for the synthesis, storage, and secretion of large amounts of protein, mainly in the form of digestive enzymes. In the resting state, the apical portion of the acinar cell is filled with eosinophilic zymogen granules that are about 1 μm in diameter. After ingestion of a meal or administration of a secretagogue, protein secretion by acinar cells is accompanied by a rapid decrease in both the size and the number of zymogen granules. The basal portion of the acinar cell contains the nucleus and extensive rough endoplasmic reticulum, and is separated from the zymogen granules by a highly developed Golgi complex. The apices of the acinar cells converge on a central lumen continuous with a duct lined with flattened centroacinar cells that contain relatively few organelles and no secretory granules. Around each acinus lie a rich capillary network and nerve fibers that terminate adjacent to the acinar cells ([Fig. 117.2](#)).

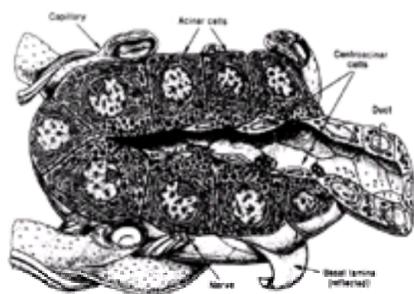

FIGURE 117.2. The organization of the pancreatic acinus and surrounding capillaries and nerves. (From Fawcett DW. *Bloom and Fawcett: a textbook of histology*, eleventh ed. New York: Chapman & Hall, 1986:718, with permission.)

The acini empty into intralobular ducts lined by cuboidal epithelium. These then join to form interlobular ducts that empty into the main pancreatic duct. These larger ducts, lined primarily by tall columnar cells, with occasional goblet and argentaffin cells, are accompanied by arterial and venous blood vessels and nerves, and are surrounded by extensive connective tissue.

Casts of the pancreatic duct system formed by retrograde injection of the duct with silicon demonstrate that the organization of ducts and acini is complex. Acini are not merely spherical units at the ends of the duct system, similar to a bunch of grapes. Rather, acini are commonly curved, branching tubules that anastomose, occasionally loop, and ultimately end blindly ([Fig. 117.3](#)).

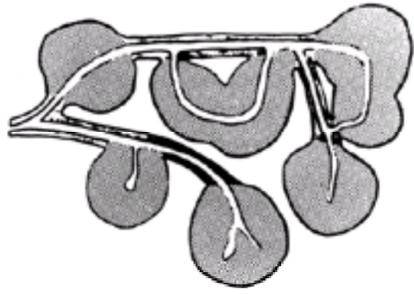

FIGURE 117.3. The complex relationship between pancreatic ducts (*heavily shaded*) and acini (*stippled*). Acini may exist as terminal structures of ducts or form anastomotic loops that connect to ducts at both ends. (From Bockman DE. Anatomy of the pancreas. In: Go VLW, Gardner JD, Brooks FP, et al. eds. *The exocrine pancreas: biology, pathobiology, and diseases*. New York: Raven Press, 1986:1, with permission.)

Recently, stellate cells have been identified in the pancreas that appear to be very similar to the extensively studied stellate cells of the liver (where they have also been called lipocytes and fat storage, or Ito, cells). When activated, these cells undergo a marked morphologic change to resemble myofibroblasts and express genes for collagen synthesis. In the liver these cells are the major cell type responsible for the synthesis of extracellular collagen and are believed to be the critical factor in the development of fibrosis in response to liver injury. It is likely that stellate cells play a similar role in the pancreas.

The endocrine pancreas consists of about 1 million islets of Langerhans that are about 0.2 mm in diameter, typically round or oval, and separated from the surrounding exocrine tissue by fine fibers of connective tissue. The most common types of islet cells are the insulin-secreting b cell (in the center of the islet) and the glucagon-secreting a cell (in the periphery). The other major cell types are the somatostatin-secreting d cell and the pancreatic polypeptide-secreting cell.

Each islet is surrounded by an extensive network of capillaries lined by fenestrated endothelium. Afferent arterioles bring blood into the capillary glomerulus. This blood then travels from the islets in efferent capillaries, bathing the surrounding exocrine tissue and creating an insuloacinar portal system. Other arterioles supply blood directly to acinar tissue without passing through islets. The result of the insuloacinar portal system is that acini surrounding islets (peri-insular acini) are exposed to much higher concentrations of islet hormones (e.g., insulin, glucagon) than acini located away from islets. This may explain the observation that peri-insular acini have larger cells and nuclei and more zymogen granules (with different enzyme composition) than other acini.

COMPONENTS OF PANCREATIC JUICE

Water and Electrolytes

Pancreatic juice is isosmotic with extracellular fluid, with water entering passively along osmotic gradients. The major cations are Na^+ and K^+ , which are secreted at concentrations similar to plasma concentrations and independent of secretory rates. Although the total anion concentration does not vary with secretory rate, the amounts of the major cations, HCO_3^- and Cl^- , do. At low secretory rates the concentration of HCO_3^- is only 30 to 60 mmol per liter, but it rises to about 135 mmol per liter at high secretory rates, with a corresponding decrease in Cl^- concentration.

This flow-related reciprocal relation of HCO_3^- and Cl^- concentrations in pancreatic juice appears to involve two components. Firstly, acinar cells secrete a plasma-like fluid with a low HCO_3^- concentration, whereas centroacinar and duct cells secrete bicarbonate-rich fluid. Because the fluid secretory capacity of the centroacinar and duct cells is much greater than that of the acinar cells, the bicarbonate-rich fluid predominates at higher rates of stimulated secretion. Secondly, HCO_3^- in pancreatic juice is exchanged for Cl^- in the pancreatic duct in a time-dependent diffusional process. At high secretory flow rates, more of the HCO_3^- escapes this exchange process.

In addition to the four main cations and anions, pancreatic juice also contains Ca^{2+} (1 to 2 mEq per liter) and minute amounts of Mg^{2+} , Zn^{2+} , HPO_4^{2-} , and SO_4^{2-} .

Proteins

In humans, pancreatic juice has a protein concentration ranging from about 1% to about 10%. Most of these proteins are digestive enzymes or cofactors, which include 20 isozymes of 12 different enzymes. The remainder are pancreatic secretory trypsin inhibitor, several trypsin-like enzymes that do not serve primarily as digestive enzymes, plasma proteins, and glycoproteins.

The four major categories of digestive enzymes are proteases (digesting proteins and peptides), amylase (digesting starch), lipases (digesting triglycerides and phospholipids), and nucleases (digesting nucleic acids) ([Table 117.1](#)). In addition, pancreatic juice contains colipase, a peptide cofactor that contributes to lipolysis by binding to bile salt–lipid surfaces, enhancing the ability of lipase to digest triglycerides. All the proteases, as well as phospholipase and colipase, are secreted by the pancreas as inactive proenzymes (zymogens). After entering the intestinal lumen, trypsinogen is converted to trypsin by enterokinase (enteropeptidase), an intestinal brush-border enzyme. Trypsin then can activate the other proenzymes as well as trypsinogen molecules. Unlike the other digestive enzymes, amylase, lipase, and ribonuclease are secreted in active form.

Enzyme	Substrate	Site of Action	Products
Amylase	Carbohydrate (amylose, amylopectin, glycogen)	α -1,4 linkage between hexoses (but not at branch points or end points)	Maltose, maltotriose, α -limit dextrins
Endopeptidases (trypsin, chymotrypsin, elastase)	Peptides, proteins	Internal peptide bonds	Smaller peptides
Exopeptidases (carboxypeptidase A and B)	Peptides, proteins	Peptide bonds at carboxyl terminal	Smaller peptides
Lipase	Triglycerides	Ester linkage of fatty acid in position 1	Fatty acids, monoacylglycerols
Phospholipase	Phospholipid (e.g., lecithin)	Ester linkage in position 2	Fatty acid, 1'-diacylglycerol (e.g., lysolecithin)

TABLE 117.1. SITES OF ACTION OF PANCREATIC DIGESTIVE ENZYMES

The acinar cell synthesizes and secretes in low concentration a trypsin inhibitor capable of inhibiting trypsin and, to some extent, chymotrypsin. The presence of pancreatic secretory trypsin inhibitor appears to be a protective mechanism against damage to the pancreas due to premature activation of trypsin in pancreatic tissue or juice. However, once pancreatic juice enters the intestine, trypsinogen is activated by enterokinase so rapidly and to such an extent that the relatively small amount of trypsin inhibitor present does not interfere with the normal digestive process. An additional protective mechanism against the potential harmful effects of premature trypsin activation within the pancreas is the ability of several trypsin-like molecules synthesized by the acinar cell and of trypsin itself to destroy trypsin and trypsinogen molecules.

CELLULAR MECHANISMS OF SECRETION

Water and Electrolytes

Most of the stimulated secretion of water and electrolytes by the pancreas appears to come from centroacinar cells and the epithelial cells lining the intralobular and small interlobular ducts. The peptide hormone secretin is the most potent stimulus for water and bicarbonate secretion, binding to receptors on the basolateral surface of the duct cells, producing an increase in intracellular cyclic AMP (cAMP) concentration resulting in activation of protein kinase A. However, the peptide hormone cholecystokinin (CCK) and, particularly, cholinergic neural stimulation also appear to contribute to the observed postprandial increase in water and bicarbonate secretion by potentiating the effects of secretin. Bicarbonate is secreted by pancreatic centroacinar and duct cells against large concentration and electrochemical gradients. Most of the HCO_3^- is derived from CO_2 in blood, which is converted to HCO_3^- by the action of the enzyme carbonic anhydrase. The HCO_3^- is exchanged for Cl^- at the apical (luminal) cell surface by an active process that appears at least in part driven by the active secretion of H^+ across the basolateral cell surface into the interstitial space mediated by an Na^+, H^+ pump (in turn driven by Na^+, K^+ -ATPase) and other active proton transport mechanisms. Secretion of Cl^- across the apical cell surface is an important step in water and electrolyte secretion, and it takes place through a Cl^- channel that is the cystic fibrosis transmembrane conductance regulator (CFTR). The primary cations, Na^+ and K^+ , reach the pancreatic duct by paracellular routes.

Proteins

The secreted proteins of the exocrine pancreas, primarily digestive enzymes, are synthesized on ribosomes of the rough endoplasmic reticulum in acinar cells. Newly synthesized proteins enter the cisternal space of the endoplasmic reticulum through insertion into the membrane of a lipophilic "signal" or "leader" sequence of amino acids at the amino-terminal end of each protein. Once inside the cisternal space, the signal peptide is cleaved by peptidases, resulting in the secretory protein that will remain membrane-bound until secreted into the acinar lumen. The secretory proteins are transported as a mixture to the Golgi complex in transition vesicles that bud from the endoplasmic reticulum. Additional post-translational processing (e.g., glycosylation, peptide cleavage) occurs in the Golgi complex. The final mixture of secretory proteins buds from the Golgi complex to form condensing vacuoles that ultimately become zymogen granules, the storage compartment for digestive enzymes and other secretory proteins immediately before secretion. In zymogen granules, secreted proteins appear to be arranged in a tightly packed, crystalline-like state. Zymogen granules move toward the apices of acinar cells by a process involving microtubules. When the acinar cell is stimulated to secrete, the zymogen granule membrane and plasma membrane fuse, and a fusion pore forms, opening the zymogen granule and leading to release of digestive enzymes and other secreted proteins into the fluid component of the acinar lumen (exocytosis).

Stimulation of protein secretion by pancreatic acinar cells is due to specific binding to receptors on the basolateral cell surface by the cholinergic neurotransmitter acetylcholine and, at least in some species, by CCK. This begins an intracellular cascade by which phospholipase C is activated by a G-protein-mediated mechanism.

Phospholipase C in turn cleaves phosphatidylinositol to inositol 1,4,5-triphosphate ($1,4,5\text{-IP}_3$) and 1,2-diacylglycerol (DAG). The $1,4,5\text{-IP}_3$ causes an increase in cytosolic calcium concentration due to the release of calcium from intracytoplasmic stores. Protein kinase C is activated by DAG, and calcium activates several additional protein kinases and a protein phosphatase by binding to calmodulin. These protein kinases and phosphatases are believed to bring about digestive enzyme secretion by altering the phosphorylation of a number of proteins, producing specific effects yet to be fully identified.

REGULATION OF PANCREATIC SECRETION

Basal

During the basal or fasting state, the volume of pancreatic juice secreted into the duodenum is low, with enzyme secretion about 10% of maximal levels and bicarbonate secretion only 2% of maximal. However, brief periods of increased pancreatic enzyme and bicarbonate secretion occur about every 60 to 120 minutes in temporal association with the increased motor activity of phase III of interdigestive migrating motor complexes (see [Chapter 108](#)). Cholinergic neural input is the primary regulator of the increase in both motor and secretory activity, and secretion of the peptide motilin from duodenal endocrine cells into the blood appears to play a role in the initiation of phase III. α -Adrenergic tone acts as an inhibitor of pancreatic secretion in the fasting state.

Postprandial

After ingestion of a meal, the exocrine pancreas secretes bicarbonate and enzymes at about 60% to 75% of the levels attained after intravenous infusions of maximally effective doses of secretagogues such as secretin and CCK. The meal-related regulation of secretion is usually divided into cephalic, gastric, and intestinal phases, although considerable overlap occurs.

The cephalic phase is stimulated by the thought, sight, taste, or smell of food. It can produce a secretory response 25% to 50% of maximal and is regulated primarily by vagal cholinergic innervation. The gastric phase has not been studied extensively. However, gastric distention produces a small increase in pancreatic secretion that appears to be mediated by vagal cholinergic reflexes. Current data do not support a significant role for gastrin in this process. By determining the rate of entry of acid and nutrients into the duodenum, gastric emptying strongly influences the intestinal phase, which is the predominant phase in the pancreatic response to a meal.

During the intestinal phase secretin is released into the blood from the duodenum in response to duodenal acidification. Fatty acids and bile may also help stimulate the secretion of secretin. The rise in plasma secretin concentration after a meal (potentiated by vagal cholinergic stimulation and circulating CCK) is responsible for the increase in pancreatic water and bicarbonate output.

Increased enzyme secretion is stimulated by fatty acids, oligopeptides, amino acids, and Ca^{2+} entering the intestine. This leads to release of CCK from the duodenum into the circulation and activation of cholinergic enteropancreatic reflexes, both of which stimulate pancreatic enzyme secretion. As is the case with secretin-stimulated water and bicarbonate secretion, cholinergic neural input appears to be essential for the full effect of physiologic levels of CCK to be exerted on pancreatic secretion, particularly in humans. Because studies examining human pancreatic tissue have thus far failed to demonstrate conclusively the presence of high-affinity (secretion-stimulating) CCK receptors on pancreatic acinar cells, it is possible that CCK may regulate pancreatic secretion in humans by binding to afferent or efferent vagal neurons rather than to acinar cells themselves.

FEEDBACK REGULATION

Feedback inhibition of pancreatic enzyme secretion by intraduodenal pancreatic proteases such as trypsin, chymotrypsin, and elastase has been clearly demonstrated in the rat. Several studies suggest that bile acids may also participate in feedback inhibition in some species. More limited data in humans support the existence of feedback inhibition of enzyme secretion by intraduodenal proteases, mediated by cholinergic nerves. The relative importance of this in either normal physiology or disease remains to be determined.

INHIBITORS OF EXOCRINE SECRETION

Postprandial exocrine secretion by the pancreas reaches only 60% to 75% of the maximal levels attained when pharmacologic concentrations of secretagogues are administered. This suggests the existence of physiologic inhibitory mechanisms. The islet cell peptides glucagon, pancreatic polypeptide, and somatostatin (also released from the small intestine) have all been suggested as possible mediators of such inhibitory processes.

Another potential candidate is peptide YY (PYY), found in intestinal endocrine cells in the ileum and colon and released in response to intraluminal lipid. PYY and perhaps other factors may act as the “ileal brake” to reduce pancreatic secretion after digestion of a meal has been largely completed. It is likely that inhibitors of pancreatic exocrine secretion act primarily by altering cholinergic neural transmission.

PANCREATIC BLOOD FLOW

Although ingestion of a meal increases overall splanchnic and portal blood flow, postprandial changes in pancreatic blood flow have not been extensively evaluated. The pancreas has a rich arterial blood supply; and physiologic levels of stimulation (due to CCK, secretin, or duodenal acidification) do not appear to increase total pancreatic perfusion. This indicates that, under physiologic conditions, pancreatic secretion is not limited by blood flow.

ACUTE PANCREATITIS

Acute pancreatitis is an inflammatory process arising in the exocrine pancreas, with variable involvement of peripancreatic tissues or remote organ systems. It ranges in severity from a mild, self-limited disease to a catastrophic one with multiple potentially severe complications and the risk of death. However, if the patient survives and the primary cause of pancreatitis can be identified and eliminated, the pancreas usually returns to normal clinically, biochemically, and morphologically (at least insofar as these aspects are routinely assessed).

Various studies report an incidence of acute pancreatitis from about 10 to as high as 50 per 100,000 per year. Although some series suggest a substantial increase in incidence over approximately the last 30 years, it is unclear to what extent this reflects improvements in our ability to make the diagnosis.

ETIOLOGIC FACTORS

Gallstone disease and excessive alcohol use account for about 70% to 80% of cases of acute pancreatitis in industrialized countries ([Table 117.2](#)). Other definable etiologic factors account for about 10% of cases, including genetic hyperlipidemia (with serum triglycerides typically higher than 1,000 mg per deciliter on presentation with acute pancreatitis), chronic hypercalcemia, surgery (particularly upper abdominal surgery and thoracic procedures involving cardiopulmonary bypass), solid organ transplantation (liver, heart, kidney), abdominal trauma (blunt or penetrating), endoscopic retrograde cholangiopancreatography (ERCP; incidence of 1% to 10%), sphincter of Oddi manometry (incidence of 10% to 20%), and infections (e.g., ascariasis, clonorchiasis, mumps, cytomegalovirus infection). Pancreatic cancers and ampullary tumors infrequently present as acute pancreatitis, as do, even more rarely, cancers metastatic to the pancreas. Benign anatomic abnormalities interfering with emptying of the pancreatic duct, such as choledochal cysts or duodenal diverticula, are also uncommon causes of acute pancreatitis.

Category	Specific Etiologic Factors
Gallstone disease	Chronic excessive alcohol use
Drugs (e.g., azathioprine, 6-mercaptopurine, didanosine, pentamidine, sulfonamides, valproic acid, trimethoprim-sulfamethoxazole, methimazole, metronidazole, lisinopril, enalapril, aminosalicylates, erythromycin, nitrofurantoin, furosemide, rifampicin, clozapine, diltiazem, ranitidine, acetaminophen, salicylates, some nonsteroidal anti-inflammatory drugs)	Infections (e.g., ascariasis, clonorchiasis, mumps, cytomegalovirus, cytomegalovirus, tuberculosis, <i>Agrobacterium anatum</i> complex)
Block or penetrating abdominal trauma	Surgery
Endoscopic retrograde cholangiopancreatography, sphincter of Oddi manometry	Genetic hypertriglyceridemia
Chronic hypercalcemia	Pancreatic or ampullary tumors
Pancreatic or ampullary tumors	Sphincter of Oddi dysfunction
Sphincter of Oddi dysfunction	Duodenal disease (e.g., peptic ulcer, Crohn's disease, periantral lymphadenopathy)
Duodenal disease (e.g., peptic ulcer, Crohn's disease, periantral lymphadenopathy)	Choledochal cyst
Choledochal cyst	Transcystic cholangiolithiasis (ascariasis, scorpion venom)
Transcystic cholangiolithiasis (ascariasis, scorpion venom)	Pancreas divisum
Pancreas divisum	Vancomycin (e.g., erythromycin, nifedipine, systemic lupus erythematosus, thrombotic thrombocytopenic syndrome, Hantavirus, Schistosoma guineaensis)
Vancomycin (e.g., erythromycin, nifedipine, systemic lupus erythematosus, thrombotic thrombocytopenic syndrome, Hantavirus, Schistosoma guineaensis)	Cystic fibrosis
Cystic fibrosis	Hereditary disease (e.g., mutation in cationic trypsinogen gene)
Hereditary disease (e.g., mutation in cationic trypsinogen gene)	Idiopathic disease

TABLE 117.2. MAJOR CAUSES OF ACUTE PANCREATITIS

Nearly 90 drugs have been implicated as potential causes of acute pancreatitis, although strong confirmatory evidence is available for only about 20 ([Table 117.2](#)). Some of these drugs typically produce acute pancreatitis within a month of starting treatment, presumably by a hypersensitivity reaction. These include azathioprine, mercaptopurine, sulfonamides, metronidazole, lisinopril, enalapril, and aminosalicylates. Other drugs (e.g., didanosine, pentamidine, and valproic acid) may produce pancreatitis after months of administration, suggesting perhaps the cumulative effects of the drug or toxic metabolites,

A still debated potential cause of acute pancreatitis is pancreas divisum, a variant of pancreatic ductal anatomy that involves 5% to 7% of the general population. In these persons, the duct of Santorini, draining the larger portion of the gland (arising from the embryologic dorsal pancreas) through the accessory papilla, does not fuse with the duct of Wirsung, draining the smaller embryologic ventral pancreas through the major papilla. In persons with pancreas divisum, the accessory papilla may be inadequate to accommodate the volume of pancreatic secretions under some circumstances, leading to relative obstruction to flow and recurrent acute pancreatitis. This appears to be the case for some patients; but given the prevalence of pancreas divisum, it is important to evaluate for other potential etiologic factors before ascribing pancreatitis to this common anatomical variant.

Another controversial proposed cause is sphincter of Oddi dysfunction. This has been diagnosed on the basis of finding, by endoscopic sphincter of Oddi manometry, a transient or fixed elevation of basal sphincter pressure of more than 40 mm Hg.

Patients with AIDS have an incidence of acute pancreatitis of as high as 4% to 20% in some series. This is due in part to infections involving pancreatic tissue (cytomegalovirus infection, cryptosporidiosis, cryptococcosis, toxoplasmosis, or infection with *Mycobacterium tuberculosis* or *Mycobacterium avium* complex) and in part to drug toxicity (e.g., didanosine, pentamidine, trimethoprim–sulfamethoxazole). Patients with AIDS also frequently have an elevated serum amylase concentration in the absence of pancreatitis either by clinical evaluation or by pancreatic imaging studies. It is unclear as to whether this hyperamylasemia is due to abnormalities in renal tubular function, increases in the salivary isoamylase fraction of total serum amylase, or subclinical pancreatic inflammation below the threshold for detection by imaging studies.

About 10% of adult patients are categorized as having idiopathic acute pancreatitis, although some series quote figures as high as 20% to 30%, depending on the criteria used to classify patients etiologically. Several studies have suggested that occult gallstone disease (biliary microlithiasis or gallbladder sludge) can be demonstrated in 50% to 75% of these patients by microscopic examination of bile or duodenal juice for cholesterol and bilirubinate crystals or by repeated abdominal ultrasonographic examinations. Treatments directed at gallstone disease (e.g., cholecystectomy, endoscopic sphincterotomy, or ursodeoxycholic acid therapy) significantly reduce the likelihood of recurrent acute pancreatitis in these patients. Other work has suggested that sphincter of Oddi dysfunction may account for 15% of cases of acute pancreatitis otherwise considered idiopathic. In addition, studies are under way to determine whether some less common mutations of CFTR may result in otherwise unexplained episodes of recurrent acute pancreatitis in adults.

Acute pancreatitis complicates anywhere from 1 in 100 to 1 in 4,000 pregnancies, generally due to gallstone disease and occurring in the third trimester. Acute pancreatitis in childhood is uncommon; the leading causes are trauma, biliary tract disease, drugs, and infections. Other causes in children include genetic hyperlipidemia (chylomicron disease), congenital malformations (pancreas divisum; choledochal, pancreatic ductal, or duodenal duplication cysts), cystic fibrosis, Reye's syndrome, and glycogen storage disease type I.

Recently, the genetic defect has been identified in some kindreds with hereditary pancreatitis, which is inherited as an autosomal dominant trait and may present in childhood or adolescence as recurrent acute pancreatitis.

These patients have a point mutation in the gene coding for cationic trypsinogen on chromosome 7, which impairs a mechanism in the acinar cell that protects the pancreas against the premature activation of trypsinogen to trypsin. About 20% of cases of acute pancreatitis in children are ultimately classified as idiopathic, although some of these may turn out to be related to less common mutations in CFTR.

PATHOGENESIS

Acute pancreatitis is believed to begin as an autodigestive process within the gland resulting from premature activation of zymogens (digestive enzyme precursors) within the acinar cell, duct system, or interstitial space. As trypsinogen activation to trypsin can lead to activation of all other zymogens, this appears to be an essential early step, a concept supported by the finding that a mutation in the trypsinogen gene results in hereditary pancreatitis. Whether trypsinogen is autoactivated or whether this process is mediated by other molecules such as lysosomal enzymes remains undetermined. Premature digestive enzyme activation can then result in acinar cell damage and necrosis and pancreatic edema and inflammation. In addition to digestive enzyme activation, oxidative stress, impaired microcirculation of blood in the pancreas, and release of cytokines (in particular interleukin-1 (IL-1), tumor necrosis factor, platelet-activating factor, and nitric oxide) also appear to contribute to both pancreatic injury and extrapancreatic complications ([Fig. 117.4](#)).

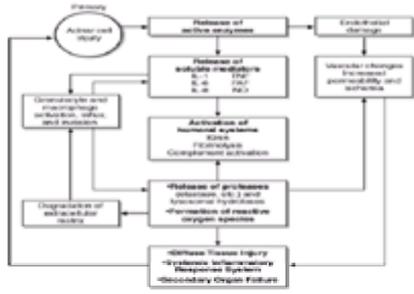

FIGURE 117.4. Proposed mechanisms involved in the pathophysiology of acute pancreatitis. IL, interleukin; TNF, tumor necrosis factor; PAF, platelet-activating factor; NO, nitric oxide. (Modified from Gorelick FS. Acute pancreatitis. In Yamada TA, Alpers DH, Owyang C, et al. eds. *Textbook of gastroenterology*, second ed. Philadelphia: JB Lippincott, 1995:2064.)

Extension of this inflammatory process beyond the pancreas frequently leads to localized complications and can result in various systemic complications ([Table 117.3](#)). For reasons that remain unknown, in about 75% to 85% of cases the inflammatory process is self-limited, involving only the pancreas and peripancreatic tissues and resolving spontaneously in a few days to a week. In the other 15% to 25%, a severe course ensues, with multiple local and systemic complications, prolonged hospitalization, and risk of death.

TABLE 117.3. COMPLICATIONS OF ACUTE PANCREATITIS

The overall mortality rate for hospitalized patients with acute pancreatitis is about 3% to 5%. Many of the systemic complications of acute pancreatitis appear to result from the development of a cytokine-mediated systemic inflammatory response syndrome.

Gallstone disease initiates the autodigestive process resulting in acute pancreatitis when a stone, usually only a few millimeters in diameter, migrates down the common bile duct and reaches the duodenal papilla ([Fig. 117.5](#)). Impaction of a stone at the papilla may then lead either to a sudden increase in pressure in the pancreatic duct, resulting in a "secretory block" of digestive enzymes at the level of the acinar cell, or to reflux of bile or duodenal juice into the pancreatic duct. Other etiologic factors involving obstruction of the bile or pancreatic duct may function in a similar way, although it is unclear why conditions such as pancreatic and ampullary tumors or pancreas divisum only infrequently produce acute pancreatitis.

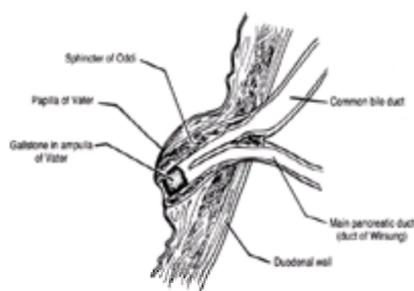

FIGURE 117.5. The proposed mechanism for the initiation of acute pancreatitis due to gallstones: impaction of a stone in the ampulla of Vater. (From Steinberg W, Tenner S. Acute pancreatitis. *N Engl J Med* 1994;330:1198, with permission.)

The mechanisms by which acute pancreatitis is induced by causative factors other than gallstones, pancreatic infections, or direct trauma to the gland remain unknown. However, experimental studies and some clinical observations suggest that development of a secretory block in the acinar cell may be a common feature of acute pancreatitis due to a number of causes.

Although acute pancreatitis that develops after a single binge involving excessive alcohol (ethanol) use has been occasionally reported, it is unclear if alcohol was the primary or sole cause in these cases. Typically, alcoholic acute pancreatitis occurs in persons with long-standing heavy ethanol use. Although chronic alcoholics have been reported to have about a 15-fold increased risk of developing acute pancreatitis compared to nonalcoholic controls, only about 5% of chronic heavy-alcohol users develop pancreatitis, indicating a major role for other hereditary or environmental risk factors. Alcoholic pancreatitis has been proposed to develop only in a gland that is already demonstrating the morphologic abnormalities of chronic pancreatitis. However, recent reports suggest that—at least for some patients—alcohol can produce acute and potentially reversible pancreatitis.

A variety of possible adverse effects of ethanol on the sphincter of Oddi and the pancreas have been described both in humans and in experimental animals. These

have included an increase in pressure or spasm of the sphincter of Oddi, protein plug formation in the pancreatic ducts, increased fragility of lysosomes and zymogen granules in acinar cells, and various alterations in pancreatic juice, including an increase in protein concentration and in the ratio of trypsin to trypsin inhibitor. Alcohol-related abnormalities in acinar cell signaling or in defense mechanisms against oxidative stress have been proposed. Whether or how these factors may be involved in the development of alcoholic acute pancreatitis remains to be established.

CLINICAL FEATURES

Abdominal pain, the primary manifestation of acute pancreatitis, is present in about 95% of patients. Pain is epigastric and radiates to the back in one-half to two-thirds of patients and is typically worsened by ingesting food or alcohol or by vomiting. Cessation of eating and drinking, leaning forward (doubling up), or assuming a knee-to-chest position may provide some relief of pain. Nausea, vomiting, and abdominal distention are also common symptoms. Hematemesis, melena, or diarrhea infrequently occur.

On examination, abdominal tenderness is usually present. It may be mild and limited to the epigastrium or marked, diffuse, and accompanied by abdominal rigidity and rebound tenderness. Depending on the severity of the presentation, patients may exhibit fever, tachycardia, tachypnea, and hypotension. Icterus may be present, usually in patients with biliary obstruction or concomitant liver disease. Dullness to percussion, diminished breath sounds, or rales over the lung bases may be noted in the presence of atelectasis or pleural effusion.

Other symptoms and signs may develop related to the onset of the complications listed in [Table 117.3](#). Dissection of blood or blood-tinged ascites along fascial planes to subcutaneous tissues may result in bluish discoloration of the skin in the periumbilical area (Cullen's sign) or the flanks (Turner's sign). However, these are only rarely present in acute pancreatitis and can be observed in other conditions, such as a ruptured abdominal aortic aneurysm.

DIAGNOSIS

Although the diagnosis of acute pancreatitis may be strongly suggested by the history and physical examination, a number of other diseases may present in a very similar way. Therefore, laboratory testing or abdominal imaging is necessary to confirm the diagnosis.

Laboratory Testing

During the development of acute pancreatitis, digestive enzymes leak from damaged acinar cells or ducts and eventually reach the systemic circulation, raising the circulating levels of these enzymes above normal. Measurement of the serum amylase concentration has been used for the diagnosis of acute pancreatitis for over 70 years; if measured within the first hours from the onset of symptoms, the level appears to be elevated in 80% to 85% of all patients with acute pancreatitis but in only 65% to 70% with acute pancreatitis due to alcohol abuse. Serum amylase levels may also be elevated in several conditions that can closely mimic acute pancreatitis (e.g., cholangitis, gastrointestinal (GI) perforation or ischemia, ruptured ectopic pregnancy) as well as in diseases of the salivary glands and in acute or chronic renal failure (due to diminished renal excretion of amylase). Determination of serum lipase concentration, at least by some methods, is as sensitive as or more sensitive than amylase (perhaps because lipase levels remain elevated in serum longer than amylase levels) and has greater specificity. This is so despite the fact that lipase levels may also be elevated in other diseases (such as GI perforation or ischemia) or due to acute or chronic renal failure. However, all of the current methods of measuring lipase (especially some of the autoanalyzer methods) may not perform equally well, particularly in terms of specificity. Clinical studies indicate that elevations in serum amylase or lipase due to impaired renal function should not exceed three times the upper limit of normal.

Measurement of urinary amylase excretion, serum amylase isozymes, or serum concentrations of other pancreatic enzymes (e.g., trypsin, elastase, phospholipase, procarboxypeptidase) has not proven to be more useful than standard serum amylase or lipase determinations. Although measurement of serum alanine aminotransferase (ALT) or aspartate aminotransferase (AST) is not useful in making the diagnosis of acute pancreatitis, a threefold or greater increase above the upper limit of normal of ALT or AST in a patient with acute pancreatitis suggests gallstones as the cause.

Abdominal Imaging

Abdominal imaging, particularly computed tomography (CT), has made the greatest contribution to the rapid and accurate diagnosis of acute pancreatitis and many of its complications. Abdominal ultrasonography may be useful in determining whether gallstones are the cause of an episode of acute pancreatitis; however, the sensitivity of ultrasonography in diagnosing acute pancreatitis is low, and examinations are often technically inadequate in patients with significant ileus. The CT scan may be normal in 15% to 30% of patients with mild acute pancreatitis, although the gold standard for establishing the diagnosis in these patients is often uncertain. CT is virtually always abnormal in moderate to severe disease ([Fig. 117.6](#)). Thus, CT is the most useful means—short of laparotomy—for differentiating severe acute pancreatitis from other catastrophic intra-abdominal processes that can mimic pancreatitis.

FIGURE 117.6. Typical findings on computed tomography in acute pancreatitis. The pancreas is edematous and inhomogeneous (*large arrows*), and inflammation has resulted in an increase in the density of the tissue surrounding loops of intestine near the tail of the pancreas (*small arrow*). (From Grendell JH. Acute pancreatitis. In: Grendell JH, McQuaid KR, Friedman SL, eds. *Current diagnosis and treatment in gastroenterology*. Stamford, CT: Appleton & Lange, 1996:435, with permission.)

Thus far, magnetic resonance imaging (MRI) has not improved on CT as a technique for diagnosing acute pancreatitis or its complications. However, it may be a useful substitute for evaluating patients who cannot receive intravenous contrast agents for CT or if detailed, noninvasive imaging of the bile or pancreatic ducts is also desired (magnetic resonance cholangiopancreatography).

Estimation of Severity

Extensive efforts have been devoted to establishing methods for predicting the severity of acute pancreatitis, so that the 75% to 85% of patients who will have a relatively mild course can be differentiated from those patients destined for more serious illness and possible death.

Assessment of Ranson's criteria (based mainly on patient age and various laboratory values) has been the most commonly used prognostic indicator in the United States, whereas the modified Glasgow (Imrie) criteria, similar to Ranson's criteria, have been used in the United Kingdom ([Table 117.4](#)). For both sets of criteria, the more risk factors a patient accrues, the greater the probability of a prolonged, complicated course and death. However, neither the Ranson nor the Glasgow score can be computed until the patient has been hospitalized for 48 hours, and neither can be recomputed to follow the patient's course. A more useful but complex scoring system is the Acute Physiologic and Chronic Health Evaluation (APACHE) II score, which can be calculated at the time of admission and then recalculated throughout the course of hospitalization to measure improvement or worsening. However, the APACHE II score has been criticized for assigning too heavy a weighting to age.

Variable	Normal	Abnormal
Age	< 60	> 60
Albumin	> 3.0	< 3.0
BUN	< 1.5	> 1.5
Calcium	> 2.0	< 2.0
Glucose	< 150	> 150
Hematocrit	> 30	< 30
Hemoglobin	> 10	< 10
WBC	< 12,000	> 12,000
APACHE II	< 8	> 8

TABLE 117.4. RANSON'S AND MODIFIED GLASGOW CRITERIA OF SEVERITY

In addition, because a number of studies have suggested that obesity is a risk factor for morbidity and mortality in acute pancreatitis, it has been proposed that the use of APACHE II for estimating the severity of acute pancreatitis could be improved by adding a factor to account for body mass index. When values obtained at 48 hours after admission are compared, the Ranson, Glasgow, and APACHE II scores perform similarly in predicting the severity of disease.

Dynamic (bolus contrast-enhanced) CT has been used as a predictor of severity, but the criteria have not been well standardized, the optimal timing of the examination is uncertain, and the technique is costly. In addition, there is a risk of nephrotoxicity from intravenous contrast agents; and concern has been raised, based on work in experimental models of pancreatitis, that pancreatitis could be worsened due to contrast-induced alterations in the pancreatic microcirculation. So far there has been no convincing evidence for the latter from clinical observation.

MRI and various laboratory tests are being evaluated as potential indicators of severity. The laboratory tests have the advantage of being relatively simple and inexpensive, and include measurement in blood of C-reactive protein, IL-6 and IL-8, leukocyte elastase, and, in urine or blood, trypsinogen activation peptide. Some initial reports are promising, but these tests require more extensive validation in general clinical practice.

Although a number of predictors (especially APACHE II) effectively define or stratify groups of patients for clinical research, none so far is clearly superior to close observation and careful judgment by an experienced physician as a basis for making therapeutic decisions.

DIFFERENTIAL DIAGNOSIS

Various relatively common intra-abdominal processes may present similarly to acute pancreatitis, and some may even elevate serum amylase or lipase levels. These include penetrating duodenal ulcer, perforated gastric or duodenal ulcer, cholangitis, intestinal ischemia or infarction, and ruptured ectopic pregnancy. A ruptured abdominal aortic aneurysm may present with similar symptoms and signs as well as such uncommon entities as acute intermittent porphyria, familial Mediterranean fever, and lead poisoning.

MANAGEMENT

The goals of therapy of acute pancreatitis are to provide supportive care, to decrease pancreatic inflammation and its consequences, and to prevent or to identify and treat complications.

Mild Acute Pancreatitis

Most patients have a mild, self-limited course requiring only bed rest, no oral intake, intravenous hydration and electrolytes, and analgesia. Traditionally, meperidine has been the analgesic of choice because of reports that it is less likely than other opiates to raise sphincter of Oddi pressure. However, the clinical importance of this is uncertain, and other narcotics can be substituted if needed. Nasogastric suction does not shorten the course of the disease but is useful in relieving symptoms of nausea, vomiting, or abdominal distention. Patients may be cautiously fed once abdominal pain and tenderness have abated and serum amylase or lipase values have begun to approach normal.

Severe Acute Pancreatitis

The care of the patient with severe acute pancreatitis poses a much greater challenge. In the earliest stages, vigorous resuscitation with intravenous hydration and electrolytes is critical to prevent or treat hypovolemia and shock. Volume requirements may be remarkably large; and these patients often need an intensive care unit with careful attention to monitoring of hemodynamics (including mean arterial pressure, cardiac index, and pulmonary capillary wedge pressure), urine output, and respiratory and renal function. Patients should initially be kept at bed rest with no oral intake, and large amounts of intravenous narcotic analgesics are typically needed for pain relief as well as nasogastric suction for treatment of severe ileus, nausea, and vomiting.

Several pharmacologic agents have been tried to inactivate trypsin and other serine proteases (e.g., aprotinin, gabexate), decrease pancreatic secretion (atropine, somatostatin and the somatostatin analog octreotide), or reduce inflammation (corticosteroids, indomethacin). None of these approaches has been shown to be beneficial in good clinical studies. In addition, the efficacy of early peritoneal lavage or operative approaches ("necrosectomy," debridement and drainage) in the absence of documented pancreatic infection remains to be demonstrated.

The recognition that cytokines and other mediators of inflammation are major contributors to both pancreatic injury and the later development of systemic complications in severe acute pancreatitis has engendered optimism that pharmacologic therapy directed either at inhibiting proinflammatory cytokines (e.g., IL-1, tumor necrosis factor, platelet-activating factor) or augmenting anti-inflammatory ones (e.g., IL-10) may prove to be effective in reducing the severity of acute pancreatitis. Unlike the activation of trypsin and other zymogens within the pancreas that may be largely completed by the time a patient is first seen by a physician, production of cytokines and development of distant organ dysfunction develop later, providing a possible "interventional window" during which drugs which specifically block the effects of inflammatory mediators could prevent or mitigate some of the life-threatening complications of severe pancreatitis (Fig. 117.4). However, the first such agent tested in a large, prospective, randomized, placebo-controlled trial, a potent antagonist of platelet-activating factor, failed to show any benefit. Nevertheless, a variety of other experimental drugs are at various stages of evaluation for this purpose.

In addition to organ failure, septic complications of acute pancreatitis are a major cause of morbidity and mortality. Earlier attempts to prevent this by prophylactic administration of antibiotics failed to show a benefit. However, the patients studied were on the milder end of the spectrum of severity (and thus less likely to develop septic complications) and the antibiotic used, ampicillin, was later shown not to penetrate inflamed pancreatic tissue well. Renewed interest in the use of prophylactic antibiotics has resulted from recent small studies suggesting a benefit from administration of either imipenem or a quinolone (e.g., ciprofloxacin) and metronidazole to patients with predicted severe pancreatitis. However, the currently available studies have limitations; and there is concern that prolonged use of prophylactic antibiotics, particularly imipenem, may increase the frequency of fungal infections. Until results of larger and more definitive studies are available, if prophylactic antibiotics are to be given, their use should be restricted to patients with predicted severe pancreatitis or suspected cholangitis. The combination of ciprofloxacin and metronidazole is the best choice to reduce the risk both of fungal infection for the patient and of development of imipenem-resistant organisms in the hospital.

Four randomized controlled studies have examined the value of ERCP with sphincterotomy and stone extraction, if indicated, in diminishing the severity of presumed gallstone pancreatitis. Gallstones should be suspected as the most likely cause in high-incidence areas (e.g., Hong Kong) and among patients who abstain from or moderately use alcohol, in women, in persons older than age 60, in those with a serum ALT elevated above the upper limits of normal by a factor of at least 3, in those with a history of gallstones, or in those with a dilated common duct visualized on abdominal ultrasonography or CT. If associated cholangitis is suspected due to the presence of right upper quadrant abdominal pain and tenderness, fever higher than 39°C, leukocyte count greater than 20,000 per milliliter, or bilirubin greater than 5 mg per deciliter, then urgent ERCP should be performed. However, in Western societies cholangitis is associated with acute gallstone pancreatitis in fewer than 10% of cases. Currently available studies yield conflicting results concerning whether ERCP performed within 24 to 72 hours of hospital admission reduces the severity of

the disease for patients with presumed gallstone pancreatitis of moderate to severe degree who do not have cholangitis.

Oral feedings should not be resumed too soon for patients with severe acute pancreatitis or major complications (e.g., organ failure or infected pancreatic necrosis or abscess), as this may lead to exacerbation of the disease and further complications. Such patients should receive either enteral tube feedings (preferably of an elemental diet delivered to the more distal jejunum to reduce pancreatic stimulation) or total parenteral nutrition (TPN). Enteral feeding has the advantages of fewer complications and lower cost, and it may promote maintenance of intestinal mucosal integrity, thus reducing the risk of septic complications resulting from bacterial translocation from the gut. Lipid emulsions can be safely used as a component of TPN if care is taken to maintain the serum triglyceride concentration below 500 mg per deciliter. Oral feedings should not be started until any major complications have been effectively treated and the patient is free of pain and nausea and has near-normal serum amylase or lipase concentrations. If operative debridement and drainage is performed for infected necrosis or abscess (or if used for sterile necrosis), surgical placement of a tube jejunostomy greatly facilitates subsequent nutritional management.

COMPLICATIONS

In the initial 24 to 48 hours after admission, shock is the most lethal potential complication. Shock results from a combination of factors: marked hypovolemia due to transudation and exudation of fluid into the retroperitoneum and peritoneum, third-spacing of fluid into the dilated stomach and intestine, and (in some patients) a "leaky capillary" syndrome, as well as from myocardial depression due to unidentified factors presumably released as a consequence of the inflammatory process. Treatment is vigorous rehydration guided by hemodynamic monitoring in an intensive care unit, supplemented by vasopressor administration, if needed.

Although hypocalcemia is common and one of the adverse prognostic factors in the Ranson and Glasgow criteria for severity, clinically significant reductions of circulating ionized calcium are uncommon. Calcium administration is required only for patients with clinical findings related to hypocalcemia. If hypomagnesemia is also present, magnesium correction is required. The mechanisms by which hypocalcemia occurs are uncertain, but the disorder is probably multifactorial and may involve sequestration of calcium in saponified fat in the retroperitoneum and peritoneum, a decrease in the serum albumin concentration, and an impaired mobilization of calcium by parathyroid hormone.

Elevations in serum transaminases, alkaline phosphatase, and bilirubin are common in acute pancreatitis. However, they are usually mild and of no clinical significance, except as a possible indicator of gallstones as an etiologic factor (e.g., ALT more than three times the upper limit of normal). Jaundice is present in about 15% to 20% of patients, with total serum bilirubin usually below 4 mg per deciliter. A higher level or protracted elevation indicates coexisting parenchymal liver disease (e.g., alcoholic hepatitis or cirrhosis, chronic viral hepatitis) or obstruction of the common bile duct by a gallstone, tumor, pancreatic inflammatory mass, or pseudocyst. Surgical or endoscopic intervention may be required for treatment of bile duct obstruction.

Pulmonary abnormalities are common in patients with acute pancreatitis. About 60% of patients demonstrate hypoxemia on room air arterial blood gas determination; and 30% to 60% have abnormal chest film findings, ranging from atelectasis and pleural effusions (usually left-sided) to diffuse bilateral infiltrates indicative of adult respiratory distress syndrome. At about 3 to 7 days after admission, respiratory failure develops in about 5% to 10% of patients, requiring mechanical ventilation. Acute renal failure may also develop during the first week in the hospital, necessitating dialysis. The presence of respiratory or renal failure is associated with a markedly increased mortality rate approaching 50% in some series, but both complications are reversible if the underlying pancreatic inflammation abates and other complications (e.g., sepsis) do not supervene.

Patients with moderate to severe acute pancreatitis are at risk for septic complications resulting from infected pancreatic necrosis or abscess. This usually presents a week or more after admission as clinical deterioration (e.g., worsening pain or nausea and vomiting), fever (especially if higher than 39.5°C), or leukocytosis (especially if greater than 20,000 per milliliter). Over the past 20 years, earlier diagnosis and aggressive treatment of infected pancreatic necrosis and abscess have led to a reduction in mortality rates for septic complications from 70% to 80% to 10% to 20%. This has resulted from the widespread use of CT scanning and needle aspiration in the early evaluation of patients with suspected infected necrosis or abscess. Suspicious (low-density) areas in the pancreas or of fluid collections adjacent to it should be aspirated, sent for culture, and, most importantly, immediately Gram-stained. The presence of both bacterial organisms and polymorphonuclear leukocytes on the Gram-stained smear strongly indicates infected necrosis or abscess. Patients with these findings generally should undergo emergency surgery with extensive debridement and drainage. Several recent reports have proposed that some patients can be adequately treated with endoscopic or percutaneous catheter drainage or even antibiotics alone. However, the selection criteria have yet to be established in terms of which patients may do well with nonoperative approaches because the viscous nature of the infected material and the frequent presence of loculations make catheter drainage difficult and antibiotic penetration uncertain. Patients who develop signs of recurrent sepsis after initial operative treatment for infected necrosis or abscess should be carefully evaluated for possible fungal (usually *Candida*) sepsis.

Operative debridement and drainage has been proposed to benefit patients with severe acute pancreatitis who have sterile necrosis (CT-guided aspirates negative for bacterial or fungal organisms), particularly if it is complicated by respiratory or renal failure. However, it has not been established that this group of patients does better after surgery than similar patients treated only with aggressive nonoperative care.

Two-thirds to three-fourths of patients with acute pancreatitis have fluid collections (peripancreatic effusions) demonstrated early in their illness by abdominal ultrasonography or CT. Only about 10% to 15% of patients with acute pancreatitis develop an encapsulated collection of inflammatory fluid and pancreatic juice—a pseudocyst. If pseudocysts are asymptomatic or only mildly symptomatic (e.g., mild pain), acute pseudocysts should be followed by ultrasonography or CT for at least 6 weeks to determine if they will resolve (about half will) or decrease in size without treatment. Asymptomatic acute pseudocysts less than 6 cm in diameter or those diminishing in size can be watched without treatment indefinitely.

Symptomatic acute pseudocysts, expanding pseudocysts, and those larger than 6 cm in diameter (particularly if larger than 10 cm) should be considered for therapy if they persist for more than 6 weeks after an episode of acute pancreatitis. In the past the standard definitive treatment was open internal drainage of the pseudocyst into the stomach, duodenum, or a Roux loop of jejunum. More recently in selected patients, newer approaches, including minimally invasive (laparoscopic) surgical techniques, percutaneous catheter drainage, and endoscopic internal drainage, have been successfully employed. The treatment decision should be based on the specific circumstances for a given patient and the local expertise. For clinically infected pseudocysts (patients who typically have fever, leukocytosis, and pseudocyst aspirates demonstrating both polymorphonuclear leukocytes and bacterial organisms on Gram-stained smear), percutaneous catheter drainage is as effective as the previous operative approach (open external drainage), with a lower rate of pseudocyst recurrence and fistula formation.

Significant hemorrhage (requiring blood transfusion) is a rare complication of acute pancreatitis. Potential causes include stress gastritis, Mallory–Weiss tear, development of a pseudoaneurysm in the peripancreatic arterial circulation, bleeding from small vessels in the wall of a pseudocyst into the cyst contents, or gastric varices due to splenic vein thrombosis. Bleeding from stress gastritis, a Mallory–Weiss tear, or gastric varices usually presents with hematemesis, melena, and a falling blood hemoglobin concentration, and is best diagnosed by upper GI endoscopy. Bleeding from a pseudoaneurysm or into a pseudocyst from the cyst wall may not communicate with the GI tract (in which case it is best diagnosed by CT); or it may result in bleeding via the pancreatic duct (hemorrhage pancreaticus), with melena and blood or clot at endoscopy in the region of the duodenal papilla without any mucosal lesion that could account for it. Angiography is of great value in identifying the site of bleeding from a pseudoaneurysm. Frequently, pseudoaneurysms can be definitively treated by angiographic embolization, but some require direct operative control.

MANAGEMENT AFTER RECOVERY FROM ACUTE PANCREATITIS

Once a patient has recovered from an attack of acute pancreatitis, the most likely cause should be identified and treated, if possible, to prevent a recurrence. Patients with gallstone disease should generally undergo cholecystectomy. However, if the gallbladder has already been resected or if the patient is not a good operative candidate, endoscopic sphincterotomy is also highly effective. For the occasional patient with a gallbladder in place and cholesterol gallstones who, for whatever reason, cannot undergo surgery or ERCP, bile acid dissolution therapy can be considered. If alcohol is the cause, patients should be strongly advised to abstain. Genetic hyperlipidemia requires treatment with diet, avoidance of contributing factors (e.g., alcohol, estrogens, thiazides), good control of diabetes mellitus if present, and, in some cases, lipid-lowering drugs. If a specific drug is believed to be the causative factor, it should not be restarted.

In a relatively small number of patients, no etiologic process is established after the initial history and physical examination, determination of serum triglyceride and calcium concentrations, and abdominal ultrasonography. Several reports have suggested that at least half of these patients have occult gallstone disease (e.g., microlithiasis, biliary sludge); this is best identified by stimulating the gallbladder to contract with cholecystikinin and examining the bile or duodenal juice for cholesterol and bilirubinate crystals or by performing repeated abdominal ultrasonographic examinations for sludge in the gallbladder. Other studies have proposed that about 15% of these patients may have sphincter of Oddi dysfunction. Genetic hyperlipidemia is often missed because serum triglycerides are not measured until

after the patient has been fasting for several days, by which time triglyceride levels may have fallen substantially. The more common causes of “idiopathic” acute pancreatitis and the means of diagnosing them are given in [Table 117.5](#).

Cause	Useful Diagnostic Tests
Occult gallstone disease (ultrasound-negative)	Biliary drainage for crystal analysis; repeated abdominal ultrasound exams (ERCP)
Undiagnosed hypertriglyceridemia	Previous serum triglyceride values, if available; serum triglyceride determination after patient resumes regular diet and medications
Abnormalities of the ampulla, bile duct, or pancreatic duct	ERCP
Sphincter of Oddi dysfunction	ERCP with sphincter of Oddi manometry
Pancreatic cancer; ampullary or other tumors	CT-guided fine-needle aspiration biopsy ERCP; serial determination of serum CA 19-9 levels
Cystic fibrosis	Measurement of sweat chloride; molecular genetic testing

ERCP, endoscopic retrograde cholangiopancreatography; CT, computed tomography.

TABLE 117.5. POSSIBLE CAUSES OF OCCULT (“IDIOPATHIC”) ACUTE PANCREATITIS

CHRONIC PANCREATITIS

Chronic pancreatitis is an inflammatory process involving the pancreas that results in irreversible fibrosis of the gland and atrophy of both exocrine and endocrine tissue. The pancreatic ducts are often involved, with the formation of intraductal protein plugs (which may calcify), ductal strictures, and dilatation of ducts upstream from strictures. Individual episodes of acute pancreatitis do not appear to lead to chronic pancreatitis in the absence of a significant stricture of the main pancreatic duct or its outflow. There are few reliable data on the prevalence or incidence of chronic pancreatitis. Estimates of prevalence from autopsy data range from 0.04% to 5%. One prospective study from Denmark in 1978–1979 estimated a prevalence of 26 cases per 100,000 population, whereas data from Germany covering the period 1988–1995 suggested an incidence of 6.6 cases per 100,000 population per year, resulting in a prevalence of about 132 cases per 100,000 population.

ETIOLOGIC FACTORS

In industrialized countries, alcohol consumption accounts for about 70% of cases ([Table 117.6](#)). Typically patients give a history of at least 6 to 12 years of consumption of 150 to 175 g of ethanol per day. However, there does not appear to be a statistical threshold for alcohol consumption because consumers of 1 to 20 g of ethanol per day have a small but statistically significant increase in the risk of developing chronic pancreatitis compared with abstainers. The form in which alcohol is consumed does not appear to affect the risk. A diet high in protein and either very high or very low in fat may predispose to chronic pancreatic injury from alcohol. Genetic, dietary, and other environmental predisposing factors probably have a significant influence on the risk of chronic pancreatitis because only 10% to 15% of individuals with the highest levels of alcohol use develop this disease.

Chronic excessive alcohol use (70% of cases in industrialized countries)
Tropical chronic pancreatitis (primarily in India, Indonesia, Africa)
Chronic obstruction of the pancreatic duct
Ampullary stenosis or neoplasm
Pancreatic tumors
Pseudocysts
Pancreatic duct stents
Traumatic or inflammatory strictures
Pancreas divisum (uncertain)
Pancreatic trauma
Genetic hypertriglyceridemia
Hyperparathyroidism
Cystic fibrosis (including <i>CFTR</i> mutations that do not produce pulmonary disease)
Hereditary disease (e.g., mutation in the cationic trypsinogen gene)
Idiopathic disease (10–30% in industrialized countries)

TABLE 117.6. MAJOR CAUSES OF CHRONIC PANCREATITIS

The tropical or nutritional form of chronic pancreatitis is observed primarily in areas of India, Indonesia, and Africa. Patients typically present in childhood with abdominal pain and diffuse pancreatic calcifications, malnutrition, and diabetes mellitus, and they often die in early adulthood of complications of the disease. Although malnutrition appears to be a major factor, with patients consuming a low-protein and very-low-fat diet, it is not the only one; regions of India with comparable degrees of childhood malnutrition do not always have comparable prevalences for tropical chronic pancreatitis.

Long-standing obstruction of the main pancreatic duct or outflow from it may lead to obstructive chronic pancreatitis. This type of obstruction can result from papillary stenosis or ampullary neoplasms, pancreatic tumors, endoscopically placed pancreatic duct stents, pseudocysts, and strictures of the pancreatic duct as a consequence of trauma or, rarely, a severe episode of acute pancreatitis. Whether pancreas divisum can result in chronic pancreatitis (in addition to producing episodes of recurrent acute pancreatitis) remains a matter of dispute, with different clinical studies yielding conflicting results. Obstructive chronic pancreatitis, which appears to be a distinct type of chronic pancreatitis, is characterized by dilatation of the main pancreatic duct and acinar atrophy and fibrosis. However, unlike the case of alcoholic chronic pancreatitis, protein plugs or stones in the pancreatic duct are very uncommon; and morphologic and functional abnormalities may regress substantially once the obstruction is relieved.

Chronic pancreatitis may also develop in association with pancreatic trauma, genetic hyperlipidemia, hyperparathyroidism, and cystic fibrosis. A hereditary form presents with symptoms usually beginning in childhood and an autosomal pattern of inheritance with about 80% penetrance. The genetic defect is a point mutation on the gene on chromosome 7 coding for the pancreatic zymogen cationic trypsinogen, which renders the molecule less susceptible to intracellular mechanisms that protect the acinar cell against the premature activation of trypsinogen to trypsin. Other familial clusterings of what may be hereditary chronic pancreatitis have been described, with the onset of disease in the third or fourth decade.

About 10% to 30% of patients with chronic pancreatitis in industrialized countries have no apparent definable etiologic factor and are classified as having an idiopathic form. These patients seem to cluster in two age groups: a younger one (approximately age 15 to 30 years), in whom abdominal pain predominates, and an older group (approximately age 50 to 70 years), with pancreatic exocrine insufficiency and diabetes mellitus, often in the absence of pain. Recent studies have suggested that patients with idiopathic chronic pancreatitis have an increased incidence of a variety of defects in the *CFTR* gene that do not produce the pulmonary abnormalities typical of classic cystic fibrosis but that may alter pancreatic secretion in a way predisposing to development of chronic pancreatic injury. A possible autoimmune cause for some cases of idiopathic chronic pancreatitis has also been proposed.

PATHOGENESIS

The pathogenesis of chronic pancreatitis remains uncertain. For alcohol-related disease, current theories can be broadly divided into two main types. The first is that alcohol-related alterations in the physicochemical properties of pancreatic juice or in the function of the sphincter of Oddi lead to duct obstruction as the principal cause of pancreatic damage (duct obstruction theories). The second is that repeated or continuous injury to pancreatic acinar cells produces inflammation, necrosis, and fibrosis, with duct obstruction, when present, as a secondary event (toxic–metabolic theories).

The leading variant of the duct obstruction theories proposes that protein plugs (some of which may calcify) initially precipitate in intralobular and small interlobular ducts due to one or more changes in pancreatic juice, such as an increase in protein and calcium concentration and viscosity, a decrease in citrate concentration, and alterations in solubility and the function of specific proteins (e.g., lithostathine, glycoprotein 2). Obstruction to smaller ducts produced by these plugs could trigger the

inflammatory process, leading to fibrosis, atrophy, and ultimately involvement of the main pancreatic duct. Consistent with this theory is the finding that protein plugs are often found in pancreatic juice from patients with alcoholic chronic pancreatitis; a clinical natural history study involving serially performed ERCP suggested that in most patients branch ducts are deformed early in the course of the disease, before the main duct suffers increasing damage. Conversely, however, protein plugs can be found in the pancreatic juice from alcoholics without chronic pancreatitis and even in normal controls. This theory also fails to explain why protein plugging would occur early in chronic pancreatitis, before any reduction in pancreatic juice flow, and how the plugging of small ducts would initiate such a severe inflammatory response.

The toxic–metabolic theories propose that chronic pancreatitis results from chronic or repetitive injury to pancreatic acinar cells, leading to inflammation, atrophy, and fibrosis. Ductal plugging and stricturing could occur as a secondary event, perhaps related to decreased secretion and periductal fibrosis. In these theories, alcohol could act primarily by producing a direct toxic injury to acinar cells or by causing low-grade recurrent or persisting “acute” pancreatitis, which could be analogous to the role proposed for alcoholic hepatitis in the pathogenesis of cirrhosis of the liver.

There is insufficient evidence to consider any theory concerning the pathogenesis of alcoholic chronic pancreatitis (or of any other cause of chronic pancreatitis) as established. Probably more than one mechanism is involved, and it is likely that different mechanisms may predominate in different patients or even at different stages of the disease in the same patient.

CLINICAL FEATURES

Pain is the most common presenting symptom. It is usually epigastric, dull, and constant in character, radiating to the back, to both upper quadrants, and even (occasionally) to the lower quadrants, particularly the left. The pain may be partially relieved by sitting bent forward or lying prone. In about half of patients, episodes of pain last for several days, with intervening pain-free intervals; the other half have near-constant pain. Pain is typically worsened by ingesting food or alcohol and may be accompanied by nausea and vomiting. For some patients, the pain diminishes or resolves completely over long periods of time (5 to 15 years), coincident with the appearance of pancreatic calcifications, steatorrhea, and diabetes (“burnout” of the gland). About 10% to 20% of patients with chronic pancreatitis have little or no pain, particularly the older age group of patients with idiopathic disease.

Patients with chronic pancreatitis typically lose weight due to pain and nausea, malabsorption due to pancreatic exocrine insufficiency, and poorly controlled diabetes mellitus. Overt steatorrhea occurs in about 30% to 50% of patients after the pancreas’s capacity to secrete lipase and other digestive enzymes has been reduced to less than 10% of normal (Fig. 117.7). The quantity of fat in the stool in pancreatic insufficiency generally exceeds that found in other diseases producing steatorrhea. In the absence of ingestion of exogenous lipid oils (e.g., mineral oil), a history of oil leakage from the anus or an “oil slick” in the toilet is highly suggestive of pancreatic insufficiency. Although body stores of fat-soluble vitamins (A, D, E, and K) may be diminished, clinical deficiencies are rarely observed. Hypoproteinemia is also uncommon.

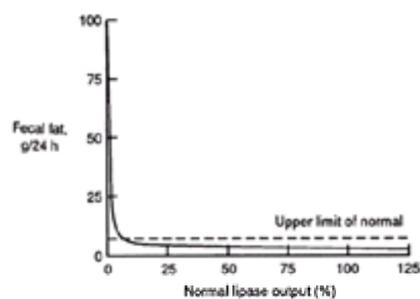

FIGURE 117.7. The relation of fecal fat excretion to secretion of pancreatic lipase into the duodenum in patients with chronic pancreatitis. Steatorrhea is not observed until lipase secretion is reduced to less than 10% of normal. (Adapted from DiMagno EP, Go VLW, Summerskill WHJ. Relations between pancreatic enzyme outputs and malabsorption in severe pancreatic insufficiency. *N Engl J Med* 1973;288:813.)

Clinically evident diabetes mellitus occurs in about 50% of patients, usually after the diagnosis has been well established. However, patients with little or no pain may present initially with diabetes, as may patients with tropical chronic pancreatitis. For similar durations of diabetes, retinopathy and neuropathy appear to occur as often as in primary forms of diabetes; however, ketoacidosis and nephropathy are uncommon.

During episodes of pain, patients with chronic pancreatitis usually have demonstrated mild to moderate epigastric tenderness without guarding or rebound tenderness. Generally, the abdominal tenderness is less impressive than the degree of pain reported. A rounded, palpable abdominal mass suggests the presence of a pseudocyst, although most are not palpable. Bulging flanks and shifting dullness indicate the possible presence of pancreatic ascites, and dullness to percussion or diminished breath sounds at the lung bases may be signs of a pancreatic pleural effusion.

DIAGNOSIS

Chronic pancreatitis should be suspected when a patient presents with the typical pattern and character of abdominal pain, particularly if accompanied by symptoms suggestive of steatorrhea or diabetes mellitus. The finding on plain abdominal film of calcifications in the region of the pancreas (Fig. 117.8) is present in about one-third of patients and establishes the diagnosis with a high degree of reliability; no further diagnostic testing is necessary. In increasing order of sensitivity, cost, and invasiveness, abdominal ultrasonography, CT, and ERCP can be used to confirm the diagnosis in patients without calcification on plain film. On ultrasonography and CT scanning (Fig. 117.9), typical findings are calcifications (which can be below the resolution of plain film), dilatation of the pancreatic duct, and pancreatic pseudocysts. ERCP provides exquisitely detailed views of the pancreatic duct system, demonstrating strictures and ectatic changes in the pancreatic duct and its main branches (which are common findings, particularly in alcoholic chronic pancreatitis; Fig. 117.10). Magnetic resonance cholangio-pancreatography provides a noninvasive means of imaging the main pancreatic duct, but its utility and role in the diagnosis of chronic pancreatitis remains to be determined. Of all of the tests of pancreatic structure, endoscopic ultrasonography (EUS) is the only one that can provide a detailed evaluation of both the duct system and the parenchyma. Therefore, it can identify subtle changes in early or mild chronic pancreatitis not seen with other imaging modalities. However, the accuracy of EUS is highly dependent on the skill and experience of the person performing the procedure, and EUS is not as widely available as abdominal ultrasonography, CT, or ERCP.

FIGURE 117.8. Abdominal plain film demonstrating calcifications throughout the pancreas in a patient with chronic pancreatitis.

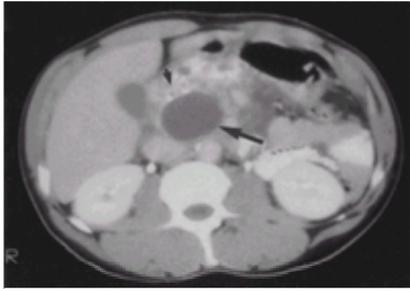

FIGURE 117.9. Typical findings on computed tomography in chronic pancreatitis. There is an area (*small arrow*) containing multiple bright-appearing calcifications and a pseudocyst (*large arrow*) in the head of the pancreas. (From Forsmark CE. Chronic pancreatitis and pancreatic insufficiency. In: Grendell JH, McQuaid KR, Friedman SL, eds. *Current diagnosis and treatment in gastroenterology*. Stamford, CT: Appleton & Lange, 1996:441, with permission.)

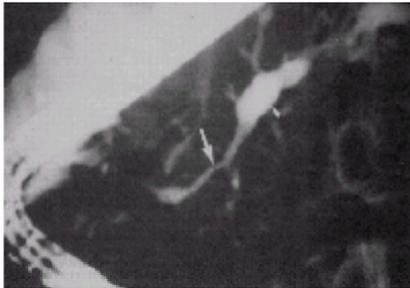

FIGURE 117.10. Typical findings on endoscopic retrograde pancreatography in chronic pancreatitis. Throughout the pancreatic duct, there are multiple alternating areas of stricture (*large arrow*) and duct dilatation (*small arrow*), creating a “chain of lakes” appearance.

An alternative approach to the diagnosis of chronic pancreatitis is the testing of pancreatic exocrine function. The most sensitive and reliable tests involve collection of either duodenal or “pure” pancreatic juice (by cannulation of the pancreatic duct at ERCP) and measuring either the concentration of bicarbonate after administration of secretin or the concentration of one or more of the pancreatic digestive enzymes after administration of a test meal or CCK (or its analog cerulein). These direct tests of function are most useful in suspected mild or early chronic pancreatitis, particularly if idiopathic or due to causes other than alcohol, a situation in which calcifications or abnormalities in the pancreatic duct are frequently not present on imaging studies. However, direct test of pancreatic function are technically cumbersome, expensive, and not widely available. Indirect or “tubeless” tests of pancreatic function include measurement of fecal concentrations of the pancreatic enzymes chymotrypsin or elastase, and the bentiromide and pancreolauryl tests. These latter two tests involve oral administration of a test substance that is cleaved by pancreatic enzymes in the small intestine, releasing a marker that can be measured in urine or blood. Unfortunately, these inexpensive and relatively convenient indirect tests are reliable only in patients with advanced disease (e.g., those with steatorrhea), for whom the diagnosis is generally not difficult to establish by plain film or other abdominal imaging.

The most sensitive imaging studies, EUS and ERCP, and the direct tests of pancreatic function (e.g., secretin stimulation test for measurement of bicarbonate concentration) are abnormal in most patients with chronic pancreatitis and correlate well in those with moderate to severe disease. However, in patients suspected of having mild or early chronic pancreatitis, any two of these three tests yield conflicting results in 15% to 30% of cases, creating diagnostic uncertainty that is difficult to resolve in the absence of pancreatic histologic examination, which is rarely available.

The hallmark of pancreatic insufficiency is the presence of steatorrhea which is defined as fecal fat excretion of more than 7 g per 24 hours on a diet of 100 g of fat per day. Qualitative stool fat determinations (Sudan staining) generally become positive when steatorrhea results in a stool fat excretion of 12 to 15 g per day or more.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in patients with upper abdominal pain includes peptic ulcer disease, gastric or pancreatic cancer, chronic partial obstruction of the small intestine, and functional abdominal pain syndromes. Steatorrhea from pancreatic insufficiency must be distinguished from that due to diseases of the small intestine.

MANAGEMENT

Pain

For patients with alcoholic chronic pancreatitis, abstinence from alcohol may result in improvement in pain, particularly for patients with early or mild disease (before the development of extensive calcifications and steatorrhea). Oral analgesics, including potent narcotics, are often needed for pain relief. For patients disabled either by pain or by the amount of narcotics required to control pain, a trial of high doses of a nonenteric-coated pancreatic enzyme supplement (e.g., Viokase or Ku-Zyme HP, 8 with meals and at bedtime along with a gastric proton pump inhibitor) can be instituted in the hope of ameliorating pain by enhancing feedback inhibition of pancreatic enzyme secretion. This approach appears to have the greatest prospects for success in patients with idiopathic chronic pancreatitis without steatorrhea. Results of celiac plexus and splanchnic nerve blocks have generally been disappointing; even if some pain relief is achieved, it is usually short-lived.

Thoracoscopic splanchnicectomy performed in the mediastinum is being evaluated to determine if it will result in a more effective and durable form of pain relief.

Patients whose pain is not adequately managed by oral analgesics and who have not responded to a trial of pancreatic enzymes should be considered for operative treatment. Preoperative evaluation by CT and, frequently, ERCP is essential in determining the type of operation to be performed and in identifying complications (e.g., pseudocysts or pancreatic cancer). Patients with alcoholic chronic pancreatitis often have alternating areas of stricture and dilatation of the pancreatic duct (“chain of lakes” appearance). For these patients a lateral pancreaticojejunostomy (modified Puestow procedure) produces resolution or significant improvement in pain in 70% to 80% of patients when pain is assessed at 6 months after surgery. However, when pain is assessed 3 to 5 years after surgery, successful outcomes decrease to about 50%.

Patients with dominant strictures in the body or tail of the pancreas should undergo distal pancreatectomy. Patients with inflammatory masses of the head of the pancreas or nondilated ducts generally benefit most from resection of the head of the pancreas, either by a modified Whipple procedure or by one of several duodenum-sparing techniques. Carefully selected patients have been reported to have good results in 80% to 85% of cases, and these good results have tended to persist over time. However, pancreatic resection carries the risk of precipitating or worsening diabetes and insulin dependence.

Rarely patients who continue to have incapacitating pain after previous unsuccessful attempts at surgical relief undergo total pancreatectomy. However, this should be considered an extreme measure because of the extent of the operation and the difficult-to-manage diabetes that results. In this setting, autotransplantation of the pancreas or of pancreatic islets has been attempted to try to prevent or mitigate diabetes.

A number of approaches have been tried to reduce the need for surgery in patients with chronic pancreatitis and poorly controlled pain. A combination of antioxidants has been administered to prevent or reduce oxidative injury to the pancreas, and the inhibitory somatostatin analog octreotide has been given to reduce the metabolic

workload of the gland; but neither of these is of proven efficacy.

Currently, there is considerable interest in endoscopic dilatation and stenting of strictures and removal of stones from the pancreatic duct and in destruction of pancreatic duct stones with extracorporeal shock wave lithotripsy. Uncontrolled studies in highly selected groups of patients report symptom improvement in 60% to 70% of patients over several years of follow-up. Prospective randomized, controlled trials are needed to assess the benefits and risks of these approaches in comparison with those of surgery and symptomatic medical care.

Malabsorption

Patients with significant degrees of steatorrhea should receive pancreatic enzyme supplements with meals and snacks. Generally, a total of at least 30,000 units of lipase taken before and during each meal substantially reduces (but usually does not completely correct) steatorrhea, and permits stabilization of body weight and amelioration of diarrhea and bloating. As pancreatic enzymes are degraded by gastric acid, the effectiveness of enzyme supplementation can be enhanced by acid suppression, neutralization of acid by bicarbonate, or the use of enteric-coated preparations. For the rare patient unable to tolerate a fat intake sufficient to maintain an adequate body weight despite pancreatic enzyme supplementation, medium-chain triglycerides can be added to the diet, which do not require intraluminal lipolytic activity for their absorption.

COMPLICATIONS

Pseudocyst

About 10% of patients with chronic pancreatitis develop pseudocysts, usually in the body or tail of the gland. Pseudocysts less than 6 cm in diameter are usually asymptomatic, but larger ones can produce pain and relatively infrequently become infected, bleed, rupture, or obstruct the bile duct or GI tract. Pseudocysts are easily diagnosed by abdominal ultrasonography or CT. Asymptomatic pseudocysts in patients with chronic pancreatitis do not require treatment and may resolve spontaneously. Symptomatic pseudocysts and pseudocysts greater than 6 cm in diameter that are expanding should be treated. Open operative internal drainage has been the standard treatment; however, percutaneous catheter drainage and endoscopic internal drainage are being increasingly employed, and laparoscopic operative techniques have been developed. Clinically infected pseudocysts should be drained using percutaneous catheters.

Pancreatic Ascites and Pleural Effusion

Leakage of pancreatic juice from a pseudocyst or disrupted duct may result in collections of fluid with high protein and amylase concentrations in the peritoneum or in the pleural space, usually on the left. In about half of these patients, conservative treatment with no oral intake, TPN or jejunal feeding of an elemental diet, octreotide administration to decrease pancreatic secretion, and repeated aspiration of ascites or pleural effusions leads to resolution in 2 to 3 weeks. The remaining patients should undergo ERCP to identify the site of leakage and to plan therapy. Selected patients can be successfully treated by endoscopic stenting of the pancreatic duct. Others, depending on the location of the leak, will require distal pancreatectomy or internal drainage of a pseudocyst or damaged duct to a Roux limb of jejunum.

Bile Duct or Duodenal Obstruction

Bile duct or duodenal obstruction occurs in 5% to 10% of patients with chronic pancreatitis. Bile duct obstruction typically develops due to fibrosis in the head of the pancreas that produces a long, tapered stricture of the common bile duct. This is usually diagnosed by a combination of liver tests (elevated serum levels of alkaline phosphatase and bilirubin), abdominal ultrasonography, and ERCP. Biliary bypass surgery is warranted only in patients who develop cholangitis or whose liver tests or liver biopsy findings show evidence of progressive damage attributable to chronic bile duct obstruction. Endoscopic stenting of the common bile duct is an option in patients who are poor operative candidates. Duodenal obstruction can result from a large pseudocyst or an inflammatory mass in the head of the pancreas. If clinically significant, drainage of the pseudocyst or gastrojejunostomy is required.

Splenic Vein Thrombosis

Inflammation or compression of the splenic vein due to chronic pancreatitis can produce splenic vein thrombosis with splenomegaly, gastric varices, and upper GI bleeding. This should be suspected in any patient with known pancreatic disease or a history of chronic heavy alcohol use who presents with upper GI bleeding and is found at endoscopy to have gastric varices in the absence of significant esophageal varices. Splenectomy is highly effective in treating this condition.

Pancreatic Cancer

Patients with chronic pancreatitis of any etiology appear to have an increased risk of developing pancreatic cancer. This increase appears to be modest for most etiologic factors but may be substantially higher for patients with tropical or hereditary chronic pancreatitis. The diagnosis of pancreatic cancer in patients with chronic pancreatitis is often very difficult to make because the symptoms, signs, and CT, ERCP, or EUS findings can be very similar. A progressive rise in the serum level of the tumor marker CA 19-9 suggests a cancer. Cytologic examination of aspirates of pancreatic juice or brushings from the pancreatic duct has a sensitivity of only 25% to 50% for the diagnosis of pancreatic cancer; CT-guided fine-needle aspiration biopsies have a sensitivity of 80% to 85%. Although K-*ras* mutations are found in pancreatic juice or aspiration biopsies of most patients with pancreatic cancer, its specificity is not known because K-*ras* mutations have also been reported in specimens from patients with chronic pancreatitis without apparent pancreatic cancer. Thus, no recommendations for screening patients with chronic pancreatitis for pancreatic cancer can be made at this time. Unfortunately, at the time of diagnosis, pancreatic cancer in patients with chronic pancreatitis is only very rarely curable by surgery.

CHAPTER 118: PANCREATIC CANCER AND GUT NEUROENDOCRINE TUMORS

DANIEL G. HALLER

[Pancreatic Cancer](#)
[Gut Neuroendocrine Tumors](#)
[Gastrointestinal Hormones](#)
[Characteristics of Endocrine Tumors of the Gastrointestinal Tract](#)

PANCREATIC CANCER

Adenocarcinoma of the pancreas is one of the most enigmatic malignancies of the gastrointestinal (GI) tract in terms of etiologic factors, diagnosis, and therapy. As one of the leading causes of cancer death, this tumor represents one of the greatest challenges for patients and physicians alike. Unlike esophageal and gastric cancer, there are no clear epidemiologic risks for this cancer. Although there are minor geographic and gender differences, these are less strong than for other common tumors. The most consistently documented environmental risk is cigarette smoking, documented by case-control and case-cohort studies. Dietary factors similar to those observed in colorectal cancer, such as diets high in animal fat and low in fiber and antioxidant vitamins, have also been implicated in the development of pancreatic cancer. Although a number of medical factors, such as chronic pancreatitis and diabetes, are variably associated with a higher risk of developing pancreatic cancer, causative links have not been definitively established. Recently, a familial pancreatic cancer has been described, although studies would suggest that such genetic causes account for a relatively small proportion (less than 5%) of cases. However, the ability to screen a known high-risk patient population could allow for earlier diagnosis and therapy.

NATURAL HISTORY AND DIAGNOSIS

The biology of pancreatic cancer has begun to impact on the understanding of pancreatic carcinogenesis and prognostication. Specific point mutations in the *K-ras* and *p53* oncogene have been described in most pancreatic cancer specimens. *K-ras*, in particular, has been thought to be one of the earlier genetic events in the development of pancreatic cancer. Locoregional extension of tumor is an early and common event, and provides both an explanation for poor outcome and the rationale for combined-modality treatment programs. Because of the location of the pancreas and the propensity for locoregional spread, preoperative staging is of primary importance in selecting optimal patients for surgical resection. The majority of patients present with unresectable or metastatic disease, and diagnostic techniques to spare such patients unnecessary surgery are of chief importance. For the small number of patients who do undergo surgical resection, the expected 5-year survival ranges from 5% to 25%. Preoperative staging studies include either computed tomography (CT) or magnetic resonance imaging (MRI) (see [Chapter 128](#)) and endoscopic ultrasound (see [Chapter 127](#)). In many institutions, magnetic resonance angiography has replaced standard angiograms as the diagnostic study of choice to assess vascular involvement; such involvement typically represents a relative contraindication to surgical resection with curative intent. Endoscopic retrograde cholangiopancreatography may also be useful in some patients to define the nature of a pancreatic mass, to obtain cytologic specimens for definitive diagnosis, and to distinguish tumors of the pancreas from those of the ampulla of Vater or the duodenum. Endoscopic ultrasonography is now being used in many institutions both to assess resectability based on vascular involvement and for transduodenal biopsies to obtain histologic diagnosis. Although adenocarcinoma is the most common malignancy of the pancreas, other tumors—with widely divergent natural histories and treatments—may also develop in the pancreas and surrounding structures, such as islet cell tumors, lymphomas, germ cell tumors, and low-grade pancreatic neoplasms. For this reason, histologic or cytologic confirmation of malignancy is imperative, particularly when therapeutic decisions, such as neoadjuvant treatment, are under consideration. Fine-needle aspiration of the pancreas is generally considered safe, although it is anecdotally associated with tracking of tumor cells in the path of the biopsy needle. The decision to perform a major surgical resection or combined-modality chemotherapy and radiation therapy without a preoperative or intraoperative biopsy is controversial.

TREATMENT

For patients with pancreatic cancer that appears resectable by preoperative staging, surgery remains the standard curative treatment option. The pancreaticoduodenectomy (Whipple's procedure) is the procedure of choice for most patients with tumors of the head or body of the pancreas, with operative mortality as low as 2% in centers that perform large numbers of cases. For tumors in the tail of the pancreas, distal pancreatectomy may be considered, although few patients with tumor in this location present in a localized manner to allow curative resection. Conversely, patients who present with painless jaundice alone (attributable to a small tumor strategically placed in the head of the pancreas) are most likely to be cured with surgery. Late postoperative complications include the development of pancreatic exocrine insufficiency, which may complicate the interpretation of weight loss in a patient with a history of pancreatic cancer. This condition is easily remedied by administration of exogenous enzymes. Only a small proportion of patients who undergo Whipple's procedure develop insulin dependence.

There are many patients with pancreatic cancer who have localized but unresectable disease. Some local problems can be dealt with by nonsurgical techniques, including biliary stenting by endoscopy for obstructive jaundice (see [Chapter 127](#)). In some patients whose survival is thought to be good (better than 6 to 9 months), optimal therapy for biliary and duodenal obstruction may include surgery to bypass the tumor. For patients with pain, either with localized tumor or with metastases, celiac axis nerve bloc may help to minimize dependence on narcotics.

Active antitumor therapy for patients with unresectable pancreatic cancer has traditionally consisted of radiation, typically given in conjunction with 5-fluorouracil (5-FU)-based chemotherapy. The initial trials of such therapy were carried out by the Mayo Clinic and confirmed by the Gastrointestinal Tumor Study Group (GITSG). The GITSG trial established that, when radiation is given, 4,000 cGy with 5-FU was superior to 6,000 cGy alone and equivalent to 6,000 cGy with 5-FU, in terms of median survival (10 versus 6 months). Although considered by most to be standard practice, few other studies have confirmed or addressed the potential superiority of combined-modality chemoradiation to radiation alone. In selected centers with appropriate equipment, intraoperative radiation, given before standard external-beam radiation, is the preferred treatment, with higher intraoperative doses of radiation allowing for the possibility of better local control of the primary tumor. Although retrospective studies have suggested benefit from intraoperative radiation in local control and overall survival, there are no data from large, randomized controlled trials to confirm this conclusion.

In some institutions, preoperative (neoadjuvant) chemoradiation has been used in two groups of patients: those with tumors thought initially to be resectable and those with tumors considered initially to be of borderline resectability. There is a clear downstaging effect from such treatment, but the proportion of patients whose tumors are rendered resectable for cure, despite their initially having been thought to be unresectable, is unclear. Nonrandomized comparisons of preoperative chemoradiation to surgery followed by chemoradiation have not demonstrated a survival advantage to the neoadjuvant approach, likely because improvements in local control of the primary tumors may not limit the development of life-threatening metastatic disease. However, many investigators still prefer neoadjuvant therapy for patients with resectable pancreatic cancer because of improved tolerability when such treatment is given preoperatively.

For patients who undergo curative resection of pancreatic cancer, the 5-year survival rate in most series is poor, ranging from 5% to 25%, supporting the need for effective adjuvant therapy to control micrometastases remaining after surgery. In spite of the number of patients who could benefit from such treatment, there have been few prospective trials addressing the role of postoperative adjuvant treatment. The most widely accepted, yet controversial, study is from the GITSG. In 1973, this group began a randomized trial comparing surgery alone to postoperative radiation with both concurrent and sequential chemotherapy with 5-FU. Accrual to the trial was extraordinarily slow, in part due to fear of complications of postoperative treatment. For the 43 patients who were randomized, the median survival for the combined-modality treatment was 20 months, compared to 11 months for the surgery-alone group. The 5-year survival was 14% and 5%, respectively. When the trial closed to randomized accrual, the group subsequently entered more patients into the combined-modality treatment, with similar results. Nonrandomized, retrospective studies of postoperative combined-modality therapy support the results from the GITSG trial, but there are no large, contemporaneous controlled trials to fully confirm the level of benefit of this widely accepted treatment. It is nonetheless the standard of care in most large institutions in which pancreatic resections are performed, making it difficult to perform prospective randomized trials in which surgery alone is the standard arm. A new adjuvant therapy trial is comparing two schemes of postoperative combined-modality therapy for resected patients, one using 5-FU and the other gemcitabine, with either drug given sequentially with radiation and concurrent continuous infusion 5-FU.

ADVANCED DISEASE

Many patients with pancreatic cancer present with metastatic disease and most develop it during the course of their illness, resulting in poor survival and mandating the development of successful systemic treatment and supportive care strategies. Although early trials of biologics, such as *K-ras* vaccines and antisense compounds,

are currently under way, the mainstay of systemic therapy for pancreatic cancer remains cytotoxic chemotherapy. Broad phase II trials of new agents have typically shown that pancreatic cancer is generally considered to be a relatively chemotherapy-resistant disease. Until recently, only a few drugs showed any measurable antitumor activity by standard drug screening and clinical trials techniques, including 5-FU, mitomycin, and streptozocin. Combination therapy with these drugs has not yielded significantly improved benefits, and standard practice until recently has been to administer 5-FU for palliation. Measurable response rates with this drug are typically less than 10%, and palliative benefits have been difficult to quantify.

Recently, a new drug, gemcitabine, has entered clinical practice for the management of advanced pancreatic cancer. Noted to have some activity in early clinical testing, phase II trials were similarly encouraging. A phase III trial of gemcitabine compared to weekly 5-FU alone has been completed, in which gemcitabine was considered to be superior to 5-FU in clinical benefit (palliation). Using a scale of clinical benefit response, which combines measures of pain control and performance status, 24% of the gemcitabine-treated patients were responders, compared to 5% for 5-FU. Few patients in either group exhibited clear tumor response by conventional measures, but median survival for gemcitabine was superior (5.7 versus 4.4 months, $p = 0.0024$). At 1 year, survival was also superior for gemcitabine. In a separate study, some objective responders were seen when patients who had previously failed on 5-FU were given gemcitabine. Currently, both 5-FU and gemcitabine represent legitimate treatment options for patients with advanced pancreatic cancer. In addition, early reports of activity of docetaxel, topotecan, and cisplatin combined with gemcitabine have led to new treatment regimens that are presently under clinical investigations.

GUT NEUROENDOCRINE TUMORS

Gastrointestinal hormones coordinate in a highly integrated fashion the intake, processing, absorption, and distribution of essential nutrients. Like other endocrine transmitters, gut hormones are secreted from endocrine cells into the blood, where they circulate to reach target tissues. However, unlike classic endocrine tissues in which homogeneous cells are concentrated in glands, endocrine cells of the gut are scattered along the GI mucosa as isolated cells. In the intestine, endocrine cells originate from stem cells within the crypts. Electron-dense, hormone-containing, secretory granules are located toward the bases of the cells, which lie in proximity to capillaries. Exposure of endocrine cells to stimuli such as food, changes in lumen pH, or other intestinal secretions within the gut lumen initiates the intracellular events resulting in secretion of hormone into adjacent capillaries. On reaching the systemic circulation, these transmitters bind to specific hormone receptors on respective target tissues to exert their physiologic effects.

Endocrine cells of the gut have been identified cytochemically by their ability to reduce silver solutions (argentaffinity) and to take up silver ions from solution (argyrophilia) or to form isoquinolones and fluoresce after hot-formaldehyde treatment. This latter method uses the acronym APUD (amine precursor uptake and decarboxylation) to identify amine-containing cells. Specific hormone-containing cells can be distinguished by their electron microscopic appearance and immunohistochemical properties.

Peptide transmitters of the GI tract also have been identified in pancreatic islets and in neurons of the brain and gut. Peptides of neural origin may function as typical neurotransmitters acting directly through synapses on target cells, or they may be secreted from nerve endings into the bloodstream to reach distant targets (neurocrine action; [Fig. 118.1](#)).

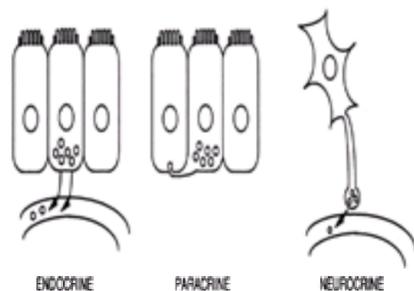

FIGURE 118.1. Transmitters of the gastrointestinal tract. The mechanisms of secretion for hormones, paracrine transmitters, and neurocrine agents of the gastrointestinal tract are represented schematically.

GASTROINTESTINAL HORMONES

Many GI hormones are similar in amino acid sequence. This evidence is taken to imply a common ancestry and evolution through gene duplication and divergence. Six groups of peptides have been identified in the GI tract. These include the gastrin–cholecystokinin family, the secretin family, the pancreatic polypeptide (PP) group, the opioids, the tachykinins, and the bombesin-like peptides. Several GI peptides share no structural homologic features with other mammalian peptides. These so-called “orphan peptides” include somatostatin, motilin, and neurotensin. Bioactive GI peptides that have been extracted from the GI tract are listed in [Table 118.1](#).

TABLE 118.1. PEPTIDES OF GASTROINTESTINAL TRACT

CHARACTERISTICS OF ENDOCRINE TUMORS OF THE GASTROINTESTINAL TRACT

Endocrine tumors of the pancreas often present as fascinating and bizarre diagnostic puzzles. The specific manifestations of these tumors depend on the release of biologically active substances. The released mediators include the hormones gastrin, insulin, vasoactive intestinal peptide (VIP), glucagon, and somatostatin, and biologically active amines such as serotonin and its metabolites. Discrete syndromes result from the overproduction and secretion of each of these potential transmitters and provide an intriguing array of clinical findings for the physician. Endocrine tumors of the pancreas share many similarities in location, histologic features, growth rate, manner of spread, association with multiple endocrine neoplasia type I (MEN I) syndrome, and response to hormonal treatment and chemotherapy. In the management of gut neuroendocrine tumors, clinicians must always keep in mind that individual patients may have signs or symptoms of hormone-related disorders, or of tumor bulk, or both. In some diseases, such as gastrinomas, there has been a paradigm shift for morbidity and mortality away from the complications of gastrinemia toward the more typical tumor-related complication of metastatic disease.

Histologically, endocrine tumors of the pancreas are made up of small, uniform cells with little mitotic activity. On electron microscopic examination, these cells contain abundant secretory granules. Hormone-secreting tumors stain positively with selective markers, such as chromogranin A, neuron-specific enolase, or antisera against specific hormones. Because of their innocuous histologic appearance, endocrine tumors of the pancreas once were thought to be benign, and some were given the

name carcinoid (“cancer-like”) tumor. Despite their appearance, most GI hormone–secreting tumors behave in a malignant manner. Within the GI tract, most endocrine tumors are found in the pancreas, where they are believed to be of islet cell origin. Glucagon-secreting tumors (glucagonomas) almost invariably are confined to the pancreas. Most gastrin-secreting tumors (gastrinomas) also are found in the pancreas, despite the fact that there are no gastrin cells in the adult pancreas. Some gastrinomas may also be found in the gut and in paraintestinal lymph nodes. Carcinoid tumors, which demonstrate uniform serotonin production, may originate in any organ derived from the primitive endoderm, although the most common sites are the appendix, rectum, and small intestine.

Gut neuroendocrine tumors are typically slow growing and often are diagnosed only because of their elaboration of bioactive transmitters. These tumors usually metastasize to the liver but may spread to lymph nodes, bone, and lung.

Many endocrine tumors of the pancreas are associated with MEN I and are accompanied by tumors of the pituitary and parathyroid. The pancreatic tumors usually secrete GI hormones, including gastrin, insulin, glucagon, PP, and, rarely, VIP. MEN I is inherited as an autosomal dominant disorder and affects 1 in 20,000 individuals. Genetic mutations responsible for the disorder (the *MEN1* gene) have been localized to a specific area on the long arm of chromosome 11 (11q13), and recently the gene has been identified and named *menin*. The function of the gene is currently not well defined. Hyperparathyroidism with accompanying hypercalcemia is the most common clinical manifestation of MEN I. Pancreatic tumors occur in 50% to 65% of patients with this syndrome, and gastrinoma is the most common functioning islet cell tumor. Patients with endocrine tumors associated with MEN I seem to have longer life expectancies than do those with sporadic endocrine tumors of the pancreas, implying that MEN I–associated pancreatic tumors have a less malignant course than sporadic pancreatic tumors.

GASTRINOMAS

Gastrin-secreting tumors are the most common endocrine tumors of the GI tract, with an incidence of 0.5 to 1.0 per million population. Zollinger and Ellison originally reported the syndrome in 1955, when they described two patients with atypical peptic ulceration, gastric hypersecretion, and non–b-cell islet tumors. The compilation of symptoms and physical findings caused by a gastrin-secreting tumor is referred to as Zollinger–Ellison syndrome (ZES; see also [Chapter 107](#)). Before the availability of radioimmunoassays for measuring blood levels of gastrin, patients had severe complications of gastric acid hypersecretion. Typical manifestations of the disease included intractable or complicated peptic ulcer disease with abdominal pain and multiple ulcers or ulceration in unusual locations, such as the jejunum. More recently, it has become difficult to distinguish patients with gastrinoma from those with common peptic ulcer disease; this is likely the result of common and effective therapies for reducing gastric acid secretion.

The clinical manifestations of gastrinoma are listed in [Table 118.2](#). Abdominal pain remains the most prominent symptom, occurring in about 75% of patients. Pain usually is caused by peptic ulceration of the stomach, duodenum, or jejunum. Diarrhea is also common, and results from the destruction of mucosal integrity by gastric acid hypersecretion, excessive fluid secretion, and the deleterious effects of gastric acid on pancreatic enzymes and bile acids leading to malabsorption. Gastrinoma accounts for 0.1% of all patients with peptic ulcer disease.

Manifestation	Incidence (%)
Peptic ulcer disease	80
Abdominal pain	75
Gastroesophageal reflux disease	60
Diarrhea	30
Diarrhea and abdominal pain	25
Upper gastrointestinal tract bleeding	10
Perforated ulcer	7

TABLE 118.2. MANIFESTATIONS OF GASTRINOMA

Because peptic ulcer disease is common, a high index of suspicion is needed to make the diagnosis of a gastrin-secreting tumor ([Table 118.3](#)). Gastrinoma should be suspected in individuals with peptic ulcer disease who have diarrhea or multiple ulcers, or ulcers in unusual locations such as the jejunum. Suspicion should be high in patients with a family history of peptic ulcer disease, pancreatic tumor, MEN I, or manifestations of MEN I such as hyperparathyroidism or hypercalcemia. Anyone considered for surgery for peptic ulcer disease should be evaluated for gastrinoma because its existence may alter the surgical approach or the need for surgery.

Duodenal or gastric ulcer associated with
Diarrhea
Family history of peptic ulcer disease
Hypercalcemia
Nephrolithiasis
Multiple endocrine neoplasia type I
Ulcers in the distal duodenum or jejunum
Recurrent peptic ulcer after ulcer surgery
Ulcer disease refractory to medical therapy or ulcer surgery
Evidence of gastric rugal hypertrophy
Unexplained secretory diarrhea
Refractory gastroesophageal reflux disease

TABLE 118.3. PATIENTS IN WHOM TO SUSPECT GASTRINOMA

The single best test for gastrinoma is measurement of serum gastrin (see also [Chapter 107](#)). In general, the higher the serum gastrin level, the more probable is the diagnosis of gastrinoma, particularly in the setting of low gastric pH. A serum gastrin level of more than 1,000 pg per milliliter in the presence of a gastric pH of less than 3 is virtually diagnostic of gastrinoma. Other causes of hypergastrinemia include antisecretory therapy, such as H₂ blockers and H⁺,K⁺-ATPase inhibitors, renal failure, retained gastric antrum, extensive small-bowel resection, gastric outlet obstruction, G-cell hyperfunction, and achlorhydria, which accompanies diseases such as pernicious anemia and atrophic gastritis.

When serum gastrin levels are only mildly elevated, several provocative tests can be used to make the diagnosis of gastrinoma. The most useful of these is the secretin stimulation test, in which 2 units per kilogram of secretin is infused and serial serum gastrin levels are measured over 30 minutes. If gastrin levels increase by more than 200 pg per milliliter and if basal acid hypersecretion is present, then the diagnosis of gastrinoma is confirmed.

After the diagnosis of gastrinoma is confirmed, it is important to localize the tumor because many gastrinomas may be cured by surgical resection. Imaging studies used to localize the primary tumor and identify metastases include ultrasonography (including endoscopic ultrasonography), CT, MRI, angiography, and nuclear medicine scanning, including radiolabeled somatostatin scans. Angiography or MRI may be useful in determining whether an identified tumor appears resectable. Intraoperative ultrasonography may help localize tumors that were not identified before surgery. Patients who have not had a primary tumor localized before laparotomy may have an excellent prognosis, primarily because of low tumor burden.

Before the availability of effective gastric acid antisecretory therapy, the leading causes of death in gastrinoma were complications arising from gastric acid hypersecretion. With the development of H₂ receptor antagonists and H⁺,K⁺-ATPase inhibitors, gastric acid secretion can be controlled; death now results from the malignant nature of the tumor itself. Therefore, the treatment of gastrinoma is aimed at controlling acid secretion while localizing the tumor to effect a surgical cure. In a recent series of 212 patients with gastrinoma followed at the U.S. National Institutes of Health for a mean of nearly 14 years, one-third of the patients died. However,

none of them died from acid-related causes. Gastrinoma tumor growth was responsible for half of the deaths, and the other half died of non-ZES-related causes. Tumors localized to the lymph nodes or duodenal wall often are cured by surgical resection, with subsequent normalization of serum gastrin levels. Tumors of the pancreas fare less well because they often have metastasized by the time of diagnosis. In patients with gastrinomas and MEN I, parathyroidectomy usually reduces serum gastrin levels and may improve symptoms, and should be indicated as an initial surgical approach to this syndrome. Gastrinomas associated with MEN I often are multiple, lowering the likelihood of surgical resection being curative. If curative surgery is not possible, medical treatment can be combined with tumor-debulking procedures. Standard medical management consists of the administration of high doses of H₂ receptor antagonists or an H⁺,K⁺-ATPase inhibitor to control acid secretion and symptoms, with or without surgery. Control of symptoms can be achieved in nearly all patients using an H⁺,K⁺-ATPase inhibitor, such as omeprazole.

For patients who have metastatic disease at the time of diagnosis, several chemotherapeutic approaches have been adopted. However, because of the low incidence of gastrinoma, many treatment protocols have incorporated all patients with islet cell tumors. Most protocols include streptozocin, alone or in combination with 5-FU or doxorubicin. The overall success of chemotherapy in islet cell tumors, while not extensively tested, has shown objective response rates in excess of 50% in patients treated with doxorubicin and streptozocin, with some complete responses in both tumor size and excess hormone secretion. Chemotherapy may be the only option for patients suffering from the bulk effects of metastatic disease. The synthetic analog of somatostatin, octreotide, has been shown to reduce gastric acid secretion and serum gastrin levels, and may improve symptoms. However, because there are more effective therapies for controlling gastric acid, octreotide usually is not recommended as initial therapy.

INSULINOMAS

Insulinomas, which arise from b cells of the pancreas, usually are solitary, benign neoplasms that secrete large amounts of insulin. The disease has an incidence of 8 per 10 million population, occurs primarily in the fifth to seventh decade of life, and is associated with MEN I in 10% of cases. The hallmark of insulinoma is uncontrolled insulin release from an autonomously functioning neoplasm that causes profound and life-threatening hypoglycemia. Symptoms range from mild confusion to coma, and associated with hypoglycemia is a compensatory adrenergic surge that is responsible for tachycardia, palpitations, and diaphoresis. Rarely, the presentation of an insulinoma results from the mass of the tumor itself, with complications such as pancreatic or biliary duct obstruction, or abdominal or back pain that may resemble adenocarcinoma of the pancreas.

The first step in the evaluation of suspected hypoglycemia is measurement of the fasting blood glucose level. Whipple's triad describes features associated with clinical hypoglycemia: a fasting glucose level of less than 2.5 mmol per liter, signs and symptoms of hypoglycemia during prolonged fasting, and prompt reversal of symptoms after the administration of glucose.

Measurement of fasting glucose and insulin levels is critical for determining the cause of fasting hypoglycemia ([Table 118.4](#)). Normally, proinsulin undergoes cleavage of a connecting peptide (C peptide) to yield the active insulin molecule. Excess production of endogenous insulin is accompanied by high circulating levels of C peptide. Hypoglycemia caused by insulinoma can be distinguished from that caused by the surreptitious injection of insulin. This is attributable to the fact that in the latter condition C-peptide levels are low because the production of endogenous insulin is suppressed when insulin is injected. However, the effect of ingestion of oral hypoglycemics, such as sulfonylureas (which release endogenous insulin), can be distinguished from the effects of insulinoma only by a careful history or by detection of hypoglycemic agents in the blood or urine. Hypoglycemia resulting from decreased glucose production is accompanied by low insulin levels and is easily distinguished from insulinoma.

	Serum Insulin Levels	C-Peptide Levels	Other
Excess Insulin			
Insulinoma	Increased	Increased	
Insulin administration	Increased	Decreased	Insulin antibodies
Oral hypoglycemic drugs	Increased	Increased	Positive drug test
Autoimmune hypoglycemia	Decreased	Decreased	Antibodies to insulin or insulin receptor
Decreased Glucose Production			
Liver disease/ethanol ingestion	Decreased	Decreased	Suspected by history, abnormal liver function tests
Knee fluid ingestion	Decreased	Decreased	Suspected by history

TABLE 118.4. CAUSES OF HYPOGLYCEMIA AND DIAGNOSTIC TESTS

Within 24 hours of fasting, 70% to 80% of patients with insulinoma have elevated insulin levels and hypoglycemia. In the absence of surreptitious drug use, this test is diagnostic of insulinoma. Measurement of proinsulin levels increases the sensitivity of testing to 90%. If insulin levels are not elevated with this test, prolonging the fast from 24 to 72 hours will reveal an additional 10% to 15% of patients with the disease. Fasting as a provocative test should be conducted in the hospital, where patients can be monitored carefully so that complications of hypoglycemia do not develop. Additional provocative tests include stimulation with the hypoglycemic agent tolbutamide, calcium infusion, or glucagon administration. A rapid increase in circulating insulin levels in response to one of these agents is a strong indication of insulinoma.

Up to 80% of insulinomas are single, benign lesions that are small at the time of diagnosis, presumably because they present with symptoms of hypoglycemia early in their course. Once the diagnosis of insulinoma has been established, an attempt should be made to localize the tumor, since the only curative therapy is surgical resection. Ultrasonography of the pancreas, abdominal CT, MRI, or nuclear medicine scanning should be performed, but many insulinomas escape detection by these modalities. Insulinomas are not rich in somatostatin receptors, thus making radiolabeled somatostatin scans less sensitive. Angiography produces positive results in about 60% of patients; with the simultaneous infusion of calcium, the sensitivity increases to 85%. Depending on experience, endoscopic or intraoperative ultrasonography may have a high sensitivity, complementing other techniques. Metastases are much less common with insulinomas than with other endocrine tumors of the pancreas. The presence of MEN I should not preclude localization of the tumor and attempted curative surgery, even though it is more probable that multiple tumors exist.

Once the diagnosis of insulinoma has been made, it is important that subsequent hypoglycemia be prevented. This can be achieved by monitoring hypoglycemic symptoms and giving small, frequent meals while attempts are made to localize the tumor. The antihypertensive agent diazoxide suppresses insulin release and controls the symptoms of hypoglycemia in about 50% of patients with insulinomas. Octreotide also may reduce insulin secretion and raise blood glucose levels, but its long-term use in these patients remains unclear. For insulinomas that cannot be removed surgically, chemoembolization of liver metastases or systemic chemotherapy may reduce tumor size and insulin secretion.

GLUCAGONOMAS

Glucagon-secreting tumors are rare neoplasms that arise from a cells of pancreatic islets. Most glucagonomas are malignant and 50% are metastatic at the time of diagnosis. The manifestations of the tumor result from the increased secretion of glucagon, the primary physiologic actions of which are to cause gluconeogenesis, glycogenolysis, and decreased GI motility. A triad of a characteristic rash, anemia, and diabetes associated with an a-cell pancreatic neoplasm typifies the glucagonoma syndrome. The disease often occurs in the fifth decade and can be associated with the MEN I syndrome.

The most common manifestation of glucagonoma is mild diabetes or glucose intolerance, which is directly attributable to the excess secretion of glucagon ([Table 118.5](#)). Accelerated gluconeogenesis leads indirectly to decreased levels of circulating amino acids. The rash, *migratory necrolytic erythema*, occurs in more than 70% of patients and typically develops only after the tumor has metastasized. Up to one-third of patients experience thromboembolic phenomena, although the cause of the clotting tendency is unknown. Weight loss, mucositis, stomatitis, and neuropsychiatric manifestations also may be associated with glucagonoma.

Glucose intolerance or diabetes mellitus
Necrolytic migratory erythema
Anemia
Weight loss
Thromboembolic disease
Low circulating amino acid levels
Psychoneurologic manifestations

TABLE 118.5. CLINICAL MANIFESTATIONS OF GLUCAGONOMA

Chronic dermatitis in conjunction with diabetes or glucose intolerance is highly suggestive of glucagonoma. However, only measuring fasting levels of glucagon can make the diagnosis. In this syndrome, glucagon levels often exceed 1,000 pg per milliliter (normal levels are less than 150 pg per milliliter). Renal failure, liver disease, or stress can cause less extreme elevations of glucagon, which usually are easily distinguishable from glucagonoma. Because patients usually are seen late in the disease course, glucagonomas often are larger than 5 cm in diameter, and are found most often in the body or tail of the pancreas. Radiolabeled somatostatin receptor scans may be used to localize these tumors and to identify metastases.

Surgical resection is the preferred therapy for glucagonoma and offers the only hope for cure. Although many patients have large tumors or metastatic disease at the time of diagnosis, debulking the tumor may reduce serum glucagon levels, ameliorate symptoms, and provide long-term palliation. Chemotherapeutic regimens, such as doxorubicin and streptozocin, may reduce tumor burden, which may result in improvement of symptoms. Octreotide may normalize serum glucagon levels and improve symptoms, including neuropsychiatric manifestations, but has had no reproducible effect on tumor growth. Interferon, alone or in combination with chemotherapy or octreotide, has been shown to improve the rash, decrease glucagon levels, and reduce tumor size in glucagonoma and other islet cell tumors.

VASOACTIVE INTESTINAL POLYPEPTIDE-SECRETING TUMORS

Tumors that secrete VIP are rare, occurring in 1 in 10 million individuals. These tumors differ from other endocrine tumors of the pancreas in that they usually are not associated with MEN I. Their clinical manifestations are directly attributable to the effects of elevated serum VIP levels. The syndrome is characterized by profuse watery diarrhea, hypokalemia, and achlorhydria, and is referred to as the WDHA syndrome, pancreatic cholera, or Verner–Morrison syndrome. The major manifestation of VIP-secreting tumors is profound intestinal secretion, with large volumes of fluid that overwhelm the absorptive capacity of the colon, resulting in watery diarrhea. Virtually all patients have stool volumes of more than 700 mL per day, and 70% excrete more than 3 L per day, even during imposed fasting. With excessive stool losses, hypokalemia and dehydration often occur. Because of the gastric inhibitory effects of VIP, achlorhydria is common.

VIP-secreting tumors should be considered during the evaluation of secretory diarrhea. Elevated circulating VIP is the hallmark of this disease, and levels exceeding 60 pmol per liter are diagnostic. Seventy-five percent of these tumors are confined to the pancreas, 20% are ganglioneuromas, and a few involve the lung, colon, or liver. VIP-secreting tumors often are large, and 75% can be localized by CT.

The initial goal in the treatment of VIP-secreting tumors is to control the diarrhea and replace fluid and electrolyte losses. Intravenous fluid administration often is necessary during the early course of the illness until the diarrhea can be reduced. Octreotide is extremely useful in reducing diarrhea in this disease. As with other endocrine tumors, surgical resection is the only curative approach, and once the tumor has been localized it should be removed. About one-half of these tumors are metastatic at the time of diagnosis. However, surgical debulking or hepatic artery embolization and systemic chemotherapy in selected patients have led to improvement of symptoms related to hormone secretion or bulky tumors.

SOMATOSTATINOMAS

Somatostatin has profound inhibitory actions on the GI tract. As a regulatory hormone, it reduces gastric and pancreatic secretion, gallbladder motility, and the secretion of many other hormones. As a result, somatostatin may reduce both the secretion and the target tissue response of hormones. Tumors that elaborate somatostatin are rare, usually arise in the pancreas (rarely from the intestine), and often are large tumors with hepatic or lymph node metastases at the time of diagnosis.

The clinical manifestations of somatostatinomas include diabetes mellitus, steatorrhea, and gallstones. These findings result from the inhibitory effects of somatostatin on insulin secretion, pancreatic exocrine secretion, and gallbladder contraction, respectively. Almost all patients have reduced gastric acid secretion or achlorhydria.

The diagnosis of somatostatinoma can be confirmed by documenting elevated somatostatin levels in serum. The radiographic diagnosis and treatment of these tumors is similar to that of other pancreatic islet cell tumors.

OTHER HORMONE-SECRETING TUMORS

Rarely, islet cell tumors produce other hormones. About 10% of islet cell tumors secrete adrenocorticotrophic hormone (ACTH), and about 10% of all ectopic ACTH production is from endocrine tumors of the pancreas, making these lesions an uncommon cause of Cushing's syndrome. Even less common are tumors that produce neurotensin. PP-producing tumors may present as a pancreatic mass, yet despite high circulating levels of PP, this disease does not have prominent clinical manifestations. Nonfunctioning endocrine tumors may also occur, and a high index of suspicion for these lesions is important in the diagnosis of a patient with a pancreatic mass, poorly differentiated histology on biopsy, and a clinical course that seems more benign than typical adenocarcinoma of the pancreas. Histopathologic examination, with immunohistochemical stains, frequently resolves this diagnostic problem.

CARCINOID TUMORS

Carcinoid tumors differ from other hormone-secreting tumors of the GI tract because they secrete nonpeptide transmitters. Because these tumors originate from cells of the peripheral neuroendocrine system, they can occur anywhere in the GI tract, lungs, or other tissues. Carcinoid tumors are the most common neuroendocrine tumors of the GI tract, with 1 to 2 new cases per 100,000 in the United States each year.

Carcinoid tumors are made up of small, round, uniform cells that stain for argentaffin. The cells contain numerous neurosecretory granules in which silver particles are accumulated, accounting for their argyrophilia. In addition, these granules contain chromogranins, neuron-specific enolase, and synaptophysin.

Pathophysiologically, carcinoids can be divided into those that originate from the foregut, midgut, or hindgut ([Table 118.6](#)). Foregut carcinoids arise from the respiratory tree, pancreas, stomach, or proximal duodenum and can produce any of several potential transmitters, including 5-hydroxytryptophan (5-HTP), serotonin, histamine, and ACTH. Flushing may occur with foregut carcinoids, although it is less common than with midgut carcinoids. This symptom probably results from the production of histamine, as it responds to treatment with antihistamine medications.

	Foregut	Midgut	Hindgut
Anatomical distribution	Esophagus, stomach, duodenum, pancreas	Small bowel, ileum, ascending colon	Transverse and descending colon, rectum
Argentaffin	+++	+	Usually absent
Argentaffin staining	+	+++	+
Secretory products	5-HT, histamine, serotonin	Serotonin	Rare
Clinical symptoms	Flushing, diarrhea	Flushing, diarrhea	Rare
Metastases	Rare	Liver	Rare

SHT: 5-Hydroxytryptamine

TABLE 118.6. CARCINOID TUMORS

Carcinoids of the midgut arise in the duodenum, jejunum, ileum, or right side of the colon. These tumors usually contain large amounts of serotonin and are argentaffin-positive. Midgut carcinoids are primarily responsible for carcinoid syndrome, which invariably occurs only once they have metastasized to the liver. Tumors that have not metastasized rarely produce this syndrome, presumably because the transmitters are metabolized and inactivated in the liver before reaching the systemic circulation. The appendix is the most common site of carcinoids, representing one-third of all newly diagnosed cases. Carcinoids of the hindgut, although less common, are being discovered more often with the routine use of sigmoidoscopy. These tumors may produce serotonin, but they often contain other mediators, such as neuropeptides or catecholamines.

The classic symptoms of carcinoid syndrome are flushing, diarrhea, and asthma, although other findings include facial telangiectasia and valvular heart disease. Flushing typically is of the face and upper body, and although initial attacks are transient, they become longer lasting as the disease progresses. Episodes of flushing may be accompanied by diarrhea. Elevated plasma serotonin levels are found in most patients with carcinoid syndrome, and this is believed to be the most probable cause of symptoms, including diarrhea. However, a few patients do not have elevated serotonin levels, and some patients are asymptomatic despite high levels of circulating serotonin. Treatment with serotonin antagonists does not affect flushing, making it likely that other mediators contribute to different manifestations of carcinoid syndrome. Cardiac fibrosis involving the tricuspid and pulmonic valves may be the result of growth factors elaborated by these tumors. In the GI tract, carcinoids often cause a desmoplastic reaction that can result in kinking or obstruction of the bowel ([Fig. 118.2](#)).

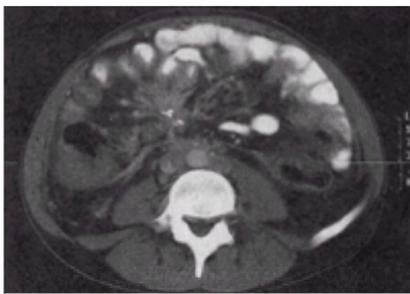

FIGURE 118.2. An abdominal computed tomographic scan with intravenous and oral contrast media shows a spiculated, calcified mesenteric mass in a 34-year-old man with a carcinoid tumor of the small bowel. In the mesentery, these tumors classically induce a desmoplastic reaction, which results in radiating strands of tissue that fix and separate small-bowel loops. The scan also shows para-aortic and aortocaval lymphadenopathy. (Courtesy of Dr. Erik Paulson, Duke University Medical Center, Durham, NC.)

In a patient suspected of having a carcinoid tumor, measurement of serotonin or serotonin metabolites is critical for the diagnosis. The major metabolite of serotonin is 5-hydroxyindoleacetic acid (5-HIAA), which is excreted primarily in the urine. Normally, urinary 5-HIAA levels range from 2 to 8 mg per day. Elevated urinary 5-HIAA levels are suggestive of carcinoid tumors; however, many foods that are rich in serotonin, including certain fruits and nuts, particularly bananas, pineapples, walnuts, and pecans, can cause false-positive results. Measurement of platelet serotonin levels is not affected by the ingestion of serotonin-rich foods and may complement urinary 5-HIAA levels. Serial plasma or urinary serotonin measurement is not useful because of wide variations during the day. Provocative testing with the infusion of pentagastrin releases serotonin in 75% and causes flushing in nearly 100% of patients with carcinoid syndrome. This test can be used when the diagnosis remains unclear, even after the measurement of urinary 5-HIAA or platelet serotonin levels. Plasma chromogranin A levels may also be monitored, and levels of greater than 5,000 µg per milliliter have been shown to be an independent predictor of poor prognosis.

Up to 50% of patients with carcinoid tumors do not have symptoms of carcinoid syndrome. The diagnosis is difficult in these cases and usually is made only after the tumors produce abdominal pain or evidence of metastatic disease.

Once the diagnosis of carcinoid syndrome has been made, the tumor should be localized. Many carcinoid tumors occur outside the GI tract. Most bronchial carcinoids can be detected by chest radiography. Tumors of the stomach, duodenum, or colon can be detected by endoscopy, but those of the small bowel beyond the reach of the endoscope are difficult to detect by any modality. Small-bowel barium radiography or CT may show thickening or fixation of small-bowel loops suggestive of carcinoid tumor. Ultrasonography, CT, or MRI can detect liver metastases. Localization with radiolabeled molecules, such as the catecholamine [¹³¹I]MIBG (*m*-iodobenzylguanidine), and radiolabeled somatostatin analogs has been used to identify APUD tumors. Comparisons of conventional CT scans and radiolabeled somatostatin analogs have suggested that these techniques are complementary. Positron emission tomography performed with ¹¹C-labeled 5-HTP, which is taken up by carcinoids, has been used for the identification of metastases.

The treatment of carcinoid tumors depends on their size, location, and, perhaps, somatostatin receptor status. Surgery usually is recommended for appropriate candidates. However, anesthesia must be undertaken cautiously because severe hypotension can occur during its induction. Premedication with octreotide has been advocated to prevent or treat crises ([Fig. 118.3](#)). The size of the primary tumor correlates well with the presence of metastases to lymph nodes and liver.

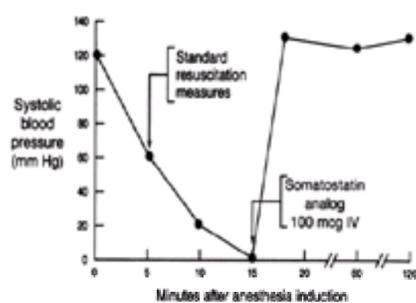

FIGURE 118.3. Response of carcinoid crisis to somatostatin analog therapy. (From Moertel CG. An odyssey in the land of small tumors. *J Clin Oncol* 1987;5:1502, with permission.)

Appendiceal and rectal carcinoids smaller than 1 cm rarely metastasize, whereas those larger than 2 cm may be associated with local and distant metastases. For tumors smaller than 1 cm, excision alone is sufficient therapy. For larger tumors, more extensive cancer surgery should be undertaken to achieve more accurate staging and potentially curative resection of locoregional disease. For incidentally found appendiceal carcinoids larger than 2 cm, a right hemicolectomy usually is performed after initial appendectomy. When local lymph nodes are involved in resection specimens from GI carcinoids, patients may live for extended periods without apparent recurrence, but long-term follow-up usually demonstrates continuing relapse over many years.

In addition to primary surgery, cytoreductive surgery for palliation or cure should be considered for neuroendocrine tumors of the GI tract. Surgical palliation of bowel obstruction from tumor masses or mesenteric fibrosis may improve the quality of life significantly in patients with carcinoid tumors. Hepatic surgery for liver metastases may render some patients free of disease for prolonged periods, and cytoreduction of large liver metastases also may reduce or eliminate symptoms caused by hormone release. The most aggressive form of liver-directed surgery transplantation also has been performed in highly selected patients with metastatic neuroendocrine tumors. As with all such surgery, patient selection is paramount, with ideal candidates having a long disease-free interval since initial diagnosis and a demonstrably long period of indolent disease confined to the liver, as well as exhaustive sequential staging studies demonstrating no evidence of extrahepatic tumor.

Other forms of liver-directed therapy can be considered for patients who have liver-only or liver-dominant disease but who are not ideal candidates for transplantation or extensive surgical resection. In some cases, less morbid surgical techniques, such as cryosurgery or radiofrequency ablation, provide acceptable cytoreduction. Nonsurgical techniques also are being investigated, such as hepatic arterial embolization and chemoembolization. Early studies have suggested a role for surgical hepatic arterial ligation in the treatment of typically hypervascular neuroendocrine liver metastases. Ligation of the hepatic artery may provide brief, but profound, regression of tumor masses and clinical syndromes resulting from hormone release, but this technique has largely been replaced by selective arteriographic embolization. These techniques, performed by interventional radiologists, may provide equivalent tumor control with less morbidity. Retrospective studies of patients treated with these procedures have demonstrated that more than half of all patients with carcinoid and islet cell tumors experience an objective regression, the duration of which may be prolonged with the addition of systemic chemotherapy, particularly in the more chemosensitive islet cell tumors.

In addition to surgery and liver-directed therapies, another local treatment option is radiation therapy. As with other malignant tumors, radiation to bone metastases or bulky tumors may provide substantial relief of symptoms. Hepatic radiation also may be beneficial in selected patients with hormone-producing or painful liver metastases.

For many patients with metastatic gut neuroendocrine tumors, local therapy alone is insufficient for the palliation of symptoms caused by hormone release or tumor bulk. For patients in whom hormone-related syndromes cause the most problems, somatostatin analog often provides the most effective control, without significant toxicity. This drug usually should not be used for trivial symptoms that can be controlled with other medications, and the cost and need for frequent subcutaneous injections has made somatostatin analog an unattractive option for some patients. However, for patients whose symptoms from islet cell or carcinoid tumor syndromes are severe or life threatening, somatostatin analog is standard therapy. There is emerging evidence that response to somatostatin analog may be predicted by the presence of somatostatin receptors in tissue specimens; this observation also appears to be true for somatostatin radionuclide imaging. A long-acting octreotide acetate formulation has largely supplanted the use of frequent subcutaneous dosing.

For patients who are unresponsive to somatostatin analog, or who have ceased to respond, additional systemic treatments are required, particularly when tumor bulk is the chief clinical problem. For more than a decade, interferon- α has been used in investigational protocols for the treatment of patients with carcinoid and islet cell tumors. In carcinoid tumors, occasional tumor regression is observed with interferon, with a higher proportion of patients achieving reductions of 5-HIAA, with relatively brief symptom control. Higher response rates, with more prolonged duration, have been observed in patients with islet cell tumors who are treated with interferon. Studies are under way to evaluate the use of interferon combined with somatostatin analog and with systemic chemotherapy.

Systemic chemotherapy has not been evaluated extensively and systematically in patients with gut neuroendocrine tumors, in part because of the indolent natural history of many of these malignancies and in part because there are a variety of nonchemotherapeutic options. For selected patients, however, systemic chemotherapy is a valid option, particularly for islet cell tumors and for poorly differentiated gut neuroendocrine tumors with aggressive biologic potential.

In carcinoid tumors, drugs that have been studied most often include 5-FU, streptozocin, doxorubicin, and dimethyltriazenoimidazole carboxamide. Objective remissions for each of these drugs used as a single agent occur in less than 20% of patients. Combinations of these drugs have been investigated prospectively in large-scale cooperative group trials. Overall, the combination of 5-FU and streptozocin has been the most consistently active and tolerable regimen, with a suggestion of a survival advantage compared with other regimens in phase III trials. Systemic chemotherapy for islet cell tumors typically has been much more successful and represents a legitimate treatment option for patients with bulky tumors or poorly controlled syndromes. In early trials, the combination of 5-FU and streptozocin was found to produce objective responses in most patients with islet cell tumors. With the identification of doxorubicin as an active agent in islet cell tumors, combination chemotherapy with this drug also has been investigated. A trial comparing streptozocin and doxorubicin with streptozocin and 5-FU demonstrated that the doxorubicin-containing regimen was superior, with a 69% objective remission rate and a significantly superior median survival. Long-term, durable responses were seen in some patients. This regimen should be considered standard therapy for patients with islet cell tumors who are considered candidates for systemic chemotherapy. For patients with poorly differentiated gut neuroendocrine tumors, the selection of chemotherapy is similar to that for small-cell carcinomas of the lung.

CHAPTER 119: VIRAL HEPATITIS

FREDERICK NUNES

[Hepatitis A](#)
[Hepatitis B](#)
[Hepatitis C](#)
[Hepatitis D](#)
[Hepatitis E](#)

Viral hepatitis is a major cause of chronic liver disease in the United States and worldwide. Five hepatotropic (hepatitis A, B, C, D, and E) viruses have their principal site of injury in the liver ([Table 119.1](#)). In addition, hepatitis G virus (HGV) has been described but a relation between HGV and clinical hepatitis has not been proved.

Virus	Genome	Transmission	Can Cause Chronic Disease	Prevention of Transmission	Prevalence of Chronic Infections (US)
A	RNA	Oral-fecal	No	Pre- and postexposure immunization	0
B	DNA	Parenteral Perinatal	Yes	Pre- and postexposure immunization	1–1.2 million
C	RNA	Parenteral Perinatal	Yes	Blood donor screening and risk behavior modification	13 million
D	RNA	Parenteral Perinatal	Yes	Pre- and postexposure immunization	70,000
E	RNA	Oral-fecal	No	Safe drinking water	0

TABLE 119.1. HEPATOTROPIC VIRUSES

All five hepatotropic viruses cause acute viral hepatitis. Hepatitis A and E (HAV and HEV) cause self-limited disease, whereas hepatitis B (HBV), hepatitis D (HDV), and hepatitis C (HCV) may also cause chronic inflammation. Chronic infection with HBV, HDV, or HCV may lead to cirrhosis and liver failure. Hepatocellular carcinoma is an important complication of chronic viral hepatitis and cirrhosis. This chapter discusses the diagnosis and therapy of the five well-characterized hepatotropic hepatitis viruses ([Table 119.1](#)). Other viruses, such as cytomegalovirus (CMV), Epstein–Barr Virus (EBV), adenovirus, or members of Flaviviridae—all of which can affect the liver as part of a systemic disturbance—are not considered here.

The clinical presentation of patients with acute viral hepatitis is similar, regardless of the causative virus. Many cases are subclinical or present as a flulike illness that would not be recognized as being due to viral hepatitis unless liver chemistry blood tests are performed. Serum transaminase levels are often greater than 20 times the normal limit. A minority of patients present with the classic pattern of a viral prodrome, followed by overt jaundice. Specific serologic tests usually identify the offending viral agent ([Chapter 104](#)).

The development of chronic viral infection depends on host and virus factors. Treatment of chronic viral hepatitis is therefore aimed at both host immune modulation and direct antiviral treatment. Host immune modulation, particularly with interferon- α , has been the major approach to date. Interferons have a number of toxicities. Interferon-treated patients often develop a flulike syndrome, with fever, chills, nausea, and myalgia. Neurologic or psychological effects such as sleep disturbance, depression, or agitation may limit long-term use of interferon. Hematologic (white blood cells and platelet decreases) and endocrine (thyroid dysfunction) effects necessitate laboratory monitoring while a patient is on therapy.

HEPATITIS A

INCIDENCE AND EPIDEMIOLOGY

HAV has a worldwide distribution and is almost universally prevalent during childhood in developing countries because of poor sanitary conditions and overcrowding. Hepatitis A is transmitted almost exclusively through the fecal–oral route. HAV infections frequently occur in small outbreaks caused by fecal contamination of drinking water or food. Travel to endemic areas is a common source of infection for persons from nonendemic areas. In the United States, 125,000 to 200,000 acute infections occur per year, with highest attack rates in late childhood (ages 5 to 14).

ETIOLOGY

HAV is an RNA-containing virus. Although HAV isolates may vary in nucleotide sequence, they all belong to one serotype.

PATHOGENESIS

HAV is not cytopathic, and the mechanisms by which it leads to cellular injury have not been defined.

CLINICAL FINDINGS

HAV causes a self-limited infection. Hepatitis A is most often a subclinical disorder in children, but adults are usually symptomatic. Cholestasis may be a prominent feature of type A infection but is unusual with the other well-described hepatitis viruses. The viral incubation period ranges from 15 to 45 days. Most cases are self-limited, and many are unrecognized by the host. When acute HAV infection results in jaundice, patients continue to shed virions for up to 14 days after the onset of jaundice. In rare instances, HAV causes fulminant hepatitis that may lead to death ([Chapter 105](#)). Persons with underlying chronic liver disease, such as chronic hepatitis B and C, have an increased risk for severe HAV infection.

LABORATORY FINDINGS

The diagnosis of acute HAV is made by serology ([Fig. 119.1](#)). Anti-HAV IgM antibody is positive in acute infections. It occurs early and lasts generally 3 to 6 months after the onset of clinical disease. As the IgM antibody decreases, IgG anti-HAV rises and persists probably for life. Tests for total (IgG and IgM) anti-HAV are helpful in determining immunity to HAV reinfection, but are not helpful in making a diagnosis of acute HAV.

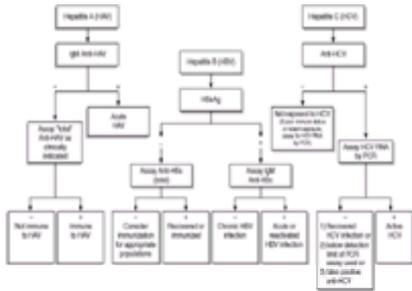

FIGURE 119.1. Approach to diagnosis of Hepatitis A infection.
EVIDENCE LEVEL: C. Expert Opinion.

OPTIMAL MANAGEMENT

The treatment of patients with HAV infection is supportive. In rare cases of HAV infection that result in fulminant hepatic failure, orthotopic liver transplantation may be indicated.

HAV vaccine is an attenuated strain of HAV grown on tissue culture cells and chemically inactivated. The HAV vaccine confers immunity in 80% to 90% of those treated and is effective for *preexposure* prophylaxis (Table 119.2). Its use is recommended for persons traveling to endemic areas. Other possible candidates include children in communities with high rates of HAV infection, day care center staff, staff of custodial institutions, sewage workers, homosexual men, intravenous drug abusers, and residents in communities experiencing hepatitis A outbreaks. Immune globulin is effective as postexposure prophylaxis for HAV. Postexposure prophylaxis is recommended within 2 weeks of exposure for household and sexual contacts of patients with HAV infection.

Preexposure
Populations at increased risk for HAV infection or the adverse consequences of infection
Travel or work in countries with intermediate or high endemicity of infection
Children in communities with high rates of HAV and periodic HAV outbreaks
Homosexual men
Intravenous drug users
Persons who have chronic liver disease
Persons who have clotting factor disorders
Food handlers
Sewage workers
Vaccination in outbreak settings
Routine examination of children 2 years of age and accelerated vaccination of older children
Postexposure (non vaccinated)
Close personal contact
Day care centers
Common source exposure

HAV, Hepatitis A virus.

TABLE 119.2. HEPATITIS A PREEXPOSURE AND POSTEXPOSURE PROPHYLAXIS

HEPATITIS B

INCIDENCE AND EPIDEMIOLOGY

Worldwide, there are approximately 300 to 350 million HBV carriers. The prevalence of HBV infection varies greatly throughout the world. Endemic areas with a high prevalence of infection include certain parts of Africa, Asia, and the Mediterranean basin. Approximately 40,000 to 320,000 acute HBV infections occur per year in the United States, with a prevalence of chronically infected persons of approximately 1 to 1.25 million. The virus is primarily transmitted by percutaneous exposure or by inapparent skin or mucosal exposure. HBV has been found in almost every body fluid obtained from an infected person. Intimate (sexual) contact and perinatal transmission are important nonpercutaneous means of HBV transmission. The incidence of chronic disease depends on the person's age and immunologic status at the time of infection. The proportion of patients who become chronically infected declines with age, ranging from 90% for infants infected at birth to 70% for those infected in childhood and less than 5% for healthy adults.

ETIOLOGY

HBV is a DNA-containing virus that replicates in the liver via an RNA intermediate, using reverse transcriptase activity. A number of virally encoded proteins are produced and secreted into the serum. These proteins and the immune response they induce form the basis for the diagnosis of HBV (Fig. 119.1; Table 119.3).

Case	Anti-HBc			Anti-HBc IgG			Anti-HBc IgM	HBV DNA	Comments	Antibiotic Treatment
	HBsAg	Anti-HBc	Anti-HBc	HBsAg	Anti-HBc	Anti-HBc				
Not exposed	-	-	-	-	-	-	-	-	Intentional hepatitis B vaccine, high-risk persons, health-care workers	No treatment
Acute	+	+	-	+	+	-	+	+		Supportive care; treatment considered
Chronic high titer	+	+	-	+	+	-	+	+		Treatment considered
Chronic low titer	+	+	-	+	+	-	+	+		No treatment
Resolved	-	+	+	-	+	+	-	-	Recovery; resolution of infection; HBsAg may be undetectable in patients with chronic infection	No treatment
Resolved	-	+	+	-	+	+	-	-	Recovery; resolution of infection; HBsAg may be undetectable in patients with chronic infection	No treatment

HBsAg, hepatitis B surface antigen; anti-HBc, antibody to hepatitis B core antigen; anti-HBc IgG, antibody to hepatitis B core antigen; anti-HBc IgM, antibody to hepatitis B core antigen; HBV, hepatitis B virus; HBV DNA, hepatitis B virus DNA.

TABLE 119.3. DIAGNOSIS OF HEPATITIS B

PATHOGENESIS

HBV is not cytopathic, except perhaps when the expression of the virus is greatly enhanced such as in immunosuppressed persons. The damaging effects of infection are thought to result from the immune response of the host to virally encoded proteins. Portions of the DNA genome may integrate into the host's genome.

CLINICAL FINDINGS

Most patients with acute HBV infection are asymptomatic or present with mild flulike symptoms. Jaundice occurs in less than one-third of cases. The incubation period varies from a few weeks to 6 months. A prodrome of fever, arthralgias or arthritis, and rash may occur in 10% to 20% of cases of acute HBV infection. This prodrome is due to circulating hepatitis B surface antigen (HBsAg)/antibody to HBV surface antigen (anti-HBs) complexes that activate complement after depositing in the

synovium and walls of cutaneous blood vessels. These symptoms generally resolve early in the illness, before the symptoms of liver disease become apparent.

LABORATORY FINDINGS

Detection of HBsAg in serum establishes the diagnosis of HBV infection. HBsAg appears in the blood about 6 weeks after infection and is usually cleared within 3 months in patients with transient disease. Persistence of HBsAg after 6 months from the onset of the infection implies chronic infection. The presence of IgM antibody to HBV core antigen (anti-HBc IgM) signifies an acute or reactivated chronic infection. Polyclonal anti-HBs is generally detectable 3 months after infection and implies recovery and immunity to HBV. However, in a subset of individuals with chronic HBV infection, both HBsAg and anti-HBs are detectable.

HBV DNA is a sensitive measure of viral replication. HBe antigen (HBeAg) is a secreted product that is produced as a result of intracellular modification of the protein product of the gene, which encodes precore and core protein. The presence of HBeAg in the bloodstream correlates with HBV viral DNA synthesis and thereby correlates with viral replication and infectivity. Antibody to HBV e antigen (anti-HBe) is usually an indicator of lower infectivity. Occasionally, HBV DNA is positive in the setting of a negative HBeAg. This finding is due to the expression of a mutant form of HBV, referred to as the “non-e-antigen–secreting, precore mutant virus.” In patients with chronic HBV infection, a liver biopsy can assist in assessment of the degree of inflammation, in evaluation for presence of scar tissue, and in detection of viral antigens.

OPTIMAL MANAGEMENT

Serologic and molecular tests assist in determining prognosis and stratifying patients for treatment. The various forms of HBV infection are outlined in [Table 119.3](#). Treatment is indicated for patients with a replicative form of infection (HBeAg or HBV DNA–positive or both). Interferon alfa-2b (Intron A) is an approved treatment for HBV infection. The standard dose of interferon alfa-2b for patients with well-compensated chronic HBV is 5 million units subcutaneously daily or 10 million units subcutaneously three times per week for 4 to 6 months ([Table 119.4](#)). Interferon therapy is associated with approximately 40% conversion from a replicative form to a nonreplicative form of HBV infection recognized serologically by HBV e Ag becoming undetectable. Clearance of HBV DNA and remission of disease can be obtained in approximately one-third of treated persons. Patients with higher serum aminotransferases and lower HBV-DNA levels are more likely to respond ([Table 119.5](#)). Patients with normal serum aminotransferases or patients with decompensated cirrhosis are generally not candidates for interferon therapy.

Virus	Approved Treatments	Variables of Standard Treatment	Experimental Treatments
Hepatitis A	Supportive		
Hepatitis B	1. Interferon alfa-2b 5 MIU subcutaneously daily for 16 weeks 2. Lamivudine 100 mg daily	Interval of treatment Duration of treatment	Nucleoside analogues Therapeutic vaccine
Hepatitis C	1. Interferon α combined with ribavirin 1000–1200 mg/d for 6–12 mo 2. Interferon alfa-2b 5 MIU subcutaneously 3 times for 12 months	Higher dose Daily administration Longer duration of treatment	Long-acting interferons
Hepatitis D	Interferon alfa-2b 5 MIU subcutaneously 3 times		
Hepatitis E	Supportive		

TABLE 119.4. TREATMENT OF CHRONIC VIRAL HEPATITIS

Indications for Treatment	Positive Predictive Factors for Treatment
HBV Persistent elevation of serum aminotransferases HBeAg +, HBsAg +, HBV DNA + Chronic hepatitis on liver biopsy Compensated liver disease	High serum aminotransferases Low serum HBV DNA Short duration of illness before treatment Active histologic hepatitis Fibrosis on liver biopsy No major current illnesses Absence of immunosuppression, including HIV
HCV Persistent elevations of serum aminotransferases Serum HCV RNA +, anti-HCV + Chronic hepatitis on liver biopsy Compensated liver disease	HCV genotypes 2 or 3 Age < 45 yr Duration of disease < 5 yr Absence of cirrhosis Low levels of HCV RNA before treatment

HBe, hepatitis B virus; HBsAg, hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HCV, hepatitis C virus.

TABLE 119.5. INDICATION FOR TREATMENT

Lamivudine, an agent that inhibits reverse transcriptase enzymes is an approved therapy for chronic hepatitis B associated with viral replication and active inflammation. Treatment with this type of antiviral medication is restricted to HBV, because the other known hepatitis viruses do not require a reverse transcriptase enzyme for replication. HIV testing should be offered to all patients before initiating lamivudine therapy because a lower dose is administered to treat HBV than HIV. If a patient is HIV-positive, combination therapy with a higher dose of lamivudine combined with other antiviral agents is desired to lower the probability of HIV drug resistance. Lamivudine is administered orally and is rarely associated with serious side effects at the standard HBV dose of 100 mg per day. Dose adjustment is necessary for impaired renal function. Lamivudine therapy is approved for 1 year; however, the optimal duration of therapy is not known. Relapse after discontinuation of lamivudine treatment is common. Lamivudine-resistant mutants arise in approximately 25% of patients treated for 1 year, but the long-term significance of these mutants is not known.

Newer approaches under investigation include therapeutic vaccines and multiple nucleoside analogues in combination.

Orthotopic liver transplantation is an accepted treatment for end-stage liver disease due to chronic HBV ([Chapter 132](#)). Although initial results were poor owing to aggressive recurrent HBV infection, long-term survival has been achieved by treatment with HBV immunoglobulin to block graft infection.

The primary strategy for the prevention of HBV is immunization. Transmission of HBV can be prevented by preexposure prophylaxis with HBV vaccine or, after exposure, by the combination of vaccination and HBV immune globulin (HBIG). Postexposure prophylaxis is recommended for exposed persons, including babies born to infected mothers. Preexposure prophylaxis with HBV vaccine is recommended for all babies at birth, children ages 11 to 12 if not previously vaccinated, and high-risk persons of any age including health care workers ([Table 119.6](#)).

Population Exposure	Immunoglobulin Administered	Vaccine Administered	Comments
Random or HBV-infected mother	Yes	Yes	
All newborns	No	Yes	Recommended
Children 11–12 who have not been vaccinated	No	Yes	Recommended
High risk	No	Yes	Includes health care workers

TABLE 119.6. PASSIVE AND ACTIVE IMMUNIZATION FOR PREVENTION OF HEPATITIS B

HEPATITIS C

INCIDENCE AND EPIDEMIOLOGY

Hepatitis C is widely prevalent throughout the world. Hepatitis C is a common cause of chronic liver disease, and in the United States it affects approximately 3.9 million people. The incidence of acute HCV infection in the United States has declined since its peak in 1989. Currently, there are approximately 35,000 acute new infections of HCV in the United States each year. Most infected persons (greater than 75%) develop a chronic infection. Hepatitis C is transmitted through percutaneous and permucosal routes. The major identified risk factors are listed in [Table 119.7](#). Transmission of HCV is most efficient via percutaneous exposure, such as the sharing of contaminated needles among intravenous drug users or the transfusion of infectious blood products. Screening tests to exclude infectious donors has markedly decreased the risk of transfusion-associated HCV now estimated between 0.01% and 0.001% per unit transfused. The incidence of HCV among intravenous drug users has declined because of changing drug use practices. Intravenous drug users account for approximately 50% of all new acute infections and 50% or more of chronic infections. It may be difficult to obtain a history of injection drug use because many patients have stopped intravenous drug exposure many years before the recognition of HCV.

- Blood transfusions before 1992
- Intravenous drug use
- Body piercing and tattooing
- Infants born to infected mothers
- Frequent exposure to blood products (chronic renal failure, organ transplantation, hemophilia)
- Infants born to HCV-infected mothers
- Intranasal cocaine use
- Hemodialysis
- Occupational exposure to blood and blood products

TABLE 119.7. RISK FACTORS FOR THE ACQUISITION OF HEPATITIS C VIRUS (HCV)

The incidence of sexual transmission of HCV is not certain, but it probably occurs, although rarely. At present, no specific recommendations are made to change sexual practices in monogamous relationships, in which one partner is anti-HCV–positive. Sexually active patients who are anti-HCV–positive, but who are not in a long-term monogamous relationship, should be advised to use “safe sex” barrier precautions. Maternal–fetal transmission occurs occasionally (<5%) at the time of birth. Coinfection of the mother with HIV appears to facilitate transmission of HCV to the neonate. Infection of the neonate after birth occurs rarely, and at present breast-feeding is not discouraged for mothers chronically infected with HCV. Household contact is not considered a risk factor for HCV infection; however, anti-HCV–positive persons should not share personal items such as toothbrushes and razors.

There is a high prevalence of anti-HCV antibody among alcoholic patients with liver disease. Alcohol use appears to increase HCV replication, progression to fibrosis and cirrhosis, and risk of hepatocellular carcinoma. Whether this potential synergistic relation between alcohol and HCV occurs with more modest alcohol intake is not yet clear. It seems prudent, however, to counsel HCV-infected persons to abstain or minimize alcohol intake.

ETIOLOGY

HCV is an RNA-containing virus of the family Flaviviridae, identified in 1989 by molecular biologic techniques. HCV is a genetically heterogeneous family of viruses with at least six distinct genotypes and many subtypes identified worldwide. Genotype 1 is the most common in the United States present, found in approximately 75% of infected patients. The frequency of the various genotypes varies among geographic regions.

CLINICAL FINDINGS

Most acute and chronic HCV infections are clinically asymptomatic. The incubation period after exposure to HCV ranges from 2 weeks to 2 months. If symptoms or jaundice occur as a result of acute HCV infection, symptoms generally last 2 to 12 weeks. A small number of persons with chronic HCV have signs and symptoms of liver disease. The major manifestation of chronic HCV infection may be chronic fatigue, but it may be difficult to determine whether symptoms are attributable to chronic HCV or to another cause. Other symptoms may include mild right upper quadrant discomfort, nausea, anorexia, myalgias, and arthralgias.

Clinically apparent extrahepatic manifestations of HCV develop in 1% to 2% of chronically infected people. The most significant of these are essential mixed cryoglobulinemia and membranoproliferative glomerulonephritis. Cryoglobulinemia may present as skin rashes, myalgias and arthralgias, glomerulonephritis, and the presence of serum cryoglobulins. Porphyria cutanea tarda is associated with chronic HCV and excessive hepatic levels of iron. The possible association between HCV and diabetes mellitus is under active clinical and laboratory investigation.

There is a spectrum of HCV disease outcomes; thus, estimating prognosis in individual patients is difficult. However, longitudinal studies suggest that cirrhosis develops in at least 20% of patients over a 10- to 20-year period. Those who have had chronic HCV for an extended period of time and have developed moderate to severe hepatitis are at risk for progression to cirrhosis, hepatic failure, and hepatocellular carcinoma. In the United States, an estimated 8,000 to 10,000 persons die annually as a result of HCV-associated liver disease, and chronic HCV infection is the most common reason for performing liver transplantation in many liver transplantation centers ([Chapter 132](#)). The number of deaths attributed to HCV is expected to triple over the next 10 to 20 years based on a cohort effect of persons infected with HCV in the 1970s and 1980s.

LABORATORY FINDINGS

Serum alanine aminotransferase (ALT) is usually less than five times the upper limit of normal. The incidence of persistently normal ALT levels among carriers is not well known but may be as high as 15%. Occasional normal ALT levels occur in many infected individuals. Alkaline phosphatase, albumin, prothrombin time, serum bilirubin, and platelet count are normal until the development of advanced liver disease. Iron and ferritin levels may be slightly elevated.

The diagnosis of HCV infection is based on serologic tests to detect anti-HCV antibody and molecular tests to identify viral RNA ([Fig. 119.1](#); [Table 119.8](#)). Initial testing to detect HCV antibody (anti-HCV) is performed with second- or third-generation enzyme immunoassay (EIA). False-positive HCV EIA tests occur particularly when screening low-prevalence populations such as blood donors. Confirmation of HCV exposure requires a supplemental test such as the second-generation recombinant immunoblot assay. Anti-HCV antibody titers are present in almost all patients 1 month after onset of acute HCV, but may never become detectable in immunosuppressed or immunocompromised persons. The anti-HCV antibody is not neutralizing, and it does not confer immunity ([Fig. 119.1](#)).

Method	Test	Purpose
Serologic	Detect anti-HCV antibodies	Screening for HCV
	Enzyme immunoassay (EIA)	Used as supplemental antibody test
	Second-generation recombinant immunoblot assay (RIBA-2)	
Molecular	Detect and characterize HCV RNA	Confirm active HCV infection
	Qualitative reverse transcriptase polymerase chain reaction (RT-PCR)	Determine viral RNA levels and may correlate response to treatment
	Quantitative test for HCV RNA level	Correlates with response to therapy
	Genotype determination	

*Not all patients with active HCV infection are detected with EIA screening.

TABLE 119.8. DIAGNOSTIC TESTS FOR HEPATITIS C VIRUS (HCV)

Testing for the presence of HCV RNA in serum or liver tissue is the gold standard for diagnosing active HCV infection. This may be required in patients with acute HCV and patients on dialysis, patients who are taking corticosteroids or immunosuppressive medications, and patients who have hypogammaglobulinemia.

The presence of HCV RNA in the serum is detectable by the reverse transcription–polymerase chain reaction (RT-PCR) assay. This assay can be very sensitive (100 or less viral genomes per milliliter of serum). However, RT-PCR is not standardized and is subject to variability as a result of specimen handling, serum storage conditions, and PCR technique. Controversy exists as to the value in a clinical, rather than a research, setting of quantifying the HCV viral load. HCV viral load does not correlate with severity of hepatitis nor does it portend a poor prognosis. In many studies, a low level of viremia correlates with probability of response to antiviral therapy.

Genotype 1 is the most common in the United States, and affected patients are less likely to respond to antiviral therapy compared with those with genotypes 2 and 3.

A liver biopsy is not necessary for diagnosis but assists in determining the degree of inflammation and presence of scar tissue. In general, there is a poor correlation between serum ALT level and liver disease activity determined by histology. A liver biopsy is also helpful in excluding other causes of liver disease, including iron overload, autoimmune liver disease, and alcoholism.

OPTIMAL MANAGEMENT

No effective vaccine is available for HCV, perhaps as a result of the great deal of variability of the hepatitis C viral envelope. Postexposure prophylaxis with immunoglobulin is not effective in blocking HCV infection and is not recommended.

Interferon- α monotherapy and the combination of interferon- α and ribavirin are two regimens approved for the treatment of HCV in the United States. Three recombinant α interferons have been approved for treatment of chronic HCV in the United States (interferon α -2a, α -2b, and α -con-1). The optimal dose, interval of administration, and duration of treatment with interferon- α is not known. The standard therapy for chronic HCV with these interferons in a patient with well-compensated liver disease, is 3 million units three times per week, or in the case of α -con-1 interferon, 9 μ g three times per week for 12 months administered by subcutaneous injection ([Table 119.4](#)). Long-term response to therapy for hepatitis C is defined as persistently negative serum HCV RNA by PCR for at least 6 months after completion of treatment. A long-term response is observed in approximately 10% to 15% of patients treated with interferon- α monotherapy for 6 to 12 months. The presence of HCV genotype 1, cirrhosis, a high viral load as measured by quantitative PCR, or a long duration of infection (greater than 15 years of probable infection), are negative predictors for a long-term response to interferon monotherapy ([Table 119.5](#)).

Flu-like side effects of fever, malaise, headache, chills, arthralgias, and myalgias occur within 8 hours of interferon- α administration. These side effects can be ameliorated by acetaminophen. Later side effects include fatigue and malaise. Severe depression may occur and limit treatment with interferon- α . Thyroid dysfunction has been reported in 2.55% to 20% of patients. Interferon- α is generally contraindicated in patients with severe depression, autoimmune hepatitis, uncontrolled hyperthyroidism, coronary heart disease, or decompensated cirrhosis.

The combination of interferon and ribavirin is associated with higher sustained response rates compared with the three interferon- α monotherapies now available. Ribavirin is an oral nucleoside analogue with activity against a wide spectrum of viruses. The mechanism by which it improves the sustained response to interferon therapy is not known. Ribavirin causes a dose-related hemolytic anemia necessitating frequent hemoglobin monitoring. Because ribavirin is teratogenic, patients must use a medically accepted form of birth control while on therapy and for 6 months after discontinuation of therapy.

Combination therapy with interferon and ribavirin leads to a sustained response (loss of HCV RNA from the serum for at least 6 months after completion of treatment) in approximately 30% to 40% of previously untreated patients.

Orthotopic liver transplantation is an accepted treatment for end-stage liver disease secondary to HCV. HCV is the most common indication for orthotopic liver transplantation in the United States ([Chapter 132](#)). Response rates may be higher or lower depending on the HCV genotype.

Future research will aim to optimize combination treatment regimens. Alternative forms of interferon may require less frequent administration and improved sustained response rates. Future therapies may include anti-inflammatory agents, anti-fibrotic agents, immune modulators, and compounds that directly inhibit HCV encoded enzymes.

HEPATITIS D

INCIDENCE AND EPIDEMIOLOGY

HDV is transmitted by blood and blood products. HDV infection has a worldwide distribution, but the areas of highest endemic rate are the Mediterranean countries, the Middle East, and certain parts of South America. It is found infrequently in Asia, Western Europe, and North America. In nonendemic areas such as North America, HDV occurs most commonly among intravenous drug users and multiply transfused patients.

ETIOLOGY

HDV is a small circular RNA-containing virus. HDV is a defective virus that can infect only in the presence of HBV infection. Acute HDV infection may occur coincident with acute HBV infection or as a superinfection in a person chronically infected with HBV.

PATHOGENESIS

The delta agent may be cytopathic, but the precise mechanism of hepatic injury is not known.

CLINICAL FINDINGS

HDV coinfection with HBV causes severe acute disease, but a low risk of chronic infection. Superinfection with HDV of a chronic HBV-infected person generally results in chronic HDV infection and a higher risk for severe chronic liver disease.

Typically, acute HDV is accompanied by a biphasic aminotransferase pattern, with one peak level resulting from HBV-induced liver cell injury and the other from the delta agent. The serologic response to acute HDV infection as measured by commercial immunoassays is often undetectable or represented by transient appearance of IgM antibody. By methods confined to research laboratories, delta antigen and HDV RNA can be detected transiently in liver tissue and serum during acute

infection.

LABORATORY FINDINGS

Acute and chronic HDV is diagnosed by the presence of HDV antibody (anti-HD). IgM anti-HD and delta antigen, although helpful in diagnosing acute HDV infection, are not routinely available in the United States.

OPTIMAL MANAGEMENT

An HDV vaccine is not available. Prevention is best obtained by immunizing against HBV and education to reduce high-risk behaviors. HDV may also be treated with interferon alfa-2b ([Table 119.4](#)). In one randomized controlled trial, there was a 50% response rate to 9 million units of interferon alfa-2b administered three times per week subcutaneously for 48 weeks. However, relapse at the end of treatment was common.

HEPATITIS E

INCIDENCE AND EPIDEMIOLOGY

HEV is transmitted through the oral–fecal route. The incubation period is 40 days on average, with a range of 15 to 60 days. Large outbreaks of HEV have been identified in India, Bangladesh, and Central and South America. The case fatality rate is reported as 1% to 3% overall and 15% to 25% in pregnant women. Sporadic cases can occur in developed countries after travelers return from an endemic area.

ETIOLOGY

HEV is a RNA-containing virus. Blood-borne transmission has not been demonstrated, and a carrier state has not been observed. Antibody to HEV is detectable at disease presentation.

PATHOGENESIS

There is no chronic hepatitis or carrier state resulting from this agent.

LABORATORY FINDINGS

Serologic testing for HEV is not routinely available but may be obtained through a research laboratory.

OPTIMAL MANAGEMENT

Therapy is supportive.

responsiveness to corticosteroids and ursodeoxycholic acid, and histologic improvement is not common.

CLINICAL FEATURES

The presentation of AH is diverse, ranging from asymptomatic transaminase elevations to subfulminant hepatitis. The most common symptom is fatigue, anorexia and weight loss, and the presence of pruritus or pain argues against this diagnosis. Occasionally, patients present with cirrhosis, and the complications of portal hypertension. Women may develop primary or secondary amenorrhea as the initial manifestation. Before treatment most patients have elevated serum transaminase levels, bilirubin, and alkaline phosphatase. The hypergammaglobulinemia of AH is polyclonal but predominantly of the immunoglobulin G fraction. Cryoglobulins may be present, but are rarely clinically significant. Extrahepatic immunologic disorders are often associated with AH ([Table 120.3](#))

Autoimmune thyroiditis	Nephritis
Graves' disease	Coombs'-positive hemolytic anemia
Chronic ulcerative colitis	Idiopathic thrombocytopenic purpura
Systemic sclerosis	Erythema nodosum
Pernicious anemia	Fibrosing alveolitis
Rheumatoid arthritis	
Leukocytoclastic vasculitis	

TABLE 120.3. EXTRAHEPATIC IMMUNOLOGIC DISORDERS ASSOCIATED WITH AUTOIMMUNE HEPATITIS

Liver biopsy is necessary for diagnosis of AH to assess the severity and stage of inflammation and assist with the determination of prognosis. AH is characterized by periportal mononuclear infiltrates extending into the lobule (piecemeal necrosis), but some patients may have a predominantly plasma cell infiltrate. Patients with severe cases have necrosis from portal tracts to the central vein or nonspecific cirrhotic histology at the time of biopsy. Histologically, AH may occasionally be difficult to distinguish from viral chronic viral hepatitis, primary biliary cirrhosis, or primary sclerosing cholangitis. Periportal hepatitis on biopsy predicts cirrhosis for 17% of patients but 5-year survival is normal. Survival rate drops to 58% at 5 years if cirrhosis is established on biopsy. Bridging necrosis or multilobular necrosis is intermediate with 45% 5-year mortality rate, and 82% develop cirrhosis within 5 years. Rarely, hepatocellular carcinoma can occur in cirrhosis.

MANAGEMENT

Without immunosuppressive therapy, patients with autoimmune hepatitis usually progress to liver failure, with a mean survival of 5 years. The indications for treatment are based on symptoms, clinical progression, and manifestations of inflammation by laboratory or histologic evaluation. Cirrhotic patients with inflammatory activity on histology may still respond to corticosteroids, and a trial should be initiated. Prednisone alone or a lower dose of prednisone in combination with azathioprine is effective. The combination is preferred because of a lower risk of corticosteroid-related side effects such as osteopenic bone disease, obesity, cushingoid features, brittle diabetes, hypertension, or emotional lability. Initial treatments are either prednisone 30 mg per day and azathioprine 50 mg per day or 60 mg of prednisone per day with a weekly tapering of prednisone to 10 mg per day (combination therapy) and 20 mg per day (single-drug regimen).

Patients with multilobular necrosis on histologic examination who have no normalization of at least one laboratory parameter or whose pretreatment hyperbilirubinemia does not improve during a 2-week treatment period have a high rate of immediate mortality. These patients should be evaluated for liver transplantation if there are features of decompensation.

Remission is defined as an absence of symptoms, serum aspartate aminotransferase less than two times normal, and other serum markers normal and inactive or very minimally active biopsy. Sixty-five percent of patients experience remission within 2 years of therapy. When remission is achieved, corticosteroids should be tapered to the lowest possible maintenance dose. Liver biopsy examination before drug withdrawal is necessary to establish remission. More than 50% of patients have inflammatory activity on liver tissue examination. Histologic remission can lag behind biochemical evidence of remission by several months, and therapy should be extended for this duration. Relapse occurs in 50% of patients within 6 months of discontinuation of therapy.

Progressive symptoms, increasing aspartate transaminase and bilirubin levels, or worsening inflammation of liver biopsy defines treatment failure, which occurs in 9% of treated patients. High-dose prednisone alone (60 mg daily) or prednisone (30 mg daily) in conjunction with azathioprine (150 mg daily) induces clinical remission in 70% of failures within 2 years of the increased therapy. No remission after 3 years of continuous therapy (incomplete response, 13%) requires long-term maintenance with low dose (<10 mg) prednisone. Ten-year survival rates for treated patients with and without cirrhosis at presentation are 89% and 90%, respectively, and are comparable to a healthy age- and sex-matched cohort (94% at 10 years).

LIVER TRANSPLANTATION

Liver transplantation is effective therapy for decompensated disease in patients who have failed therapy or have advanced disease at presentation. Five-year survival rate after transplantation is 92%. Recurrence of autoimmune hepatitis in the graft is a common event (20% to 30%) with an incidence that increases over time as immunosuppressive therapy is reduced. Although response to treatment is poor, patient and graft survival do not appear to be decreased. Transplant recipients with AH should not undergo complete withdrawal of corticosteroid, and azathioprine should probably be part of the immunosuppressive regimen.

PRIMARY BILIARY CIRRHOSIS

DIAGNOSIS AND EPIDEMIOLOGY

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease characterized by progressive inflammatory destruction of smaller intrahepatic bile ducts. The diagnosis should be considered in the setting of elevated serum alkaline phosphatase, hypercholesterolemia, and antimitochondrial antibodies. The natural history of PBC is that of a slowly progressive cholestasis marked by fatigue, pruritus, and the development of cirrhosis with its concomitant complications. PBC usually affects middle-aged women, and presentation is rare in those younger than 30 years or over 80 years. PBC is diagnosed in all races, but is more frequently seen in whites. PBC accounts for up to 2% of deaths from cirrhosis worldwide. It is diagnosed more frequently in developed countries, but whether this represents improved access to health care or a true difference in disease incidence is not known.

ETIOLOGY AND PATHOGENESIS

Although the cause of PBC is unclear, immunologic and genetic factors appear to play a role. For example, antimitochondrial antibodies are present in 95% of patients with PBC. In general, this family of antibodies are non-species- and non-organ-specific, and their presence or titer does not affect the course or severity of the disease. However, one of the antimitochondrial antibodies, anti-M2, appears specific for PBC. It is directed against the pyruvate dehydrogenase complex on the inner membrane of the mitochondrion. Additional immunologic abnormalities associated with PBC include IgM hypergammaglobulinemia, circulating immune complexes, and decreased populations and function of suppressor T cells. Other (extrahepatic) autoimmune diseases associated with PBC include systemic scleroderma, CREST syndrome (calcinosis, Raynaud's disease, esophageal dysmotility, sclerodactyly, and telangiectasia), autoimmune thyroiditis, rheumatoid arthritis, psoriatic arthritis, and Sjögren's syndrome. A genetic component to the pathogenesis of PBC is suggested by its link to the HLA-DRw8 antigen. However, the lack of concordance of disease in identical twins suggests that some triggering event is required to initiate PBC in a genetically susceptible person.

The pathogenesis of PBC appears to be due to two related processes that culminate in hepatic damage and the clinical features of the disease. Activated lymphocytes may be the mediators of the chronic small bile duct destruction that is the hallmark of this disease. In contrast to that which occurs in healthy persons,

patients with PBC express increased amounts of class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR) histocompatibility antigens on bile duct cells. These may provide a better target for activated cytotoxic T lymphocytes. Histologically, the bile duct lesions resemble those that are known to be mediated by cytotoxic T lymphocytes, such as graft-versus-host disease and rejection of transplanted organs.

CLINICAL FEATURES

Many of the clinical manifestations of PBC are caused by the gradual destruction of small intrahepatic bile ducts ([Table 120.4](#)). The resulting diminution in the number of such ducts results in retention of bile acids, bilirubin, copper, and other substances that are normally secreted or excreted into bile, causing further damage to the liver cells. Other substances concentrate in the blood and soft tissues, causing symptoms such as itching. The pruritus is not due to the naturally occurring primary or secondary bile acids but to some other substance that is secreted into bile and bound by cholestyramine, a nonabsorbed, quaternary ammonium resin. In addition, serum levels of endogenous opioids are increased in those with PBC, and opioid antagonists relieve itching in some patients.

Feature	Percent
Asymptomatic	25
Fatigue	65
Pruritus	50
Hepatomegaly	25
Splenomegaly	15
Xanthelasma	10

TABLE 120.4. PRESENTATION OF PRIMARY BILIARY CIRRHOSIS

Hyperlipidemia and xanthoma formation are also consequences of long-standing cholestasis. Approximately 10% of patients eventually develop xanthelasmas that correlate with the degree of hypercholesterolemia. These lesions can be found on the palms of the hands, on the soles of the feet, over the extensor surfaces of the elbow and knees, on the eyelids or buttocks, and in the tendons of the ankles and wrists. The impaired secretion of bile causes a diminished concentration of bile acids in the intestinal lumen. If bile acids fall below the critical micellar concentration, complete digestion and absorption of neutral triglycerides in the diet may become inadequate. This accounts for the fat malabsorption seen in some patients and can be accompanied by malabsorption of the fat-soluble vitamins A, D, E, and K and by calcium malabsorption.

Some PBC patients with sicca syndrome may also suffer from pancreatic insufficiency. The pathogenesis of the osteopenic bone disease that occurs in at least 25% of PBC patients is likely to be multifactorial in nature and can lead to vertebral compression and long bone fractures. In patients whose osteoporosis is due to PBC, liver transplantation eventually leads to increased bone mineral density. Copper retention can rarely result in the finding of Kayser–Fleischer rings on eye examination or renal tubular acidosis because of excessive deposition of copper in the distal renal tubule.

Natural history studies have identified several variables associated with decreased survival in patients with PBC, such as bilirubin level greater than 10 mg per deciliter. The course of the disease has been described as being divided into three periods: a lengthy presymptomatic phase of up to 20 years, a symptomatic phase of pruritus, fatigue, and mild jaundice that may span 10 years, and a preterminal phase accompanied by marked jaundice and the complications of cirrhosis. The preterminal phase may be approximately 2 years, unless transplantation intervenes. Statistical models to predict survival have been validated and are valuable in management of medical care and the timing of liver transplantation. The most powerful predictor is the serum bilirubin level. Patients with bilirubin levels higher than 10 mg per deciliter usually survive less than 2 years; such a finding should prompt evaluation for liver transplantation. Other indications for liver transplantation include hepatorenal or hepatopulmonary syndromes, complications of portal hypertension, severe osteoporosis, evidence of malnutrition, and hepatocellular carcinoma (rare).

Many patients are asymptomatic at the time of diagnosis, but the signs and symptoms of cholestasis develop as the disease progresses. Once symptoms appear, and fatigue, pruritus, muscle wasting, progressive jaundice, and hepatic dysfunction develop. These can culminate in the complications of cirrhosis and portal hypertension and the need for liver transplantation. The diagnosis of PBC should be considered in patients with unexplained cholestasis or elevation of serum alkaline phosphatase. A percutaneous biopsy is necessary to confirm the diagnosis and determine prognosis. The pathognomonic lesion is characterized by patchy destruction of interlobular bile ducts with a mononuclear inflammatory infiltrate. Granulomas may be present but are not required for the diagnosis of PBC.

The severity of histologic damage can be classified into stages I to IV. Procedures to exclude other causes of cholestasis may include ultrasonography (which demonstrates normal-sized bile ducts), and computed tomography helps exclude ductal dilatation and may reveal portosystemic collaterals suggestive of portal hypertension. Endoscopic retrograde cholangiopancreatography may be used in patients lacking appropriate markers. The PBC patient has normal large bile ducts, but may have irregularities of smaller bile ducts. In end-stage PBC the physical signs of cirrhosis will be present and can include spider angiomas, temporal and extremity wasting, ascites, and signs and symptoms of hepatic encephalopathy.

TREATMENT

There is no proven medical treatment for the underlying disease of PBC, although drugs such as ursodeoxycholic acid, colchicine, and methotrexate are promising, and their use is associated with improvement in histology in some patients. Ursodeoxycholic acid (12 to 15 mg per kilogram body weight per day) improves serum bilirubin, alkaline phosphatase, aminotransferases, and IgM levels in several trials. It has also been reported to decrease pruritus in up to 50% of patients. Note that it has been shown to improve survival and to delay time to transplantation. Recently, pretransplantation treatment with ursodeoxycholic acid has been shown not to have an adverse impact on post-transplantation survival. Several small trials have demonstrated that methotrexate can effect a reduction in serum alkaline phosphatase and cholesterol and improve histology in some patients with PBC. However, other trials have not shown efficacy. A National Institutes of Health–sponsored double-blind, randomized controlled trial of methotrexate for treatment of PBC is currently underway. Corticosteroids, D-penicillamine, and azathioprine do not alter the course of the disease or improve survival and have no role in treatment of PBC.

Transplantation is the treatment of choice for PBC patients with complications of portal hypertension, severe symptomatic osteopenic bone disease, intolerable symptoms of pruritus, or a predicated survival of less than 2 years ([Table 120.5](#)). In properly selected candidates, liver transplantation is highly successful in treating PBC, and 5-year survival rates exceed 75%. Under adequate immunosuppression, recurrent PBC in the graft is rare.

Complication	Percent
Hypercholesterolemia	85
Osteopenia	75
Pruritus	70
Fat-soluble vitamin deficiency	20

TABLE 120.5. COMPLICATIONS OF PRIMARY BILIARY CIRRHOSIS

The pruritus that accompanies cholestasis may limit normal activity, lead to sleep deprivation, and prompt suicidal ideation. It is often the earliest specific complaint and is characteristically worse at bedtime. Pruritus may occur during the third trimester of pregnancy and persists after delivery in some patients. Currently, treatment options for pruritus may not completely relieve symptoms in all patients. Therefore, transplantation may be considered in patients whose quality of life is greatly diminished by the pruritus, regardless of evidence of hepatic decompensation. Cholestyramine, a nonabsorbed resin relieves pruritus in many patients, with a usual dosage of 4 g in divided doses per day. The onset of action may be delayed by several weeks. Colestipol is as effective as cholestyramine. Antihistamines may be helpful in the early phases of PBC, when pruritus is not severe, and may primarily induce sleep.

Fat malabsorption can lead to complaints of nocturnal diarrhea, bulky stools, weight loss despite good appetite, increased caloric intake, and malabsorption of vitamins A, D, E, and K associated with clinical syndromes of deficiency. Steatorrhea can be treated with a low-fat diet supplemented by medium-chain triglycerides. If sicca syndrome accompanies PBC, then pancreatic insufficiency may be present and can be evaluated by the bentiromide test. If present, it can be treated with pancreatic enzyme replacement. Fat-soluble vitamin levels should be measured and specific supplements provided. Cholestyramine can bind these supplements and should be administered in separately timed doses.

Osteopenic bone disease is a nearly universal finding in women with PBC. Testing for vitamin D deficiency is essential, and supplementation is appropriate to prevent osteomalacia. Patients may require high-dose calcium supplementation and bisphosphonates and estrogen therapy if the patient is postmenopausal. Advanced osteoporosis with bone fracture is an indication for hepatic transplantation.

Hypercholesterolemia as a complication of chronic liver disease is unique to the cholestatic liver disorders and to PBC in particular. Some patients with PBC are initially diagnosed during evaluation for hypercholesterolemia. Serum cholesterol can exceed 300 mg per deciliter, but it is predominantly composed of high-density lipoprotein. Despite the elevation in cholesterol, a Mayo Clinic case-matched controlled retrospective study has demonstrated that PBC patients do not have an increased risk for coronary artery disease. As patients develop advanced cirrhosis, serum cholesterol may fall dramatically.

INCIDENCE AND EPIDEMIOLOGY

In the United States, at least 18 million people are problem drinkers and alcoholics, and alcohol abuse with or without alcohol dependence is one of the most important causes of chronic liver disease. Cirrhosis accounts for 75% of all medical deaths among alcoholics. The peak incidence of alcoholic liver disease (ALD) occurs in the age range of 40 to 55 years, and the male-to-female ratio is about 3:1. ALD includes three major histologic stages: fatty liver (or steatosis), hepatitis, and cirrhosis. Two or more of these histologic stages of ALD often coincide, as they represent a spectrum of the liver's response to injury from alcohol. A common concurrence is alcoholic steatosis and hepatitis, called *alcoholic steatohepatitis*; it should be distinguished from nonalcoholic steatohepatitis (NASH). Alcoholic hepatitis also frequently coexists with cirrhosis. Simple alcoholic fatty liver is the most benign and reversible form of ALD. By comparison, alcoholic hepatitis is much more serious and is the most important precursor of (although not an absolute requisite for) cirrhosis. Before the discovery of hepatitis C virus, it was noted that cirrhosis often developed in alcoholic patients without being preceded by alcoholic hepatitis. This puzzle is now partly solved because we know that roughly 20% to 40% of alcoholics with cirrhosis are infected with hepatitis C virus and that hepatitis C virus acts at least additively, if not synergistically, with alcohol to produce cirrhosis. In addition to the major types of ALD just listed, [Table 121.1](#) summarizes several minor types. Among the minor types, alcoholic fatty liver with perivenular fibrosis is also a known precursor of alcoholic cirrhosis.

Alcoholic fatty liver with perivenular fibrosis
Alcoholic foamy degeneration (alcoholic microvesicular steatosis)
Sclerosing hyaline necrosis
Alcoholic cirrhosis with chronic hepatitis^a
Cholestasis
Iron overload

^a A significant percentage of these patients may have concomitant hepatitis B or hepatitis C infection.

TABLE 121.1. MINOR TYPES OF ALCOHOLIC LIVER DISEASE

ETIOLOGY

The cause of ALD is multifactorial. In the past, it was attributed to malnutrition (e.g., “Laennec's nutritional cirrhosis”). However, alcoholic cirrhosis occurs in well-nourished persons, and cirrhosis does not occur in patients with simple malnutrition. Epidemiologic studies have shown a direct correlation between national per capita consumption of alcohol and prevalence of ALD and between individual alcohol consumption and the risk of alcoholic hepatitis or cirrhosis. Historically, a dramatic decrease in ALD was associated with diminished alcohol intake during war rationing and prohibition. Both the amount of ethanol ingested and the duration of intake are important factors in the induction of ALD. A daily intake of ethanol as low as 40 g in men or 20 g in women over more than 10 years results in a significant increase in the incidence of cirrhosis. Note that 1 ounce of 80-proof spirits, a 12-ounce bottle of 4% beer, or a 4-ounce glass of wine each contains approximately 10 to 12 g of ethanol.

Other studies have suggested that alcoholic hepatitis or cirrhosis is unlikely in persons who consume less than 80 g of alcohol per day for 10 to 20 years. The amount of ethanol that can be safely consumed is uncertain, but it is probably less than 20 g per day for men and less than 10 g for women. Neither the pattern of drinking nor the type of alcoholic beverage plays an important role in the development of liver disease. In comparison with agents such as carbon tetrachloride, ethanol is a weaker hepatotoxin, and studies suggest that a threshold cumulative dose must be consumed, amounting to 600 kg for men and 150 to 300 kg for women to produce liver injury. To achieve a cumulative dose of 600 kg of ethanol, one has to consume 72 ounces of beer, 1 liter of wine, or 8 ounces of distilled spirits per day for 20 years.

The notion that ethanol itself can cause ALD is supported by animal experiments. Rats and baboons chronically given large amounts of ethanol in a nutritionally balanced diet developed fatty liver and increased hepatic collagen. About 30% of the baboons, but not the rats, developed cirrhosis after 1 to 5 years. Rats fed by constant intragastric infusion of a nutritionally adequate liquid diet containing ethanol and comprising 50% of total calories developed fatty liver, necrosis, and fibrosis. However, a secondary role of dietary imbalance or malnutrition cannot be dismissed. Arguments in favor of nutritional contributions to ALD are shown in [Table 121.2](#).

- Hepatitis (nonalcoholic steatohepatitis) and cirrhosis similar to those seen in alcoholics are seen in some obese patients, especially those who have diabetes, or hyperlipidemia or have undergone bariatric surgery.
- Nutritional deficiencies caused by decreased dietary intake, impaired absorption, altered metabolism, diminished utilization, decreased storage, and increased excretion are common among alcoholics.
- Intravenous amino acids have led to significant improvement of ascites, serum bilirubin, and plasma albumin in patients with alcoholic hepatitis in several controlled trials.
- The degree of liver injury produced in alcohol-fed rats can be modulated by carbohydrate content or by the amount and type of protein and fat (fats that worsen ethanol-induced injury are fish oil [containing ω -3 polyunsaturated fatty acids] and polyunsaturated fat; fats that tend to decrease ethanol-induced injury are medium-chain triglycerides or saturated fats) in the diet.
- As the fat content in the Japanese diet has increased, there has been an increase in the incidence of alcoholic hepatitis.
- Epidemiologic studies suggest that alcoholic liver disease is more common in populations that consume more polyunsaturated fats and in alcoholics who are obese.
- Polyunsaturated lecithin (particularly dimyristoyl phosphatidylcholine) can reduce the severity of fibrosis in the baboon model of alcoholic liver injury.

TABLE 121.2. EVIDENCE FOR NUTRITIONAL FACTORS IN ALCOHOLIC LIVER DISEASE

Genetic, hormonal (gender-related), immunologic, and environmental factors are also important in modulating the individual variation in susceptibility to the toxicity of ethanol. In the baboon model, only a small proportion of the animals developed cirrhosis. In humans, no more than 35% of heavy drinkers develop alcoholic hepatitis, and only 20% develop cirrhosis. Alcoholic hepatitis and cirrhosis develop with shorter duration of alcohol abuse and after lower cumulative alcohol intake in women than men. This gender-related differential susceptibility may be due to a lower volume of distribution for ethanol and decreased first-pass (gastric or hepatic or both) metabolism of ethanol in women and other sex hormone-related factors that lead to increased alcohol metabolism, altered cytokine release, inadequate induction of

hepatic fatty acid-binding capacity, and insufficient compensatory increases in α -hydroxylation in females. Postulated immunologic mechanisms are complex and involve the effects of ethanol, acetaldehyde, and endotoxin on an array of cytokine interactions that include activation of Kupffer cells, hepatic stellate cells, and sinusoidal endothelial cells. Further details of these interactions are discussed in a later section. Finally, there is a high prevalence of hepatitis B and C infections in alcoholics with cirrhosis, suggesting an interaction between viral infections and ethanol.

METABOLISM OF ETHANOL

Ethanol is rapidly absorbed from the gastrointestinal tract, and most of it is metabolized in the liver. When moderate amounts of ethanol (e.g., 10 to 30 g) are consumed by normal adult males in the “fed” state, a sizable first-pass metabolism of ethanol can be easily detected, but whether the stomach or liver or both is responsible for this phenomenon is debated. In favor of gastric metabolism are the facts that gastric mucosa contains alcohol dehydrogenase (ADH) and that peak blood alcohol levels are higher in those with decreased gastric ADH activity, such as women and patients who have a gastrectomy or chronic gastritis or who are taking cimetidine. However, the total ethanol oxidizing capacity of the stomach is low, suggesting a hepatic contribution.

After absorption, ethanol is distributed in the body water space. In the liver, it is metabolized to acetaldehyde by ADH in the cytosol and the cytochrome P450IIE1 (CYP2E1) in microsomes (Table 121.3 and Fig. 121.1). The role of catalase is very minor. Because there is no way to store ethanol and no feedback control of the rate of ethanol oxidation, its metabolism dominates other oxidative pathways, producing dramatic metabolic changes described in the following text.

Enzymes	Intracellular Location	Polymorphisms
Alcohol-Metabolizing Enzymes		
Alcohol dehydrogenase	Cytosolic	ADH ¹ , 2 ¹ , 2 ² ADH ¹ , 3 ¹
Cytochrome P450IIE1	Microsomal	Promoter variants
Catalase	Peroxisomes	None known
Acetaldehyde-Metabolizing Enzymes		
Aldehyde dehydrogenase-2	Mitochondrial	ALDH ² ¹ , ALDH ² ²
Aldehyde dehydrogenase-1	Cytosolic	None known

TABLE 121.3. ETHANOL-METABOLIZING ENZYMES IN HUMANS

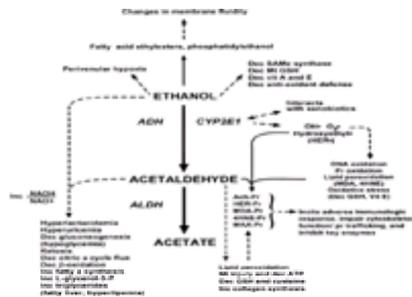

FIGURE 121.1. Pathways of ethanol metabolism and metabolic effects of ethanol, acetaldehyde, and acetate. *Dec*, decreased; *Inc*, increased; *Mt*, mitochondrial; *SAMe*, S-adenosyl-methionine; *GSH*, glutathione; *ADH*, alcohol dehydrogenase; *CYP2E1*, cytochrome P450 IIE1; *ALDH*, aldehyde dehydrogenase; *vit*, vitamin; *Pr*, protein; *Ach*, acetaldehyde; *HER*, hydroxyethyl radical; *MDA*, malondialdehyde; *4-HNE*, 4-hydroxynonenal; *MAA*, malondialdehyde-acetaldehyde.

ADH is responsible for the bulk of ethanol oxidation. The ADH reaction rate is controlled by the amount of ADH, the acetaldehyde level, and the free NADH/NAD⁺ ratio in the cytosol. The latter is ultimately determined by the rate of mitochondrial electron transfer. ADH is not inducible with chronic alcohol exposure; rather, its content and the ethanol elimination rate are decreased with fasting, protein deficiency, and liver disease. In humans, there are seven ADH gene loci, two of which are polymorphic. Different people, especially of different racial groups, inherit different sets of ADH isoenzymes. The kinetic properties of the various ADH isoenzymes differ widely in vitro. Although the *ADH2**2 allele appears to be protective against alcoholism, no specific ADH polymorphism has been firmly identified as a factor that predisposes to the development of ALD.

CYP2E1 is associated with NADPH-cytochrome P450 reductase in the microsomal membrane and reduces molecular oxygen to water as ethanol is oxidized to acetaldehyde. Although CYP2E1 normally oxidizes only a small fraction of alcohol, it is inducible by chronic alcohol use, especially in the perivenular zone, and it may contribute to the increased rates of alcohol elimination in heavy drinkers. CYP2E1 can also be induced by starvation and by a diet high in fat. CYP2E1 has a high K_m for ethanol and may be more important in ethanol metabolism at high blood levels. CYP2E1 and other P450 isoenzymes that can oxidize ethanol also metabolize certain drugs. Alcoholics, when sober, exhibit increased metabolism of these drugs (Table 121.4); however, since ethanol competes with these drugs for metabolism, there is a decreased rate of drug elimination when the patient drinks. Acute alcohol ingestion also increases the pharmacodynamic action of several drugs (Table 121.4). The interaction between induction of CYP2E1 in alcoholics and acetaminophen-induced hepatitis is clinically very important. Although therapeutic doses of acetaminophen are harmless when consumed by alcohol-naive persons, in alcoholics such doses can produce serious and sometimes fatal liver disease with extremely high aminotransferase levels, massive perivenular hepatic necrosis, pancreatitis, and renal failure. This disorder is sometimes called the “acetaminophen-alcohol syndrome.” Thus, heavy drinkers should be warned to avoid acetaminophen entirely.

Increased Drug Metabolism	Increased Drug/Chemical Toxicity	Increased Drug Tolerances
Barbiturates	Acetaminophen	Anesthetics
Meprobamate	Vitamin A	Barbiturates
Warfarin	Isoniazid	Meprobamate
Thiazamide (and other sulfonamides)	Phenylbutazone	Benzodiazepines
Phenytoin	Ketofene	
Cocaine	Ethionine	
Salicylic acid	Carbon tetrachloride	
Alkylsulfonamide	Benzoic acid

TABLE 121.4. INTERACTIONS BETWEEN CHRONIC ALCOHOL ABUSE AND DRUG ACTIONS AND METABOLISM

Acetaldehyde is further oxidized by aldehyde dehydrogenases (ALDHs; Table 121.3) to acetate, which is released from the liver and metabolized by heart and muscle. The enzymes are inhibited by disulfiram (Antabuse). Consumption of alcohol while taking disulfiram or several other drugs results in the accumulation of acetaldehyde, producing vasodilation, cutaneous flushing, tachycardia, nausea, and vomiting (Table 121.4). This reaction is also observed in about 50% of Asians who are deficient in ALDH2. These individuals drink less and have a low prevalence of alcoholism. High blood acetaldehyde levels are also observed in alcoholics

when they drink. This is probably due to the adaptive increase in ethanol oxidation and reduction in the ability of mitochondria to oxidize acetaldehyde. The increased acetaldehyde level in alcoholics perpetuates alcoholic liver injury because acetaldehyde is much more toxic than ethanol.

METABOLIC EFFECTS OF ETHANOL OXIDATION

Oxidation of ethanol is coupled to the production of NADH. As shown in [Figure 121.1](#), the high NADH concentration shifts the equilibria of several enzymatic reactions toward the formation of reduced metabolites (e.g., conversion of pyruvate to lactate and of dihydroxyacetonephosphate to L-glycerol-3-phosphate). Increased lactate formation results in mild hyperlacticemia and contributes to hyperuricemia owing to impaired renal excretion of urate. The reduction in pyruvate and dihydroxyacetone phosphate concentrations inhibits gluconeogenesis and may result in hypoglycemia. Alcoholic hypoglycemia occurs during fasting, when blood glucose levels are maintained by gluconeogenesis. Alcoholic ketoacidosis also occurs in alcoholics who are fasting while drinking heavily. They exhibit very high free fatty acid levels, low insulin levels, and high levels of glucagon and catecholamines.

The concentration of β -hydroxybutyrate (not detected by urine dipsticks) characteristically exceeds that of acetoacetate. Increased NADH concentration in the mitochondria inhibits other NAD⁺-linked pathways, such as the citric acid cycle, amino acid oxidation, and fatty acid oxidation. Fatty acid synthesis is also accelerated with chronic alcohol exposure. Increased levels of L-glycerol-3-phosphate and fatty acids result in accelerated synthesis of triglycerides. The liver secretes some of this fat as very low density lipoprotein (VLDL), increasing plasma VLDL. The secretion of VLDL does not keep pace with the increased synthesis of triglycerides, so the liver cells become filled with fat.

Ethanol oxidation by way of CYP2E1 produces an array of metabolic effects. In addition to being inducible by chronic alcohol use and high fat intake, this enzyme is unusually "leaky" and generates reactive oxygen species (ROS) including hydroxyl radical (OH[·]), superoxide anion (O₂⁻), and hydrogen peroxide (H₂O₂). Thus, CYP2E1 is a major source of oxidative stress. This P450 enzyme also has unusual capacity to activate many xenobiotics to toxic metabolites and thereby contributes to a wide spectrum of alcohol-related pathology.

PATHOGENESIS OF ALCOHOLIC LIVER DISEASE

ALCOHOL-INDUCED FATTY LIVER OR STEATOSIS

The altered hepatic NADH/NAD⁺ ratio produced by ethanol and the inhibition of fatty acid oxidation are largely responsible for the development of alcoholic fatty liver. Because the high periportal to low perivenous oxygen gradient normally present within the liver acinus is made steeper by chronic alcohol ingestion, perivenous hepatocytes become much more hypoxic. As a result, the effect of alcohol metabolism on the redox state and on fat accumulation is most severe in perivenous cells. Fat accumulation does not continue indefinitely because the redox state changes are attenuated with continuing chronic alcohol use. The fat that accumulates in alcoholic fatty liver can come from different sources: diet, adipose tissue, and de novo hepatic synthesis from carbohydrates, depending on the diet.

ALCOHOL-INDUCED CELL DEATH AND FIBROSIS

The mechanisms by which chronic alcohol consumption leads to irreversible liver damage are also summarized in [Figure 121.1](#). The accumulation of fat is accompanied by induction of microsomal proteins and fatty acid-binding protein and by retention of secretory proteins (due to impaired cytoskeleton function and protein trafficking pathways caused by formation of acetaldehyde-protein adducts) and water. This causes the hepatocytes to swell and is called *ballooning* or *hydropic degeneration*. This swelling interferes with blood flow to the perivenous zone. There is also increased oxygen consumption in the liver of rats after prolonged alcohol consumption. Increased oxygen consumption coupled with decreased blood flow may induce perivenular hypoxia and thus pericentral apoptosis/necrosis and fibrosis.

Other mechanisms of ethanol hepatotoxicity include the induction of physical alterations in cell membranes. Acute exposure to ethanol increases membrane fluidity, whereas chronic alcohol consumption usually results in compensatory decreases in the fluidity of plasma and subcellular membranes, which may affect activities of membrane-bound receptors and enzymes involved in signal transduction. Changes in membrane fluidity can be mediated by the formation of abnormal lipids such as fatty acid ethyl esters and phosphatidyl ethanol. Alcohol use also adversely affects antioxidant defense in hepatocytes by decreasing the activity of S-adenosylmethionine synthase, diminishing mitochondrial glutathione contents, and depleting the stores of vitamins A and E. In addition, alcohol use promotes the oxidation of DNA, proteins, and lipids as a result of increased production of ROS.

Lipid peroxidation is a well-known deleterious chain reaction of lipid radical formation that is initiated by ROS attack on unsaturated lipids in cell membranes. Lipid peroxidation has been demonstrated in experimental animals exposed to alcohol and in patients with ALD. Lipid peroxidation leads to production of reactive aldehydes such as malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE). ROS are generated principally by CYP2E1 in hepatocytes and Kupffer cells, but debate exists about their relative quantitative importance. CYP2E1 is more active in perivenular hepatocytes where glutathione levels are normally lowest; therefore, high levels of ROS and other radicals such as hydroxyethyl radicals (HER derived from OH-radical attack on ethanol) are generated in the perivenular zone of the liver where alcohol-induced injury is most pronounced. In addition to tissue damage, lipid peroxidation may also promote collagen production by transformed hepatic stellate cells. Iron overload, which accompanies chronic alcohol abuse, accelerates ROS production, accentuates lipid peroxidation, and is likely to contribute to liver injury. Induction of microsomal enzymes also increases the hepatotoxicity of a number of agents ([Table 121.4](#)). For instance, hepatic vitamin A is metabolized more rapidly in alcohol-fed animals, depleting vitamin A stores and causing increased toxicity of vitamin A when it is given as a supplement. Acetaldehyde is an important factor in hepatic injury because it injures mitochondria, thereby depleting cellular adenosine triphosphate. It chemically reacts with glutathione and cysteine and modifies proteins, phospholipids, and components of the cytoskeleton by forming adducts.

In addition to acetaldehyde, a number of reactive aldehydes derived from lipid peroxidation and HER have been shown to react with proteins. As shown in [Figure 121.1](#), these adducts include acetaldehyde-, HER-, MDA-, 4-HNE- and mixed malondialdehyde-acetaldehyde-protein adducts. Antibodies directed against membrane and soluble proteins of the hepatocyte modified by acetaldehyde and by HER are detected in alcoholics and constitute a possible immune component to liver injury. Acetaldehyde damages the cytoskeleton, and this inhibits protein secretion. Abnormal transport of proteins through the Golgi apparatus may also alter the properties and function of surface proteins. A major acetaldehyde-modified protein in alcohol-fed rats was recently identified to be an enzyme in the bile salt synthetic pathway (D⁴-3-ketosteroid 5 β -reductase). In addition, Mallory bodies are formed from cytokeratin intermediate filaments. Injury to the intermediate filaments may contribute to ballooning degeneration.

Recent research has implicated a complex cascade of autocrine and paracrine cytokine pathways that involves increased intestinal permeability and increased absorption of endotoxin (lipopolysaccharides [LPS]), oxidative stress and activation of Kupffer cells, proliferation and transformation of hepatic stellate cells, and stimulation of sinusoidal endothelial cells ([Fig. 121.2](#)). Cytokines are a diverse group of mediators that exhibit inflammatory, cytotoxic, fibrogenic, and growth-promoting properties. Patients with alcoholic hepatitis frequently have elevated levels of endotoxin, tumor necrosis factor (TNF)- α , interleukin (IL)-1, and IL-8 in circulation. IL-8 and TNF- α levels in particular correlate inversely with survival from alcoholic hepatitis.

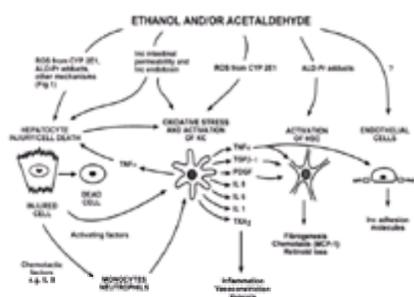

FIGURE 121.2. Effects of ethanol and acetaldehyde on hepatocytes, Kupffer's cells, stellate cells, and endothelial cells. This figure summarizes the toxicity of ethanol on the liver cells, the mechanisms of activation of Kupffer's (KC) and hepatic stellate cells (HSC), and the roles played by various cytokines in alcoholic liver disease.

ROS, reactive oxygen species; *ALD-P₁*, aldehyde-protein; *TXA₂*, thromboxane A₂. The other cytokines are defined in the text.

The mechanisms whereby alcohol or acetaldehyde activates Kupffer cells are not completely known. Recent studies point to injured hepatocytes, endotoxin, and perhaps ethanol per se as important factors. Hepatocytes injured by ethanol release chemotactic factors to attract monocytes and neutrophils. Injured hepatocytes also release factors that activate Kupffer cells. Chronic alcohol ingestion is thought to allow the increased absorption of endotoxin by increasing intestinal permeability. Endotoxin can activate Kupffer cells by binding first to a LPS-binding protein and then to a surface glycoprotein called CD14. Kupffer cells can also be activated by ethanol oxidation by CYP2E1. Oxidative stress from endotoxin and CYP2E1 activates an oxidative stress-sensitive nuclear transcription factor, NF- κ B, which coordinately increases the expression of a wide range of genes. Activated Kupffer cells secrete TNF- α , transforming growth factor TGF- β 1, platelet-derived growth factor (PDGF), IL-8, IL-6, and IL-1, as well as ROS, nitric oxide, proinflammatory/vasoactive eicosanoids, and proteolytic enzymes. TNF- α exhibits a sensitizing effect on hepatocytes, making ethanol much more toxic. IL-8 functions as a major neutrophil chemotactic agent and activates neutrophils. IL-6 is an acute-phase reactant and also serves as a hepatocyte-stimulating factor. PDGF promotes proliferation of stellate cells, whereas TGF- β 1 induces stellate cells to transform into myofibroblasts; the latter secrete collagen, metalloproteinases, proteoglycans, and other matrix material. Stellate cells are also important in regulating portal pressure and in modulating inflammatory responses, as in the expression of monocyte chemoattractant protein-1 (MCP-1), a monocyte-specific chemokine.

In addition to cytokines, acetaldehyde, malondialdehyde (MDA), and 4-HNE can induce stellate cells to express collagen genes. In alcoholic hepatitis and cirrhosis, sinusoidal endothelial cells are known to express important adhesion molecules that include E-selectin, vascular cell adhesion molecule (VCAM-1), and intracellular adhesion molecule (ICAM)-1. Selectins and ICAM-1 are required for neutrophils to tether to the sinusoidal wall, whereas other molecules, notably VCAM-1, mediate lymphocyte tethering. These adhesion molecules bind neutrophils and lymphocytes by way of β_1 and β_2 integrins.

PATHOLOGY

ALCOHOLIC FATTY LIVER

The fatty liver is enlarged and firm and may be pale yellow. Microscopically, there is great variation in the number of fat droplets found and the number of cells affected, with a distinct tendency for fat accumulation in the perivenous and midzones of the liver lobule. Occasionally, hepatocytes rupture to form a fatty cyst, and then a lipogranuloma. Generally, there is sparse cell necrosis or inflammation. Fatty liver may be complicated by intrahepatic cholestasis and mild cholangiolitis in the absence of extrahepatic biliary obstruction. Perivenular fibrosis may be present and has been shown to be a precursor of cirrhosis. Another variant known as *alcoholic foamy degeneration* is characterized by pericentral hepatocytes filled with foamy, microvesicular fat, focal cell necrosis, but no inflammation.

ALCOHOLIC HEPATITIS

In alcoholic hepatitis, ballooning degeneration, focal hepatocyte necrosis, and a neutrophilic inflammatory infiltrate occur. About 30% of patients develop alcoholic hyaline (i.e., aggregates of perinuclear, eosinophilic, amorphous material). Although highly suggestive of ALD, hyaline is also seen in other diseases ([Table 121.5](#)). Hepatocellular necrosis and neutrophilic infiltration of the liver are considered absolute criteria for the diagnosis of alcoholic hepatitis. Other pathologic findings in alcoholic hepatitis include steatosis and fibrosis (steatohepatitis) and cirrhosis. On a case-by-case basis, it is difficult to distinguish histologically alcoholic hepatitis from NASH (see [Chapter 123](#)). However, statistically, periportal fibrosis, bile duct proliferation, and cirrhosis are more frequently seen in alcoholic steatohepatitis, and nuclear vacuolation is much less prevalent. Pericellular and perisinusoidal fibrosis seen in both alcoholic steatohepatitis and NASH give rise to a characteristic “chicken wire” appearance, and perivenular sclerosis leads to deposition of a collar of collagen in the wall of the central vein. Conditions known to be associated with NASH are listed in [Table 121.6](#). In a few cases of alcoholic hepatitis, there is sclerosing hyaline necrosis, that is, severe, irregular, confluent, centrilobular necrosis with obliteration of the central vein by collagen.

ALCOHOLIC CIRRHOSIS

The end stage of ALD is cirrhosis, characterized by fibrous bands connecting portal triads with central veins and by regenerative nodules. The nodules are typically small (1 to 3 mm) and uniform in size. Although fibrosis may be reversible, regression is impossible when significant nodular regeneration occurs. Over time and with abstinence from alcohol, nodular regeneration becomes more vigorous and forms large nodules; hence, mixed micro-/macronodular or macronodular cirrhosis develops. There is commonly superimposed fatty change and alcoholic hepatitis. There may also be increased stainable iron in biopsy samples. Iron overload in alcoholic cirrhosis can be differentiated from genetic hemochromatosis by gene analysis of HFE mutations or by quantitative iron analysis. In genetic hemochromatosis, the hepatic iron index (hepatic iron content expressed as μ mol per gram dry weight divided by the patient's age) in the cirrhotic liver is greater than 1.9, whereas that in the cirrhotic liver of alcoholics is invariably less than 1.9. In some patients with alcoholic cirrhosis, there is portal inflammation with piecemeal necrosis. This feature may reflect an autoimmune component of ALD, unsuspected Wilson's disease (particularly in young patients), or most commonly, coexistent chronic viral hepatitis (particularly hepatitis C virus infection).

CLINICAL FINDINGS

ALCOHOLIC FATTY LIVER

The spectrum of ALD ranges from asymptomatic hepatomegaly to hepatocellular failure from alcoholic hepatitis or end-stage cirrhosis. Hepatomegaly may be the only positive finding; however, stigmata of alcoholism (e.g., Dupuytren's contractures, testicular atrophy, loss of the male pattern of body hair, palmar erythema, spider angiomas, and gynecomastia) may also be present. Symptoms and signs of hypogonadism and feminization are evident in alcoholic men, whether or not they have liver disease. These endocrine changes can be explained by a number of factors, including toxic effects of ethanol on Leydig cells leading to decreased testosterone production; impairment of hypothalamic–pituitary function by ethanol resulting in lack of appropriate increase in luteinizing hormone; induction of aromatase in adipose tissue by ethanol and thus increased conversion of androgens to estrogens; and ingestion of nonsteroidal estrogens found in plants called *phytoestrogens* in alcoholic beverages that then can lead to increased estrogenic effect.

More advanced disease may cause weakness, cachexia, fever, anorexia, nausea, vomiting, jaundice, hepatic tenderness, splenomegaly, or ascites. Most likely, such cases represent a combination of fatty liver and alcoholic hepatitis, since the classic lesions of alcoholic hepatitis are difficult to find in livers massively infiltrated with fat. Rarely, alcoholic fatty liver is complicated by cholestasis and produces a picture that mimics both alcoholic hepatitis and extrahepatic biliary obstruction. Patients with alcoholic fatty liver may suffer fat embolism, alcohol withdrawal symptoms, or hypoglycemia.

ALCOHOLIC HEPATITIS

Patients with alcoholic hepatitis usually complain of anorexia, nausea, malaise, weakness, abdominal pain, icterus, weight loss, and fever; however, a few are totally free of symptoms. At the opposite end of the clinical spectrum, many patients present with severe jaundice, ascites, azotemia, and hepatic encephalopathy and may progress rapidly to death. Such patients commonly deteriorate early in the hospital stay, despite stopping drinking. Physical examination reveals the findings summarized in [Table 121.7](#).

Finding	Incidence (%)
Hepatomegaly	95
Hepatic tenderness	50–70
Signs of portal hypertension (splenomegaly, prominent abdominal veins, and ascites)	40–70
Stigmata of chronic parenchymal liver disease and alcoholism (bruising, leukonychia, palmar erythema, spider angiomas, edema, parotid gland enlargement, and testicular atrophy)	30–60
Jaundice	55
Fever	50
Upper gastrointestinal bleeding	30
Hepatic encephalopathy	20

TABLE 121.7. CLINICAL FINDINGS IN ALCOHOLIC HEPATITIS

ALCOHOLIC CIRRHOSIS

Patients with alcoholic cirrhosis may be asymptomatic in 10% to 20%, but commonly present with the complications of chronic liver disease and the usual stigmata. Among male patients with cirrhosis from a variety of causes, hypogonadism and feminization are most prominent in patients with ALD and are comparable to those with genetic hemochromatosis. Complications of alcoholic cirrhosis include cachexia, coagulopathy, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatic encephalopathy, hepatocellular carcinoma, and gastrointestinal bleeding from esophageal and gastric varices ([Chapter 105](#)). Other less common causes of bleeding are ectopic varices and portal hypertensive gastropathy.

LABORATORY FINDINGS

Macrocytosis is common in alcoholics, and its presence in an otherwise healthy person suggests occult alcohol abuse. Some cases are characterized by the presence of thick macrocytes caused by folate deficiency or a toxic effect of alcohol on the bone marrow. In most cirrhosis, regardless of the cause, the macrocytes are thin target cells resulting from changes in the lipid composition of the red cell membrane. Thin target macrocytes disappear very slowly with improvement in liver function.

ALCOHOLIC FATTY LIVER

In alcoholic fatty liver, hyperbilirubinemia (usually less than 5 mg per deciliter) is observed in about 25% of cases. In almost all types of ALD, serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are usually less than 300 IU per liter. In contrast to viral and toxic hepatitis and NASH in which serum ALT is equal to or higher than serum AST, the serum AST is usually higher than serum ALT (with the AST/ALT ratio ≥ 2 in 80% of the cases) in ALD. In the absence of cholestasis, alkaline phosphatase is only modestly elevated (less than 300 IU per deciliter). In patients with ALD, a γ -glutamyltranspeptidase to alkaline phosphatase ratio of more than 5 is characteristic. Serum albumin and globulin levels are abnormal in less than 25% of patients with alcoholic fatty liver, and the serum globulin level rarely exceeds 4 g per deciliter.

ALCOHOLIC HEPATITIS

Laboratory abnormalities are more severe in alcoholic hepatitis. Anemia occurs in 50% to 70% of patients, secondary to toxic effects of ethanol on the bone marrow, impaired vitamin B₆ metabolism, folic acid deficiency, iron deficiency from blood loss, or hypersplenism. Leukocytosis is observed in 25% to 75% of cases. Leukopenia and thrombocytopenia are present in 10% to 15% and may reflect folate deficiency, alcohol-induced marrow suppression, or hypersplenism. Serum AST and ALT are elevated in all cases of alcoholic hepatitis, and alkaline phosphatase is elevated in 80% of cases. Peak AST levels rarely exceed 300 IU per liter except in patients with sclerosing hyaline necrosis or acetaminophen overdose, in which case AST levels may be much higher. Serum bilirubin is increased in 90% of the cases. Serum albumin is usually decreased and prothrombin time is often prolonged. Electrolyte abnormalities are common in alcoholic hepatitis and include hyponatremia, hyperchloremia due to partial renal tubular acidosis, hypokalemia from poor dietary intake, vomiting, or diarrhea, hypomagnesemia from increased urinary loss, and respiratory alkalosis.

ALCOHOLIC CIRRHOSIS

The liver test abnormalities in alcoholic cirrhosis are less pronounced than those in alcoholic hepatitis. In fact, in compensated cirrhosis, many of the liver tests are nearly normal. Laboratory abnormalities may include mild increases in AST, ALT, and alkaline phosphatase, depression of serum albumin, elevation of serum globulins (greater than 4 g per liter), prolongation of prothrombin time, leukopenia, thrombocytopenia, and anemia. Hypersplenism by itself rarely leads to platelet counts lower than 40,000/ μ L, and splenectomy is almost never indicated.

DIAGNOSIS AND MANAGEMENT

There are two pitfalls in the diagnosis of ALD: (1) failing to consider ALD in patients not fitting the stereotype of the skid-row alcoholic and (2) assuming that abnormal liver tests in an alcoholic patient are due to ALD. Alcoholism should be considered in any patient with liver disease, and a careful drinking history should be obtained from the patient and a reliable third party. The history should include either the most commonly used simple questionnaire called the CAGE test or the more detailed screening instrument, the MAST test. The MAST test has a shortened version of 12 questions rather than the long version of 25 questions. The CAGE test uses the following questions: Have you felt the need to CUT DOWN on drinking? Are you ANNOYED by references to your drinking? Do you feel GUILTY about your drinking?

Do you ever need an EYE-OPENER (i.e., an alcoholic drink in the morning)? A positive response to two or more of these questions strongly suggests the possibility of alcohol abuse and should prompt a more thorough history. The sensitivity of the CAGE test for alcohol abuse is 70% to 96%, and the specificity is 91% to 99%. The diagnostic accuracy of the CAGE test is about 80%, whereas that of the MAST test is 90%. However, the CAGE test is easier to use than the MAST.

The history should also include an estimate of the number of grams of ethanol consumed daily and the duration of drinking. As pointed out earlier, up to 40% of patients with presumed alcoholic liver disease are infected with hepatitis C virus, and testing for hepatitis C virus antibody is mandatory.

A liver biopsy is necessary to differentiate fatty liver, alcoholic hepatitis, and cirrhosis reliably. Before the discovery of hepatitis C virus, it was reported that up to 20% of liver biopsies done on alcoholic patients showed nonalcoholic (and sometimes treatable) liver diseases. Appropriate blood tests and biopsy should be performed to exclude nonalcoholic causes of liver disease and to define the severity of disease. However, tense ascites, severe thrombocytopenia (less than 80,000/ μ L), or prolonged prothrombin time (international normalized ratio [INR] greater than 1.4) may preclude percutaneous needle biopsy. If a percutaneous biopsy cannot be performed, a safer but more expensive alternative is a transjugular liver biopsy.

DIFFERENTIAL DIAGNOSIS

Alcoholic Fatty Liver

As outlined in [Table 121.8](#), fatty liver can result from many processes. Several series of focal fatty changes, either focal fat or focal fat sparing, found by ultrasonography or computed tomography (CT) have been reported. This lesion should not be confused with space-occupying lesions such as tumor or abscess. ^{99m}Tc -sulfur colloid scanning or magnetic resonance imaging (MRI) is useful in distinguishing focal fatty change from space-occupying lesions because the scan is normal in the former. However, ultimately a liver biopsy may be necessary to make the diagnosis. When one encounters massive hepatomegaly (the liver span exceeds 15 cm in the midclavicular line), the differential diagnosis includes fatty liver, right heart failure, constrictive pericarditis, Budd–Chiari syndrome, infiltrative processes (e.g., amyloidosis, myeloproliferative disorders, reticuloendotheliosis, and lipid storage diseases), and neoplasms. In evaluating the cause of hepatomegaly, a helical CT scan with dual contrast and arterial/venous phases should be performed to exclude neoplasms, because this is more sensitive in detecting focal hepatic masses than either ultrasonography or sulfur colloid scan.

Macrovesicular Fat (Large Droplets)
Alcoholic steatohepatitis
Nonalcoholic steatohepatitis (see Table 121.6)
Hepatitis C
Toxic causes: methotrexate, halogenated hydrocarbons, and so on
Wilson's disease
Microvesicular Fat (Small Droplets)*
Reye's syndrome
Parenteral alimentation
Intravenous tetracycline
Toxic shock syndrome
Jamaican vomiting disease
Acute fatty liver of pregnancy
Salicylate overdosage in children
Valproic acid
Yellow fever
Certain metabolic diseases: cholesterol ester storage disease, galactosemia, and Wolman's disease

* Microvesicular fatty liver is usually the result of mitochondrial damage and metabolic defects.

TABLE 121.8. DIFFERENTIAL DIAGNOSIS OF FATTY LIVER

Alcoholic Hepatitis

The distinctive histologic appearance of alcoholic hepatitis usually establishes the diagnosis. However, it is mimicked by nonalcoholic steatohepatitis (NASH). Clinically, patients with alcoholic steatohepatitis are usually much sicker than those with NASH. Since fever, leukocytosis, right upper quadrant pain, jaundice, and cholestasis can occur in those with alcoholic hepatitis, imaging of the liver and biliary tree by US or CT may be necessary to exclude extrahepatic cholestasis. Since these noninvasive tests are more specific (86% to 100%) than sensitive (50% to 95%) in detecting extrahepatic biliary obstruction, endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography may be required to exclude obstruction.

Alcoholic Cirrhosis

Alcoholic cirrhosis is usually micronodular but may be macronodular. Thus, the differential diagnosis of alcoholic cirrhosis includes posthepatic cirrhosis (whether due to chronic viral infection, drugs, metabolic disorders, or autoimmune hepatitis), the cirrhotic stage of primary biliary cirrhosis, secondary biliary cirrhosis, Wilson's disease, hemochromatosis, and cirrhosis caused by NASH. These diagnoses require a careful history of drug use and exposure to hepatitis viruses, tests for hepatitis B surface antigen, hepatitis C antibody, autoantibodies (antinuclear, anti-DNA, antimitochondrial, and anti-smooth muscle antibodies), serum ceruloplasmin, α_1 -antitrypsin level, copper and iron studies, and the measurement of the metal content of the liver biopsy. Alcoholic cirrhosis with features of chronic active hepatitis may reflect superimposed hepatitis B or C or an autoimmune process incited by alcoholic injury. Disease processes that mimic cirrhosis (e.g., constrictive pericarditis, Budd–Chiari syndrome, veno-occlusive disease, idiopathic portal hypertension, portal vein thrombosis, and myeloid metaplasia) should be considered.

PROGNOSIS AND TREATMENT

Alcoholic Fatty Liver

Alcoholic fatty liver is benign unless accompanied by perivenular fibrosis or foamy degeneration. Patients with these conditions have a high risk for developing hepatic failure or cirrhosis. Treatment includes abstinence from alcohol and correction of nutritional deficits. Bedrest has no proven value. Under this regimen, fatty liver regresses in 3 to 6 weeks.

Alcoholic Hepatitis

The early mortality rates for alcoholic hepatitis vary from 19% to 78% (mean 49%). In the subset of patients with severe disease and spontaneous hepatic encephalopathy, the early mortality rate was higher (59%). It is not surprising that the worst prognosis was observed in patients with severe jaundice, encephalopathy, renal failure, ascites, and variceal bleeding. Several laboratory tests are prognostic indicators: prothrombin time of more than 4 seconds above control despite vitamin K treatment, total bilirubin greater than 5 mg per deciliter, and serum creatinine that increases more than 0.6 mg per deciliter during the first 10 days of hospitalization. The severity of fibrosis or cirrhosis found on liver biopsy is also a prognostic indicator. That is, with little fibrosis, the 5-year survival rate was 72%, but with severe fibrosis, it was 48%. In a series with 6-year follow-up, no patients with alcoholic hepatitis who continued to drink reverted to a healthy liver, 58% had persistence of alcoholic hepatitis, and 42% progressed to cirrhosis. In other series, up to 80% ultimately developed cirrhosis. In patients who abstained or reduced drinking, 70% reverted to normal, 15% continued to have alcoholic hepatitis, and 15% developed cirrhosis. A 50% mortality rate over 7 years was found in patients with alcoholic hepatitis who continued heavy drinking. This mortality rate decreased to 24% in those who reduced drinking or abstained.

In a Veterans' Affairs Cooperative Study that involved 280 patients with severe alcoholic liver injury, more than two-thirds of those with alcoholic hepatitis and cirrhosis had died within 2 years of follow-up. One study evaluated the predictive power of Child's–Turcotte–Pugh scoring system, the combined clinical laboratory index of the University of Toronto, and Maddrey's discriminant function to predict 30-day mortality of patients with alcoholic hepatitis who participated in the VA Cooperative Study. All three scoring systems correlated with survival, but Maddrey's discriminant function exhibited the highest predictive value.

Maddrey's discriminant function

$$= 4.6 \times [\text{PT (seconds) - control}] + \text{bilirubin (mg/dL)}$$

where PT = prothrombin time.

A discriminant function higher than 32 predicts a 50% mortality within 1 month. Other studies indicate that the presence of hepatic encephalopathy is as predictive as the discriminant function.

Cessation of alcohol drinking is paramount in the treatment of alcoholic hepatitis and is best accomplished by detoxification, followed by referral to an intensive outpatient alcohol treatment program and then to Alcoholics Anonymous or to an outpatient follow-up counseling program. Other supportive therapy includes a nutritious diet.

Protein calorie malnutrition is common finding in patients with ALD. In the VA Cooperative Study on Alcoholic Hepatitis, more than 75% of patients with severe liver disease exhibited signs of kwashiorkor, marasmus, or both, and malnutrition worsened prognosis of alcoholic hepatitis. Several small controlled trials have tested the effect of parenteral amino acid therapy or enteral amino acid/protein therapy in alcoholic hepatitis. Uniformly, these trials have shown faster improvement in serum bilirubin, serum albumin, and ascites and no deterioration in hepatic encephalopathy. Amino acid mixtures enriched in branched-chain amino acids are not superior to standard mixtures. Only one of the controlled trials has demonstrated an improved mortality rate. Certainly, most patients with alcoholic hepatitis are malnourished, and this should be addressed either enterally or parenterally.

Corticosteroids modulate the immune system and inhibit fibrogenesis. The use of corticosteroids (prednisone, prednisolone, or 5-methylprednisolone in the dosage range of 35 to 80 mg per day for 4 to 6 weeks) in the treatment of alcoholic hepatitis has been extensively studied by at least 12 randomized controlled trials. Five studies showed decreased mortality with corticosteroids, and seven showed no difference. These studies have been subjected to meta-analyses and demonstrated the following: (1) Only patients with hepatic encephalopathy or Maddrey's score higher than 32 should be treated with corticosteroids. (2) Treatment with corticosteroids should exclude patients with gastrointestinal bleeding, active infection, renal failure, and acute pancreatitis. (3) Corticosteroids reduces mortality risk by 25%. (4) One has to treat seven patients to avoid one death. In all, we believe that corticosteroid therapy benefits some patients with severe alcoholic hepatitis who have no contraindications.

Anabolic-androgenic corticosteroids such as oxandrolone have been tested in an attempt to enhance recovery, that is, to increase the removal of hepatic fat, to stimulate protein synthesis, and to accelerate cell repair and hepatic regeneration. Oxandrolone was tested in a VA Cooperative Study in a 30-day trial in patients with moderate to severe alcoholic hepatitis and compared with prednisolone or placebo. Oxandrolone did not improve survival in the short term, but surprisingly, it improved long-term outcomes in patients who ingested sufficient calories during the trial. Oxandrolone cannot be recommended for clinical use until more data are available.

Propylthiouracil has been used to treat alcoholic hepatitis, possibly by decreasing the hypermetabolic state induced by alcohol and protecting perivenous cells from hypoxic injury. It also inhibits neutrophil myeloperoxidase. In one study, propylthiouracil improved symptoms and laboratory tests, but in another series of more severely ill patients, it was not effective. In the largest controlled trial, 310 patients with ALD were randomized to either propylthiouracil or placebo and followed up for up to 2 years. Propylthiouracil therapy resulted in a cumulative mortality rate half of that in the placebo group among moderately ill patients and in a subgroup of severely ill patients. Thus, propylthiouracil therapy may benefit patients with moderate to severe alcoholic hepatitis. However, since these earlier studies, there has been little subsequent interest in the use of propylthiouracil. It should not be used routinely pending further studies.

Several other agents including polyunsaturated lecithin and S-adenosylmethionine are being tested in multicenter trials. The potential actions of polyunsaturated lecithin may include phospholipid replacement for liver cell membranes, attenuation of activation of Ito cells, and stimulation of collagenase activity. S-adenosylmethionine administration has been shown to be useful in experimental animals by replenishing this transmethylation agent, enhancing the synthesis of polyamines, and providing cysteine for glutathione synthesis.

Alcoholic Cirrhosis

The prognosis of alcoholic cirrhosis depends on whether the patient continues to drink, the coexistence of alcoholic hepatitis, and the severity of the disease. The Copenhagen Study Group for Liver Disease indicated that the 5-year survival rate was nearly 85% for abstainers without jaundice, ascites, or gastrointestinal bleeding. Continued drinking lowered survival to 60%. The presence of jaundice or ascites reduced the survival rate to 50% in abstainers and to 30% in drinkers. Gastrointestinal bleeding carried the worst prognosis, with a 5-year survival rate of 35% in abstainers and 20% in drinkers. It is prudent to urge complete abstinence for patients with any form of ALD.

Alcoholic cirrhosis has been treated with corticosteroids without effect on survival. Prophylactic nonselective portocaval shunting also does not improve survival; it merely shifts the cause of death from gastrointestinal bleeding to hepatic coma. Colchicine (1 mg per day, 5 days per week) improved survival in one study with a 14-year follow-up and is being studied further in an ongoing VA Cooperative Study.

Advanced (Child's B or C) alcoholic cirrhosis can be treated by liver transplantation provided that patients (1) do not have other alcohol-related comorbid disorders, (2) have undergone intensive outpatient treatment and rehabilitation, and (3) have at least a 6-month period of documented abstinence ([Chapter 132](#)). Guidelines for treatment for alcoholism before transplantation vary from center to center, but the 2-year survival of these carefully selected patients compares well with those undergoing transplantation for other indications. In addition, the quality of life of these transplant recipients is excellent with many of them returning to part-time or full-time employment. The rates of recidivism vary between 10% and 30%, depending on the candidate selection process and the criteria in defining recidivism. End-stage ALD now accounts for approximately 25% of adult liver transplantations in the United States.

A PRACTICAL CLINICAL APPROACH TO AN ALCOHOLIC PATIENT WITH LIVER DISEASE: MEDICAL EVALUATION OF SICK ALCOHOLIC PATIENTS

It is common for alcoholic patients to be admitted to the hospital seriously ill. These patients must be cared for on an emergency basis before their liver disease or alcoholism can be directly addressed. Four categories of medical emergencies are encountered: metabolic disorders, infections, altered neurologic status, and abnormal renal function.

METABOLIC DISORDERS

Two problems unique to alcoholic patients are alcoholic ketoacidosis and hypoglycemia. These conditions may be confused with intoxication. They are readily reversible by administration of fluids and glucose. Most patients are phosphate- and magnesium-deficient as well and need to have these electrolytes replaced.

INFECTIONS

Alcoholics are very prone to infections as a result of malnutrition, immunosuppression by alcohol, and liver disease. The most severe infections may be heralded only by a deterioration in mental status, hypotension, or nonspecific symptoms and frequently are not accompanied by fever. Bacteremia and spontaneous bacterial peritonitis are common in patients with cirrhosis who are unwell and require hospitalization ([Chapter 105](#)). Other infections include pneumonia and lung abscess, bacterial meningitis, and urinary tract infections. Patients with possible infections should have a chest x-ray, urinalysis, blood cultures, and perhaps lumbar puncture. A sample of ascites, if present, should be analyzed for serum ascites albumin gradient, cell count, differential, and culture in blood culture bottles at bedside. An absolute neutrophil count over 250/ μ L indicates infection. Direct inoculation of ascitic fluid into blood culture bottles at the bedside substantially improves the chances of culturing an organism, since the concentration of bacteria in the fluid is low. The presence of *Bacteroides* species or multiple organisms strongly suggests the possibility of a perforated viscus. Many studies now support the prophylactic use of antibiotics active against gram-negative rods for all cirrhosis patients with gastrointestinal bleeding—variceal or not.

If examination of the ascites suggests infection, the patient should be started on a third-generation cephalosporin to treat the most likely organisms, streptococci and enteric gram-negative rods. The use of aminoglycosides should be avoided because of a high risk for renal impairment. A repeat paracentesis should be done 48 hours after initiation of therapy. If the neutrophil count has not decreased, secondary bacterial peritonitis or a resistant organism should be suspected. Many trials support the use of quinolones as secondary prophylaxis for recurrent spontaneous bacterial peritonitis and primary prophylaxis in cirrhosis patients who have a high

risk for developing spontaneous bacterial peritonitis, which may be particularly useful for patients awaiting transplantation.

ALTERED NEUROLOGIC STATUS

It is difficult to evaluate sick, intoxicated alcoholic patients. The major differential diagnoses are stroke; head trauma; chronic or acute subdural hematoma; meningitis; hypoglycemia; hyponatremia; postictal state; drug, ethylene glycol, or methanol ingestion; Wernicke–Korsakoff syndrome; hepatic encephalopathy; and alcohol or drug withdrawal syndromes. If trauma is a serious consideration, an urgent head CT scan is mandatory. CT scans are highly desirable before performing lumbar puncture on almost any patient, unless the clinical suspicion of meningitis is high, in which case lumbar puncture should be done promptly and antibacterial therapy initiated. Alcoholic patients often abuse drugs other than alcohol, and they may ingest toxic substances by mistake. Depressant drugs, narcotics, and phenothiazines can be detected by rapid blood and urine tests. Methanol or ethylene glycol poisoning is suggested by unexplained metabolic acidosis. Because the requirement for thiamine is increased by carbohydrate, alcoholic patients should be given thiamine on admission to the hospital before receiving dextrose solutions. Supplementation of other water-soluble vitamins, especially pyridoxine and folate, is advisable. Vitamin K should be given if the prothrombin time is prolonged.

Hepatic encephalopathy may be difficult to diagnose (see also [Chapter 105](#)). Generally, there is physical evidence of chronic liver disease. The presence of fetor hepaticus (the odor of methionine catabolites) is distinctive. Arterial blood levels of ammonia are usually elevated. Asterixis is an indicator of metabolic encephalopathy but is not specific or sensitive, and it disappears with deep coma. An electroencephalogram may help to distinguish hepatic encephalopathy from alcohol withdrawal. When hepatic encephalopathy is diagnosed, a careful search must be made for the factors that precipitated it (e.g., gastrointestinal bleeding; electrolyte and acid–base imbalance; high protein intake; severe constipation; noncompliance with medications; drug use, including acetaminophen, sedatives, and narcotic analgesics; infection; renal failure; and hepatoma). Alcohol withdrawal syndromes and their treatment are described in [Chapter 440](#). Drug therapy of patients with liver disease must take into consideration alterations of pharmacodynamics and pharmacokinetics, as outlined in [Table 121.4](#).

RENAL DYSFUNCTION

Patients with ALD may have renal dysfunction at the time of admission, or it may develop during hospitalization. If the patient has advanced, chronic liver disease with tense ascites or has been treated vigorously with diuretics, the hepatorenal syndrome should be considered ([Chapter 105](#)), but other causes of renal failure should be excluded. The urine sodium is low (less than 10 mEq per liter) initially, and the urine osmolality is high, with no proteinuria and an acellular urinary sediment. Potentially reversible renal disease must be considered (e.g., a drug side effect, radiocontrast-induced nephropathy, urinary tract obstruction, sepsis, rhabdomyolysis, and acute tubular necrosis). Intravascular volume depletion must be excluded by measuring the central venous pressure or pulmonary artery wedge pressures and performing a fluid challenge. The therapy for hepatorenal syndrome should include paracentesis and careful crystalloid and colloid administration; fresh frozen plasma may be superior to albumin. Peritoneovenous shunts have not been shown to improve survival in hepatorenal syndrome. A potential role of placement of a transjugular intrahepatic portal-systemic shunt in the treatment of hepatorenal syndrome is being assessed, but preliminary data indicate that it is also ineffective.

EVALUATION OF ALCOHOLIC PATIENTS WITH SUSPECTED OR WORSENING LIVER DISEASE

Alcoholic patients may have historical or physical findings that suggest liver disease or that previously diagnosed liver disease has worsened. Of course, it cannot be assumed that the abnormalities all are due to alcohol abuse. The patient may have nonalcoholic liver disease or may have ALD with superimposed viral hepatitis, drug hepatitis, hepatoma, or biliary obstruction. Up to 30% of patients with ALD may have gallstones, usually bilirubin pigment stones. Therefore, a systematic approach should be taken to delineate the liver disease or diseases present. The patient should be closely questioned about ingestion of drugs or toxins. Exposure to viruses (e.g., by sexual contact, blood and blood product transfusions, or intravenous or nasal drug use) must be investigated. The physical examination should be directed toward finding stigmata of chronic liver disease, organomegaly, abnormal masses, visible or palpable gallbladder, abdominal tenderness, Murphy's sign, and so on. The finding of stigmata requires further investigation and often mandates liver biopsy. The liver tests may help to decide which diagnostic (and often invasive) tests to perform next, but they do not help in the differential diagnosis of intrahepatic versus extrahepatic causes of cholestasis. Hepatomegaly suggests fat, tumor, mass, or infiltrative lesions.

Ultrasonography or CT scan should be performed before biopsy so that mass lesions can be biopsied under radiologic guidance. Jaundice raises many possibilities, including biliary tract obstruction. Radiologic imaging should be performed to look for dilated ducts. If the ducts are dilated, obstruction is present, and a cholangiogram should be obtained. If the patient has symptoms suggestive of intermittent obstruction (attacks of pain or symptoms of biliary infection) but no dilation of the ducts, a cholangiogram should also be performed. If neither biliary obstruction nor masses are present, the appropriate blood tests should be obtained and the liver should be biopsied. In particular, serum iron saturation, ferritin, ceruloplasmin, and urine copper studies should be done before the biopsy so that liver metal content can be analyzed if these measurements suggest hemochromatosis or Wilson's disease.

PREVENTION

The prevention of ALD depends on the development of effective treatment of alcoholism. The success of therapies for alcohol abuse varies from 30% to 90%. Improved results await programs for the detection of alcohol abuse in an early stage when the patient still has support from family and employers; methods for monitoring alcohol consumption in patients who are under treatment; and the development of pharmacologic agents that reduce the urge to drink. There is evidence from animal and clinical studies that serotonin uptake inhibitors and opioid antagonists can improve the results of alcoholism treatment, and naltrexone was recently approved for use in treatment of alcoholism in conjunction with behavioral or psychological therapy. Additional medications to reduce craving, such as acamprosate, are expected to be approved in the coming years.

CHAPTER 122: DRUG-INDUCED HEPATIC INJURY

SHELLY C. LU AND LAWRENCE S. MALDONADO

[Biotransformation](#)
[Drug-Induced Hepatic Injury](#)
[Examples of Drug-Induced Hepatic Injury](#)
[Diagnosis and Treatment of Drug-Induced Hepatic Injury](#)

Drug-induced hepatic injury is associated with more than 800 different drugs, accounting for 4% to 7% of adverse drug reactions. Although adverse drug reactions comprise only 2% to 3% of hospital admissions for jaundice, they cause up to 25% of cases of fulminant hepatic failure and 40% of acute hepatitis cases in persons older than 50 years. Furthermore, drugs cause chronic liver diseases such as chronic active hepatitis, cirrhosis, and liver tumors. Drugs cause disproportionately more of the serious forms of liver disease. The clinician evaluating a patient with abnormal liver test results must be aware that drug-induced hepatic injury can mimic almost any liver disorder.

Most drugs and xenobiotics (chemicals taken up by the body but not incorporated into the normal cellular metabolic economy) enter the body as lipophilic compounds through the gastrointestinal tract and hepatocyte membranes. Hepatic biotransformation converts endogenous substances and exogenous chemicals to more polar compounds that can be excreted in the bile or urine. The process of hepatic excretion involves three important steps: membrane transport of organic substances, biotransformation, and bile secretion. *Membrane transport* refers to specific mechanisms by which charged and uncharged molecules enter hepatocytes at their sinusoidal poles and leave at their sinusoidal or canalicular poles. Although many of these mechanisms are poorly characterized, specific transport mechanisms have been identified for bile acids, organic anions, organic cations, and neutral organic compounds. In addition, many lipophilic substances bound to plasma proteins diffuse passively into hepatocytes. These substances are processed or metabolized in hepatocytes and appear mainly in bile. Excretion in bile is not the fate of all compounds metabolized in the liver, however. Some polar products of biotransformation are transported into plasma and eliminated in urine ([Fig. 122.1](#)).

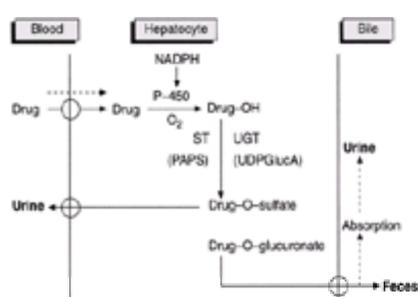

FIGURE 122.1. Scheme of hepatic biotransformation. Drugs may enter the hepatocyte by specific membrane transport processes shared with endogenous substances or by simple diffusion through the plasma membrane based on lipophilia. Once inside the cell, the drug may access sites of biotransformation by lateral diffusion through intracellular membranes or by binding to nonspecific sites on cytosolic proteins (e.g., ligandin). In this typical example, biotransformation then proceeds by P-450–catalyzed hydroxylation (phase 1) and subsequent sulfation or glucuronidation (phase 2) of the hydroxyl group. If the drug already contains an appropriate acceptor group, phase 2 can proceed directly. The highly polar metabolites are then exported by carrier-mediated transport processes. GSH and glucuronide conjugates are probably transferred preferentially to bile, whereas sulfate conjugates are transferred to plasma and then eliminated in urine. Polar metabolites excreted in bile may be absorbed from the intestine and appear in urine. *ST*, sulfotransferase; *UGT*, UDP-glucuronosyltransferases, *PAPS*, 3'-phosphoadenosine-5'-phosphosulfate; *UDPGlucA*, UDP-glucuronic acid.

BIOTRANSFORMATION

The processes of hepatic biotransformation usually are equated with drug metabolism. The hepatocyte contains a wide variety of enzymes that can process drugs. These enzymes are found in the endoplasmic reticulum, the cytosol, and, to a lesser extent, other organelles. [Table 122.1](#) lists the key families of enzymes involved in hepatic biotransformation. Each enzyme represents a large family of distinct gene products, all of which share a common cofactor or endogenous cosubstrate. Different xenobiotics induce specific gene products. The substrate specificity of individual components of any enzyme family is tremendously redundant. Nevertheless, subject to genetic control, individual forms of any family may exhibit some unique substrate specificity. Although biotransformation usually detoxifies xenobiotics, the products of these reactions sometimes are more toxic than the parent compounds.

Enzyme Family	Cofactor	Subcellular Location
Cytochrome P-450	NADPH, O ₂	Endoplasmic reticulum
Glucuronosyltransferases	UDP-glucuronic acid	Endoplasmic reticulum
Sulfotransferases	PAPS	Cytosol
GSH S ₂ transferases	GSH	Cytosol and endoplasmic reticulum

GSH, reduced glutathione; NADPH, nicotinamide adenine dinucleotide phosphate; PAPS, 3'-phosphoadenosine-5'-phosphosulfate; UDP, uridine diphosphate.

TABLE 122.1. CONSTITUENTS OF HEPATIC BIOTRANSFORMATION

Most drugs are metabolized by the liver in two sequential processes, known as phase 1 and phase 2 reactions. In phase 1, a series of reactions involving oxidoreductases, hydrolases, and transferases transforms solutes into more polar substances. Most oxidations are performed by the mixed-function oxidase system. In phase 2, these metabolites are conjugated with glucuronic acid; glycine, sulfates, glutathione (GSH); and other substances, yielding more polar products for subsequent excretion. Some drugs are metabolized primarily by phase 2 reactions. Knowledge of the sequence and relative importance of these reactions in handling drug metabolism is critical in understanding the hepatotoxicity of certain drugs. For example, acetaminophen is metabolized predominantly by phase 2 reactions, resulting in polar, nontoxic metabolites. However, about 5% of an ingested dose is oxidized by cytochrome P-450, producing a reactive, toxic intermediate (see Acetaminophen-Induced Hepatotoxicity).

Advanced liver disease impairs phase 1 reactions, but leaves phase 2 reactions relatively preserved. For example, cirrhosis severely impairs cytochrome P-450 metabolism of diazepam but does not affect glucuronosyltransferase metabolism of another benzodiazepine, oxazepam. Awareness of such considerations helps in managing drug therapy in patients with advanced liver disease.

Another important feature of hepatic biotransformation is the zonation or lobular heterogeneity of enzymes, cofactors, cofactor synthesis, and induction. In rodents, phenobarbital induces cytochrome P-450 selectively in zone III of the hepatic acinus (centrilobular). Hepatotoxins activated by cytochrome P-450 and detoxified by

GSH tend to produce zone III necrosis, possibly because of the larger content of cytochrome P-450 and smaller content of GSH in this location.

In addition to genetics and liver disease, other factors that affect biotransformation include age, gender, nutrition, cofactor availability, pregnancy, and the concomitant use of other drugs. Different enzymes have different developmental patterns, even within the same supergene family. Although severe malnutrition has major effects on the metabolism and pharmacokinetics of drugs, moderate undernutrition has little effect. Exceptions include GSH S-transferase-mediated reactions and glucuronidation. Fasting decreases levels of GSH and enhances the toxicity of drugs detoxified by GSH, such as acetaminophen. Fasting also may affect glucuronidation by limiting the availability of its cosubstrate, uridine diphosphate-glucuronic acid (UDPGlucA). In animal studies, various phase 1 and 2 activities decrease late in pregnancy. Similar studies in humans are lacking.

CYTOCHROME P-450

Cytochrome P-450, phospholipids, and nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P-450 reductase are the main components of the mixed-function oxidase system. Only one form of NADPH-cytochrome P-450 reductase exists, but there are more than 40 different members of the human cytochrome P-450 superfamily and, collectively, they are probably the most significant enzymes for the metabolism of drugs, carcinogens, and corticosteroids.

Genes of the cytochrome P-450 superfamily encode a group of enzymes that share the following characteristics: they contain a noncovalently bound heme moiety; they are proteins bound to intracellular membranes, mainly the endoplasmic reticulum; and they use NADPH or occasionally nicotinamide adenine dinucleotide (NADH), and atmospheric oxygen (O_2) to oxygenate substrates. A second enzyme transfers the reducing equivalents from NADPH or NADH to cytochrome P-450. These physicochemical parameters suggest that the cytochrome P-450 genes share common structural features. The prosthetic group (a thiolate-bound heme) is identical in all, but the apoprotein structures differ, accounting for the different substrate specificities.

Nomenclature

Most nomenclature systems are based on global alignments of complete amino acid sequences. The cytochrome P-450 gene superfamily is subdivided into families, subfamilies, and individual genes. The italicized root symbol *CYF* (representing cytochrome P-450) is used for humans (*Cyp* is used for the mouse). Families are designated by Arabic numbers and share at least 40% amino acid sequence identity. Subfamilies are identified by capital letters and share more than 55% to 60% similarity. Individual forms of cytochrome P-450 within a subfamily are numbered sequentially. This system does not depend on cytochrome P-450 catalytic activities or function. Forms of cytochrome P-450 in separate subfamilies can have overlapping catalytic activities.

Evolution and Genetic Polymorphism

Various forms of cytochrome P-450 occur in prokaryotic and eukaryotic organisms. The evolution of cytochrome P-450 probably began 2 to 3 billion years ago, when only a few genes encoded forms of cytochrome P-450 that metabolized endogenous substrates such as corticosteroids, fatty acids, and eicosanoids. With evolutionary demand, cytochrome P-450 gene duplications and conversions increased, producing genes coding new forms of cytochrome P-450, which metabolized xenobiotics or endogenous substrates. One consequence of human cytochrome P-450 gene evolution is the polymorphism of drug metabolism, leading to marked differences in individual responses to the toxic and carcinogenic effects of drugs and other environmental chemicals. The differences among individuals, races, and ethnic groups are manifested in the varying levels of expression of forms of cytochrome P-450, as evidenced by differences in the metabolism of certain drugs. One well-known example of genetic polymorphism is *CYP2D6*, the activity of which is absent in 7% of whites, owing to numerous mutations. Perhexiline, a substrate of *CYP2D6*, causes peripheral neuropathy and cirrhosis only in persons deficient in *CYP2D6*. These genetic polymorphisms demonstrate typical mendelian inheritance.

Some forms of cytochrome P-450 show wide interindividual variability without genetic polymorphism. For example, a 20-fold interindividual variation in the activity of *CYP3A*, the main subfamily of cytochrome P-450 in man, accounts for almost 50% of human hepatic forms of cytochrome P-450. *CYP3A4* is the main isoenzyme metabolizing substrates, such as nifedipine, macrolide antibiotics, cimetidine, cyclosporine, FK506, and corticosteroids. Low levels of *CYP3A* in donor liver grafts increase cyclosporine and FK506 toxicity; conversely, high levels of *CYP3A* increase graft rejection, presumably because of an insufficient level of immunosuppressants. Knowledge of hepatic *CYP3A* activity before transplantation could guide immunosuppressive therapy.

Structure

Human forms of cytochrome P-450 are hydrophobic, intrinsic membrane proteins tightly associated with intracellular membranes. The cytochrome P-450 protein is a globular structure embedded into the membrane lipid bilayer by its amino-terminal peptide. The bulk of the enzyme is exposed to the cytoplasmic surface of the endoplasmic reticulum, and the heme iron is parallel with or at a slight angle to the membrane. This orientation is ideal for cytochrome P-450 interaction with hydrophobic and hydrophilic substrates and for cooperative association with NADPH-cytochrome P-450 reductase.

Reactions

The catalytic mechanisms of all forms of cytochrome P-450 appear to be similar. First, substrate binds to the oxidized cytochrome P-450, and the complex subsequently is reduced to the ferrous form in a reaction catalyzed by NADPH-cytochrome P-450 reductase in which one electron is transferred from NADPH to the hemoprotein. The reduced cytochrome P-450 substrate complex then binds oxygen, and the electron from the ferrous cytochrome P-450 is transferred to oxygen, forming a transient ferric-(O_2^-) substrate complex. A second electron then is transferred from the reductase (in some cases, the second electron is derived from NADH by cytochrome b_5), generating the ferric (O_2^-) cytochrome P-450. The oxygen-oxygen bond is split, and one oxygen atom is released in water while the other remains bound to heme. This putative (FeO)³⁺ species is a powerful oxidant responsible for the oxygenation of bound substrate. Oxygen transfer from the heme to the substrate involves initial abstraction of a hydrogen atom (or electron) from substrate, followed by oxygen "rebound" from the heme to the bound substrate radical. This produces the oxygenated product which then dissociates from the active site and completes the catalytic cycle. In addition to hydroxylation, other oxidative reactions, such as epoxidation, *N*-demethylation, *O*-dealkylation, and *N*-oxidation, are catalyzed similarly by forms of cytochrome P-450.

Sometimes, the products of cytochrome P-450-mediated reactions are more toxic than the parent compounds. These toxic products are electrophiles because they exhibit reactive centers that seek electrons. Therefore, covalent binding or alkylation of nucleophilic centers (electron-donating sites) on cellular constituents can ensue. Defense against electrophiles sometimes involves GSH conjugation. Phase 1 reactions may be "toxifying" and phase 2 reactions detoxifying.

For some reactions, many cytochrome P-450 enzymes overlap considerably in their catalytic efficiency; different forms of cytochrome P-450 catalyze the same reaction, although at different rates. However, in other cases, a single enzyme may be responsible for most of the activity, because of its much more rapid intrinsic rate or because other cytochrome P-450 enzymes are not plentiful. In vivo metabolism is a function of the efficiency of a cytochrome P-450 for a substrate and the abundance of that particular cytochrome P-450 relative to other forms of cytochrome P-450 in the cell.

Induction, Inhibition, and Drug-Drug Interactions

Multiple drugs induce different forms of cytochrome P-450. Sometimes exposure to specific substrates induces certain forms of cytochrome P-450, usually the forms that metabolize those substrates. Specific examples are phenobarbital (the *CYP2B* family), ethanol (*CYP2E1*), isoniazid (*CYP2E1*), clofibrate (*Cyp4* in rats), and corticosteroids (*Cyp3* in rats). In addition, smoking induces *CYP1A1* in human liver and extrahepatic tissues. Induction may be important in promoting hepatotoxicity if the form induced also activates a hepatotoxin, as in acetaminophen toxicity in chronic alcoholics. Chronic ethanol exposure induces *CYP2E1*, which oxidizes acetaminophen to an electrophilic toxic product. This is the predominant mechanism of enhanced susceptibility to acetaminophen hepatotoxicity in chronic alcoholics (see Acetaminophen-Induced Hepatotoxicity). Moreover, *CYP2E1* is preferentially expressed in the centrilobular zone, which may explain the histologic pattern of acetaminophen hepatotoxicity. Precise mechanisms of enzyme induction are poorly understood; increased transcription, messenger RNA or protein stabilization, or even selective translational enhancement may be involved.

Cytochrome P-450-associated activities in humans may vary on the basis of competitive or noncompetitive enzyme inhibition. Competitive inhibition occurs when two substrates compete, such as cimetidine and ketoconazole, or when one drug is a nonsubstrate inhibitor of a particular enzyme, such as quinidine and *CYP2D6*. Such interactions also may occur with food. An interesting example is grapefruit juice, which dramatically inhibits the oxidation of *CYP3A4* substrates such as nifedipine or cyclosporine. This may mandate dose reductions of these drugs or dietary counseling. A cytochrome P-450 also may oxidize a compound to a product, which then inhibits that enzyme. Certain antibiotics are nitrosylated and bind extremely tightly to the ferrous heme (e.g., troleandomycin). In other cases, the inhibition is truly

mechanism-based, with a reactive intermediate covalently binding to the apoprotein or porphyrin. The effects of some of these inhibitors can be dramatic and produce clinical consequences.

Advanced liver disease suppresses some cytochrome P-450 apoproteins, leading to impaired drug elimination. The availability of the cosubstrates O_2 and NADPH also may be critical. Impaired hepatic perfusion, as in shock and congestive failure, may lead to decreased O_2 and interfere with drug elimination. Conversely, decreased O_2 may enhance the reductive metabolism of certain substrates, such as carbon tetrachloride and halothane. Sometimes the availability of the electron donor for cytochrome P-450, NADPH, is an important limiting factor. For example, ethanol metabolism in hepatocytes acutely interferes with mitochondrial NADPH production. Even minimal elevations in blood ethanol levels may inhibit cytochrome P-450 activities as a result of markedly decreased NADPH. High blood ethanol levels can lead to direct inhibition of forms of cytochrome P-450 by direct binding.

Drug–drug interactions often are associated with enzyme induction or inhibition by one of the drugs. Levels of *CYP3A4* are elevated by the administration of rifampin or barbiturates, resulting in more rapid elimination of 17 α -ethinyl estradiol or cyclosporine and loss of contraceptive or immunosuppressive action, respectively. Oxidation of acetaminophen by cytochrome P-450 is inhibited by the coadministration of cimetidine.

Many of the cytochrome P-450 substrates are procarcinogens. Most of the activation of these chemicals in humans is attributable to only a few forms of cytochrome P-450: *CYP1A1* activates several polycyclic hydrocarbons; *CYP1A2* activates many arylamines; *CYP2E1* activates urethane, vinyl monomers, and small halogenated hydrocarbons; and *CYP3A4* activates aflatoxins, polycyclic hydrocarbon dihydrodiol, and some arylamines. Increased levels of these enzymes are associated with a higher incidence of cancer.

URIDINE DIPHOSPHATE-GLUCURONOSYLTRANSFERASE

Uridine diphosphate-glucuronosyltransferase (UGT) is a family of enzymes located in hepatic endoplasmic reticulum and various extrahepatic tissues, such as kidney, intestine, and olfactory epithelium. The UGT isoenzymes convert hydrophobic endobiotic and xenobiotic substances, such as bilirubin, steroid and thyroid hormones, and many drugs, into water-soluble glucuronides. In general, glucuronides are less toxic and active than their parent compounds and are excreted more readily in the bile. However, exceptions are discussed later, and the role of glucuronides in toxification has received increasing attention. As with other biotransformation processes, a family of enzymes with overlapping substrate specificities ensures the ability of the liver to eliminate many xenobiotics.

Nomenclature

Molecular biologic techniques are instrumental in the understanding of UGTs because conventional purification techniques failed as a result of the instability of these isoenzymes. Cloning of complementary DNAs and the expression of various isoenzymes has enabled classification of the UGT isoenzymes according to their genetic origin in a fashion analogous to the classification of forms of cytochrome P-450. More than 25 UGT complementary DNAs have been cloned. An international workshop in the Netherlands proposed a UGT classification scheme in which the root symbol UGT represents uridine diphosphate-glucuronosyltransferase in humans, an Arabic numeral denotes the family, a letter designates the subfamily, and a number represents the individual gene. Families share less than 50% amino acid sequence identity, whereas subfamilies share more than 60%.

Molecular Forms, Induction, and Deficiency

Human UGTs can be subdivided into two families. UGT family 1 consists of at least four members that catalyze the glucuronidation of phenols and bilirubin. These four isoenzymes are encoded on a single UGT gene on chromosome 2 and represent alternative splicing products of a common primary transcript. Although they are derived from the same primary transcript, they can be induced differentially and their perinatal development differs considerably. Clofibrate and phenobarbital induce bilirubin glucuronidation, whereas 3-methylcholanthrene induces planar phenol glucuronidation. Bilirubin UGTs are expressed after birth, whereas phenol UGTs are expressed before birth.

At least three UGT family 2 genes are on chromosome 4. Induction of this family has not been described.

Few “inborn errors” of glucuronidation have been discovered. Only deficiencies in bilirubin glucuronidation have been described in humans (the Crigler–Najjar syndrome and Gilbert’s disease, which are discussed in [Chapter 103](#)).

Topology and Reactions

The UGTs are deeply embedded within membranes, particularly smooth endoplasmic reticulum, and are anchored by only one peptide fragment. Most of the enzyme is on the luminal side of the endoplasmic reticulum; only a small fragment of the protein is on the cytosolic side. The cosubstrate, UDPGlucA, interacts in the lumen of the endoplasmic reticulum. UDPGlucA is synthesized from UDP-glucose by the cytosolic enzyme UDP-glucose dehydrogenase. To gain access to UGT, therefore, UDPGlucA is transported from the cytoplasmic to the luminal side of the endoplasmic reticulum.

Glucuronidation transfers the glucuronic acid group from UDPGlucA to a substrate acceptor group, forming ether, ester, thiol, N, and C glucuronides, and greatly enhancing water solubility. This is an S_N2 reaction in which a nucleophilic acceptor group on the substrate attacks the electrophilic C-1 atom of the glucuronic acid group. A high conjugation rate requires appreciable lipid solubility, possibly because the substrate-binding site is hydrophobic.

Many drugs are direct substrates of the various UGTs, including acetaminophen, morphine, oxazepam, and zidovudine. Most have a phenolic acceptor group, so sulfation is a competing reaction. Carboxylic acids such as ibuprofen, probenecid, and endogenous bilirubin are eliminated almost exclusively by glucuronidation. In addition, most other drugs can be metabolized by phase 1 reactions to generate acceptor groups for glucuronic acid. As a result, many drugs are excreted at least partially as glucuronides.

Determinants of Rate of Glucuronidation

A high rate of glucuronidation requires a sufficient supply of UDPGlucA, which fasting depletes. UDPGlucA is synthesized from UDP-glucose by a nicotinamide-adenine dinucleotide (NAD⁺)–dependent dehydrogenase in the cytosol. Therefore, the availability of UDPGlucA is determined by the level of UDP-glucose, which depends on adenosine triphosphate (ATP) levels and glycogen stores. Severe liver disease impairs glucuronidation efficiency, although UGT activity in liver samples of such patients is hardly affected. An extrahepatic contribution to conjugation may ensure residual capacity if liver function is lost.

Role of Glucuronidation in Regulation of Biologic Activity of Drugs and in Toxification

Although glucuronidation is mainly a detoxifying and inactivating reaction, for several xenobiotics, the glucuronide is more toxic than the parent compound. In addition, glucuronide conjugates may mediate important pharmacologic activities. For instance, the glucuronide conjugate formed at the 6 position of morphine is a much more potent agonist than is morphine, whereas the glucuronide formed at the 3 position is an extremely potent antagonist. Glucuronidation at the 17b position leads to cholestatic conjugates of endogenous estradiol and the oral contraceptive ethinyl estradiol. The toxicity of drugs containing carboxylic groups may result from the formation of acyl glucuronides at those groups. These conjugates are reactive because of acyl bond instability, releasing electrophilic intermediates that may bind covalently to plasma proteins and present as haptens to the immune system. This happens with zomepirac, a muscle relaxant, and led to its withdrawal from clinical use.

SULFOTRANSFERASES

The human liver contains at least three well-characterized classes of sulfotransferase enzymes, dehydroepiandrosterone sulfotransferase and two phenol sulfotransferases. At least 13 eukaryotic complementary DNAs of sulfotransferase enzymes and two human liver complementary DNAs of dehydroepiandrosterone sulfotransferase have been cloned. Dehydroepiandrosterone sulfotransferase catalyzes the sulfation of 3-hydroxysteroids, such as dehydroepiandrosterone, corticosteroid hormones such as estrone, bile acids such as lithocholic acid, the cardiac glycoside digitoxin, and even cholesterol. One of the two phenol sulfotransferases is thermostable, preferentially catalyzes the sulfation of “simple” planar phenols, and is inhibited by 2,6-dichloro-4-nitrophenol. The other phenol sulfotransferase is thermolabile, preferentially uses phenolic or catechol monoamines as substrates, and is resistant to 2,6-dichloro-4-nitrophenol inhibition. Levels of

activity for dehydroepiandrosterone sulfotransferase and the two forms of phenol sulfotransferases vary widely among individuals, suggesting genetic polymorphism.

Reactions

The enzymes use 3'-phosphoadenosine-5'-phosphosulfate as a sulfate donor. 3'-Phosphoadenosine-5'-phosphosulfate is synthesized from two molecules of ATP and one sulfate that comes from dietary sources or hepatic cysteine degradation. The enzymes transfer sulfate mainly to hydroxyl groups, including simple alcohols, bile acids, and phenolic compounds such as thyroxine, isoproterenol, methyl dopa, and acetaminophen.

Inhibition

Clinically significant inhibition is caused by limited 3'-phosphoadenosine-5'-phosphosulfate availability. 3'-Phosphoadenosine-5'-phosphosulfate production capacity is extremely limited. Many drugs or their cytochrome P-450 metabolites contain hydroxyl groups that can be sulfated or glucuronidated. In general, glucuronidation is a low-affinity and high-capacity reaction, whereas sulfation is a high-affinity and low-capacity reaction. At higher doses, glucuronidation predominates largely because of limited 3'-phosphoadenosine-5'-phosphosulfate availability. Conversely, at low drug levels, sulfation predominates because of higher sulfotransferase affinities. If both enzymes can catalyze a substrate, the substrate concentration will determine which pathway predominates.

Role of Sulfation in Toxication

Although sulfation usually results in inactive or less active compounds that are more water-soluble, the sulfate ester sometimes is more toxic than the parent molecule. For example, certain *N*-hydroxy sulfates of polycyclic hydrocarbons are more reactive than the parent *N*-hydroxy compounds.

GLUTATHIONE S-TRANSFERASES

Glutathione *S*-transferases play a selective but important role in hepatic biotransformation. The central molecule is GSH, which is involved in all reactions catalyzed by GSH *S*-transferases. In conjugation reactions, GSH reacts with any sufficiently electrophilic centers, which are potentially toxic. Although the liver conjugates with GSH far less frequently than it glucuronidates or sulfates to prepare substances for excretion, GSH conjugation is critical in detoxification.

Glutathione Metabolism

Glutathione is a tripeptide (γ-glutamylcysteinyl glycine) found in all mammalian tissues, with especially high hepatic concentrations that are essential for the survival of aerobic cells. GSH exists in thiol-reduced (GSH) and disulfide-oxidized (GSSG) forms, but the former predominates, existing in millimolar concentrations in most cells (about 5 mmol per liter in hepatocytes). The GSSG content is less than 1% that of GSH. Ninety percent of cellular GSH is cytosolic. The peptide bond linking the glutamate and cysteine of GSH is through the γ-carboxyl group of glutamate rather than the conventional α-carboxyl group. This unusual arrangement is hydrolyzed by only one known enzyme, γ-glutamyl transpeptidase, which occurs only on the external surfaces of certain cell types. Consequently, GSH resists intracellular degradation and is metabolized only outside the cell by organs with γ-glutamyl transpeptidase.

GSH serves several vital functions, one of the most important being detoxification of electrophiles. The liver has a large reserve of GSH for detoxification and maintains interorgan homeostasis of GSH by exporting nearly all the GSH it synthesizes into plasma and bile through carrier-mediated transport systems. In rats, plasma GSH comes almost entirely from sinusoidal efflux of hepatic GSH. The released GSH then is broken down by the ectoenzyme γ-glutamyl transpeptidase to amino acids such as cysteine, which can be taken up and reincorporated into GSH.

The synthesis of GSH from its constituent amino acids, L-glutamate, L-cysteine, and glycine, involves two sequential enzymatic steps requiring ATP. The first step of GSH biosynthesis, catalyzed by γ-glutamylcysteine synthetase, is rate-limiting and is regulated by feedback competitive inhibition by GSH. GSH synthesis is influenced significantly by the availability of intracellular cysteine. This is especially important when GSH is severely depleted (e.g., after massive acetaminophen overdose), because the synthesis rate will increase from loss of feedback inhibition. Cysteine normally is derived from diet, from protein breakdown, and, in the liver, from methionine through transsulfuration. Providing cysteine promotes GSH synthesis when GSH utilization is markedly increased. The most well-known example is the use of *N*-acetylcysteine to treat acetaminophen overdose (see Acetaminophen-Induced Hepatotoxicity).

Maintenance of normal hepatic γ-glutamylcysteine synthetase activity requires insulin and glucocorticoids. Hepatic γ-glutamylcysteine synthetase activity and GSH levels decrease 25% to 40% in insulin-deficient diabetic rats and in adrenalectomized rats, but remain normal with hormonal replacement. This small decrease in the hepatic GSH level is unlikely to affect GSH-dependent detoxification, but may predispose to toxicity after hepatotoxin overdose.

Another aspect of GSH metabolism is its redox cycle. GSH is a substrate for selenium-dependent GSH peroxidase, an important enzyme in the detoxification of hydrogen peroxide. Aerobic cells produce a small amount of hydrogen peroxide, and generate larger amounts under oxidant stress. GSH peroxidase reduces H₂O₂ to water while oxidizing GSH to GSSG, which is efficiently reduced back to GSH by NADPH-dependent GSSG reductase. GSSG also is transported into bile in direct proportion to its steady-state concentration. This reduction of H₂O₂ and the accompanying GSH redox cycle constitute the most important GSH function in the absence of xenobiotics and are especially critical in mitochondria.

Isozymes and Genetics

The GSH *S*-transferases are cytoplasmic enzymes made up of two subunits. As is common among biotransforming enzymes, the subunits of these enzymes represent multiple distinct gene products with broad, overlapping substrate specificity and constitute a superfamily. Three major families have been described: α, μ, and π. In humans, α is represented by at least three genes on chromosome 6; two are expressed in liver and one in skin. The α class enzymes exhibit GSH peroxidase activity and high-affinity organic anion binding. The major human α gene is on chromosome 1, whereas two related μ genes for muscle and brain enzymes are on chromosome 3. Expression of the μ enzyme is genetically polymorphic. About 50% of all whites and Asians do not express the hepatic and leukocyte μ enzyme. Preliminary evidence suggests that smokers lacking the μ enzyme have a higher risk for lung cancer. The human π class gene is on chromosome 11. The product encoded by this gene is expressed in placenta, intestine, and bile ducts but not in hepatocytes and its expression is increased in several human cancers. Accordingly, the π gene product may serve as a tumor marker and may contribute to resistance to chemotherapy.

A distinct microsomal form occurs in rodents and humans, which is structurally unrelated to the cytosolic enzyme. The importance of the microsomal form in detoxification is suggested by its activation by thiol alkylating agents, oxidized GSH, and superoxide anion.

Reactions

The GSH *S*-transferases all noncovalently bind GSH to an active site. The thiol of GSH can ionize; the pH of the thiol drops from pH 9.3 when GSH is free to 7.4 when it is bound. In addition, an adjacent site binds a wide variety of lipophilic xenobiotics. The enhanced affinity of GSH for nuclei and its proximity to bound electrophiles favor catalysis.

Three types of reactions occur: substitution, addition, and reduction. Substitution reactions involve GSH replacing a leaving group, such as bromide displaced from sulfobromophthalein. The product is a GSH conjugate. Additional reactions involve direct GSH conjugate formation with an electrophilic site, such as conjugation of leukotriene A₄ with GSH to form leukotriene C₄. These enzymes have few known endogenous substrates. GSH *S*-transferases also reduce organic peroxides, but not hydrogen peroxide. This peroxidase activity produces GSSG. Its importance in decreasing lipid peroxidation compared with selenium-dependent GSH peroxidase is uncertain.

The importance of GSH conjugation catalyzed by GSH *S*-transferases is illustrated by acetaminophen. Cytochrome P-450 converts the drug to an electrophile that readily reacts with thiols of proteins and GSH. However, despite this chemical nonselectivity, biologic preference for GSH is exhibited. This is the GSH threshold. Covalent binding to protein thiols occurs only after GSH levels fall near zero. The high preference for GSH is explained by GSH *S*-transferases catalyzing detoxification.

TABLE 122.3. HISTOLOGIC CLASSIFICATION OF DRUG-INDUCED LIVER DISEASE

Zonal Necrosis

Zonal necrosis usually is caused by predictable hepatotoxins. Agents that cause centrilobular necrosis include acetaminophen and carbon tetrachloride, whereas yellow phosphorus causes middle-zone necrosis, and allyl alcohol causes periportal necrosis. Usually, little or no inflammation results, and damaged cells may accumulate triglycerides. Clinically, patients may be asymptomatic or suffer fulminant liver failure. Biochemically, signs of liver cell dysfunction and necrosis, such as elevated serum transaminase levels and, in severe cases, elevated bilirubin levels and prolonged prothrombin times, occur. In most instances of acute injury of this type, the process resolves completely or terminates fatally without progression to chronicity.

The molecular basis for zonal selectivity for these agents is unclear, but probably reflects zonal differences in the determinants of injury. For example, zonal distribution of the different enzymes of biotransformation, defense mechanisms (e.g. GSH levels), bioavailability of drugs, and even differences in oxygen tension probably play significant roles in determining these patterns.

Hepatitis

Nonspecific Hepatitis

In nonspecific hepatitis, an inflammatory response is the essential histologic feature. Typically, a few scattered foci of hepatocellular necrosis, usually associated with a mononuclear cell infiltrate, and variable portal inflammation are seen. The characteristic features of viral hepatitis, such as bile stasis, lobular disarray, and acidophil bodies, are missing. Nonspecific hepatitis occurs with a wide variety of drugs, virtually never produces serious or progressive hepatic injury, and reverses fully on discontinuation of the responsible agent.

Lesions Resembling Acute Viral Hepatitis

Many drugs can cause histologic lesions that are indistinguishable from viral hepatitis. Examples include isoniazid, methyldopa, and halothane. This form of injury often challenges clinicians. In some cases (e.g., phenytoin-induced hepatitis), prominent peripheral or tissue eosinophilia suggests a nonviral cause, but more often these features are absent. Note that drug-induced acute hepatitis carries a higher case fatality rate than does acute viral hepatitis; drug-induced acute hepatitis associated with overt jaundice carries a mortality rate of more than 10% compared with less than 1% in viral hepatitis. Possible reasons for the higher mortality rate include older patient age, more rapid disease progression, and often continuation of the unrecognized offending agent. As is true of most cases of acute drug-induced hepatic injury, recovery is the rule on discontinuation of the responsible agent. However, chronic hepatitis (see later in text) can develop with continued or repeated exposure.

Granulomatous Hepatitis

Drug-induced granulomatous hepatitis is characterized by noncaseating granulomas accompanied by variable numbers and types of inflammatory cells. The granulomas may contain abundant eosinophils, suggesting hypersensitivity-based injury. Typical offending agents are quinidine, allopurinol, phenylbutazone, sulfonamides, and sulfonylurea derivatives. Up to one-third of granulomatous hepatitis cases result from drugs.

Chronic Hepatitis

Drug-induced chronic hepatitis is a heterogeneous group of disorders differing in pathogenesis and histologic features. Chronic active hepatitis is associated with isoniazid and methyldopa, whereas focal nonspecific hepatic necrosis is associated with long-term aspirin use. In general, these hepatic injuries result from continued exposure rather than from a self-perpetuating process started by an acute insult. Often, the agent is taken in doses regarded as therapeutic rather than toxic. Careful inquiry into the use of prescription and nonprescription drugs is essential in evaluating all patients with chronic liver disease.

Fatty Liver

The lipid that accumulates in the liver in almost all forms of hepatotoxicity is predominantly triglyceride. Two histologic patterns of fatty liver occur, macrovesicular and microvesicular steatosis. In macrovesicular fatty liver, the more common form, triglyceride deposits in relatively large globules, effectively filling the hepatocyte and displacing the nucleus and other intracellular constituents peripherally, making it appear adipocyte-like. This pattern is associated with ethanol abuse and various nutritional disorders such as obesity, malnutrition, diabetes mellitus, and jejunoileal bypass surgery. It also is associated with drugs such as amiodarone (see following section), methotrexate, and corticosteroids. Liver function is relatively well preserved unless other processes such as hepatitis are associated.

The other histologic form of fatty liver has small droplets of fat dispersed throughout the cytoplasm so that the nucleus remains central and the cell remains recognizable as a hepatocyte. This pattern is seen in a few unusual disorders, such as Reye's syndrome, fatty liver of pregnancy, Jamaican vomiting sickness, and certain rare inborn errors of metabolism in the urea cycle. Drugs associated with this hepatic injury include high doses of intravenous tetracycline, valproic acid, and fialuridine (FIAU). Mitochondrial β -oxidation of fatty acid is impaired, leading to depletion of the ATP pool and disruption of cellular metabolism. This type of injury causes much more severe liver dysfunction and necrosis, with marked increases in serum transaminase and bilirubin levels, prolonged prothrombin times, and significant mortality rates.

Alcoholic-Like Liver Disease

Hepatitis with Fibrosis or Cirrhosis

Some of the drugs that can cause a histologic picture identical with alcoholic hepatitis are amiodarone (an antiarrhythmic agent), perhexiline maleate (an antianginal agent), and 4,4'-diethylaminoethoxyhexestrol (a coronary artery vasodilator). These drugs are structurally unrelated, but all are amphiphilic weak bases. This similarity may determine their hepatotoxicity.

Amiodarone, an iodine-containing benzofuran derivative, produces multisystem toxicity, including thyroid dysfunction, pulmonary fibrosis, and liver disease. Mild transaminase elevation occurs in 20% to 40% of patients receiving the drug. The histologic features on light microscopy are identical with alcoholic hepatitis, namely, Mallory bodies in hepatocytes, mixed inflammatory infiltration around proliferating bile ducts, macrovesicular fat, granular cytoplasm with foamy changes, and fibrosis with cirrhosis. On electron microscopy, prominent concentric lysosomal inclusions resembling those found with primary phospholipidoses, such as Fabry's, Niemann-Pick, or Tay-Sachs disease, are seen. The mechanism involves trapping amiodarone (a weak base) in its ionized form in acidic lysosomes, leading to inhibition of phospholipid breakdown because amiodarone is a potent competitive inhibitor of lysosomal phospholipase A1. How lysosomal phospholipidosis injures the liver is unclear.

Perhexiline maleate also is associated with lysosomal phospholipidosis and can produce the same histologic picture as amiodarone hepatotoxicity. Genetic polymorphism plays a significant role in determining susceptibility to perhexiline maleate hepatotoxicity (see Evolution and Genetic Polymorphism). Seven percent of caucasians lack *CYP2D6*, the isoform responsible for hydroxylating perhexiline maleate during its drug excretion. This phenotypic expression can be measured by the rate of hydroxylation of the test compound, debrisoquine, because perhexiline maleate hepatotoxicity occurs only in persons who hydroxylate debrisoquine poorly. The accumulation of unmetabolized perhexiline maleate in acidic lysosomes promotes secondary phospholipidosis.

Quiescent Fibrosis or Cirrhosis

Numerous drugs and chemicals can cause alcoholic-like quiescent fibrosis or cirrhosis. Classic examples are methotrexate, vitamin A, arsenicals, and vinyl chloride.

binds covalently and highly selectively to nucleophilic cysteinyl thiol groups on proteins and GSH. The hepatocyte normally protects itself by conjugating NAPQI with GSH, and the GSH conjugate ultimately is excreted as mercapturic acid and cysteine derivatives in urine (Fig. 122.2). In addition, NAPQI is reduced back to acetaminophen by protein-SH (thiol) and GSH, forming disulfide, indicating that NAPQI is an oxidant and an electrophile. Hepatocyte injury occurs when hepatic GSH is depleted.

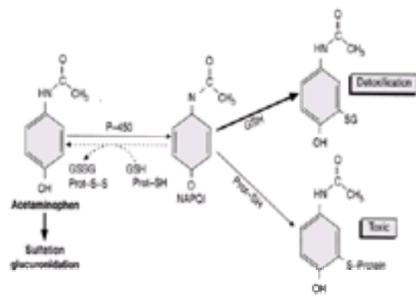

FIGURE 122.2. Hepatic acetaminophen metabolism. (From Kaplowitz N. Drug metabolism and hepatotoxicity. In: Kaplowitz N, ed. *Liver and biliary diseases*. Baltimore: Williams & Wilkins, 1992:673, with permission.)

At least three isoenzymes of cytochrome P-450 oxidize acetaminophen: *CYP2E1*, *CYP1A2*, and *CYP3A4*. The K_m of *CYP3A4* for acetaminophen is low (0.25 mmol per liter, which corresponds to hepatic concentrations of the drug after therapeutic doses), whereas that of *CYP1A2* is high. One study using a bank of human liver microsomal fractions showed that *CYP3A4* contributed between 1% and 20% to total NAPQI formation; *CYP2E1* catalyzed the rest. This explains why long-term ingestion of alcohol (which induces *CYP2E1* and possibly *CYP3A4*) and use of anticonvulsants such as phenobarbital, phenytoin, and carbamazepine (which induce *CYP3A4*) increase susceptibility to acetaminophen hepatotoxicity, but cigarette smoking (which induces *CYP1A2*) does not. The histologic pattern of injury (zone III necrosis) corresponds to the distribution of *CYP2E1*.

There is considerable debate as to how acetaminophen causes cell death. Both covalent binding of NAPQI to critical protein-SH groups and oxidative stress secondary to the electrophilic properties of NAPQI and GSH depletion have been proposed. Covalent binding of NAPQI to critical mitochondrial targets may be responsible for cell death. However, this simply may reflect profound mitochondrial GSH depletion. Mitochondrial GSH is a critical requirement for the detoxification of normally produced oxygen free radicals; therefore, profound mitochondrial GSH depletion predisposes to cell death through oxidative stress. Oxidative stress causes many changes in the cell, but notably causes the oxidation of cysteine residues of many proteins, presumably resulting in their altered function, although the critical protein targets of oxidative attack are largely unknown. Finally, a provocative pathogenetic role for Kupffer cells has been proposed because inhibition of these cells attenuated acetaminophen-induced hepatotoxicity by a mechanism independent of NAPQI production.

Factors Influencing Acetaminophen-Induced Toxicity

Because the oxidation of acetaminophen is a cytochrome P-450-mediated reaction, inducers (e.g., ethanol, isoniazid or phenobarbital) and inhibitors (e.g., cimetidine) of cytochrome P-450 isoenzymes increase or decrease the risk of toxicity, respectively. Conditions decreasing the rate of glucuronidation or sulfation also increase the likelihood of toxicity (e.g., fasting may decrease both). Because hepatic GSH is critical in detoxifying NAPQI, conditions that lower GSH levels (e.g., starvation or chronic alcoholism) predispose to acetaminophen toxicity.

Therapeutic doses of acetaminophen can cause hepatotoxicity in chronic alcoholics. Their increased susceptibility is related to the induction of *CYP2E1* and, possibly, to decreased cytosolic and mitochondrial GSH levels. Even though chronic alcoholics are more susceptible to acetaminophen-induced injury, acute alcohol administration in laboratory animals protects against acetaminophen hepatotoxicity because cytochrome P-450 may metabolize ethanol preferentially over acetaminophen, resulting in the production of less toxic metabolites. In addition, acute ethanol administration may decrease cytochrome P-450 activity by reducing the cellular concentration of NADPH, a required cofactor.

Clinical Presentation

The clinical course of acetaminophen toxicity is fairly predictable, occurring in four phases. In phase 1, acute gastrointestinal tract symptoms begin within a few hours of ingestion. The patient typically has nausea and occasional vomiting and may become moderately obtunded, particularly if sedatives were ingested with the acetaminophen. Phase 2, which lasts about 2 days, begins within 24 hours of ingestion when the nausea and vomiting abate and the patient feels relatively well. During this abatement of symptoms, biochemical evidence of hepatic injury appears; the patient also may experience pain and tenderness in the right upper quadrant and oliguria may develop. During phase 3, 3 to 5 days after ingestion, overt hepatic damage becomes clinically evident. Phase 4, or recovery, occurs in most patients 1 week after ingestion.

Biochemically, acetaminophen hepatotoxicity resembles other forms of acute liver necrosis. Within 24 to 48 hours after acetaminophen overdose, transaminase levels increase up to 10,000 IU per liter, and serum alkaline phosphatase and bilirubin levels rise to a lesser degree. Severe coagulation disturbances occur early in most severe cases. Leukocytosis, hypoglycemia, and metabolic acidosis also may occur. Serum bilirubin levels and prothrombin times are prognostic indicators.

The most important prognostic factor of acetaminophen toxicity is the plasma acetaminophen level, which correlates well with the severity of liver damage. A nomogram of the plasma level of acetaminophen measured 4 to 12 hours after ingestion predicts liver injury. Patients with drug levels above 300 µg per milliliter at 4 hours usually develop overt hepatic damage; those with values below 150 µg per milliliter usually do not. However, this nomogram applies only to single acetaminophen overdoses in nonalcoholics and requires knowledge of the time of ingestion. If the time is unknown, the toxic potential can be estimated by measuring levels 4 hours apart. An acetaminophen level that falls by at least half suggests normal metabolism; slower declines suggest toxic metabolite formation. However, levels may not peak until 4 hours after ingestion. In alcoholic patients with acute liver decompensation, acetaminophen toxicity must be considered in the differential diagnosis, regardless of the acetaminophen level.

Treatment

Treatment begins with gastric lavage in any patient suspected of overdose because gastric atony is common and acetaminophen can be recovered from the stomach even 48 hours after ingestion. This is followed by specific antidote therapy by the oral or intravenous route. *N*-acetylcysteine (Mucomyst) protects against acetaminophen hepatotoxicity by increasing GSH biosynthesis. When patients are treated within 16 hours, mortality is virtually abolished. Although the effectiveness of *N*-acetylcysteine therapy gradually is lost the longer therapy is withheld, benefit may occur even by the fourth day after overdose. This agent should be given to any patient strongly suspected of acetaminophen overdose, regardless of the time of ingestion, to try to abort liver failure.

Of patients who develop acute liver failure, the clinician must identify those likely to die; early referral for emergency hepatic transplantation may be life-saving. Several objective severity scores (e.g. King's or APACHE II) can help identify these patients. Early experience with bioartificial liver devices also suggests that transient support with these devices may allow patients to recover without hepatic transplantation.

HALOTHANE-INDUCED HEPATOTOXICITY

The overall incidence of halothane-induced hepatotoxicity is 1 in 10,000 recipients. However, the risk increases markedly with repeated exposure (1 in 3,000) and is especially high in obese women, perhaps because of the larger doses of halothane that are administered, with accumulation of the anesthetic in adipose tissue. Alternatively, obesity is associated with increased expression of *CYP2E1*, which mediates the oxidation of halothane and the generation of hepatotoxicity.

Mechanism of Injury

Halothane is metabolized by two different cytochrome P-450-mediated reactions (Fig. 122.3). With high O_2 , halothane is oxidized to a trifluoroacetylhalide that can acetylate protein amino groups and induce an immune response. With low O_2 , halothane undergoes reductive metabolism, generating a free radical that can cause lipid peroxidation. Toxicity appears to be immune-mediated. Fever, eosinophilia, and accelerated response after repeated exposure suggest a hypersensitivity reaction. Furthermore, circulating antibodies in patients recovering from halothane hepatotoxicity recognize trifluoroacetylated proteins (products of oxidative metabolism) and some nontrifluoroacetylated native proteins on the cell surface and in the microsomal fraction of hepatocytes. Antibody-dependent cell-mediated cytotoxicity has been demonstrated in vitro. Trifluoroacetylated microsomal proteins occur in all recipients of halothane, but overt liver disease is rare. Which of these proteins are antigenic and what determines autoimmunity are unknown.

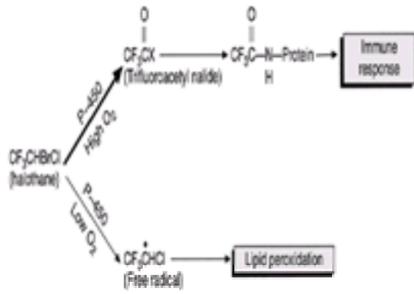

FIGURE 122.3. Oxidative and reductive halothane metabolism. (From Kaplowitz N. Drug metabolism and hepatotoxicity. In: Kaplowitz N, ed. *Liver and biliary diseases*, Baltimore: Williams & Wilkins, 1992:673, with permission.)

Clinical Presentation

Fever, an early sign of halothane hepatotoxicity, almost always precedes jaundice. Symptoms usually appear within 7 to 14 days after initial exposure, but within 12 to 24 hours after subsequent exposures. Jaundice appears within 10 to 14 days. A diffuse rash erupts in 10% of patients, and about 30% have myalgia. Rapid progression to fulminant liver failure occurs in some patients, requiring liver transplantation. No specific treatment is available other than general supportive care and, in fulminant cases, liver transplantation.

DIAGNOSIS AND TREATMENT OF DRUG-INDUCED HEPATIC INJURY

Drug-induced hepatic injury must be considered in any patient with acute or chronic hepatobiliary disease. A complete drug history, including prescription and nonprescription drugs (including vitamins and herbs), is essential. A history of any anesthetic exposure and the patient's reaction should be obtained. Signs of hypersensitivity such as fever, rash, and eosinophilia are particularly helpful. The development of symptoms within days or weeks of starting therapy with a new medication may suggest an acute drug reaction, especially when a rapid fall of more than 50% in transaminase levels follows its discontinuation. However, although some drugs induce hepatotoxicity soon after initiation (within 1 month with phenytoin and allopurinol), others have a long latency period (isoniazid and methotrexate). In addition, some drugs have delayed toxicity, developing after discontinuation. Liver histology usually is not diagnostic but may provide useful prognostic information in fulminant hepatitis.

In most cases, the only required therapy is withdrawal of the offending agent (except in acetaminophen hepatotoxicity, which has a specific antidote). Patients with fulminant liver failure may require liver transplantation. The efficacy of corticosteroids in patients with hypersensitivity has not been demonstrated, although they may suppress the marked features of systemic hypersensitivity associated with idiosyncratic reactions due to drugs such as allopurinol, diclofenac, and azulfidine.

Rechallenge with the offending agent would provide the most conclusive proof of drug toxicity, but should be avoided because it could be dangerous in patients with hypersensitivity-mediated injury. Often, patients are rechallenged inadvertently, so a careful review of the medical history may be valuable. Nevertheless, on occasion, the risk of rechallenge must be weighed against the potential therapeutic benefits of the drug. If rechallenge is considered, patients should be tested with a small initial dose and watched closely for the development of any sign of hepatic injury. Alternatively, studies of the effect of the drug on the in vitro integrity of lymphocytes from patients thought to have hypersensitivity drug reactions may prove promising. With improved understanding of the mechanisms of toxicity, the genetic polymorphism of key enzymes involved in biotransformation, and determinants of individual variability, methods soon may be developed to identify individuals who are susceptible to drug toxicity.

Although monitoring serum biochemical markers for liver injury would increase the detection of drug-induced hepatic injury, cost-benefit analysis does not justify its use in otherwise healthy persons. However, it may be reasonable to monitor groups of patients at special risk, such as those with alcoholic liver disease who are taking potentially hepatotoxic drugs (e.g., isoniazid, amiodarone, valproic acid, or methotrexate). The best way to prevent drug-induced hepatotoxicity is to teach clinicians to weigh the risks before prescribing drugs and to search for drug hepatotoxicity in any patient in whom liver disease develops.

CHAPTER 123: METABOLIC, GRANULOMATOUS, AND INFILTRATIVE DISORDERS OF THE LIVER

BRUCE R. BACON

[Hereditary Hemochromatosis](#)
[Wilson's Disease](#)
[Alpha₁-Antitrypsin Deficiency](#)
[Nonalcoholic Steatohepatitis](#)
[Hepatic Porphyrrias](#)
[Granulomatous Hepatitis](#)
[Hepatic Amyloidosis](#)
[Storage Disorders](#)

There are several metabolic diseases of the liver that should be understood by all physicians. In addition, granulomatous and infiltrative disorders of the liver must be well characterized because there may be specific treatments available. This chapter provides clarification of these disorders and recommendations for definitive diagnosis and management. [Table 123.1](#) summarizes the features of these disorders.

Disease	Prevalence	Laboratory Tests	Liver Biopsy	Treatment
Hereditary hemochromatosis	1 in 200	Transferrin saturation, ferritin, <i>HFE</i> mutation analysis	Iron, often necessary	Therapeutic phlebotomy
Wilson disease	1 in 8,000	Ceruloplasmin, 24-hour urine copper	Copper, usually necessary	Copper chelation
Alpha ₁ -antitrypsin deficiency	1 in 1,700	AAT level, R typing, <i>PIZZ</i>	AAT protein, usually necessary	Transplantation
Porphyria cutanea tarda	Uncommon	Urine porphyrins, <i>HFE</i> , anti- <i>HCV</i>	May be helpful	Phlebotomy, avoidance of alcohol, estrogen
Nonalcoholic steatohepatitis	Common	ALT > AST	Necessary	Weight loss, control of diabetes
Granulomatous hepatitis	Rare	Variable	Necessary	Corticosteroids, prednisone
Hepatic amyloidosis	Rare	Variable	Necessary	None
Storage disease	Rare	Variable	May be necessary	Enzyme replacement

ALT, α -antitrypsin; *HFE*, hereditary hemochromatosis; *HCV*, hepatitis C virus; *AST*, aspartate aminotransferase; *PIZZ*, null allele.

TABLE 123.1. EVALUATION FOR METABOLIC OR INFILTRATIVE LIVER DISEASE

HEREDITARY HEMOCHROMATOSIS

Hereditary hemochromatosis (HH) is a common disorder of iron metabolism affecting approximately 1 in 200 to 400 individuals of northern European descent. HH results in increased absorption of iron from the proximal intestine, with deposition of iron in the liver, heart, pancreas, joints, skin, and endocrine organs. Complications of chronic liver disease, including hepatocellular cancer, can lead to premature death.

Methods are now available to detect HH in asymptomatic probands and in presymptomatic relatives of patients with the disease; therefore, the diagnosis can be applied legitimately to individuals who have not yet experienced any of the toxic consequences of iron overload in tissues. Accordingly, the diagnosis should not be confined only to those individuals who are symptomatic or who manifest evidence of organ damage, such as cirrhosis, diabetes, heart failure, arthritis, or skin pigmentation. Instead, all individuals who have inherited both alleles of the mutant hemochromatosis gene (*HFE*) and who have direct or indirect markers of iron overload should be regarded as homozygous for HH.

In 1996, the gene for hemochromatosis was identified and ultimately called *HFE*. *HFE* encodes for a major histocompatibility complex class I–like molecule that requires interaction with β_2 -microglobulin for normal presentation to the surface of cells and binds with transferrin receptor. Two missense mutations have been identified in *HFE*. One results in a change of cysteine to tyrosine at amino acid position 282 (C282Y); the second results in a change of histidine to aspartate at amino acid position 63 (H63D). Approximately 85% to 90% of typical hemochromatosis patients are homozygous for C282Y. Compound heterozygotes are those patients who have one allele with the C282Y mutation and one allele with the H63D mutation. Approximately 3% to 5% of typical hemochromatosis patients are compound heterozygotes, but not all compound heterozygotes experience significant degrees of iron loading. About 10% of patients who have a clinical syndrome that is phenotypically identical to HH do not have the C282Y mutation. These patients may have another condition causing iron overload, or they may have inherited another genetic abnormality.

HH is underdiagnosed, largely because physicians often think that it is a rare disorder manifested only by the classic triad of clinical findings consisting of increased skin pigmentation, diabetes, and cirrhosis (so-called bronze diabetes). In the 1990s, HH increasingly was identified by the evaluation of patients with abnormal iron results on routine serum chemistry panels or on screening iron studies for patients with a family history of HH. When patients are identified in this way, approximately 75% of them are without symptoms and do not exhibit any of the end-stage manifestations of hemochromatosis. Very few of these individuals have diabetes, cirrhosis, skin pigmentation, or arthropathy. About 25% of them have fatigue that improves with treatment. Because HH is a common disorder, it is important for clinicians to realize that any patient with an elevated transferrin saturation and/or an elevated ferritin level (see later discussion) might have HH.

When patients experience symptoms of fatigue, right-upper-quadrant abdominal pain, arthralgias, impotence, decreased libido, heart failure, or diabetes, the clinician should consider the possibility of HH. Similarly, findings of hepatomegaly, cirrhosis, extrahepatic manifestations of chronic liver disease, testicular atrophy, congestive heart failure, skin pigmentation, and arthritis should raise the suspicion of HH. Obviously, many of these symptoms and signs are indicative of a variety of medical illnesses, but HH should be part of the differential diagnosis.

Once the diagnosis of HH is considered—by evaluation of abnormal screening iron studies, in the context of family studies, in a patient with abnormal results on genetic testing, or in the evaluation of a patient with any of the cited symptoms or clinical findings—definitive diagnosis is relatively straightforward. To diagnose HH, fasting transferrin saturation (TS, serum iron \div by total iron binding capacity or transferrin \times 100%) and ferritin levels should be obtained; both will be elevated in a symptomatic patient. TS should be measured in a fasting state, since serum iron levels have a diurnal variation and can be higher after a meal. Unfortunately, the diagnostic sensitivity and specificity of the TS and ferritin levels can be questionable when young individuals are being evaluated or when patients have abnormal results of iron studies in the context of other diseases. The advent of genetic testing (mutation analysis for C282Y and H63D in *HFE*) has helped clarify this situation. Thus, if TS and/or ferritin levels are elevated, then *HFE* mutation analysis should be carried out. If the patient is less than 40 years old, with normal liver enzyme levels but abnormal iron study results, and is homozygous for C282Y or compound heterozygous, then he or she should be considered to have HH and treated accordingly ([Fig. 123.1](#)). If the patient is older than 40 years or has abnormal liver test results, regardless of *HFE* test results, he or she should undergo percutaneous liver biopsy for histologic interpretation and quantitative iron studies. Once the diagnosis of HH is confirmed either by genetic studies or by liver biopsy [more than 3+ iron stores, increased hepatic iron concentration, and/or hepatic iron index (measured as micromoles of iron per gram dry weight of liver divided by the patient's age)], treatment for HH should be commenced.

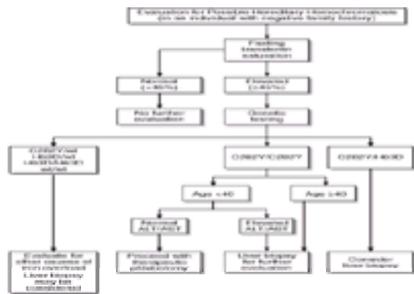

FIGURE 123.1. Proposed algorithm for evaluation for hereditary hemochromatosis.

Treatment is weekly (or occasionally biweekly) therapeutic phlebotomy of 500 mL of whole blood. This is equivalent to approximately 200 to 250 mg of iron, depending on the hemoglobin concentration of the blood removed. Therapeutic phlebotomy is typically continued until the transferrin saturation is less than 50% and/or serum ferritin levels are less than 50 ng/mL. Most patients tolerate therapeutic phlebotomy quite well and have a sense of improved well-being after the initial phlebotomies have been completed. Once excess iron stores are depleted, therapeutic phlebotomy is replaced by maintenance phlebotomy of 1 u of blood, removed every 2 to 3 months for the patient's lifetime. If treatment is initiated before complications of liver disease ensue, the prognosis is excellent and equal to an age- and sex-matched population. Family screening of all first-degree relatives should be done once a proband is identified. *HLA* typing is no longer used for family screening; instead, mutation analysis for C282Y and H63D in *HFE* is recommended.

WILSON'S DISEASE

Wilson's disease (WD) is a rare inherited disorder that occurs in 1 in 30,000 individuals. In WD, copper accumulates in the liver and brain in excess of normal metabolic needs. The defect in copper homeostasis in WD that leads to copper accumulation is a reduction in the biliary excretion of copper. Unrecognized and untreated, this disorder is progressive and fatal, with death due to neurologic deterioration and complications of end-stage liver disease. Patients can show signs of disease in childhood, adolescence, or young adulthood, among them, abnormal liver enzymes, complications of chronic liver disease, hemolytic anemia, or a variety of neurologic and neuropsychiatric disturbances. The diagnosis is established by a combination of clinical and biochemical findings. Copper deposition in Descemet's membrane in the periphery of the cornea shows characteristic Kayser-Fleischer rings. Laboratory studies show a decreased level of ceruloplasmin in approximately 85% of patients, and urinary copper excretion is elevated. Liver enzymes (alanine aminotransferase, aspartate aminotransferase) are typically high, and biochemical and hematologic signs of chronic liver disease (hypoalbuminemia, thrombocytopenia, elevated prothrombin time) can be present. Liver biopsy can show a rise in the level of copper using a variety of special stains; this increase in hepatic copper level (determined biochemically) is necessary for diagnosis. Hepatic steatosis is seen in early-stage disease; changes of chronic hepatitis occur later, and then cirrhosis develops. A small number of patients with WD have initial signs of fulminant hepatic failure, which is uniformly fatal unless emergency liver transplantation is successful.

Once the diagnosis is established (characteristic history, low ceruloplasmin level, increased urinary copper excretion, liver biopsy findings, elevated hepatic copper level), treatment of WD usually is initiated with copper chelation therapy using D-penicillamine. Side effects from D-penicillamine can occur, and some patients are better treated with trientine, another copper-chelating drug. The use of dietary zinc supplementation can impair the absorption of copper and also can induce metallothionein synthesis, which binds copper in the gut, decreasing the amount of copper that is absorbed. The gene for WD (called *ATP7B*) has been identified and codes for a P-type ATPase transmembrane protein that is involved in membrane copper transport. In contrast to the use of genetic markers for the diagnosis of hemochromatosis, the same opportunity does not exist for diagnosing WD, since there are more than 60 mutations in the WD gene. Thus, mutation analysis has not been considered practical. If WD is diagnosed before hepatic and neurologic complications ensue and lifelong copper chelation therapy is instituted, the prognosis is excellent. Family screening of all first-degree relatives should be undertaken when a proband is identified. In this situation, genetic testing with mutation analysis may be helpful; serum ceruloplasmin levels and urinary copper excretion should be evaluated.

ALPHA₁-ANTITRYPSIN DEFICIENCY

Alpha₁-antitrypsin (A1AT) deficiency is a relatively uncommon autosomal disease predominantly seen in Whites, which can cause pulmonary disease or hepatic disease. A1AT is a normally occurring inhibitor of proteases and elastases that is synthesized predominantly by the liver. Structural variance of A1AT is classified according to the protease inhibitor (Pi) phenotype system, as defined either by agarose electrophoresis or isoelectrofocusing. The Pi classification system assigns a letter to each position of migration of A1AT in these gel systems, using alphabetical order for low to high isoelectric point. The most common normal variant migrates to an intermediate isoelectric point, which has been designated "M." Individuals with the most common severe deficiency have an A1AT allelic variant that migrates to a high isoelectric point, which has been designated "Z." More than 75 different allelic variants have been reported. In homozygous PiZZ A1AT deficiency, which affects approximately 1 in 1,600 to 1,800 individuals, there is a single amino acid substitution (Glu 342 @ Lys); this amino acid substitution results in the selective accumulation of an abnormally folded A1AT molecule within the endoplasmic reticulum of hepatocytes. Accumulation of A1AT in the endoplasmic reticulum of hepatocytes is thought to be related directly to subsequent liver injury; however, only about 20% of PiZZ individuals go on to show signs of significant liver disease. This may be due to a second abnormality in those individuals who show signs of disease—an alteration in intracellular degradation of the mutant A1AT protein.

Patients with A1AT deficiency initially may have elevated liver enzymes, signs of advanced liver disease, or early-onset chronic obstructive pulmonary disease. Diagnosis is made by measuring serum A1AT levels and by Pi typing. Liver biopsy can show changes of chronic hepatitis or may show only "bland" cirrhosis. On hematoxylin and eosin stains, reddish globules are found in hepatocytes at the periphery of cirrhotic nodules. Glycogen can form globules similar in appearance, but with period acid–Schiff (PAS) staining with diastase (which digests the glycogen), the inclusions due to A1AT remain. Thus, liver biopsy has characteristic "PAS-positive, diastase-resistant" inclusions. These inclusions are collections of A1AT that have not been excreted by the hepatocyte. For pulmonary disease due to A1AT, infusion of purified, plasma A1AT has been shown to be beneficial in limiting the rate of progression of lung disease. For liver disease due to A1AT, there is no specific therapy short of liver transplantation. If liver transplantation is carried out, the recipient assumes the A1AT phenotype of the donor. Once a proband with A1AT is identified, family screening should be undertaken. This is largely done to educate patients, because specific therapy is not available. In light of the fact that only about 20% of PiZZ individuals go on to experience liver disease due to A1AT, it is not clear how to evaluate siblings or children of individuals with A1AT what the nature of their risk of disease might be. While there are no clear-cut guidelines, simple screening with A1AT levels and Pi phenotype seems reasonable.

NONALCOHOLIC STEATOHEPATITIS

One of the most common causes of liver test abnormalities is the condition known as nonalcoholic steatohepatitis (NASH). The diagnosis of NASH is based on liver biopsy findings, which are similar to those seen in alcoholic hepatitis, and include steatosis, mixed inflammatory cell infiltration of the hepatic lobule, Mallory's hyalin, and perisinusoidal fibrosis that can progress to cirrhosis. The recognition of NASH as a diagnostic entity has evolved over the past 20 years as our understanding of liver disease in general has advanced. The pathogenetic basis of NASH is not known, but the disorder frequently is seen in obese, diabetic women, and the possibility of insulin resistance in a large proportion of patients has been considered. The diagnosis of NASH can be established only in the context of a carefully conducted clinical history, the most important feature of which is the exclusion of significant alcohol consumption. Thus, if patients consume more than 20 g of ethanol daily, it is inappropriate to consider a diagnosis of NASH; in this context, a diagnosis of alcoholic steatohepatitis is reasonable. In any patient with biochemical evidence of chronic liver injury, it is important to pursue the dietary history, the use of various medications, possible occupational exposure to toxins or solvents, and a family history of liver disease.

Liver biopsy is essential for the diagnosis of NASH and should be conducted for patients with unexplained elevations of liver enzymes unless there is reason to believe that a medication or an environmental factor is responsible, in which case, a diagnostic trial of avoidance is reasonable. The steatosis of NASH is typically macrovesicular. To actually visualize the fat, a frozen section must be stained with a fat-specific stain, such as oil red O. Involvement of hepatic lobules can be diffuse or localized to the centrilobular region. Inflammation is considered a necessary component of the biopsy findings in NASH. It is typically low grade and consists of a mixed neutrophilic and mononuclear cell infiltrate throughout the lobule. Glycogen nuclei are seen frequently, and Mallory's hyalin, which is usually less impressive than that seen in alcoholic liver disease, is present. Fibrosis typically occurs in the pericentral regions and is perisinusoidal; in more advanced cases, it can lead to

the development of fully established cirrhosis.

Many patients who have NASH are asymptomatic and are identified in the process of an evaluation of abnormal liver enzymes. When patients are symptomatic, fatigue and vague right-upper-quadrant pain are most common. Similarly, physical examination findings frequently can be normal or show a slight increase in liver size and right-upper-quadrant tenderness with palpation. Changes of chronic liver disease (cutaneous manifestations) with portal hypertension are evident in advanced cases. Laboratory studies confirm elevated liver enzymes, typically with the alanine aminotransferase (ALT) being higher than the aspartate aminotransferase (AST) level. This is a useful feature distinguishing NASH from alcoholic liver disease—where the AST is typically higher than the ALT level. In the absence of advanced liver disease, serum albumin levels and bilirubin levels are normal. Gamma-glutamyltranspeptidase (GGT) levels are often elevated in patients with NASH. As mentioned previously, liver biopsy is necessary to establish a diagnosis in a suspect individual. Ultrasonography and abdominal computed tomography scanning can show images suggestive of fatty infiltration of the liver, but an assessment of fibrosis and/or severity is not possible.

The natural history of NASH is poorly understood, but generally it is thought that NASH can be a progressive disease leading to cirrhosis and liver failure in about 15% of cases. Because of this concern for disease progression, there has been growing interest in treatment over the past several years. Certainly, weight loss and control of serum glucose are recommended in the case of individuals who are overweight and/or diabetic. Patients with hyperlipidemia are urged to limit cholesterol and triglycerides with diet and/or lipid-lowering agents. Since the pathogenesis of NASH is so poorly understood, more specific therapy does not exist. Some investigators have tried vitamin E or ursodeoxycholic acid, with inconclusive results.

HEPATIC PORPHYRIAS

There are several types of porphyria that are broadly classified as *hepatic* or *erythropoietic*, based on the organ in which the major overproduction of heme precursors takes place. Alterations in various steps in the heme biosynthetic pathway can occur, causing each of the various types of porphyria. The most common hepatic porphyria is porphyria cutanea tarda (PCT); three subtypes have been identified. Of these subtypes, the most common, which makes up about 75% of cases, is provoked by an acquired or sporadic, and reversible, form of deficiency of hepatic uroporphyrinogen decarboxylase activity. Clinical findings of PCT include photosensitivity, usually on the sun-exposed areas of the hands and face, marked by blistering and ulcerating lesions. These lesions often are found in association with increased alcohol ingestion, mild to moderate iron overload, or, in women, exogenous estrogen use. Diagnosis is made by recognition of the characteristic skin lesions and by detection of increased amounts of uroporphyrins excreted in the urine.

Approximately 50% of PCT patients in North America have hepatitis C, and about 30% to 50% of PCT patients have one or both of the mutations found in the hemochromatosis gene, *HFE*. Thus, when a patient with PCT is identified, testing for anti-hepatitis C virus and mutation analysis for *HFE* should be carried out in addition to evaluating liver function. Liver biopsy usually is undertaken in patients with PCT, and characteristic abnormalities have been defined. Treatment consists of abstinence from alcohol, discontinuation of estrogens or other medications that have been shown to exacerbate porphyria, and therapeutic phlebotomy to lessen hepatic iron stores. Skin lesions usually respond to these measures, and if liver enzymes are elevated, improvement usually ensues. If hepatitis C is present, consideration should be given to antiviral treatment.

GRANULOMATOUS HEPATITIS

There are a number of sources of granulomatous reaction in the liver, the most important of which are the hepatic manifestations of sarcoidosis, certain drug reactions (e.g., allopurinol), and infections either with tuberculosis or with various fungi. Some patients with sarcoidosis can experience systemic symptoms of fever, weight loss, malaise, and fatigue, and liver tests show cholestatic enzyme abnormalities with a predominant increase in alkaline phosphatase and GGT activity. Liver biopsy shows noncaseating granulomata that have features characteristic of sarcoidosis. Occasionally, fibrosis is progressive, and cirrhosis with liver failure develops, though this is uncommon. Indication for treatment of granulomatous hepatitis with glucocorticoids depends on the presence of progressive fibrosis. It is critical that infectious causes of granulomatous infiltration be ruled out by tissue culture, by special stains for acid-fast bacilli (AFB) and for fungi, and by appropriate clinical evaluation.

HEPATIC AMYLOIDOSIS

Infiltration of the liver with amyloid is a complication of systemic amyloidosis and can be an end-stage manifestation of the disease. Symptoms of weakness, increased fatigue, weight loss, and joint pain are present. Liver test parameters (ALT, AST) may be slightly high or normal. The liver typically is enlarged, often massively, and signs of portal hypertension may be evident. In the past, liver biopsy was considered quite risky because of the concern of increased bleeding due to “hepatic fracture,” but this complication has become less of a concern. Liver biopsy shows an amorphous infiltration of the protein in the perisinusoidal space of Disse, and special stains (Congo red) confirm the presence of amyloid. There is no specific treatment for hepatic amyloidosis, and the prognosis is very poor.

STORAGE DISORDERS

There are more than 40 distinct genetic diseases that can produce lysosomal storage disorders. Most are inherited in an autosomal recessive manner and are rare. Specific genetic deficiencies of particular lysosomal proteins have been identified for each disorder. Different phenotypic expression is related to various mutations in specific genes. The lysosomal storage diseases as a whole are found in approximately 1 per 8,000 births. Gaucher's disease is the most common, with a prevalence of approximately 1 per 60,000 births. In the Ashkenazi Jewish population, however, the prevalence of Gaucher's disease may be as high as 1 in 900. The typical clinical manifestations of Gaucher's disease are massive hepatomegaly with complications of portal hypertension. Onset is usually in childhood or early adulthood, and disease severity can vary considerably. In Gaucher's disease, there is a defect in b-glucocerebrosidase, which is required to catalyze the cleavage of glucocerebroside to glucoceramide. Deficiency results in the accumulation of glucocerebroside in tissue macrophages, which are known as Gaucher cells, with subsequent toxicity to these tissues. Affected macrophages are present in the liver in Kupffer cells, in the bone in osteoclasts, and in the spleen and lung. Complications of chronic liver disease can develop and cause premature death. Diagnosis is by clinical history, family history, and typical glucocerebroside-packed Gaucher macrophages seen either in the bone marrow or on liver biopsy. Treatment is largely symptomatic, but enzyme replacement therapy has been used and provides some benefit. This treatment is extremely expensive—a year of therapy costs more than \$200,000. Advances in molecular genetics will help diagnosis this disorder early, and treatment may become less expensive.

CHAPTER 124: GALLSTONES AND CHOLECYSTITIS

JOHN H. SEKIJIMA AND SUM P. LEE

[Incidence and Epidemiology](#)
[Etiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Treatment Options](#)
[Optimal Management](#)

INCIDENCE AND EPIDEMIOLOGY

Cholelithiasis is a very common disorder in the United States, and it is estimated that more than 20 million Americans are afflicted with gallstones. Moreover, by age 75 approximately 35% of women and 20% of men have or have had gallstones. Although the majority of these individuals are asymptomatic, nearly 750,000 cholecystectomies are carried out each year, and there are 5,000 to 6,000 deaths annually as a direct result of gallstone-related disease.

Around the world, the prevalence rates for cholelithiasis vary widely depending on the specific geographic location and ethnic factors under consideration. Much of the data has been derived from either autopsy studies or screening ultrasonography surveys. Native Americans, in general, and the Pimas of southwestern North America, in particular, have extraordinarily high rates of gallstone formation, such that by age 30 approximately 70% of the women have had stones. Impressive prevalence rates are also seen in Chile, the United States (among whites), and northern Europe. Much lower rates are reported from Asia and Africa.

ETIOLOGY

In the United States, as in other Western countries, cholesterol stones comprise at least 75% to 80% of all gallstones, while the remainder are classified as pigment stones. Most cholesterol stones contain between 50% and 90% cholesterol in total weight. Some analyzed stones, however, are strikingly pure in cholesterol (more than 95%). Calcium salts of bilirubin pigment, carbonate, and various proteins account for the bulk of the remaining content. Risk factors for cholesterol lithogenesis include obesity, rapid weight loss, spinal cord injury, female gender (male to female ratio, 2:1), and, to a lesser extent, parity and estrogen use ([Table 124.1](#)). Pigment stones are categorized as either black or brown, depending on their chemical composition and gross appearance. These stones also differ with respect to their pathogenesis and associated clinical manifestations. [Table 124.1](#) lists the conditions believed to be risk factors for pigment lithogenesis.

Cholesterol Gallstones	Pigment Gallstones
Obesity	Black
Ileal resection or disease	Chronic hemolysis
Pregnancy	Cirrhosis
Rapid weight loss	Total parenteral nutrition
Female gender	Advancing age
Spinal cord injury	Brown
Drugs: estrogens, clofibrates	Chronic biliary infection
Advancing age	Biliary strictures and stasis
Cystic fibrosis	

TABLE 124.1. CONDITIONS PREDISPOSING TO GALLSTONE FORMATION

PATHOGENESIS OF CHOLESTEROL STONES

Cholesterol Solubilization

Cholesterol-enriched bile may be produced by absolute cholesterol hypersecretion or a diminished bile acid pool resulting from primary bile acid hyposecretion or intestinal losses. Previously, it was thought that biliary cholesterol was packaged and solubilized by bile salts and phospholipid cholesterol exclusively in the form of mixed micelles, and much attention was focused on the rigorous physicochemical characterization of these micellar structures. It has become clear that biliary lipid vesicles also play an important role in the solubilization of cholesterol. Collectively, these unilamellar vesicles, which range in size from 40 to 100 nm, are believed to represent the primary mode of cholesterol secretion into bile. Evidence suggests that biliary vesicles initially are constructed within the hepatocyte and consist of phospholipid and cholesterol. Once the vesicles are secreted into the canaliculi, bile salts adsorb onto them and remove or strip away phospholipid and cholesterol to form mixed micelles. Two distinct cholesterol transport systems (vesicular and micellar) apparently coexist in bile in a state of dynamic equilibrium. This lipid interchange is thought to take place throughout the biliary apparatus. When the bile salt concentration is dilute (hepatic bile), relatively more cholesterol is carried in the vesicular phase. Conversely, when the bile salt concentration is at its peak (gallbladder bile), a micellar shift is favored.

Nucleation of Cholesterol Crystals

The critical emergence and precipitation of solid cholesterol crystals from supersaturated bile is termed *nucleation*. This fascinating process appears to begin with the aggregation and fusion of unilamellar biliary vesicles into multilamellar liposomes. These multilamellar structures are birefringent and compressible under polarizing light microscopy and are referred to as *liquid crystals*. Under video-enhanced microscopy, solid cholesterol crystals appear to originate directly from aggregated or fused vesicles.

Not all vesicle populations have an equal propensity to participate in nucleation, however. Vesicles in gallbladder bile are observed to nucleate more readily than vesicles in dilute hepatic bile, which seem to be stable and fairly resistant to nucleation. This phenomenon can be explained in part by the differences in their respective cholesterol/phospholipid contents. In the concentrated environment of the gallbladder, bile salts remove preferentially greater amounts of vesicular phospholipid than cholesterol during the shift to the micellar phase. This results in a residual vesicle fraction that is relatively cholesterol enriched compared with phospholipid and therefore more likely to aggregate, fuse, and nucleate.

The importance of cholesterol supersaturation in bile to the process of nucleation cannot be overstated. It has long been recognized, however, that many individuals secrete cholesterol-saturated bile but never show signs of gallstones. Gallbladder bile harvested from patients with cholesterol stones was shown to nucleate crystals more rapidly than equally saturated bile taken from control subjects. These observations led investigators to search for factors in bile that can affect nucleation. Mucin and α_1 -acid glycoprotein exhibit pronucleating properties, while immunoglobulin A, and apolipoproteins A1 and A11 are putative inhibitors. Efforts to purify other agents and to characterize their mechanisms of action are ongoing.

The striking variation in gallstone prevalence rates around the world and the identification of lithogenic genes in an inbred mouse model highlight the importance of genetic risk factors. Moreover, the apolipoprotein E-4 genotype in humans is associated with biliary cholesterol hypersecretion, rapid nucleation, and stone formation. Additional factors, such as infection, also may be important, since bacterial DNA now has been identified within cholesterol stones through molecular analyses. The precise role of bacterial infection in cholesterol lithogenesis remains unknown.

Biliary Sludge

No discussion on the pathogenesis of gallstone formation would be complete without addressing the relevance of biliary sludge. Such descriptive labels as microlithiasis, microcrystalline disease, and biliary gravel or sand have been attached to this entity. Biliary sludge is detected most often by ultrasonography. It may layer dependently within the gallbladder but, by definition, does not produce the postacoustic shadows that are pathognomonic of typical stones (Fig. 124.1). The chemical composition depends on the underlying clinical condition, but it typically consists of a conglomeration of calcium bilirubinate granules, cholesterol monohydrate crystals, and matrices of mucous gel in varying proportions. Sludge is believed to be a precursor of lithogenesis and is associated with many of the same risk factors as gallstones (Table 124.1). Other predisposing factors include bone marrow or solid organ transplantation as well as prolonged courses of ceftriaxone or octreotide medications.

FIGURE 124.1. Ultrasonographic study showing tumefactive sludge within the gallbladder. Note the ball-like concretions of sludge that do not produce postacoustic shadows.

On prospective ultrasonography, gallbladder sludge can be documented to resolve spontaneously, to come and go over time, or to result in macroscopic stone formation. Although most patients remain clinically well, some unpredictably have signs and symptoms of disease. Sludge has been implicated convincingly as a cause of classic biliary pain, acute cholecystitis, and acute pancreatitis. Moreover, a normal result on gallbladder ultrasound does not exclude sludge as a cause of pancreaticobiliary disease. Bile microscopy is crucial in this context. Intravenous cholecystikinin (0.05 to 0.1 mg per kilogram) is given, and 5 to 15 mL of dark green gallbladder bile is aspirated from the duodenum at endoscopy or via a nasoduodenal tube. The sample is centrifuged at 3,000 g for 15 minutes, and the sediment is suspended in 1 mL of distilled water and examined under a polarizing microscope. The findings of birefringent rhomboid plates typical of cholesterol crystals or reddish brown clumps of calcium/bilirubinate precipitates confirm the diagnosis of microscopic sludge. In these situations, biliary sludge can be treated as a gallstone equivalent, and, if there are no contraindications, cholecystectomy should be recommended.

Stone Formation

The spontaneous formation of biliary sludge or cholesterol gallstones is a multistep process in which several conditions and events are operative. At some point, the cholesterol concentration in bile must exceed the capacity of bile salts and phospholipid to hold it in solution. This results in the storage of gallbladder bile that is rich and supersaturated with cholesterol. As the bile is progressively concentrated, biliary vesicles aggregate and fuse into larger multilamellar vesicles. Crystals then begin to emerge when the balance of nucleator and antinucleator activity favors solid crystal formation (Fig. 124.2). The cholesterol crystals, along with precipitates of calcium bilirubinate pigment and viscoelastic gels of mucus, must be kept sequestered within the gallbladder. Gallbladder stasis is probably critical at this stage, and over time the retained sludge contents may evolve to form a solid concretion or stone.

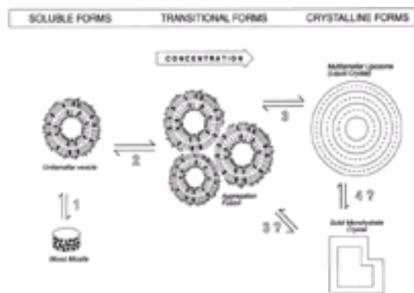

FIGURE 124.2. Schematic representation of cholesterol nucleation, as previously used.

PATHOGENESIS OF PIGMENT STONES

The pathogenesis of pigment stones remains incompletely understood, but some degree of elevation in the level of biliary unconjugated bilirubin appears to be important. Like cholesterol, bilirubin is essentially insoluble in water and must be glucuronidated to be secreted in bile. Disease states or disorders that lead to the handling of increased total bilirubin loads or to enzymatic hydrolysis of conjugated bilirubin to insoluble pigment raises the risk of pigment lithogenesis.

Black stones are formed within the gallbladder and often are associated with chronic hemolytic disorders. They are encountered more commonly in Western countries and are reported with increased frequency in patients with cirrhosis and those receiving long-term total parenteral nutrition. On gross inspection, black stones tend to be somewhat amorphous and easy to crush or fragment. From a biochemical perspective, they are believed to be composed primarily of bilirubin polymers, mucin glycoprotein, and calcium salts of phosphate and carbonate.

Brown stones consist of concentric layers of calcium bilirubinate alternating with complexes of calcium and fatty acids, such as palmitate. The pathogenesis likely involves some degree of biliary stasis and infection. Chronic bacterial infection is believed to be responsible for elevated activity levels of β -glucuronidases in bile. These enzymes may predispose to stone formation by cleaving glucuronic acid moieties from conjugated bilirubin. This results in a greater accumulation of unconjugated bilirubin, which may precipitate in bile as a calcium salt.

Brown stones rarely are found in the gallbladder, and in Western countries they are thought to form *de novo* in the common bile duct after cholecystectomy. In Asia, where they are encountered more often, they are found primarily within the intrahepatic ducts. Associated bile duct strictures and focal areas of marked dilatation and stasis often are described. Moreover, bouts of cholangitis have led to the use of such descriptive terms as *recurrent pyogenic cholangitis* or *oriental cholangiohepatitis*. Biliary cirrhosis and end-stage liver disease also may evolve as the result of the chronic and, at times, relentless nature of the disease.

CLINICAL FINDINGS

ASYMPTOMATIC STONES

The majority of gallstones remain clinically silent. In a long-term follow-up of asymptomatic gallstone patients, the cumulative risk that symptoms will develop over time was 10% at 5 years, 15% at 10 years, and 18% at 15 years. Put another way, the rates of biliary pain are approximately 1% to 2% per year soon after the diagnosis of cholelithiasis, and they appear to decline over time. Moreover, the appearance of a benign warning pain precedes the occurrence of serious complications in more

than 90% of cases.

BILIARY COLIC

Classic biliary colic represents a discrete episode of steady, severe pain, typically located in the epigastrium or right-upper quadrant. It may radiate into the back or right shoulder region but usually does not fluctuate, as implied by the term *colic*. In general, the pain comes on rapidly, lasts from 30 minutes to 3 hours, and gradually subsides. Benign biliary colic is not associated with fever, leukocytosis, or acute peritoneal signs. The presence of these symptoms or biliary pain lasting longer than 4 to 6 hours should raise the suspicion of acute cholecystitis. On occasion, it may be difficult to differentiate biliary colic from cardiac chest pain or other intra-abdominal processes. Taking a careful history is absolutely critical, since an accurate description of the quality and character of the pain often is the only criterion on which to base the decision to operate. Moreover, an ill-advised cholecystectomy for atypical or vague symptoms frequently will result in the postoperative appearance of identical complaints.

True attacks of biliary pain should be distinguished from dyspeptic symptoms, such as belching, epigastric burning, bloating, heartburn, flatulence, and fatty food intolerance. These are nonspecific complaints that should prompt consideration of other diagnoses, such as gastroesophageal reflux, peptic ulcer disease, or irritable bowel syndrome. Similarly, chronic abdominal discomfort or pain that is fleeting in nature (less than 10 to 15 minutes) should not be attributed to gallstones.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis arises as a result of repeated attacks of discrete biliary pain and/or acute cholecystitis. These episodes induce a chronic inflammatory process that may be mild and patchy or quite severe and extensive. Over time the gallbladder wall may become thickened and fibrotic, resulting in a contracted and nonfunctional gallbladder. When this happens, the gallbladder generally is not palpable on examination and will not opacify on oral cholecystography.

ACUTE CHOLECYSTITIS

Acute obstruction of the cystic duct by a stone leads to gallbladder distention and a host of potential injury-inducing mechanisms. Hydrolysis of lecithin to form lysolecithin can lead to epithelial toxicity; bile salts as well as inflammatory mediators, such as prostaglandins, are actively involved in the process. Histologic findings range from edema, erythema, and mild mucosal inflammation to gross infiltration of the wall with polymorphonuclear neutrophils and evidence of frank necrosis and perforation. Bacterial infection is not thought to be a primary or initiating step in the pathogenesis of acute cholecystitis. As a secondary event, however, superimposed bacterial infection seems to be critical in the development of such complications as empyema, emphysematous cholecystitis, or perforation.

At initial clinical examination, patients with acute cholecystitis often complain of continuous upper abdominal pain and a history of similar, but self-limited attacks. They may be nauseated but usually do not obtain relief by vomiting or changing positions. These patients typically run a fever in the range of 99°F to 101°F and exhibit right-sided subcostal tenderness and localized parietal pain because of progressive gallbladder inflammation. A classic Murphy's sign may be elicited when the patient's inspiration is halted abruptly as the result of painful palpation of the right-upper quadrant or gallbladder. Generalized rebound tenderness and an acute abdomen should raise the suspicion of a perforation.

Acute acalculous cholecystitis (cholecystitis in the absence of stone obstruction) accounts for approximately 5% to 10% of all cases of acute cholecystitis. This entity is associated most often with critical illness, major surgery, extensive trauma, or burn-related injuries. Elderly men with peripheral vascular disease or patients on prolonged total parenteral nutritional support also appear to be at greater risk. The pathophysiologic picture involves a combination of gallbladder stasis, inflammation, and ischemia. Primary infections of the gallbladder also can cause acute acalculous cholecystitis. These infections include rare cases of salmonella-induced disease in immunocompetent hosts or manifestations of cryptosporidia, microsporidia, and cytomegalovirus infection in immunocompromised patients (i.e., those with HIV disease or those who have undergone bone marrow transplantation).

Complications tend to be encountered more often in acalculous disease and may be a reflection of the underlying pathogenetic process, such as small-vessel occlusion and ischemia. Patients frequently are severely ill and may not manifest the typical signs or symptoms of acute cholecystitis. Although surgery can be contemplated, it is important to realize that percutaneous cholecystostomy often is the best option, given the significant comorbidity and high risks. This interventional radiologic technique calls for puncturing the gallbladder wall under ultrasonographic guidance and acquiring secure guide wire access. A percutaneous drainage catheter is then passed over the wire and put in place to drain. The overall complication rate is acceptably low with this approach and, in fact, may be lifesaving in the patient with prohibitive operative risks.

Complications of Acute Cholecystitis

Complications develop when severe gallbladder inflammation is allowed to progress to gangrene and necrosis. Perforation occurs in approximately 10% of cases and can result in diffuse peritonitis, localized abscess formation, or a cholecystenteric fistula. Free perforation is uncommon, but when it happens, it leads to generalized peritonitis and mortality rates approaching 30%. Fortunately, the inflamed gallbladder typically is effectively sealed off by omentum and adherent viscera. Organ rupture in this scenario results in a contained abscess or walled-off perforation.

The gallbladder also can erode and decompress its contents into a loop of bowel to form a cholecystenteric fistula. The duodenum is the most likely site, but in rare cases the colon, stomach, and jejunum also may be involved. When a particularly large gallstone passes through a fistula tract into the small bowel, it can become lodged (most typically in the distal ileum), which causes abdominal distention and vomiting. This is termed *gallstone ileus*, but it does not truly represent an ileus but rather a bonafide mechanical obstruction. Surgical retrieval of the offending stone is required. Depending on the overall stability of the patient, cholecystectomy and fistula repair may be attempted at the same operation.

Emphysematous cholecystitis results from secondary infection with gas-producing bacteria, such as clostridial organisms, *Escherichia coli*, or anaerobic streptococci. The diagnosis is suspected when gas is seen in the gallbladder wall or lumen on ultrasonography or computed tomography. Many cases are acalculous, and thus some element of underlying ischemia may be present. Diabetes is present 20% to 30% of the time.

CHOLEDOCHOLITHIASIS

Choledocholithiasis (formation of stones in the common bile duct) is found in approximately 10% to 15% of patients with symptomatic gallstones. Most of these stones originate in the gallbladder and pass through the cystic duct into the common bile duct. Although some stones pass uneventfully into the duodenum or reside in the duct without provoking apparent symptoms, the natural history of common duct stones is much less benign than that for incidental stones found in the gallbladder. Obstruction of stones in the distal duct or ampulla may give rise to serious complications of jaundice, cholangitis, or gallstone pancreatitis ([Fig. 124.3](#)).

FIGURE 124.3. Ultrasonographic study showing a markedly dilated common bile duct with a distally obstructing stone (*arrowheads*).

The term *cholangitis* refers to the presence of bacterial infection behind an obstructed bile duct. Patients with cholangitis may have initial symptoms of biliary pain, fever with chills, and jaundice (Charcot's triad). Findings on examination often are less dramatic than the parietal pain and local tenderness associated with acute cholecystitis. The results of blood cultures usually are positive, and the organisms found include *E. coli*, *Klebsiella*, *Pseudomonas*, enterococci, and gut anaerobe species (15%). Some patients respond to aggressive broad-spectrum antibiotic treatment and intravenous fluids. True cholangitis should be viewed as a medical emergency, and hypotension, mental status changes, or severe sepsis should prompt immediate drainage of the biliary system by endoscopic sphincterotomy, percutaneous transhepatic drainage, or surgery.

LABORATORY FINDINGS

The laboratory evaluation of patients experiencing an attack of routine, uncomplicated biliary colic generally is unremarkable. In contrast, acute cholecystitis often is associated with leukocytosis in the range of 10,000 to 15,000. Mild jaundice is present in approximately 15% of patients, as a consequence of edema and compression of the common duct at the level of an inflamed and obstructed cystic duct. Bilirubin values of 2 to 10 mg per deciliter in a patient with upper abdominal pain are strongly suggestive of obstructive choledocholithiasis. Moreover, acute obstruction of the common duct occasionally gives rise to a high transaminase level that peaks and then rapidly returns to baseline after directed treatment and drainage. The picture of abnormal serum liver test results and elevated amylase or lipase values is consistent with gallstone-induced pancreatitis. In jaundice due to choledocholithiasis, bilirubin levels rarely exceed 10 mg per deciliter. Substantially higher values should raise the suspicion of an underlying obstructive malignancy.

DIAGNOSTIC IMAGING STUDIES

Ultrasonography is the preferred imaging test in the evaluation of acute or recurrent biliary pain. It is performed easily, is readily available, and can detect the presence or absence of gallstones with a high degree of sensitivity and specificity ([Fig. 124.4](#)). Findings of gallbladder wall thickening (greater than 3 mm), pericholecystic fluid, and gallbladder tenderness elicited with a transducer (sonographic Murphy's sign) suggest the diagnosis of acute cholecystitis. Such complications as a gangrenous gallbladder may show irregular wall thickening and disruption, whereas findings of a dilated common bile indicate biliary obstruction and choledocholithiasis ([Fig. 124.3](#)). Ultrasonography also is quite useful in the simultaneous evaluation of other potential causes of acute abdominal pain. Although ultrasonography is superior to computed tomography in the primary detection of cholelithiasis and sludge, neither method is efficient in the diagnosis of common bile stones. Sensitivities in most cases are reported to be no better than 50%.

FIGURE 124.4. Ultrasonographic image of a gallbladder containing a single large stone. Note the classic postacoustic shadowing.

HEPATOBILIARY SCINTIGRAPHY

Radionuclide scanning of the biliary system is helpful in selected patients with symptoms and signs of acute cholecystitis and normal or inconclusive ultrasonography results. The patient is given an intravenous injection of a technetium Tc 99m-labeled iminodiacetic acid agent and undergoes scanning at regular intervals. Normally the gallbladder, common duct, and small bowel appear by 30 to 45 minutes. Failure to detect the gallbladder by 90 minutes, when the common duct and small bowel are visible, strongly points to acute obstruction of the cystic duct ([Fig. 124.5](#)). False-positive results can be caused by extremes of nonfasting or prolonged fasting states, chronic alcoholism, and chronic cholecystitis. Delayed images at 4 hours have been obtained routinely in an effort to decrease the incidence of false-positive results. The administration of intravenous morphine sulfate at 60 minutes has eliminated the need to acquire delayed images. Morphine increases the sphincter of Oddi pressure and acts to enhance isotope filling of the gallbladder through a patent cystic duct. After the morphine injection, the patient usually undergoes scanning for an additional 30 minutes, and then the films are interpreted. With very rare exceptions, a completely normal study virtually rules out the diagnosis of acute calculous cholecystitis.

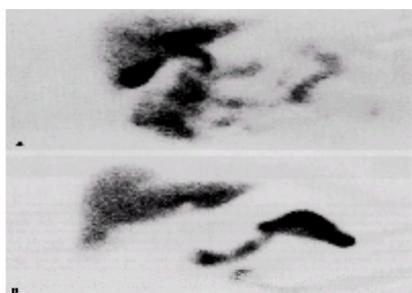

FIGURE 124.5. Hepatobiliary scintigraphy. **A:** Normal study at 60 minutes, showing the gallbladder, common bile duct, and small bowel. **B:** Abnormal study with no sign of the gallbladder. No effect was seen with morphine augmentation at 60 minutes in a patient with acute cholecystitis.

ORAL CHOLECYSTOGRAPHY

Oral cholecystography involves the oral administration of iopanoic acid contrast tablets the night before the radiographs are obtained. The contrast medium is absorbed in the small bowel, conjugated in the liver, excreted into bile, and concentrated by the gallbladder. The day of the examination, multiple spot films of the right-upper quadrant are taken to assess the visibility of the gallbladder (cystic duct patency) as well as the size and number of stones. A double dose of contrast often is favored because the gallbladder cannot be seen in 15% to 50% of patients who are given a single dose.

Although it rarely is used in the routine evaluation of patients suspected of having gallstones, oral cholecystography is useful in the assessment of a few patients in anticipation of oral bile acid dissolution treatment. The finding of small noncalcified stones floating within a functioning gallbladder represents the ideal situation for this type of therapy (see later discussion). Direct cholangiography with either endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography is used when additional delineation of the biliary tree is required or when such therapy as common duct stone extraction or biliary stent placement is contemplated ([Fig. 124.6](#)).

FIGURE 124.6. Endoscopic retrograde cholangiopancreatography examination showing both cholelithiasis and choledocholithiasis.

TREATMENT OPTIONS

NONOPERATIVE TREATMENT

In the 1980s, considerable interest was generated in the evaluation of nonsurgical treatment strategies for gallstone disease. These efforts primarily consisted of attempts to dissolve the stones or to blast them into smaller fragments. The major drawback to these approaches was that they did not address or correct the underlying pathogenesis permanently. Hence, by leaving the original metabolic defects and gallbladder intact, nonoperative treatment methods were associated with high rates of long-term recurrence. These observations, in conjunction with the increasing popularity of laparoscopic cholecystectomy, eventually led to a decline in the demand and enthusiasm for nonsurgical alternatives. Nonoperative therapy now is limited to a highly select group of patients.

ORAL BILE ACID DISSOLUTION

Chenodeoxycholic acid, the first oral bile acid agent to be introduced for the dissolution of cholesterol gallstones, later was replaced by ursodiol (ursodeoxycholic acid) because of fewer side effects and greater efficacy. At a dosage of 8 to 10 mg per kilogram per day, ursodiol is thought to act by limiting the secretion of cholesterol in bile and by depleting or extracting cholesterol from nucleation-prone vesicles, multilamellar liposomes, and mature stones. Only 15% of patients with symptomatic, uncomplicated stone disease are potential candidates for this type of therapy. Prospective patients first undergo oral cholecystography to confirm cystic duct patency, adequate gallbladder function, and the size and number of stones. Ideally, the stones should be seen floating within the gallbladder and should measure less than 1 cm. Pigment stones or calcified stones are not amenable to this type of therapy.

The overall treatment efficacy varies greatly, but when appropriate selection criteria are adhered to strictly, dissolution rates range from 60% to 90%. Unfortunately, these successful results do not appear to hold up over time; nearly half the patients have stone recurrences within 5 years of therapy. Moreover, bile acid treatment is costly and lengthy, often requiring at least 6 to 12 months to complete.

CONTACT SOLVENTS

The instillation of contact solvents directly into the gallbladder has produced promising results in limited investigations. This technique uses a percutaneous transhepatic catheter or an endoscopically placed nasobiliary tube. The agent ethyl tert-butyl ether has received the most attention. It can be infused repeatedly and withdrawn through a catheter delivery system over several hours. This technique can be used to dissolve cholesterol stones in one or more sessions. Care must be taken to prevent the ether from leaking into the duodenum, where it can induce mucosal injury and can be absorbed into the systemic circulation. Nausea, vomiting, hemolysis, and renal injury have been reported with this form of therapy. Automated systems that rely on pressure sensors to prevent overdistention and spillover and other solvent candidates, such as ethylpropionate, also have been promoted for contact therapy. Direct dissolution therapy is still regarded as experimental.

EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY

After the successes achieved in clearing renal calculi, shock wave lithotripsy was applied to the treatment of cholelithiasis. This approach uses high-energy shock waves to fracture stones into smaller bits and fragments. Shock wave pulses are generated and then targeted directly to a particular gallstone by a guiding ultrasonographic system. A functional gallbladder is mandatory, and ideally the stones should be few and small. Ursodiol is administered concomitantly to enhance the clearance rate of residual stone fragments. This technology is not approved by the Food and Drug Administration for the treatment of cholelithiasis. In the context of renal stone disease, shock wave lithotripsy can be used in selected patients to blast large common bile duct or pancreatic stones into fragments suitable for standard endoscopic removal.

LAPAROSCOPIC CHOLECYSTECTOMY

In a remarkably short time laparoscopic cholecystectomy has virtually replaced the traditional open approach to gallbladder resection. The potential advantages have been obvious, given the marked reduction in postoperative pain, shorter hospital stays, and more rapid return to usual activities and work. In fact, cholecystectomy rates were shown to rise from approximately 500,000 operations in 1987 to more than 700,000 in 1996. It has become clear that there is a substantial learning curve associated with laparoscopic surgery. The less experience and training a particular surgeon has, the higher the complication rate. In the context of laparoscopic cholecystectomy, cystic duct leaks and injuries to the common duct manifested by frank bile leakage or biliary obstruction have been seen with increasing frequency, at a rate of 0.95% versus 0.6% in open cholecystectomy. These observations have underscored the importance of establishing proper guidelines for training and granting credentials in the expanding field of laparoscopic surgery.

Conversion from a routine laparoscopic cholecystectomy to an open procedure is necessary in roughly 5% of cases, primarily when the anatomy is obscured, when the surgeon cannot retract the gallbladder or dissect it away because of inflammation or adhesions, or when there is excessive bleeding. Converting to an open approach under these circumstances reflects sound judgment and may serve to prevent a major bile duct injury or other complication. Patients who are not candidates for laparoscopic cholecystectomy include those who are in the last trimester of pregnancy and those who exhibit signs and symptoms of perforation, such as abscess, peritonitis, or fistula formation. End-stage liver disease with portal hypertension, severe coagulopathy, and suspected gallbladder malignancy are other contraindications.

OPTIMAL MANAGEMENT

Cholelithiasis is diagnosed in a variety of clinical circumstances. A patient may be asymptomatic, have a history of one or more uncomplicated biliary pain episodes, or have complications of acute cholecystitis, gangrene, jaundice, or even gallbladder cancer. Today, physicians and patients have myriad treatment options from which to choose. The optimal approach depends on the specific background and clinical circumstances. The following discussion highlights some of the salient features of treating patients with gallstone disease.

ASYMPTOMATIC STONES

Adult patients with silent or incidental stones should be observed and treated expectantly regardless of age or gender. The natural history of gallstones in these patients is generally benign, and the risk of a major complication is low. Moreover, warning symptoms of biliary pain usually manifest before a serious complication occurs, and there is no evidence to suggest that prophylactic cholecystectomy prolongs life expectancy. The potential exceptions to this recommendation relate to specific groups thought to be at higher risk of gallbladder carcinoma. These groups include individuals with calcified gallbladders (porcelain gallbladder), certain Native Americans, and perhaps patients with gallstones larger than 3 cm in size.

SYMPTOMATIC STONES

A patient with an episode of uncomplicated biliary pain has about a 30% to 50% chance of having a second attack within 1 to 2 years and approximately a 3% per year risk of complications. After the initial episode, however, as many as 30% of patients who are followed for the next 10 years will not experience further attacks. Therefore, the decision to proceed with laparoscopic cholecystectomy depends on the personal desires, attitudes, and surgical candidacy of each patient. For patients who do not want to risk the possibility of future attacks, laparoscopic cholecystectomy is recommended.

Nonoperative intervention, such as bile acid therapy, plays a limited role and is associated with a 50% recurrence rate. Moreover, it requires an initial oral cholecystogram to document adequate gallbladder function and subsequent follow-up ultrasonography studies. This costly and time-consuming form of therapy is best reserved for the symptomatic patient who declines surgery or is at high operative risk.

ACUTE CHOLECYSTITIS

Most physicians now agree that early laparoscopic cholecystectomy is indicated once the diagnosis of acute cholecystitis is secure and the patient's condition has been optimized. Selected patients are admitted, started on intravenous fluids and antibiotics, and then taken to laparoscopic surgery within 24 to 48 hours. Probably no more than one-third of the cases managed in this fashion have to be converted to an open procedure for technical reasons. Waiting longer than 72 hours increases the conversion rate to open cholecystectomy and the complication rate. For patients who have a major complication, such as a perforation, an urgent open laparotomy should be carried out. In addition, percutaneous cholecystostomy should be considered for patients with acute cholecystitis who are deemed to be at excessive risk for surgery (Fig. 124.7).

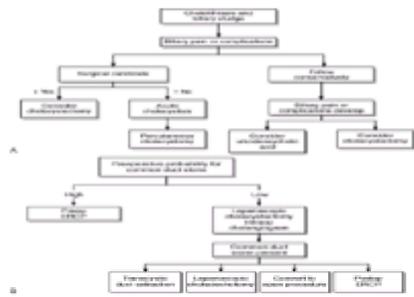

FIGURE 124.7. Management options for suspected choledocholithiasis. **A:** Cholelithiasis and biliary sludge. **B:** Preoperative probability of common duct stone.

COMMON DUCT STONES

When a patient with known gallbladder stones has signs and symptoms of concomitant choledocholithiasis, the treating physician must select from among a variety of treatment options. The presence of obstructive jaundice, with or without fever and abdominal pain, generally leads to a preoperative ERCP examination with sphincterotomy and stone extraction, as indicated. Success rates for the endoscopic removal of common duct stones approach 90% to 95% in the hands of an expert surgeon; this procedure can be followed directly by routine laparoscopic cholecystectomy. A growing number of patients with a high probability of experiencing preoperative choledocholithiasis go directly to laparoscopic surgery. An experienced surgeon cannulates the cystic duct to obtain a cholangiogram. If a common duct stone is present, it can be removed through the cystic duct with the use of choledochoscopes, balloon catheters, basket retrieval devices, or irrigation techniques. Success rates in most series range from 60% to 90%. If there is difficult biliary anatomy or the stone is too large, the common duct can be opened via a laparoscopic choledochotomy and then closed over a t-tube. Alternatively, the surgeon may elect to convert to an open common duct exploration or arrange for a postoperative ERCP (Fig. 124.7).

Whichever treatment option is ultimately pursued, it is important to stress that the chances for a successful clinical outcome are greatly enhanced by multidisciplinary participation and input. Any recommendations regarding the management of either suspected or confirmed choledocholithiasis depend largely on the local medical environment and the availability of appropriate radiologic, surgical, and endoscopic expertise.

PRESENTATION

Biliary tract disease is often only intermittently symptomatic. In an asymptomatic patient, the clinician may have only abnormal results on liver biochemical tests (noted at the time of a routine checkup) to suggest that biliary tract disease is present ([Chapter 104](#)).

SYMPTOMS SUGGESTIVE OF BILIARY TRACT DISEASE

The three symptoms of right-sided upper quadrant pain, fever, and jaundice (Charcot's triad) suggest bacterial infection of the biliary tree, but symptoms of biliary tract disease are frequently intermittent and quickly forgotten ([Table 125.1](#)). Fever associated with rigors and chills may be transient and is often minimal, particularly in the elderly. Tachycardia and/or a high white blood cell count with neutrophilia may be all that indicates underlying infection. A history of biliary tract surgery in any patient with abdominal complaints should always prompt further investigation of the liver and biliary tract.

Symptoms
Abdominal Pain
Fever, chills, rigors
Pruritus
Jaundice
Signs
Fever
Jaundice
Weight loss
Abdominal scars

TABLE 125.1. BILIARY TRACT DISEASE

Dark urine and pale stools may be noted by patients just before the onset and during the course of jaundice. In the anicteric patient these symptoms are unreliable, since concentrated urine may appear dark and certain elements of dietary intake (e.g., lack of red meat) can produce stools that are paler than usual. Chalky white stools are seen only in the context of complete biliary obstruction, in which case obvious jaundice and symptoms of steatorrhea also will be present. Generalized pruritus, which is often most troublesome at night, may not be mentioned as a symptom by patients. There is no associated skin rash, and skin emollients or antihistamines bring only partial relief. Persistent severe pruritus causes secondary neurodermatitis. Sleep disturbance and severe emotional distress can be provoked by severe, prolonged pruritus.

Patients with biliary tract disease may have initial symptoms stemming from associated disorders, such as inflammatory bowel disease (IBD) and/or osteoporotic bone fractures in subjects with primary sclerosing cholangitis (PSC). Nephrolithiasis is associated with some congenital biliary disorders (Caroli's disease), and the appearance of kidney stones may precede that of the biliary disorder. Current excessive alcohol intake or a history of alcoholism can cause a silent form of chronic pancreatitis; abnormal results suggestive of biliary tract disease on biochemical testing may be the only indication of a biliary stricture resulting from chronic pancreatitis. A history of biliary tract surgery in a patient with blood tests indicating cholestasis suggests the possibility of strictures and/or recurrent stones.

EXAMINATION

PHYSICAL SIGNS OF BILIARY TRACT DISEASE

Not infrequently, biliary tract disease may be clinically silent for many years, and only laboratory tests indicate the presence of disease. In these cases, physical examination may yield normal findings. It is essential to examine closely any patient with a history suggestive of biliary tract disease, looking for signs of bacterial infection, including fever, tachycardia, and hypotension. Scleral icterus may not be obvious unless the patient is examined in natural light. Intermittent jaundice is not unusual in patients with incomplete biliary strictures or common bile duct stones and, occasionally, in patients who have lesions involving the ampulla of Vater. Overt jaundice stemming from biliary tract disease almost always is associated with weight loss. Hence, muscle wasting and loss of subcutaneous fat in the jaundiced patient does not necessarily indicate the presence of malignant disease, because profound malabsorption and/or maldigestion accompanying "benign" disease may do the same. Overwhelming intestinal parasitic infection causing weight loss and biliary obstruction is more commonly seen in the Far East than in North America. Abdominal scars from cholecystectomy may be quite small if surgery was performed laparoscopically. It is important to ascertain whether the patient with suspected biliary tract disease has undergone any previous gastric surgery, particularly since the presence of certain anastomoses may preclude endoscopic routes of investigation of the biliary tree.

Primary tumors of the hepatobiliary system usually are confined to the right-upper quadrant of the abdomen, but metastatic disease also can lead to biliary tract obstruction, particularly lymphoma and Kaposi's sarcoma. For this reason, lymphadenopathy should be sought, and the skin should be examined for lesions. It is unusual for systemic diseases to affect the biliary tract. In rare cases, symptoms mimicking sclerosing cholangitis can develop in patients with cystic fibrosis, paroxysmal hemoglobinuria, systemic mastocytosis, or retroperitoneal fibrosis. Acute cholecystitis has been described in patients with systemic vasculitis.

DIAGNOSTIC INVESTIGATIONS

Investigation of suspected biliary tract disease should begin with a complete blood count and serum alkaline phosphatase, g-glutamyl transpeptidase, and total bilirubin levels ([Fig. 125.1](#)). It is wise to include testing for serum aminotransferase values ([Chapter 104](#)). It is essential to assess coagulation status, particularly when more invasive tests are planned; it may be profoundly, but reversibly affected by vitamin K deficiency stemming from obstructive jaundice.

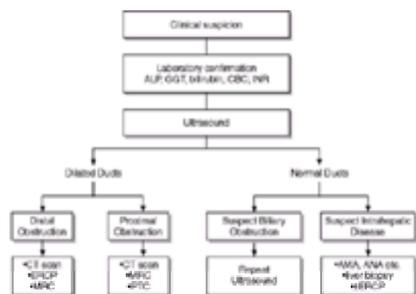

FIGURE 125.1. Investigative approach to biliary tract disease

It is rare for there to be clinically significant biliary tract disease when the liver biochemical test results are entirely normal, except in the case of a choledochal cyst. Even in patients with asymptomatic PSC and normal serum alkaline phosphatase levels, it is usual for the g-glutamyl transpeptidase level to be elevated. If the degree of hyperbilirubinemia does not correlate with the clinical picture, it may be worthwhile to fractionate the bilirubin, to assess whether the elevation is due in part to unconjugated bilirubin, which would cause more than the expected level of jaundice ([Chapter 103](#)).

Ultrasonography is the best noninvasive approach to examining the biliary tree. Overlying gas can impair interpretation, and the test may need to be repeated. If the clinical history is suggestive of extrahepatic biliary obstruction but ultrasonography does not show a dilated extrahepatic biliary system, it is necessary to conduct a second examination a week or so later. There are a number of conditions that cause biliary obstruction where dilatation of the ducts is either delayed or diminished ([Table 125.2](#)). The further investigation of patients suspected of having biliary tract disease very much depends on the results of ultrasonography, taken in concert with the clinical findings.

Carcinoma of the pancreas (early stage)
 Ampullary cell carcinoma
 Primary sclerosing cholangitis
 Biliary obstruction in cirrhosis

TABLE 125.2. CAUSES FOR DELAYED/DIMINISHED BILE DUCT DILATATION

CARE OF THE PATIENT

DILATED COMMON BILE DUCT

In the icteric patient, a dilated common bile duct evident on ultrasonography most often implies biliary obstruction stemming from a stone, tumor, or stricture. Marked dilatation of the biliary tree in the absence of jaundice can be due to the same conditions, but the differential diagnosis would include choledochal cyst. The “post-cholecystectomy syndrome” and functional dysmotility of the biliary tree may be associated intermittently with mild common bile duct dilatation.

The finding of a dilated common bile duct on ultrasonography rarely provides a conclusive diagnosis, and further investigation is necessary in most but not all circumstances. For instance, the picture of a choledochal cyst on ultrasonography may be so typical that no further investigation before surgery is needed. In most instances, however, further analysis via magnetic resonance imaging (MRI) is advisable. If a pancreatic tumor is suspected, a computed tomographic (CT) scan would be the next appropriate investigation for staging. Should surgical intervention be contemplated, it is important to assess the patency of the portal vein (via ultrasonography) and nonocclusive venous involvement with a spiral CT scan.

In a patient with a history of cholecystectomy who subsequently is found to have common bile duct dilatation, MR cholangiography (MRC) is the next step; results of this test will decide if therapeutic endoscopy or surgery is required. Common bile duct stones are seen on ultrasonography only 50% of the time. Endoscopic retrograde cholangiopancreatography (ERCP) should be carried out only by a person trained to perform therapeutic procedures. If stones are present, papillotomy and stone removal will be necessary, and if a stricture is present, papillotomy followed by stent placement may be required. If the patient has stones in the gallbladder and common bile duct obstruction, immediate surgery may be appropriate, with examination of the common duct at the time of surgery. Most surgeons would recommend ERCP, papillotomy, and stone removal first—especially in the elderly. In young patients, subsequent laparoscopic cholecystectomy is required, whereas in the elderly or otherwise sick patient the option is to leave the gallstones alone and watch the patient.

DILATED INTRAHEPATIC BILE DUCTS

When dilatation of the biliary tree is confined to the intrahepatic bile ducts, it generally indicates a tumor or stricture at the bifurcation of the common hepatic duct, for example, a Klatskin tumor if the patient is jaundiced. In rare cases, a gallbladder stone may erode through the cystic duct and obstruct the common hepatic duct high up (Mirizzi’s syndrome). When dilation of the intrahepatic biliary tree is confined to one or the other side of the liver, intrahepatic stones, stricture that develops after cholecystectomy or, less often, a Klatskin tumor or extrinsic compression from hepatocellular carcinoma or liver abscess may be the cause. MRI plus MRC are probably the most appropriate investigations to define the specific diagnosis; if these options are not available, ultrasonography and CT scan may be satisfactory.

The best therapeutic approach to intrahepatic bile duct obstruction depends on the diagnosis and the status of the patient. On occasion, invasive therapy is inappropriate, for example, if the patient has an inoperable tumor but is relatively asymptomatic apart from jaundice. When there are symptoms of sepsis and/or pruritus, however, therapeutic intervention is necessary—even though surgery may be only palliative. Palliative procedures to the intrahepatic biliary tree can rarely be approached via ERCP; the percutaneous transhepatic approach is necessary unless surgical bypass or stenting is considered optimal. Curative procedures also can be conducted percutaneously—for example, removal of intrahepatic stones and stenting of benign biliary strictures—but surgical resection plus stone removal (when appropriate) may be the best choice, depending on the individual circumstances. It is therefore essential that there be adequate consultation between the surgical team and the interventional radiologists.

NORMAL BILE DUCTS

It can be very reassuring to find bile ducts that are of normal size on ultrasonography, but if this evidence does not fit the clinical picture, it is best to proceed further. A second ultrasonographic examination conducted after 2 weeks is generally sufficient to find conditions that may have delayed changes to bile duct size ([Table 125.2](#)). If any clinical suspicion remains, further delineation of the biliary tree via ERCP or MRC may be appropriate. There are, however, a number of conditions of intrahepatic cholestasis that may lead to initial symptoms suggestive of extrahepatic biliary obstructions—drug-induced jaundice being the most common. It may be difficult to be confident of the diagnosis in the case of patients who also are found to have gallstones on ultrasonography. Sepsis outside the biliary tree may cause persistent intrahepatic cholestasis with jaundice lasting several months (particularly in a patient with cirrhosis). MRC is the least invasive test to confirm a normal biliary tree, but it is not universally available. ERCP may be necessary in ambiguous cases. Liver biopsy may be helpful, but the pathologic characteristics are not

always specific, for example, in the case of sepsis or drug-induced jaundice. In patients with anicteric cholestasis, it is useful to test for the autoantibodies [for example, antinuclear antibody, smooth muscle antibody (SMA) and antimitochondrial antibody (AMA)] before a liver biopsy.

CAUSES OF BILIARY TRACT DISEASE

A variety of disorders affect the biliary tree ([Table 125.3](#)). Stones in the common bile duct may stem from gallbladder stones, primary bile duct stones, or recurrent pyogenic cholangitis. Strictures may be due to PSC or a wide variety of insults, including surgery, trauma, pancreatitis, liver transplantation, and papillary stenosis or AIDS cholangiopathy. Tumors of the biliary tract include ampullary, pancreatic, and duodenal tumors; lymphoma; Kaposi's sarcoma; metastases; cholangiocarcinoma; and hepatocellular carcinoma (see [Chapter 129](#)). Among the infections that lead to biliary tract disease are bacterial cholangitis, parasitic invasion of the biliary tree, and liver abscess. Cysts (congenital choledochal cyst, Caroli's disease) also can lead to problems, as can such miscellaneous conditions as the so-called post-cholecystectomy syndrome, biliary dyskinesia, and hemobilia.

TABLE 125.3. CAUSES OF BILIARY TRACT DISEASE

PRIMARY SCLEROSING CHOLANGITIS

PSC is likely an autoimmune disease that causes many strictures of the extra- and/or intrahepatic bile ducts. It is more common in males than females and can affect all ages from early childhood onwards. Because the disease is often asymptomatic and there are no specific serum markers, its true prevalence remains unknown. Between 50% and 70% of patients with PSC also have IBD, predominantly ulcerative colitis. The prevalence of PSC in patients with colitis is likely 5% to 10%, depending on the method of diagnosis. The main pathologic characteristic of this disease is progressive, irreversible fibrosis of the bile ducts, so that eventually the small intrahepatic ducts become obliterated and the larger ducts strictured and narrowed. There is an approximately 10% lifetime risk of cholangiocarcinoma in patients with PSC. It is sometimes impossible to distinguish a benign from a malignant stricture. Testing for the tumor antigens carcinoembryonic antigen and CA19-9, combined with cytologic evaluation of bile duct brushings confirms the diagnosis of cholangiocarcinoma in only 60% of cases in which the tumor is present.

The pathogenesis of PSC remains unclear, but an association with certain class II human leukocyte antigens suggests an autoimmune pathogenesis. Vascular compromise of the blood supply to the bile ducts, which may follow hepatic artery stenosis after liver transplantation, sickle cell disease, and paroxysmal nocturnal hemoglobinuria, can produce a strictured biliary tree almost indistinguishable from PSC. There is no evidence, however, that vasculitis is present in patients with PSC.

There is likely a long asymptomatic phase of PSC, and progression of the disease is slow. In one study, there was an 85% survival rate at 10 years for patients with asymptomatic PSC, whereas the 10-year survival rate in patients with symptomatic PSC was only 65%. In patients with associated IBD, there is a higher prevalence of colonic malignancy—greater than that seen in IBD not complicated by PSC. The diagnosis of PSC may precede that of IBD by many years. Alternatively, PSC may be noted only long after the initial diagnosis of IBD, even after total colectomy.

Symptoms include fatigue, right-upper-quadrant pain, and pruritus. Episodes of fever and chills suggest complicating bacterial cholangitis. Osteoporosis is frequently present, even in men. Occasionally, the pancreatic duct also is strictured, causing episodes of pancreatitis. The clinical course of PSC tends to be either recurrent episodes of cholangitis or slow, silent progression of cholestasis and liver fibrosis with eventual cirrhosis and liver failure. Portal hypertension develops early in the course of disease and may be present before the onset of cirrhosis as damage to the intrahepatic portal venous system in the portal triads takes place.

A complete blood count may show leukocytosis in those patients with an infected biliary system, and thrombocytopenia may complicate portal hypertension. The liver biochemical tests generally reflect cholestasis (see [Chapter 104](#)). The clinical, biochemical, and serologic pattern may be more in keeping with autoimmune hepatitis, particularly in children (elevation in serum aminotransferase levels, positive antinuclear antibody, and hypergammaglobulinemia). There are no biochemical or serologic tests specific to PSC. Rarely, thickened bile ducts are noted on ultrasonography, as is dilatation of the intrahepatic ducts. Until recently the diagnostic test of choice for this disease was ERCP ([Fig. 125.2](#)), but improvements in MRI technology indicate that MRC is equally reliable with high-quality machines (see [Chapter 13](#)). Liver biopsy is not a helpful diagnostic tool, but it is used to determine whether cirrhosis is present. Biopsies from both lobes may be necessary, since the intrahepatic ducts can be affected unequally.

FIGURE 125.2. Endoscopic retrograde cholangiopancreatography (ERCP) in a patient with primary sclerosing cholangitis (PSC)

The management of PSC should include preventative, symptomatic, and therapeutic maneuvers. Preventive measures include checking for the presence of esophageal varices and using pharmacologic prophylaxis to lessen the chance of variceal hemorrhage. Bone mineral density should be checked regularly, and appropriate supplementation with calcium and vitamin D₃ (ergocalciferol) should be provided, as well as specific therapy for osteoporosis if necessary. There is no effective therapy for the fatigue associated with this disease. Pruritus usually can be controlled with the anion exchange resin cholestyramine. Patients who suffer recurrent bouts of bacterial cholangitis always should have a prescription for oral antibiotics on hand and carry the drug when traveling, since death from septicemia can occur within a few hours. No specific therapy has been shown to be helpful in the treatment of PSC. Dominant common duct strictures may benefit from balloon dilatation and stenting, but prolonged stent placement is not advised because any foreign body is a source of sepsis. Progressive hyperbilirubinemia in the absence of sepsis suggests the presence of complicating cholangiocarcinoma or simply progressive disease—the two may be very difficult to distinguish.

Randomized, controlled trials of the hydrophilic, dihydroxy bile acid ursodeoxycholic acid have shown that treatment improves serum biochemical test parameters without improving survival rates. Because the nature of this disease is fibrous stricturing of all the bile ducts, it is likely that medical therapy will be ineffective unless it is instituted very early in the course of the disease, before biliary stricturing and symptoms develop. Repeated therapeutic dilatation of strictures of the extrahepatic biliary tree are thought by some investigators to improve the course of this disease. There is, however, a significant risk of introducing infection into the biliary system

with each invasive procedure. Since the only cure for this disease at present is liver transplantation and septicemia would preclude transplantation, septicemia is to be avoided at all costs. The post-transplant mortality rate for PSC patients is greatest in the first 3 months after surgery; death is mainly due to sepsis.

Survival rates for PSC patients after liver transplantation are higher than for patients with any other chronic liver disease. Recurrence of PSC in the transplanted liver is seen, but not to a degree that precludes consideration of liver transplantation. If a patient with PSC is found to have complicating cholangiocarcinoma at the time of transplantation, the procedure must be abandoned—the postoperative prognosis is very poor in this situation. Hence, there is a great need to develop more accurate tests to diagnose cholangiocarcinoma before liver transplantation. Colonoscopic surveillance for colorectal carcinoma in patients with associated colitis must continue after transplantation.

SECONDARY BILIARY STRICTURES

POSTOPERATIVE AND TRAUMATIC STRICTURE

Postoperative biliary strictures occur most frequently after cholecystectomy. If these strictures are recognized immediately after surgery and are incomplete, ERCP and temporary stent placement may be all that is necessary. Surgical repair is essential if complete ligation or transection of the bile duct is present and may be necessary with incomplete occlusion if enough time has elapsed that significant fibrous stricturing not amenable to balloon dilatation has taken place. The same approach applies to traumatic strictures.

STRICTURES RESULTING FROM PANCREATITIS

Narrowing of the biliary tree early in the course of acute pancreatitis is not unusual and generally improves spontaneously as the edema and inflammation of the pancreas resolve. Much more subtle is biliary stricture that complicates chronic alcohol-induced pancreatitis (see [Chapter 123](#)). The strictures are generally long and not amenable to therapeutic endoscopic manipulations, and corrective surgery may be necessary.

HEPATIC ARTERY THROMBOSIS AFTER LIVER TRANSPLANTATION

When the diagnosis of hepatic artery thrombosis is made within 1 week of placement of the allograft, re-transplantation is generally in order because of graft failure. Many strictures of the biliary tree result from the ischemic injury. Occasionally, they can be managed by bile duct reconstruction, but more often patients require retransplantation.

AIDS CHOLANGIOPATHY

Liver test abnormalities are found frequently in individuals infected with HIV. Biochemical alterations suggestive of icteric cholestasis most often are due to papillary stenosis with or without associated cholangiopathy, though they may be due to infiltration of the liver with tumor or opportunistic infections. AIDS cholangiopathy is seen only in patients with a very low CD4 count and takes the form of jaundice, often associated with pruritus. Leukopenia is the rule, particularly in patients whose cholangiopathy is due to cytomegalovirus infection. Ultrasonographic examination of the liver shows thickened and mildly dilated extra- and sometimes intrahepatic bile ducts (the pattern is very different from that seen with PSC). Symptomatic treatment for pruritus may be helpful. Papillotomy has been advocated when papillary stenosis is present.

TUMORS AFFECTING THE BILIARY TREE

Malignant tumors external to the biliary tree may cause narrowing of the tree by invasion (metastases, lymphoma, Kaposi's sarcoma), by intermittent obstruction (ampullary cell carcinoma), or by circumferential compression (carcinoma of the pancreas or the duodenum). The clinical pictures are similar regardless of the source of the malignancy, including progressive jaundice, pruritus, and weight loss. Involvement of the duodenum may cause upper small-bowel obstruction. It is most unusual for a malignant biliary stricture to be accompanied by cholangitis unless an invasive procedure, such as ERCP or PTC, is carried out. Pain may not always be present. After cholestatic signs have been identified on biochemical tests, the clue to diagnosis is a dilated bile duct system evident on ultrasonography. Abdominal nodes or a mass also may be seen. If a malignant tumor is suspected, it is best to stage the tumor with noninvasive imaging (for example, by CT scan with or without MRI) before undertaking any invasive procedure. Tissue diagnosis via so-called skinny needle aspiration is generally not appropriate because of the risk of pancreatitis or tumor seeding. It may be useful to plan alternative therapy, however, in the patient with an obviously incurable carcinoma of the pancreas. Direct visualization via upper panendoscopy is the appropriate diagnostic test if an ampullary or duodenal tumor is suspected from the history (intermittent biliary obstruction in the case of ampullary tumors or symptoms of upper small-bowel obstruction in the case of duodenal tumors).

Gastrointestinal Kaposi's lesions may be found at endoscopy in the patient at risk. Ampullary carcinoma may be diagnosed when it is still very small, causing only an intermittent biliary obstruction; unfortunately, however, this tumor more often is diagnosed late in its course. The early-stage lesion may not be seen on noninvasive radiologic imaging, and only very careful ERCP with good drainage pictures taken after the endoscope has been removed will confirm the diagnosis. Primary lymphoma within the pancreas is rare. Lymphomatous nodes in the portal tract in a patient with previously diagnosed lymphoma are more typically the cause of biliary obstruction. In young patients with night sweats, weight loss, and a small tumor mass seen on ultrasonographic or CT scan, a pancreatic mass might be a lymphoma and not the more common adenocarcinoma.

INFECTIONS OF THE BILIARY TREE

BACTERIAL CHOLANGITIS

Bacterial cholangitis occurs only when there is impaired bile flow in the large bile ducts. Bacteria are found frequently in normal bile, and thus bacterial cholangitis may develop very rapidly after the onset of biliary obstruction. The patient may experience only short-lived symptoms before going into septic shock and may be unable to give a history on arrival in the emergency room. In a septic patient, laboratory findings suggesting obstructive jaundice and evidence of an abnormal biliary tree on ultrasonography (often with intrahepatic dilatation with or without stones) are enough to initiate urgent therapeutic ERCP and/or PTC. At the other end of the spectrum, it is not unusual for patients (generally the elderly) to have very nonspecific symptoms, though the blood glucose in diabetic patients will be out of control. In this situation abnormal liver biochemistry values with cholestatic features should prompt immediate investigation. If the biliary obstruction is confined to either the right or the left duct system, jaundice will be absent; cholangitis commonly is missed under these circumstances.

PARASITIC INVOLVEMENT OF THE BILIARY TRACT

Ascariasis, liver flukes, and echinococcus may all involve the biliary tree. Ascariasis is most common in areas of the world where hygienic conditions are substandard. Overwhelming gastrointestinal infection often is present when the biliary tract is affected. For this reason, symptoms of vomiting, abdominal cramps, and obstructive jaundice generally predominate. If endoscopic diagnosis cannot be made, a barium study will easily identify the worms, whose gastrointestinal tracts also take up barium. Therapy is with mebendazole or pyrantel pamoate.

In the Far East liver flukes are due to infection with *Clonorchis sinensis* and in the West to *Fasciola hepaticum*. Both are acquired from eating raw fish or fresh water. Patients experience right-upper-quadrant pain, fever, and possibly jaundice. The initial symptoms often are missed. In the case of *Clonorchis* infection, the diagnosis generally is made only when the parasites have induced chronic biliary tract inflammation and stricturing, which then causes bacterial cholangitis and/or intrahepatic stone disease. The primary infection responds well to common antiparasitic agents, for example, praziquantel.

It is unusual but not unknown for hydatid cysts to invade the biliary tree and provoke symptoms of biliary obstruction. Hydatid cyst disease within the liver always will be evident; depending on the age of the cysts, calcification may or may not be present. Hydatid disease is seen only in persons from rural areas where hygiene is poor and where animal (sheep, goat, moose) offal is fed to dogs and contamination of human food with dog feces has taken place. Ultrasonography is most helpful in identifying hydatid cysts. If these cysts are present in the biliary tree, surgery will be necessary once active infection has been eradicated. Percutaneous aspiration with a scolicedal agent (e.g., 95% alcohol) is being used with increasing frequency. Antiparasitic agents (e.g., albendazole) is only 40% effective.

LIVER ABSCESS

A liver abscess may be bacterial, amoebic, or fungal. The patient may have acute symptoms of severe right-upper-quadrant pain, fever, and mild jaundice or chronic symptoms of anorexia, weight loss, and mild fever and fatigue. Liver abscess due to bacterial infection spreads from the biliary tree, a colonic diverticulum, or an appendiceal abscess in two of three cases. In one-third of cases, no primary source is found. Unless the patient is immunocompromised, marked leukocytosis is present, and derangement of liver biochemistry values may be mild. In chronic cases it is usual for normocytic normochromic anemia and hypoalbuminemia to be present. Ultrasonography is the diagnostic test of choice. There may be a single or several abscesses. If there is a single abscess larger than 2 cm, aspiration and culture of the material should be undertaken and intravenous antibiotics given. When the abscesses are small and there are several, appropriate broad-spectrum intravenous antibiotics may be the only possible treatment, and the treatment may be prolonged. The prognosis of this once commonly fatal infection is now much improved, owing to excellent tissue penetration of the new antibacterial agents. Liver abscess may stem from intrahepatic stones or hepatic artery thrombosis after transplantation ([Chapter 132](#)).

Amoebic liver abscess is prevalent in parts of the world where amoebic dysentery is common. Right-upper-quadrant pain may be acute and severe enough to cause "splinting" of the diaphragm. The initial dysenteric infection itself may have gone unnoticed or been forgotten. "Punch" tenderness of the lower ribs is often detectable on the right side of the body. Confirmation with ultrasonography and immediate aspiration under ultrasonographic guidance are appropriate. The fluid obtained is said to look like anchovy sauce, since it is not pus but liquefied liver. Aspiration of all the contents is necessary, and it is the last aspiration that needs to be examined immediately under the microscope, because the amoeba hide in the wall of the abscess. Bacterial superinfection is typical, so culture of the aspirated material is necessary. Treatment with oral metronidazole (very well absorbed from the upper gastrointestinal tract) is sufficient for the abscess, but the bowel also must be treated with a 20-day course of iodoquinol to completely eradicate the amoeba. Resolution of disease is generally rapid.

CYSTIC LIVER DISEASE OF THE BILIARY TREE

CONGENITAL CHOLEDOCHAL CYSTS

Congenital choledochal cysts most often develop in childhood and symptoms are likely prompted by proteinaceous plugs; they are evidenced by abdominal pain, with or without fever and jaundice. These cysts also may be entirely asymptomatic and may be found at the time of abdominal ultrasonography conducted for an unrelated condition. Any part of the biliary tree may be involved. Surgical removal is mandatory, because malignancy complicates at least 10% of cases.

CAROLI'S DISEASE

Caroli's disease is a rare disorder of the biliary system, causing congenital cystic dilatation of the extrahepatic biliary tree. It is likely part of a spectrum of bile duct plate abnormalities that are responsible for polycystic liver disease and congenital hepatic fibrosis. It is common to find abnormalities of the kidneys as well—most often medullary sponge kidneys with or without nephrocalcinosis. Impairment of renal function may be present before any hepatobiliary abnormalities are recognized. Recurrent cholangitis complicates this disease. Liver fibrosis and hepatic decompensation may necessitate liver transplantation.

MISCELLANEOUS

Recurrent right-upper-quadrant pain after cholecystectomy suggests (a) that the original disorder for which the gallbladder was removed was not due to the patient's gallstones (e.g., irritable bowel syndrome/hepatic flexure syndrome) or (b) that there is recurrent biliary tract disease. Abnormal serum aminotransferase and/or alkaline phosphatase values suggest the latter possibility, in which case it is mandatory to examine the biliary tree. The post-cholecystectomy syndrome is considered only when common duct stones and biliary stricture have been ruled out. High intraluminal pressures are often recorded within the bile duct and are thought to be due to sphincter of Oddi dysfunction. Relief of symptoms may follow sphincterotomy. Such biliary dyskinesia may develop without previous cholecystectomy and is considered a functional motility problem of the biliary tree.

HEMOBILIA

Rarely, liver biopsy or trauma to the liver results in bleeding into the biliary tree, which causes severe right-upper-quadrant pain, anemia, and the passage of "silver" stools. If the bleeding does not stop spontaneously, surgical intervention and/or arterial embolization may be required. Extraction of the clot via endoscopy and a papillotomy are usually sufficient.

PRIMARY MALIGNANT HEPATIC NEOPLASMS

DEFINITION

Primary hepatocellular carcinoma (HCC), a malignant transformation of hepatocytes, is a well-recognized complication of long-standing liver disease of numerous causes, including alcohol abuse, chronic viral infection, toxin exposure, and inherited metabolic disorders. The diagnosis usually is made by percutaneous liver biopsy and histologic evaluation. Because HCC occurs in the context of chronic liver injury, small tumors can be difficult to differentiate from regenerating nodules and hepatic fibrosis associated with cirrhosis. Besides liver histologic examination, hepatic imaging by radiographic and ultrasonographic techniques and serum markers associated with HCC aid in identifying potential tumors.

INCIDENCE AND EPIDEMIOLOGY

Worldwide the incidence of HCC is correlated directly with the prevalence of chronic hepatitis B virus (HBV) infection. Vertical transmission at birth is the major factor contributing to the high incidence of chronic HBV infection, which is found in the distinct geographic locations of Southeast Asia, Japan, Korea, sub-Saharan Africa, and Alaska (among Native North Americans). With recognition of this mode of transmission and the availability of hyperimmune serum and effective vaccines against HBV, the incidence of HBV-associated HCC is predicted to decline significantly within the next one to two generations. In the United States and Europe, long-term alcohol abuse, alone or in combination with hepatitis C virus (HCV) co-infection, is associated with necro-inflammatory liver injury and recognized as a risk factor for HCC. Metabolic disorders, such as hemochromatosis, excess iron storage, tyrosinemia, α_1 -antitrypsin deficiency disease, Wilson's disease, and type Ia glycogen storage disease, are other important risk factors for HCC. For unknown reasons, men are at increased risk for HCC stemming from all conditions in which cirrhosis develops, including chronic HBV infection. Exposure to the mycotoxin aflatoxin B1, a by-product of *Aspergillus flavus* and *Aspergillus parasiticus*, which infect grains, rice, and peanuts; C-17-alkylated androgenic steroids; estrogen; Thorotrast (a radiographic contrast agent used from the 1920s to the early 1950s); or vinyl chloride is also recognized as carrying the risk of HCC ([Table 126.1](#)).

Category	Conditions
Infections	Chronic HBV infection Chronic HCV infection
Hereditary diseases	Hemochromatosis α_1 -Antitrypsin deficiency Hereditary tyrosinemia Glycogen storage disease (type I) Wilson's disease
Environmental hazards	Drugs Aflatoxin Chronic ethanol abuse Thorotrast Estrogens

HBV, hepatitis B virus; HCV, hepatitis C virus.

TABLE 126.1. CONDITIONS PREDISPOSING TO THE DEVELOPMENT OF HEPATOCELLULAR CARCINOMA

PATHOGENESIS

Although the precise pathogenetic mechanisms involved in the development of HCC are not fully understood, advances in molecular biology and toxicology are helping identify critical steps required for HCC formation. Chronic inflammation of any cause exposes the liver to genotoxic free radicals, which presumably leads to a series of mutations culminating in HCC formation. In HBV infection, random integration throughout the host genome produces genetic instability, increasing the chance for a mutational event. Epidemiologic studies have shown that co-infection with HCV significantly contributes to the development of HCC in the context of chronic alcoholic liver injury. Hemochromatosis and other excess iron storage diseases, such as sporadic porphyria cutanea tarda, also are associated with a high risk of HCC, presumably because of increased free radical formation caused by excess iron. Metabolic disorders, such as Wilson's disease, type Ia glycogen storage disease, and tyrosinemia, are other examples of HCC-associated disease postulated to be mediated by free radical formation.

CLINICAL FEATURES

The clinical characteristics of HCC depend in part on the presence of an associated chronic liver disease. Patients may have nonspecific symptoms related to chronic liver disease, such as fatigue, jaundice, and weight loss, or they may complain of right-upper-quadrant pain. Occasionally, a liver mass is detected by self-palpation. On physical examination, there may be clinical evidence of chronic liver disease, such as ascites, peripheral edema, muscle wasting, and jaundice. Hepatomegaly caused by a mass or a firm, cirrhotic liver with discrete nodules may be found. A right-upper-quadrant vascular bruit can be heard, and dilated abdominal veins indicating portal hypertension may be found. Occasionally, HCC takes the form of a Budd-Chiari-like syndrome—acute onset of progressive ascites without peripheral edema. HCC should be sought in patients with chronic liver disease who have hepatic decompensation with no identifiable precipitating factor.

On histologic examination, HCC looks like a liver cell cord-like structure (trabecular pattern) composed of hepatocytes of varying dedifferentiation and cytologic features. HCC is an aggressive tumor, with a median survival time of 7.1 months in one study. Fibrolamellar HCC (FL-HCC) is a distinct clinicopathologic variant of HCC with a less aggressive clinical course. On histologic evaluation, FL-HCC is composed of lamellar strands of fibrosis (typically absent in HCC) surrounding pseudoglands and cords of malignant cells. FL-HCC accounts for only 1% to 2% of all cases of HCC but up to half the cases diagnosed in patients younger than 40 years of age. FL-HCC usually is not accompanied by cirrhosis, has no male predominance, and is associated with a 50% 5-year survival rate. These tumors fail to secrete the tumor marker α -fetoprotein (AFP), which is associated with HCC, and can be treated by surgical resection or liver transplantation. The absence of cirrhosis and lack of association with chronic inflammatory liver diseases suggest a different pathophysiologic course for FL-HCC.

LABORATORY FINDINGS

Routine laboratory tests for liver injury and function; serum markers for specific diseases, such as hepatitis B and C, Wilson's disease (ceruloplasmin), and hemochromatosis (iron/total iron-binding capacity, ferritin); and α_1 -antitrypsin are used in the evaluation of HCC. Serum HCC tumor markers, most notably AFP, also can be measured. Routine serum tests of liver injury assess levels of aspartate aminotransferase and alanine aminotransferase, which are markers for hepatocellular injury; alkaline phosphatase, which is elevated in infiltrative liver diseases or cholestatic injuries caused by obstruction of the biliary tree and is associated with elevation in γ -glutamyl transpeptidase, 5'-nucleotidase, or leucine aminopeptidase; bilirubin, which reflects the excretory capacity of the liver and the patency of major bile ducts; and albumin and clotting factors, which reflect the synthetic capacity of the liver. Polycythemia, hypercalcemia, and hypoglycemia also have been reported in the context of HCC stemming from the release of tumor-generated hormones. TABLE 126.2. GENERAL CLASSIFICATION OF BENIGN LIVER TUMORS

INCIDENCE AND EPIDEMIOLOGY

The true incidence of benign hepatic tumors is unknown. As mentioned, women are at higher risk of HA, especially during the reproductive years and with the use of oral contraceptives. Patients with HA are divided into three groups: those taking oral contraceptives; those with associated diabetes mellitus or glycogen storage disease or those who are pregnant; and those with adenomatosis. Adenomatosis is a rare hepatic syndrome in which patients have 10 or more adenomas. This condition affects men and women equally and is not associated with estrogen use. These patients are at greater risk for malignant transformation of adenomas, which can be detected by increasing AFP levels. HA was a rare clinical entity until the introduction of oral contraceptives. The use of these agents is associated with a time-dependent increased risk of HA (up to a 25-fold increase in patients with more than 9 years of exposure) and a higher risk of intratumor bleeding or rupture. The relationship of these tumors to malignant transformation is unknown, though incidents of HCC transformation within HA have been reported. Epidemiologic studies in young women with HCC show that oral contraceptive use is an independent risk factor for HCC.

PATHOGENESIS

Significant differences exist in the pathologic appearance of HA and FNH. On gross examination, HA appears as a tan mass varying in size from 1 to 30 cm. It has a pseudocapsule and is located preferentially in the right hepatic lobe. On histologic evaluation, HA is made up of normal-appearing hepatocytes lining trabecular sinusoidal spaces in bland cords without portal triad elements and with microscopic and macroscopic evidence of hemolysis and necrosis. FNH is made up of all cell populations normally present in the liver and classically appears as a central vascular scar with fibrous septa radiating from it. This scar may be calcified on imaging tests, which is diagnostic of FNH. Twenty-five percent of patients with FNH have several lesions.

CLINICAL FEATURES

FNA and HA have two distinct clinical pictures. Patients with HA are of childbearing age and have histories of oral contraceptive use, whereas those with FNH are in their fifth to sixth decades and lack such histories. Eighty percent of patients with HA have symptoms, of which half are related to abdominal mass or pain and the rest to hemorrhage or rupture. Right-upper-quadrant abdominal pain may result from large tumor size, compression of the Glisson capsule, or displacement or compression of intra-abdominal organs. Patients without symptoms are identified by the presence of an asymptomatic mass noticed by the patient or palpated by the physician during routine physical examination. FNH often is discovered in asymptomatic patients during radiographic evaluation of the liver or as an incidental finding at laparotomy, with only 10% being accompanied by pain or appearing as an asymptomatic hepatic mass.

LABORATORY FINDINGS

Distinguishing benign hepatic tumors from HCC is a major diagnostic challenge (Table 126.3). Evidence of chronic liver disease should be sought through routine serum liver tests. Serologic markers for HBV and HCV should be measured if elevated transaminase levels or evidence of chronic liver disease is found. AFP levels are not elevated in patients with benign tumors and can be used to differentiate benign from malignant disease.

Features	Hepatocellular Adenoma	Focal Nodular Hyperplasia	Hepatocellular Carcinoma	Metastatic Carcinoma	Cavernous Hemangioma
Incidence (%)	3-4	3-4	1-4	1-2	48-128
Sex	M	M	M	M	M
Age (yr)	30-40	30-40	50-60	5-10	50
Characteristics	Well-circumscribed, hemorrhagic, necrotic	Well-circumscribed, hemorrhagic, necrotic	Well-circumscribed, hemorrhagic, necrotic, vascular invasion	Well-circumscribed, hemorrhagic, necrotic, vascular invasion	Well-circumscribed, hemorrhagic, necrotic, vascular invasion
Characteristics	"Trabecular" architecture, no portal triads	"Trabecular" architecture, no portal triads	"Trabecular" architecture, portal triads, vascular invasion	"Trabecular" architecture, portal triads, vascular invasion	"Trabecular" architecture, portal triads, vascular invasion
Prognosis	Good	Good	Poor	Poor	Good
Cause	Estrogen, anabolic steroids	None	HBV, HCV, aflatoxin, alcohol, cirrhosis	HBV, HCV, aflatoxin, alcohol, cirrhosis	None

TABLE 126.3. COMPARISON OF COMMON HEPATIC MASS LESIONS

Hepatic imaging and biopsy are the primary tools used to discriminate benign from malignant disease. In HA, radiographic evaluation should be undertaken first, because biopsy carries a significant risk of bleeding. Biopsy is safe in FNH. The presence of a stellate scar that may be calcified is diagnostic of FNH, but it is found in only 60% to 80% of cases. Scintigraphic studies also can help differentiate mass lesions that are not defined adequately by CT. Technetium sulfur colloid scanning also can distinguish FNH from HCC or HA; the absence of reticuloendothelial cells may appear as a photopenic area in HCC and HA, whereas these cells may accumulate radioactivity in FNH. False-positive and false-negative results have been reported with sulfur colloid scanning in HA and HCC, however, thus limiting the usefulness of this technique.

OPTIMAL MANAGEMENT

When a woman is found to have a hepatic mass, discontinuation of estrogen use is the first priority. Occasionally, large HAs shrink or resolve in the absence of hormone. Serum tests are used to identify chronic liver disease or other disorders associated with an increased risk of HCC. Radiographic imaging then is used to define the size, location, and characteristics of the lesion in preparation for potential surgical resection. Percutaneous biopsy carries a risk of significant bleeding with HA, and suspicious lesions should not be subjected to biopsy. Ultimately, exploratory laparotomy and resection may be needed to differentiate HA from other tumors. If HA is suspected, surgical resection is the preferred treatment because of the risk of rupture or hemorrhage and the documented potential for malignant transformation. If a benign tumor is not resected, its size must be monitored, because expansion of the tumor eventually may compromise normal tissue or signal malignant transformation. For FNH, no risk of bleeding or malignant transformation exists, and tumors can be removed by enucleation or wedge resection to release compression of normal liver or provide pain relief.

VASCULAR DISEASES OF THE LIVER

Vascular diseases of the liver are important entities that may appear on imaging studies as hepatic tumors. Hepatic hemangiomas, especially those larger than 3 cm (cavernous hemangiomas), may look like space-occupying lesions on hepatic imaging and now and then can be palpated. Biopsy is contraindicated because of a significant risk of bleeding. Benign hemangiomas are the most common liver tumors after metastatic disease and are estimated to be present in 0.7% to 7% of the

population.

CLINICAL AND PATHOLOGIC FEATURES

On histologic examination, hemangiomas are characterized by dilated venous spaces lined by endothelial cells. Small hemangiomas appear with equal frequency in men and women, whereas large, symptomatic lesions are found more often in women taking oral contraceptives. Patients with benign hemangiomas rarely have symptoms, except in the case of cavernous hemangiomas, which can take the form of palpable, space-occupying lesions. Hemangiomas are detected most often as incidental findings during diagnostic hepatic imaging. Lesions smaller than 1.5 cm appear as echogenic masses on US, distinguishing them from primary or metastatic lesions. Larger lesions cannot be differentiated by US. Technetium-labeled blood pool scanning may identify hemangiomas larger than 3 cm if they are located in the periphery of the liver. On T2-weighted magnetic resonance imaging, hemangiomas routinely appear as lucent lesions with low attenuation, whereas on HCT, hemangiomas have a distinctive pattern of contrast filling from the periphery to the center. Ultimately, angiography may be necessary to confirm the diagnosis. Hemangiomas have a low probability of rupture (less than 5%) and are resected only when large lesions compromise normal tissue. Women with incidental hemangiomas should refrain from using oral contraceptives.

OTHER BENIGN HEPATIC NEOPLASMS

Focal fatty infiltrates or localized absences of fatty infiltrate in fatty liver may appear on imaging tests as focal tumors. Other mesenchymal elements may be present in these lesions, and rare malignant transformations have been reported. Other benign liver tumors include teratomas, hamartomas, adrenal rest tumors, and inflammatory pseudotumors.

BENIGN AND MALIGNANT DISEASES OF THE BILIARY TRACT

Benign and malignant transformations of the bile duct epithelium are rare clinical entities. Unlike HCC, there is no association between cirrhosis and cholangiocarcinoma.

DEFINITION

Cholangiocarcinoma is a malignant transformation of cholangiocytes lining the intrahepatic and common hepatic bile ducts. The location and caliber of bile duct involvement by cholangiocarcinoma influence its clinical picture. Cholangiocarcinoma can be divided into four subtypes, depending on the location and histologic features; the cholangiocarcinomas are different from the cystadenocarcinomas that arise from premalignant biliary cystadenomas.

INCIDENCE AND EPIDEMIOLOGY

The incidence of cholangiocarcinoma is 2% to 20% higher than that of HCC. This lesion affects older patients (fifth to sixth decades) and is strongly associated with chronic inflammatory disease of the bile ducts caused by primary sclerosing cholangitis, with or without associated inflammatory bowel disease (ulcerative colitis or Crohn's disease); lithostiasis; parasitic infection of the biliary tract (eg., *Clonorchis sinensis*); congenital cystic diseases of the biliary tree; Caroli's disease; choledochocyst; and congenital hepatic fibrosis. Exposure to vinyl chloride and Thorotrast are other recognized risk factors for cholangiocarcinoma.

ETIOLOGY AND PATHOGENESIS

Cholangiocarcinoma often develops at the site of chronic inflammatory disease and may appear as a stricture. Malignant transformation within these inflammatory lesions makes it difficult to differentiate tumor from fibrotic stricture. An increased incidence of cholangiocarcinoma also has been reported in patients with primary biliary cirrhosis. Little is known about the mechanism of malignant transformation of cholangiocytes other than its association with chronic inflammation of bile ducts.

CLINICAL FEATURES

The site and caliber of bile duct involvement play an important role in the clinical manifestations of cholangiocarcinoma. Small-duct disease may manifest as a hepatic mass with nonspecific right-upper-quadrant pain. Large-duct obstruction, especially from tumors at the bifurcation of the right and left hepatic ducts (so-called Klatskin tumors), often leads to jaundice and pruritus. Because of their strategic location, these tumors usually appear earlier than peripheral tumors.

LABORATORY FINDINGS

The location of the tumor and the size of the obstructed bile ducts influence the abnormalities in serum liver test results. Small-duct disease may show only elevated alkaline phosphatase levels and normal bilirubin levels, because most of the bile ducts are patent. Large-duct obstruction often is evidenced by elevated serum bilirubin (predominantly direct) and alkaline phosphatase levels. Minimal increases in transaminase levels are present without chronic liver disease.

OPTIMAL MANAGEMENT

Treatment of these patients requires localization of the disease and biopsy sampling or cytologic evaluation of the mass. US can identify potential mass lesions and effectively detect dilated intrahepatic ducts. Large-duct obstruction manifests as dilated intrahepatic ducts (depending on the position of the tumor) and normal extrahepatic ducts, whereas peripheral tumors often appear as mass lesions. CT also can identify the location of hepatic masses and detect dilated bile ducts, but this technique is unable to distinguish cholangiocarcinoma from HCC.

Contrast studies are used to define the anatomy of the biliary tree. With endoscopic retrograde cholangiopancreatography, the ampulla of Vater can be assessed visually and the pancreatic ducts and biliary tree examined by the retrograde injection of contrast media. Brushings of strictures, lesions, or biliary fluid also can be obtained for cytologic examination. Alternatively, percutaneous transhepatic cholangiography can be carried out in patients with normal coagulation and no ascites, if the intrahepatic ducts are dilated. Irregularity of the bile duct mucosa, stricture, or the appearance of a shelf on biliary contrast studies suggest tumor, but histologic evaluation is required to distinguish cholangiocarcinoma from benign stricture. Biopsy of the mass ultimately may be required to confirm the diagnosis.

Unlike HCC, cholangiocarcinoma tends to be a slow-growing tumor that metastasizes at a later stage. Curative surgical resection is the primary treatment method. Preoperative radiation therapy to the region can minimize the metastatic potential. Cumulative 1-, 3-, and 5-year survival rates of 61.8%, 23.6%, and 23.6%, respectively, were reported in one study, and patients with hilar disease survived more than 2 years. For cholangiocarcinoma that is unresectable because of its location or size, adequate drainage of the biliary tree by dilatation or stent placement lowers the incidence of bacterial cholangitis and prevents the formation of secondary biliary cirrhosis. Cystadenocarcinomas are rare tumors arising from benign biliary cyst adenomas. Irregularities within the cyst wall or the presence of septa are radiographic findings of malignant transformation and indicate the need for surgical resection. These tumors are less aggressive than HCC or cholangiocarcinoma and have a better prognosis.

BENIGN AND MALIGNANT DISEASES OF THE GALLBLADDER

BENIGN GALLBLADDER DISEASE

Benign gallbladder diseases that have aggressive clinical courses need to be discriminated from malignant diseases. Patients may have symptoms indistinguishable from cholecystitis, such as right-upper-quadrant pain, nausea, and vomiting. Adenomyosis is a form of benign hyperplasia of the gallbladder wall that involves the entire gallbladder or a single segment, usually the fundus. On US, this lesion appears as a focal area of thickening or a bandlike stricture. The appearance of a smooth wall differentiates this lesion from adenocarcinoma. The other major benign entity is cholesterosis, which results from the accumulation of cholesterol within the connective tissue of the gallbladder wall and is not related to hypercholesterolemia or the presence of gallstones.

GALLBLADDER ADENOCARCINOMA

Gallbladder adenocarcinoma is an aggressive tumor found in about 1% of all patients with long-standing cholecystitis and gallstones. This lesion develops in the sixth to seventh decades of life and has a 4:1 female-to-male predominance. Chronic gallbladder inflammation caused by gallstones is the major risk factor for malignant transformation. A calcified gallbladder, so-called porcelain gallbladder, has an increased risk of harboring adenocarcinoma. Adenocarcinoma typically is an incidental finding in a gallbladder resected for chronic cholelithiasis.

Gallbladder adenocarcinoma spreads locally to the liver and metastasizes to local lymph nodes. On US, a thickened and irregular gallbladder wall, a complex mass in the gallbladder bed, and a polypoid lesion in the gallbladder (which must be distinguished from a benign polypoid lesion) are its distinguishing radiographic features. Adenopathy in the porta hepatis and para-aortic nodes is additional evidence of gallbladder carcinoma. The only treatment is surgical resection; most patients have metastatic disease, however, with a median survival time of only 6 months.

METASTATIC DISEASE OF THE LIVER

DEFINITION

Besides liver-specific benign and malignant tumors, tumor metastases from other sites favor the liver because of its portal system drainage and the unique vascular structure of the sinusoidal endothelial surface. Clinical studies show that resection of colorectal tumors that metastasize to the liver can improve mortality rates significantly in certain situations and warrants further evaluation.

INCIDENCE AND EPIDEMIOLOGY

The liver is a common site for the metastasis of pancreas, gallbladder, colon, and breast cancers; malignant melanomas; and neuroendocrine tumors, which have the best prognosis.

CLINICAL FEATURES

About 50% of patients with metastatic disease have hepatomegaly, and 15% have jaundice. Ascites is found in 50% of patients with metastatic gastric, ovarian, or gallbladder carcinomas. Patients with hepatic metastasis from primary tumors in the pancreas, stomach, or lung often have no symptoms. Patients with metastatic disease in the liver may have nonspecific symptoms of weight loss, anorexia, right-upper-quadrant pain, or cholestasis if there is obstruction of major bile ducts. On physical examination, firm, distinct nodules may be felt.

LABORATORY FINDINGS

In cases of metastatic disease of the liver, elevated alkaline phosphatase levels are common, and increased serum bilirubin levels may be a sign of large-duct obstruction. Serum markers for HCC, such as AFP, are not elevated in metastatic disease and are helpful in differentiating the two conditions.

OPTIMAL MANAGEMENT

As with benign and malignant hepatic tumors, anatomic localization with percutaneous biopsy to confirm the diagnosis is the first priority. CT can define the location and number of metastatic lesions and identify a primary, extrahepatic tumor within the abdomen. Resection of metastatic disease in the case of non-colorectal tumors has a dismal prognosis. In selected patients with colorectal carcinoma, resection of metastatic lesions has a better prognosis. Factors associated with a better prognosis (a 5-year survival rate greater than 30%) are the presence of three or fewer lesions, an interval of more than 1 year between bowel and liver resection, and a greater margin of normal resected liver around the tumor. Many metastatic colorectal tumors are slow growing; in considering surgery, the risk of death during surgery must be weighed against the potential for prolonged survival.

[Endoscopic Approach to Ingestion of Foreign Bodies](#)
[The Future of Gastrointestinal Endoscopy](#)

Clinicians are afforded an array of techniques for diagnosis and management of diseases of the digestive tract. These include esophagogastroduodenoscopy, small-bowel enteroscopy, colonoscopy, flexible sigmoidoscopy, endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasonography (EUS). Flexible endoscopy allows direct imaging of the upper and lower digestive tracts. It is more sensitive and specific for most conditions than are indirect imaging techniques such as contrast radiography and allows directed tissue sampling for histologic assessment. It also allows direct curative and palliative measures.

EQUIPMENT

Gastrointestinal (GI) endoscopes are long, slim instruments capable of light and image transmission. Lengths and diameters vary according to purpose. Flexible endoscopes initially relied on fiber optic bundles to transmit light and images. Videoendoscopic images now are generated electronically by means of a charge coupled device (CCD chip) located at the tip of the endoscope. Digital photographs can be printed, and images can be stored and recalled from magnetic optical discs.

Endoscopes are equipped with an air-water channel to allow insufflation of the lumen and washing of the lenses. An accessory channel allows suctioning of air and fluid from the digestive tract and facilitates passage of instruments for tissue sampling and therapeutic applications. Bidirectional controls in the handpiece allow tip deflection for steering. An array of tissue sampling and therapeutic interventions can be performed ([Table 127.1](#), [Table 127.2](#)). Occupational Safety and Health Organization guidelines are followed to protect patients and medical staff from infectious hazards during endoscopic procedures. Endoscopes are cleaned manually and subjected to a high-level disinfection process to prevent patient to patient transmission of infectious disease through instrumentation.

Forceps biopsy (directed or surveillance)
 Excisional biopsy
 Polypectomy
 Brush cytology
 Fine-needle aspiration
 Campylobacter-like organism (CLO) test
 pH Assessment
 Biliary crystal analysis
 Sphincter of Oddi manometry

TABLE 127.1. TISSUE SAMPLING AND ENHANCED DIAGNOSTIC TECHNIQUES AVAILABLE THROUGH ROUTINE ENDOSCOPIC PROCEDURES

Polypectomy (sessile and pedunculated polyps)
 Hemostasis (nonvariceal, e.g., injection, electrocautery, laser coagulation; acute variceal bleeding and subsequent obliteration of varices, e.g., sclerotherapy, rubber band ligation)
 Dilation (benign and malignant strictures)
 Management of achalasia (dilation, botulinum toxin injection)
 Foreign body extraction
 Bile duct stone extraction
 Tumor ablation (electrothermal, laser photoablation, cytotoxic)
 Insertion of endoprosthesis (stents)
 Biliary and pancreatic sphincterotomy
 Placement of enteral feeding tube

TABLE 127.2. INTERVENTIONS COMMONLY PERFORMED DURING THERAPEUTIC ENDOSCOPIC PROCEDURES

PREPARATION, SEDATION, AND MONITORING

Most endoscopic examinations are performed as elective, outpatient procedures. Patients fast for 4 to 6 hours before the procedure. Patients undergoing colonoscopy also need a bowel purge to cleanse the colon of its contents. Screening flexible sigmoidoscopy requires administration of one or more enemas to cleanse the distal colon.

Other than screening flexible sigmoidoscopy, most endoscopic examination in the United States are performed with conscious sedation. Intravenously administered medications, typically a narcotic and a short-acting benzodiazepine, are used to induce relaxation, anxiolysis, and amnesia. Although not universally needed, sedation for diagnostic endoscopy allows tolerance of otherwise unpleasant or uncomfortable procedures and makes most therapeutic procedures feasible.

GI endoscopy is generally safe and well tolerated. Major complications, such as bleeding or perforation, occur among less than 0.1% of patients. Complications are more apt to occur when therapeutic intervention is performed. Cardiorespiratory compromise associated with the use of intravenous sedation is the most common complication. For this reason, clinical and electronic monitoring is performed routinely by nurses. Heart rate, respiratory rate, blood pressure, continuous oxygen saturation, and electrocardiographic tracings commonly are monitored. The use of supplemental oxygen has become routine.

INDICATIONS FOR GASTROINTESTINAL ENDOSCOPY

GI endoscopy is indicated (a) when a change in management is apt to be based on results of endoscopy; (b) after empiric therapy for a suspected benign disorder of the digestive tract has been unsuccessful; (c) for further evaluation of abnormalities seen on radiographic images; and (d) when a primary therapeutic procedure is being considered ([Table 127.3](#)). GI endoscopy is generally not indicated when the results are not apt to contribute to management or for periodic follow-up evaluation of benign disease unless surveillance of a potentially malignant condition is warranted. GI endoscopy is contraindicated when comorbid disease causes the risks to

outweigh the benefits; when perforation of a viscus is suspected; and when patient consent or cooperation cannot be obtained for elective procedures.

TABLE 127.3. INDICATIONS FOR GASTROINTESTINAL ENDOSCOPIC PROCEDURES

GASTROINTESTINAL ENDOSCOPIC PROCEDURES

ESOPHAGOGASTRODUODENOSCOPY

Esophagogastroduodenoscopy, or upper endoscopy, with a 1 m endoscope allows inspection of the upper digestive tract—the laryngopharynx to the descending duodenum. During this procedure the examiner can see the luminal esophagus, stomach, and proximal duodenum; upper and lower esophageal sphincters; esophagogastric junction; and pylorus.

FLEXIBLE SIGMOIDOSCOPY

Flexible sigmoidoscopy with a 60 cm endoscope is used to evaluate suspected anorectal disorders and distal colonic disease and in screening for colorectal neoplasia. The patient is not sedated for these procedures. Flexible sigmoidoscopes have largely replaced rigid sigmoidoscopes. Enema preparation is used to cleanse the rectum.

COLONOSCOPY

Colonoscopy allows direct inspection of the entire colon, anal canal, and terminal ileum. Total colonoscopy requires a bowel purge and is typically performed with sedation. The colonoscope is manually advanced under direct vision and steered by means of tip deflection. Careful inspection is performed during advancement and withdrawal. Colonoscopy is more sensitive and more specific than barium enema radiographic examination. Lesions identified at barium enema examination typically necessitate total colonoscopy for confirmation and management.

SMALL-BOWEL ENTEROSCOPY

For evaluation of the proximal small intestine beyond the descending duodenum, push enteroscopy with an extended-length instrument allows directed imaging and tissue sampling. It also allows a variety of therapeutic maneuvers in the horizontal duodenum and proximal to middle jejunum. Push enteroscopy is used in the evaluation of chronic GI bleeding when upper endoscopy and colonoscopy had failed to identify a source. Arteriovenous malformations in the small intestine are the most commonly identified causes of bleeding. When arteriovenous malformations in the small intestine are identified and managed with injection or electrocautery therapy, approximately 50% of patients have a marked reduction in bleeding and transfusion requirement. Other indications for push enteroscopy include small-bowel biopsy in the evaluation of celiac sprue and evaluation of abnormalities seen on contrast radiographic images.

For evaluation of the terminal ileum, colonoscopic intubation of the ileocecal valve can be achieved in 80% to 90% of attempts. Colonoscopic inspection of the terminal ileum is an effective means of assessing involvement of this segment of intestine by Crohn's disease, lymphoma, and other diseases of the ileum. Standard tissue sampling techniques can be performed.

Sonde enteroscopy allows visualization of the entire small bowel. The long, slim instrument is passed through the nose and advanced beyond the ligament of Treitz with endoscopic or fluoroscopic assistance. A water-filled balloon affixed to the tip allows the scope to be propelled by peristalsis. Unfortunately, depth of insertion is variable and there is no capability for tip control, tissue sampling, or application of therapy. Sonde enteroscopy is used to evaluate the presence and extent of arteriovenous malformations of the small intestine and to identify tumors beyond the reach of a push enteroscope or not seen on radiographic images.

Intraoperative enteroscopy is the ultimate means of examining the entire small bowel. After laparotomy, a push enteroscope or pediatric colonoscope is advanced through the mouth. The endoscopist and GI surgeon work together to manually advance the endoscope through the entire length of small bowel. Endoscopic and operative techniques can be used to identify mucosal and vascular lesions.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

ERCP combines endoscopic and radiologic techniques to facilitate diagnosis and management of disorders of the biliary system and pancreas. A specialized side-viewing duodenoscope is negotiated into the second portion of the duodenum for *en face* viewing of the ampulla of Vater. Plastic catheters are passed through the accessory channel of the endoscope and directed selectively into the pancreatic duct or bile duct. Radiographic contrast medium is injected into the duct to produce opacification of the biliary or pancreatic ductal systems. Endoscopic retrograde pancreatography is the standard for biliary and pancreatic ductal imaging. Although magnetic resonance cholangiopancreatography is approaching parity for diagnostic accuracy, ERCP allows an array of therapeutic interventions. While it is generally safe and well tolerated, in addition to the standard risks associated with other endoscopic procedures, ERCP exposes patients to a 2% to 5% risk of pancreatitis.

ENDOSCOPIC ULTRASONOGRAPHY

EUS combines the technologies of endoscopy and ultrasonography. A fiber optic endoscope is modified with a microscopic ultrasound transducer affixed to the distal tip. The endoscopist advances the echoendoscope into the desired luminal location under endoscopic guidance. Bringing the ultrasound transducer close to the tissue or organ of interest circumvents the impediments of intervening bone, fat, and air and allows the use of high-frequency ultrasound waves that achieve high resolution. EUS is gaining broad acceptance. It is used for diagnosis and staging of abnormalities of the luminal GI wall and of periluminal organs, including the pancreas, biliary tree, and mediastinal, perigastric, and perirectal structures. Pulse Doppler ultrasound to assess vascular flow and real-time fine-needle aspiration of luminal and extraluminal lesions aligned with the endosonographic image can be performed.

EUS is used in the evaluation of focal intramural and extramural mass lesions identified at endoscopy or other imaging studies. It is used in the evaluation of biliary obstruction, pancreatic lesions, and neuroendocrine tumors when other imaging studies fail to yield a diagnosis. Its other principle role is as a staging tool. Compared with other imaging studies, EUS has been demonstrated superior for both tumor and node staging for esophageal, gastric, ampullary, biliary, and rectal carcinomas and gastric lymphoma (Fig 127.1). Once diagnosis and staging have been achieved, EUS-guided fine-needle aspiration biopsy allows tissue diagnosis in as many as 95% of attempts, a yield superior to that of other tissue sampling techniques. EUS-guided fine-needle aspiration also is effective for biopsy of celiac and mediastinal lymph nodes (Fig 127.2).

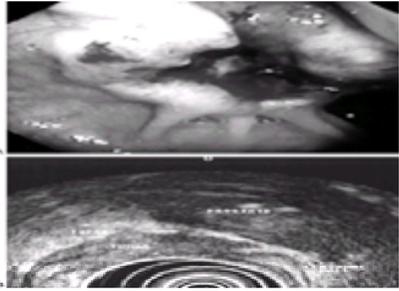

FIGURE 127.1. **A:** Colonoscopic view of ulcerated rectal carcinoma. **B:** Endoscopic ultrasound image shows the lesion as a hypoechoic mass disrupting the normal wall layer pattern with invasion into the perirectal fat and encroaching on but not directly invading the prostate gland. The multiple concentric circles are the echoscope in the lumen of the rectum.

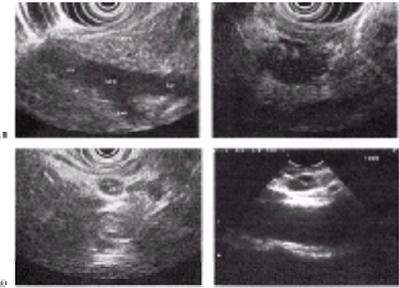

FIGURE 127.2. Endoscopic ultrasound (EUS) images of a pancreatic lesion. **A:** Normal endosonographic appearance of the pancreatic head (*panc*), pancreatic duct (*PD*), splenoportal confluence (*SPC*), portal vein (*PV*), splenic vein (*SV*), and superior mesenteric vein (*SMV*). **B:** A 1.8 cm hypoechoic mass in the genu (*between the markers*) has evidence of malignant growth. **C:** A 1 cm suspicious lymph node (*LN*) in the celiac region. **D:** Results of EUS-guided fine-needle aspiration biopsy confirmed metastatic pancreatic adenocarcinoma. Linear echoes represent the needle in the lymph node.

ENDOSCOPIC APPROACH TO ESOPHAGEAL DISORDERS

DISORDERS

Gastroesophageal Reflux

Gastroesophageal reflux disease is the most common malady of the upper digestive tract (see [Chapter 106](#)). Episodic reflux of gastric acid into the esophageal lumen is normal. Excessive exposure of the esophagus to gastric acid causes symptomatic esophagitis. Esophageal ulceration, bleeding, and peptic stricture formation may complicate severe esophagitis. Most patients with symptoms of gastroesophageal reflux respond to empiric pharmacotherapy. Endoscopy is recommended for patients who do not respond to empiric therapy or have recurrence of symptoms when therapy is reduced or eliminated and those who need tissue sampling to clarify the diagnosis. Follow-up endoscopy for uncomplicated esophagitis usually is unnecessary. Endoscopy also is indicated when symptoms are accompanied by dysphagia, odynophagia, abnormalities on radiographs, GI blood loss, and compromised immune function.

Barrett Esophagus

Barrett esophagus is the replacement of normal squamous esophageal mucosa with specialized intestinal metaplasia in response to chronic acid reflux injury (see [Chapter 106](#) and [Chapter 115](#)). Barrett mucosa is recognized at endoscopy as pink mucosa that can be differentiated from surrounding pale-white normal squamous epithelium. Forceps tissue biopsy allows histologic confirmation. Barrett mucosa is present among 5% to 15% of patients with frequent reflux symptoms. Identification of Barrett esophagus is important because this condition is associated with as much as 40-fold increased risk of esophageal adenocarcinoma. Adenocarcinoma arising from Barrett esophagus appears to emerge through grades of dysplasia that can be discriminated histologically. Patients with Barrett esophagus are advised to undergo periodic endoscopic examinations to detect dysplasia or early carcinoma. Because the prognosis for advanced carcinoma is so poor, the detection of precancerous lesions or early cancer is apt to have life-saving benefit. Endoscopic techniques for eradication of Barrett epithelium and superficial cancers by means of thermal, resection, and photochemical techniques are emerging.

Dysphagia and Odynophagia

Dysphagia, difficulty swallowing, and odynophagia, painful swallowing, are symptoms that require endoscopic investigation (see [Chapter 94](#)). Difficulty with swallowing can be caused by functional or mechanical disorders. An imaging study is needed to rule out structural lesions. Contrast radiography may be valuable in some instances to localize or characterize pathologic changes. Endoscopy is preferred, however, because it allows direct visualization, tissue sampling, and dilation therapy for mechanical processes.

Benign mechanical causes of dysphagia include peptic stricture, Schatzki's ring, congenital esophageal mucosal webs and rings, and strictures caused by radiation therapy, caustic ingestion, and surgical anastomoses. All respond to dilation therapy. Dysphagia is the most common symptom of esophageal cancer. Achalasia is an acquired neuromuscular abnormality in which the esophagus loses normal peristaltic function and the lower esophageal sphincter is hypertensive and does not relax (see [Chapter 108](#)). These features can be demonstrated at esophageal manometry. Endoscopy is necessary to exclude a pseudoachalasia due to carcinoma at the esophagogastric junction.

Odynophagia occurs when injury to the esophageal mucosa causes ulceration. Because it may be a symptom of a serious pathologic condition, odynophagia should be investigated with endoscopy. Odynophagia may be caused by acid peptic ulceration, chemical injury, infection, or neoplasia. Among immunocompromised patients *Candida*, herpes, or cytomegalovirus infection can cause infectious esophagitis. In addition to these, idiopathic AIDS ulceration may occur among patients with HIV infection.

Esophageal Cancer

Esophageal cancer is highly lethal because most patients have advanced disease at diagnosis (see [Chapter 115](#)). The absence of a serosa surrounding the esophageal wall allows esophageal tumors to expand and spread hematogenously before symptoms of luminal compromise occur. Patients with suspected esophageal cancer should undergo endoscopy, including EUS, for confirmation and to assess appropriateness of treatment options. Patients with advanced disease may benefit from endoscopic palliative therapy for dysphagia.

ENDOSCOPIC THERAPIES FOR ESOPHAGEAL DISEASE

Esophageal dilation is performed in the management of symptomatic benign and malignant esophageal strictures. Empiric dilation also may benefit patients who have dysphagia when eating solid foods and who have normal endoscopic findings. Esophageal dilation is performed most commonly with fixed-size, tapered, wire-guided, polyvinyl bougies (Savary dilators) or pneumatic balloon dilators. Savary dilators are passed over a guide wire that has been placed under endoscopic or fluoroscopic

guidance. Pneumatic dilators are passed through the scope and inflated within the stricture. Published data suggest equal efficacy of dilation methods.

Dilation improves or resolves dysphagia for most patients with benign strictures (85% to 90%). Rings and webs are managed by means of disruption through passage of one large-caliber dilator. Adequate results usually are achieved in a single session. Malignant strictures respond to dilation, but relief of dysphagia is transient, and the degree and duration of relief typically diminish with progression of disease. Esophageal dilation for achalasia is unique in that it involves forceful disruption of the lower esophageal sphincter muscle. Lower esophageal sphincter dilation to 30 to 40 mm is performed with pneumatic dilators. Endoscopic injection of botulinum toxin into the lower esophageal sphincter area has been demonstrated to achieve short-term improvement.

Endoscopic Therapy for Esophageal Cancer

Endoscopic therapy for esophageal cancer is based on the individual tumor and patient characteristics. Simple endoscopic dilation achieves rapid but short-lived symptomatic improvement. Laser therapy, delivered through flexible fibers that can be passed through the accessory channel of the endoscope, destroys tumors by means of coagulative necrosis and vaporization. It is effective in reconstituting the lumens of patients with obstructing esophageal cancer 85% of the time and in achieving marked improvement in symptomatic dysphagia 75% of the time. Endoscopic laser therapy for esophageal cancer usually is safe and well tolerated, but perforation, bleeding, pain, and fever are possible complications. Multiple sessions may be needed to achieve satisfactory initial palliation. Repeated sessions are needed in response to regrowth of the tumor.

Esophageal stent placement achieves rapid and long-lasting palliation of dysphagia associated with esophageal cancer ([Fig 127.3](#)). Expandable, coated metal, mesh stents can be placed atraumatically under endoscopic and fluoroscopic guidance. When deployed, the stents expand to reconstitute the esophageal lumen. Synthetic membrane coating prevents tumor ingrowth and effectively seals esophagorespiratory fistulas.

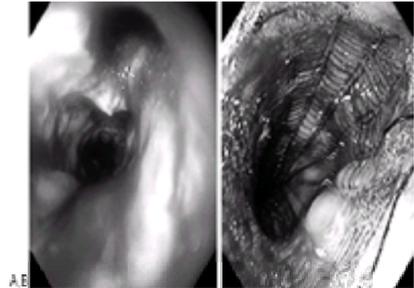

FIGURE 127.3. Endoscopic images demonstrate esophageal stricture due to carcinoma and esophagotracheal fistula before **(A)** and after **(B)** esophageal stent placement.

An emerging technique for endoscopic management of esophageal cancer is photodynamic therapy. This technique entails systemic administration of a photosensitive chemical agent that is selectively retained by tumor tissue. The impregnated tumor tissue is exposed to laser light of a specific wavelength delivered through the endoscope to the involved area. Light energy absorbed into the tissue causes a cytotoxic photochemical reaction. Tumor tissue is selectively destroyed with limited injury to surrounding normal tissue. Photodynamic therapy is currently approved for palliation of advanced esophageal carcinoma. The more compelling application however, may be the use of photodynamic therapy as an alternative to surgical resection for cure of patients with superficial carcinoma and patients with Barrett and high-grade dysplasia.

ENDOSCOPIC APPROACH TO ABDOMINAL DISORDERS

DISORDERS

Dyspepsia

Abdominal discomfort has many and varied causes. The patient history and the findings at physical examination dictate the diagnostic approach. When dyspeptic symptoms predominate, endoscopy should be considered. Dyspepsia is pain or discomfort centered in the upper abdomen. Peptic ulcer disease (15% to 25% of instances) or reflux esophagitis (5% to 15%) may produce dyspeptic symptoms. Most patients have functional symptoms and normal endoscopic findings. Endoscopy also allows assessment for evidence of gastritis suggested by erythema or erosions in the gastric mucosa and the presence of *Helicobacter pylori* infection. Less common findings, such as atrophic gastritis, intestinal metaplasia, and gastric cancer, may be uncovered. If the decision is made to examine a patient with dyspepsia, endoscopy rather than upper GI contrast radiography should be performed. When dyspepsia is accompanied by so-called trigger symptoms (weight loss, early satiety, and evidence of GI bleeding), there is universal agreement on the need for endoscopy. Early endoscopy also may contribute to patient satisfaction, offering reassurance about the absence of more sinister disease and allowing directed therapy based on endoscopic and histologic diagnosis.

Upper Gastrointestinal Bleeding

For a patient with acute upper GI bleeding, the first priorities are stabilization and resuscitation (see [Chapter 102](#)). Once these efforts have been instituted, endoscopic inspection should be performed to localize and identify the bleeding source, assess the persistence and rate of bleeding, and to determine the need for and administer endoscopic therapy. Esophagogastroduodenoscopy is highly accurate (95%) in identifying the source of acute upper GI bleeding. Accuracy decreases as the duration from presentation to endoscopy increases. Common causes of acute nonvariceal upper GI bleeding are gastroduodenal ulcer, erosive gastritis, and Mallory–Weiss tear. Endoscopy with hemostatic therapy has been demonstrated to stop active bleeding and to reduce the incidence of rebleeding, need for surgery, blood transfusion requirement, hospital mortality, and length of stay.

Chronic upper GI bleeding may be caused by an arteriovenous malformation, gastric antral vascular ectasia syndrome, portal gastropathy, erosive esophagitis, drug-induced or mechanical gastritis, or carcinoma. Endoscopy is indicated for diagnosis, and therapy is disease specific ([Fig 127.4](#)).

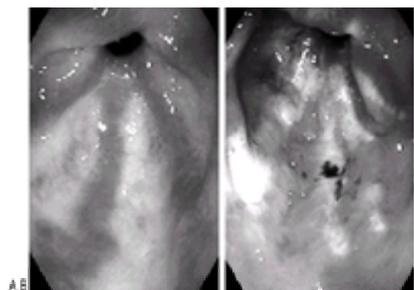

FIGURE 127.4. Endoscopic evaluation of iron deficiency anemia. **A:** Gastric antral vascular ectasia syndrome. The presence of multiple friable superficial vessels arrayed in a spoke-like pattern and emanating from the pylorus causes chronic gastrointestinal bleeding. **B:** The lesions are successfully managed with endoscopic laser photocoagulation.

Although variceal hemorrhage accounts for only 15% of instances of acute upper GI bleeding, it accounts for 30% of major instances of upper GI bleeding and is associated with 50% mortality. Endoscopy is needed to confirm the source of bleeding because as many as 50% of patients with portal hypertension and acute upper GI bleeding may have bleeding from a source other than esophagogastric varices. The other sources include portal hypertensive gastropathy, Mallory–Weiss tear, and gastroduodenal ulcer disease. Endoscopic therapy is effective in controlling acute bleeding in as many as 80% of patients. Efforts to achieve hemodynamic resuscitation and stabilization are crucial. They include attempts to correct coagulopathy among patients with advanced liver disease. Once initial bleeding is controlled, follow-up endoscopic therapy to achieve obliteration of esophageal varices reduces the risk of rebleeding.

ENDOSCOPIC HEMOSTATIC THERAPY

Endoscopic therapies for acute nonvariceal bleeding include injection with epinephrine solution or a sclerosing agent, contact probe electrocautery, noncontact cautery with laser, and mechanical hemostasis with endoscopically placed metallic clips. When active bleeding or signs of rebleeding are observed, endoscopic therapy is effective in achieving sustained hemostasis in more than 90% of cases. Among patients who have evidence of rebleeding after initial hemostasis, follow-up endoscopic therapy is favored over urgent surgery because the efficacy is similar and the morbidity and mortality are lower.

Endoscopic therapies for bleeding esophageal varices include sclerotherapy (EVS) and band ligation (EVL) (see [Chapter 102](#) and [Chapter 105](#)). EVS is performed with a hollow-bore needle-tip catheter that is advanced through the accessory channel of the endoscope and inserted directly into or adjacent to the esophageal variceal column. A sclerosing agent is injected to produce thrombosis of the vessel, to stop active hemorrhage, and to reduce risk of rebleeding. Controlled trials of EVS for the primary prevention of initial esophageal variceal bleeding have not demonstrated benefit. Local and systemic complications may occur among as many as 30% of patients undergoing EVS. The complications include chest pain, ulceration, esophageal stricture, pleural effusion, and acute respiratory distress syndrome.

EVL has fewer complications than EVS and is supplanting it as the preferred initial endoscopic hemostatic therapy. EVL is performed by means of aspirating the variceal column into a vacuum chamber affixed to the tip of the endoscope and releasing a rubber band that effectively strangulates and thromboses the vessel. Use of a multiband delivery system improves the ease and speed of deployment. Numerous randomized prospective trials comparing EVL with EVS have demonstrated equal efficacy for cessation of active bleeding. EVL is superior to sclerotherapy with respect to complications, eradicating varices more rapidly, and having a lower rate of rebleeding.

ENDOSCOPIC APPROACH TO COLONIC DISORDERS

COLORECTAL CANCER AND POLYPS

The U.S. Preventive Health Services Task Force has recommended colorectal cancer screening or surveillance based on individual risk (see [Chapter 116](#)). Screening and surveillance are recommended because colorectal cancer arises from precancerous polyps, which are readily recognizable against the background of normal mucosa ([Fig 127.5](#)). The presence of adenomatous colorectal polyps is associated with increased likelihood of the presence of or future development of colorectal cancer. Removal of adenomatous polyps by means of colonoscopic snare polypectomy followed by periodic surveillance colonoscopy prevents death due to colorectal cancer. Early cancer contained within polypoid lesions can be cured with simple endoscopic resection.

FIGURE 127.5. Adenomatous pedunculated colonic polyp found during surveillance colonoscopy for colorectal cancer. Curative resection is performed with colonoscopic electrocautery snare polypectomy.

Most polyps seen during colonoscopy can be completely removed by means of electrocautery snare resection. Colonic polypectomy has been demonstrated to be safe and effective. Electrocautery snare polypectomy is performed with a wire loop passed through the working channel of the colonoscope. Monopolar current passed through the snare wire allows concomitant cutting and coagulation through the polyp base. The resected specimen can be retrieved and submitted to the pathology laboratory for histologic interpretation. In addition to patients with a known history of colorectal polyps, colonoscopy is recommended for patients with abnormalities seen on barium enema radiographs, patients with a family history of colorectal cancer or polyps, and patients with a history of gynecologic cancer, long-standing chronic ulcerative colitis, familial adenomatous polyposis, or nonhereditary colorectal cancer syndromes.

LOWER GASTROINTESTINAL BLEEDING

Most minor rectal bleeding (see [Chapter 102](#)) is caused by benign anorectal disease, such as internal hemorrhoids, anal fissures or anal tears. The patient's age and clinical history dictate management. In nearly all cases, flexible sigmoidoscopy or anoscopy should be performed at the minimum. A determination to evaluate the more proximal colon has to be individualized. Barium enema radiographic examination or total colonoscopy are effective options. Recurrent bleeding from internal hemorrhoids may be treated with injection sclerotherapy or rubber band ligation. Bleeding from unresectable colorectal cancers or radiation proctitis may be palliated with laser photocoagulation.

The most common causes of hemodynamically significant acute lower GI bleeding are diverticulosis, arteriovenous malformations, and, less commonly, acute colitis, ischemia, and carcinoma. Because rapid upper GI bleeding can manifest as hematochezia, upper gastrointestinal endoscopy should be considered irrespective of results of nasogastric tube aspiration biopsy. These results may be negative in as many as 15% of instances of upper GI bleeding due to duodenal ulcer disease. Because most lower GI bleeding is intermittent or self-limited, colonoscopic inspection with or without preparation of the colon can be performed once the patient's condition is stabilized. Colonoscopy is effective in identifying a source of bleeding in 70% to 80% of cases of acute lower GI bleeding. Furthermore, colonoscopy is likely to have a therapeutic application that is not obtained with other diagnostic studies such as radionuclide scanning and viscera angiography.

DIARRHEA

Most instances of diarrhea are self-limited. Chronic diarrhea, defined as that lasting more than 2 weeks, requires endoscopic evaluation (see [Chapter 99](#)). When initial history and stool studies do not help identify the likely source, flexible sigmoidoscopy should be performed to rule out proctosigmoiditis. When the diagnosis remains obscure, total colonoscopy with intubation of the terminal ileal should be performed, and multiple biopsy specimens should be collected throughout normal and abnormal mucosa. The colonoscopic findings confirm the diagnosis of Crohn's disease, ulcerative colitis, microscopic colitis, including lymphocytic and collagenous colitis, ischemia, colorectal cancer, and infectious colitis ([Fig 127.6](#)). Upper gastrointestinal endoscopy should be performed with small-bowel biopsy when sprue is considered. Duodenal aspiration should be performed when bacterial overgrowth is considered.

FIGURE 127.6. Images from flexible sigmoidoscopic examination of a patient with a 2-week history of diarrhea show pseudomembranous colitis associated with *Clostridium difficile* infection. The patient had been treated with antibiotics 1 month earlier for a pulmonary infection.

INFLAMMATORY BOWEL DISEASE

Colonoscopy is an important aid in the diagnosis and management of ulcerative colitis and Crohn's disease (see [Chapter 111](#)). Although many patients with inflammatory bowel disease do not need colonoscopic examination for initial diagnosis, colonoscopy frequently is necessary to differentiate ulcerative colitis and Crohn's disease. Colonoscopy is more sensitive than a barium enema in determining the anatomic extent of the inflammatory process. Colonoscopy with multiple biopsies or polypectomy frequently is necessary in the evaluation of polypoid lesions found at barium enema examination because the differential diagnosis includes inflammatory pseudopolyps, true polyps, and carcinoma. Colonoscopy is needed to determine the cause of strictures in discriminating inflammatory from neoplastic processes. Patients with pancolitis of more than 7 to 10 years' duration and patients with left-sided ulcerative colitis of more than 15 years' duration are at increased risk of carcinoma of the colon. These patients are advised to undergo surveillance colonoscopy with multiple biopsies to assess the presence of early carcinoma or dysplasia.

ENDOSCOPIC APPROACH TO PANCREATICOBILIARY DISORDERS

ERCP is indicated for the evaluation and management of suspected biliary disorders, including jaundice, cholestasis, postcholecystectomy pain, complications of biliary surgery, acute cholangitis, acute biliary pancreatitis, and confirmation of lesions demonstrated with other imaging techniques (see [Chapter 103](#), [Chapter 117](#), and [Chapter 125](#)). Suspected pancreatic disorders warranting ERCP include obstructive jaundice with pancreatic mass, chronic upper abdominal pain, increased serum amylase or lipase level, unexplained weight loss, malabsorption, unexplained gastric varices, recurrent pancreatitis, chronic pancreatitis of uncertain causation, and lesions found with other imaging techniques.

Findings at cholangiography include choledocholithiasis, benign and malignant stricture, ampullary tumor, primary sclerosing cholangitis, congenital abnormality of the biliary system, infestation with parasites, sphincter of Oddi dysfunction, bile duct leak, and hemobilia ([Fig 127.7](#)). Pancreatographic findings may include features of pancreatic carcinoma, chronic pancreatitis, pancreatic pseudocyst, nonmalignant pancreatic neoplasia, pancreas divisum, pancreatic duct disruptions, and pancreatic duct stones. Therapeutic maneuvers include biliary and pancreatic duct sphincterotomy, stone extraction including mechanical lithotripsy, tissue sampling techniques, dilation of malignant and benign strictures, drainage of obstructed biliary systems and pancreatic pseudocysts, and stenting with polyethylene and expandable metallic endoprostheses.

FIGURE 127.7. Endoscopic retrograde cholangiopancreatography. **A:** Retained common bile duct stone (relative lucency in duct) in a patient who had recently undergone cholecystectomy for chronic cholecystitis. **B:** After endoscopic biliary sphincterotomy, the stone is removed with a retrieval basket.

ENDOSCOPIC APPROACH TO ENTERAL FEEDING ACCESS

Enteral access can be a means of providing nutritional support to patients who are unable to maintain oral intake (see [Chapter 130](#)). Percutaneous endoscopic gastrostomy has become a commonly performed procedure in the care of patients who are unable to maintain oral intake because of compromise of mental status, swallowing dysfunction, or severe dysphasia. The endoscope is advanced into the stomach, and the light of the endoscope transilluminates the abdominal wall. A trocar is advanced through the abdominal wall into the inflated stomach under visualization through the endoscope. The newly established track allows insertion of a synthetic feeding tube. Internal and external bumpers prevent migration. In patients at risk of gastrorespiratory reflux, jejunal feeding tubes can be placed with endoscopic assistance beyond the ligament of Treitz, and enterorespiratory reflux is avoided.

ENDOSCOPIC APPROACH TO INGESTION OF FOREIGN BODIES

Ingestion of foreign objects, purposeful or accidental, is common among small children and among patients with mental status compromise due to psychiatric disease, mental retardation, or inebriation. Most foreign objects that reach the stomach pass through the digestive tract uneventfully. However, long objects, sharp objects, and objects lodged in the esophagus necessitate urgent removal. Flexible endoscopy has become the procedure of choice for diagnosis and for removal of foreign objects. A variety of devices can be used to remove all kinds of objects safely and effectively avoid laparotomy or thoracotomy.

THE FUTURE OF GASTROINTESTINAL ENDOSCOPY

The increasing miniaturization of technologic devices allows expansion of the diagnostic and therapeutic capabilities of endoscopy. Computer image analysis of cellular spectrofluorescence may enable discrimination of neoplastic potential. Early cancer detection and advancing endoscopic techniques will enable endoscopic therapies to replace many surgical procedures.

CHAPTER 128: ABDOMINAL AND ALIMENTARY TRACT IMAGING AND INTERVENTIONAL RADIOLOGY

STEPHEN TRENKNER

[Upper Gastrointestinal Tract](#)
[Small Bowel](#)
[Colon and Appendix](#)
[Liver and Biliary Tract](#)
[Pancreas](#)
[The Future](#)

There are numerous imaging techniques for evaluating gastrointestinal disease. These vary from conventional radiographic techniques that have been used for decades to the latest applications of magnetic resonance (MR) imaging. The best yield from imaging studies is obtained when the radiologist is provided accurate clinical information. Knowledge of the clinical situation helps determine the best imaging modality and how it will be performed.

UPPER GASTROINTESTINAL TRACT

The widespread availability of endoscopy and the development of new drugs for the treatment of patients with peptic ulcer disease have resulted in a marked reduction in the number of barium radiographic studies of the upper gastrointestinal tract. Modified barium swallow and esophagram, however, maintain an important role in the evaluation of dysphagia (see [Chapter 94](#)). The purpose of a modified barium swallow examination is to identify a structural or functional abnormality of swallowing and to evaluate treatment options. The study often is performed jointly by a speech pathologist and a radiologist. Various consistencies of liquids and solids in various quantities are administered orally, and the study is recorded on videotape. Abnormalities such as aspiration or a prominent cricopharyngeous muscle are readily detected. The speech pathologist can vary the diet in conjunction with various swallowing maneuvers to help the patient eat safely.

If the cause of dysphagia is not identified with the swallowing study, the radiologist should obtain a complete barium esophagram. The point at which a patient perceives food sticking does not correlate well with the actual site of obstruction. Obstruction at the gastroesophageal junction is often felt in the neck. During esophagram the radiologist can evaluate the anatomic features of the esophagus, identify a hiatal hernia, observe esophageal peristalsis, and check for gastroesophageal reflux. With a modified barium swallow examination and esophagram the cause of dysphagia frequently can be identified and the patient referred to the appropriate specialist ([Fig 128.1](#))

FIGURE 128.1. Prone esophagram performed after findings of modified barium swallow radiographic examination were normal. Dysphagia is caused by hiatal hernia (*curved arrow*), short stricture (*straight arrow*), and gastroesophageal reflux.

SMALL BOWEL

Imaging plays a key role in the evaluation of small-bowel abnormalities. Although plain radiography and barium studies continue to be the major modalities, computed tomography (CT) is gaining in prominence.

There are a number of techniques for evaluating the small bowel with barium, including conventional small-bowel follow-through (SBFT) study, peroral pneumocolon, and enteroclysis. The preference of the radiologist often dictates the type of study performed. A conventional SBFT study with the addition of a peroral pneumocolon is especially helpful in examinations of patients with Crohn's disease. When orally administered barium reaches the cecum, a small catheter is passed into the rectum, and air is insufflated. The air distends the terminal ileum and gives a double contrast effect. In patients with Crohn's disease, narrowing of the ileum frequently is caused in part by spasm. Administration of air allows more accurate assessment of true luminal diameter. The double contrast effect also improves visualization of subtle abnormalities such as aphthous ulcers.

Enteroclysis allows the most detailed evaluation of the small bowel and may provide enough information for a diagnosis when findings of an SBFT study are normal. A catheter is passed through the nose or mouth and advanced to the duodenojejunal junction. Barium is administered through the tube and followed by methylcellulose. This study allows reliable distention of the small bowel and excellent depiction of the mucosal fold pattern ([Fig 128.2](#)). Indications for enteroclysis include gastrointestinal bleeding after endoscopy has failed to demonstrate an upper GI or colonic source, symptoms of intermittent or partial small-bowel obstruction, and strong suspicion of small-bowel disease.

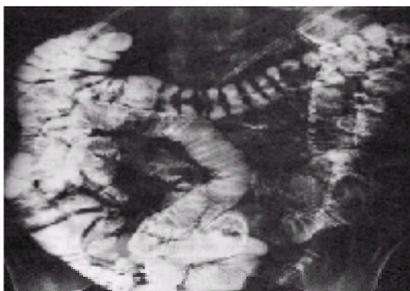

FIGURE 128.2. Normal enteroclysis. Normal fold pattern is well depicted.

As CT continues to improve, important small-bowel applications have become evident. CT has been especially helpful for evaluating small-bowel obstruction and ischemia. CT has a sensitivity of 94% in the diagnosis of small-bowel obstruction, allows correct prediction of the cause of obstruction in 73%, and is currently the best modality for detecting strangulation associated with closed-loop obstruction. The diagnosis of obstruction is based on demonstrating a transition point between dilated and decompressed bowel. When a transition point is found but there is no identifiable cause of obstruction, such as a tumor or abscess, an adhesion is suspected. Adhesions cannot be imaged directly with CT.

If a patient is believed to have acute mesenteric ischemia, angiography is the imaging study of choice. Vascular occlusion and vasoconstriction can be identified, and pharmacologic therapy can be provided through the catheter. The signs and symptoms frequently are nonspecific, however, and there is reluctance to perform an invasive procedure. Contrast-enhanced CT is an excellent tool for rapid evaluation of the entire abdomen. The sensitivity is 64% in the detection of acute mesenteric ischemia. Findings with a specificity of greater than 95% include arterial or venous thrombosis, pneumatosis intestinalis, portal venous gas, focal absence of bowel wall enhancement, and infarcts in other abdominal organs ([Figure 128.3](#)).

FIGURE 128.3. Extensive pneumatosis intestinalis (*arrow*) in a patient with acute mesenteric ischemia.

Chronic mesenteric ischemia is suspected when a patient has postprandial abdominal pain, weight loss, and an abdominal bruit (see [Chapter 112](#)). Most patients have thrombus at the origins of at least two of the three major visceral arteries (celiac axis, superior and inferior mesenteric arteries). Duplex sonography is a valuable tool for selecting patients who need angiography as the definitive test for this condition.

COLON AND APPENDIX

The widespread availability of colonoscopy and the development of cross-sectional imaging modalities have caused a reduction in the use of barium enema radiography. Contrast enema examination remains a valuable test with numerous important applications, including screening for polyps and colorectal cancer, evaluating obstruction, detecting fistulas, and evaluating the colon after a surgical procedure.

CT is an excellent modality in the diagnosis of diverticulitis or appendicitis. Many other colonic conditions also can be identified with CT that are not suspected clinically. It is not uncommon to find pseudomembranous colitis or ischemic colitis in a patient undergoing CT to evaluate a fever source or nonspecific abdominal pain.

DIVERTICULITIS

In direct comparison with barium enema radiography, CT is the best study for the diagnosis of diverticulitis. Diverticulitis is identified by the findings of stranding of the pericolic fat, thickening of the colonic wall, and abscess formation adjacent to the colon. CT can be used to guide percutaneous drainage of an abscess if clinically necessary. CT also may help identify an alternative diagnosis if diverticulitis is not present. Contrast enema examination still plays a role in the care of patients with diverticulitis when the CT findings are equivocal. The degree of obstruction and exact site and size of a fistula also are best demonstrated with a contrast enema examination.

The CT findings in pseudomembranous colitis (see [Chapter 113](#)) vary from normal in mild cases to marked, nodular colonic wall thickening in severe cases. Orally administered contrast material trapped between the thickened folds looks like an accordion. This sign is fairly specific for pseudomembranous colitis ([Fig 128.4](#)).

FIGURE 128.4. Pseudomembranous colitis with accordion sign in the sigmoid colon (*arrow*).

APPENDICITIS

Appendicitis is diagnosed clinically in most instances, but 20% of patients have atypical initial findings. This group of patients benefits most from imaging. Plain radiographs and a barium enema examination are of limited value. The most specific plain radiographic finding is an appendicolith, but one is seen in only 10% of cases. The diagnosis of appendicitis is made at barium enema radiography when there is incomplete filling of the appendix and a mass effect on the cecum. The appendix may not fill with barium in patients without appendicitis.

Ultrasound scanning and CT have become the two main imaging modalities for the evaluation of appendicitis. The ultrasound diagnosis is based on identifying a noncompressible appendix greater than 6 mm in diameter. If an appendicolith is seen at ultrasound examination, the result is considered positive even if the diameter is less than 6 mm. According to these criteria, appendicitis may be diagnosed with a sensitivity of 89.9% and a specificity of 96.2%. Ultrasonography is operator dependent and is difficult when the patient is obese and when the appendix is retrocecal. A normal appendix is infrequently seen with ultrasonography. The absence of appendicitis therefore is inferred when an appendix is not seen.

Appendicitis is diagnosed with CT when the appendix has a thickened wall, there are inflammatory changes in the fat surrounding the appendix, or an appendicolith is identified. If intravenous contrast medium is given, the wall of an abnormal appendix commonly becomes enhanced. CT also is excellent for detecting an appendiceal abscess. Sensitivities as high as 98% to 100% have been reported for the detection of appendicitis with CT. Among patients without appendicitis, CT allows an alternative diagnosis in as many as 62% of cases. In one series, CT scans were obtained of 100 patients consecutively hospitalized with the clinical diagnosis of appendicitis. CT findings led to changes in the treatment plan for 59 patients, prevented 13 unnecessary appendectomies, and showed a savings of \$447 per patient.

Ultrasound and CT are both excellent tests for appendicitis. The expertise and experience of the radiologist should be taken into account when these studies are ordered. A reasonable approach is to perform ultrasound examinations of children and women of childbearing age. CT has advantages in examinations of obese patients, the elderly, the immunosuppressed, and those with a palpable right lower quadrant mass.

COLORECTAL CANCER

The diagnosis of colorectal cancer typically is made by means of colonoscopy or barium enema radiography. Once the diagnosis is established, preoperative staging requires the evaluation of depth of tumor penetration, lymph node involvement, and presence of distant metastases, especially to the liver.

CT is superior to MR imaging in predicting tumor penetration beyond the muscularis propria but has a sensitivity of only 72%. Detecting a tumor in local lymph nodes is difficult with either CT or MR (sensitivity 49% and 23%, respectively). CT and MR depict liver metastases with a sensitivity of 62% and 70%, respectively. The ability to detect microscopic disease in lymph nodes and the liver with CT and MR imaging is limited.

LIVER AND BILIARY TRACT

CT is the dominant cross-sectional imaging modality for the liver and abdomen. With spiral or helical CT, the entire liver can be scanned during a single breath hold, eliminating misregistration due to breathing. The rapidity with which the scan can be performed allows imaging during different phases of contrast enhancement. The liver can be imaged twice during the intravenous administration of a single bolus of contrast material. The early scans depict the liver in the hepatic arterial phase, and later scans depict the liver in the portal venous phase. Biphasic CT is of particular importance in the evaluation of hypervascular tumors such as hepatocellular carcinoma and hypervascular metastases from renal cell tumors, tumors of the breast and thyroid, melanoma, carcinoid tumors, sarcoma, and pancreatic islet cell tumors. Hypervascular tumors are supplied by the hepatic artery. Therefore when imaged in the hepatic arterial phase, they appear as areas of enhancement against a relatively unenhanced liver (Fig 128.5). When imaged in the portal venous phase, hypervascular tumors may become the same density or less dense than normal liver. Hypovascular tumors such as metastases from the colon, lung, and pancreas are best imaged during the portal venous phase.

FIGURE 128.5. Metastatic renal cell carcinoma (*arrows*) imaged during the hepatic arterial phase.

MR imaging is an excellent modality for hepatic imaging and often is used to characterize lesions that are equivocal at CT. MR imaging also provides an alternative to CT in examinations of patients for whom use of iodinated contrast material is contraindicated because of allergy or renal insufficiency (Fig 128.6). A new application of MR imaging is MR cholangiopancreatography (MRCP). This technique allows images acquired with MR to be projected in a manner similar to that of endoscopic retrograde cholangiopancreatography (ERCP). The spatial resolution of MRCP is inferior to that of ERCP, but many conditions such as choledocholithiasis and biliary strictures can be diagnosed reliably. MRCP provides a means for studying the bile ducts and pancreatic duct of patients who have had unsuccessful ERCP or who have postoperative gastric anatomy that does not allow performance of ERCP. As MRCP continues to improve, it may replace diagnostic ERCP in many applications. ERCP will continue to have a strong role in therapeutic intervention.

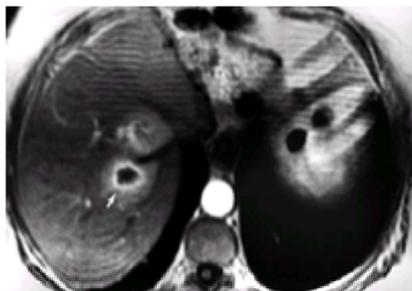

FIGURE 128.6. Gadolinium-enhanced magnetic resonance image shows liver metastases (*arrow*) from renal cell carcinoma in a patient allergic to iodinated contrast medium.

Ultrasonography is the primary imaging modality for evaluating the gallbladder and for detecting biliary dilatation. Intraoperative ultrasonography also outperforms both CT and MR imaging in the detection of hepatic metastases and should be performed during partial hepatectomy.

The evaluation of transjugular intrahepatic portosystemic shunts (TIPS) is a recent application of ultrasonography. TIPS has become a valuable option in the management of complications of portal hypertension. Ultrasonography is helpful before and after TIPS placement. The preprocedure study consists of evaluation of the liver parenchyma and assessment of spleen size and the amount of ascites. A complete upper abdominal vascular examination is performed to assure patency of the hepatic veins and to define portal venous anatomy and direction of blood flow. TIPS procedures are performed by an interventional radiologist. Vascular access is obtained through the internal jugular vein. A shunt is developed between a hepatic vein and the portal vein, which is kept open with a metallic stent. Postprocedure ultrasonography is used to assess shunt patency. The velocity of flow within the shunt is determined by means of evaluation of the Doppler signal. Stenosis of the shunt is usually caused by pseudointimal hyperplasia and is identified with either an increase or a decrease in shunt velocity compared with a baseline value.

Scintigraphy is important in hepatobiliary imaging. While conventional liver–spleen scanning rarely is used today, other techniques have taken its place. Technetium 99m HIDA scans are used to study the bile ducts and the gallbladder. When obstruction of the cystic duct is demonstrated, this study is more than 90% sensitive for the diagnosis of acute cholecystitis. Technetium 99m HIDA scans also can be used to detect bile leaks and biliary obstruction, especially in patients with postoperative anatomic features that preclude performance of ERCP.

Technetium 99m labeled red blood cell scintigraphy is an excellent study for confirming the diagnosis of hepatic cavernous hemangioma. Cavernous hemangiomas is the most common benign liver tumor and is a frequent incidental finding at ultrasound studies. When confirmation is needed, a ^{99m}Tc-labeled red cell study is an alternative to CT or MR imaging.

New imaging agents are being developed for specific indications. Indium 111 octreotide is a somatostatin analog that can be used to image neuroendocrine tumors, especially gastrinoma. Fluorodeoxy glucose (F-18FDG) has an affinity for colorectal neoplasms, and imaging with this agent may have a role in the evaluation of colorectal cancer when a patient has an elevated carcinoembryonic antigen level.

PANCREAS

CT is currently the best initial imaging study for evaluation of the pancreas. Two common indications for CT of the pancreas are pancreatic carcinoma and pancreatitis. The ability to obtain rapid contrast-enhanced images by means of spiral CT has improved the imaging of pancreatic carcinoma. Just as hepatic scanning has been improved by imaging during the arterial phase and the portal venous phase of contrast enhancement, pancreatic imaging has been improved by scanning during the pancreatic phase. The pancreatic phase falls between the arterial phase and the portal venous phase. At this time the difference in attenuation between hypovascular pancreatic cancer and contrast-enhanced normal pancreas is the greatest. Enhancement of surrounding vascular structures also is optimal during the pancreatic phase. For full staging of pancreatic carcinoma, the primary tumor must be imaged and assessed for local or distant spread. This is best done with imaging of the pancreas in the pancreatic phase and the liver in the portal venous phase.

Contrast-enhanced CT is the imaging study of choice for patients with pancreatitis. Lack of enhancement of portions of the pancreas indicates pancreatic necrosis, the presence of which is predictive of substantial morbidity and mortality ([Fig 128.7](#)). CT is useful for diagnosis of other complications of pancreatitis such as pseudocyst, abscess, hemorrhage, and pseudoaneurysm. CT also can be used to guide drainage of pseudocysts and abscesses.

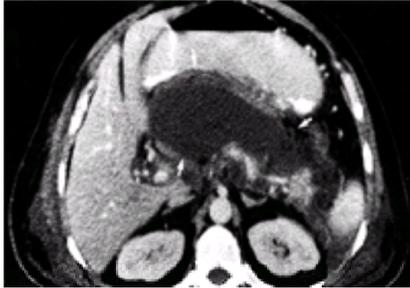

FIGURE 128.7. Lack of enhancement of the pancreas (*arrows*) suggests the diagnosis of pancreatic necrosis.

THE FUTURE

The near future for abdominal radiology involves increasing applications for the noninvasive imaging of luminal structures. MRCP will continue to improve as an alternative to diagnostic ERCP. MR angiography is replacing conventional angiography. CT colography (virtual colonoscopy) may become the screening study of choice for the detection of polyps and colorectal cancer. This procedure is performed by means of imaging the colon with spiral CT. The data are reformatted into two- and three-dimensional images of the entire colon. The three-dimensional images look like colonoscopic images.

CHAPTER 129: DIAGNOSTIC TESTS IN GASTROINTESTINAL MOTILITY AND PHYSIOLOGY

WILLIAM L. HASLER

[Gastrointestinal Motility Testing](#)
[Breath Testing in Gastroenterology](#)
[Secretory Testing in Gastroenterology](#)

For many organic diseases of the gastrointestinal tract, structural evaluation with endoscopic or radiographic studies is needed for diagnosis. However, certain disorders of the gastrointestinal tract exhibit no visible abnormalities. To detect these conditions, a broad range of physiologic tests of visceral motor and secretory function can be performed.

GASTROINTESTINAL MOTILITY TESTING

Disorders of gastrointestinal motility may produce a variety of symptoms depending on the anatomic region involved and the severity of dysfunction (see [Chapter 108](#)). For each luminal segment, tests of motor function provide diagnostic information that can be used to direct treatment.

ASSESSMENT OF ESOPHAGEAL MOTOR FUNCTION

Common symptoms related to dysfunctional esophageal motor activity include dysphagia (see [Chapter 94](#)), noncardiac chest pain (see [Chapter 95](#)), and gastroesophageal reflux (see [Chapter 106](#)). Less common signs and symptoms of esophageal dysmotility include a globus sensation of fullness in the throat, pharyngeal irritation, and pulmonary complications such as asthma, recurrent bronchitis, and aspiration pneumonia.

Esophageal Manometry

Indications

Esophageal manometry is used most commonly to evaluate patients with unexplained dysphagia who have no evidence of esophageal obstruction. It is used specifically in the diagnosis of achalasia and other esophageal motor disorders. The test also is used to detect esophageal dysmotility among patients with chest pain after cardiac disease has been excluded. Esophageal manometry is performed on selected patients with gastroesophageal reflux, especially those being considered for surgical therapy.

Methods

After induction of topical anesthesia of the nasal cavity and throat with viscous lidocaine, a water-perfused or solid-state manometric catheter is passed so that all recording sites are initially in the stomach. The examiner slowly withdraws the catheter while looking for a positive deflection representative of lower esophageal sphincter (LES) pressure. After establishment of LES pressure, the catheter is left in place so that a distal recording site continuously measures LES pressure and three or more proximal sites record esophageal body pressure. The response to swallowing is assessed and should include generation of an aborally propagative peristaltic contraction and >90% reduction in LES pressure. Tone and relaxation of the upper esophageal sphincter (UES) and a crude assessment of pharyngeal peristalsis also can be measured for patients with cervical dysphagia; however, manometric evaluation of this region may be limited by patient tolerance and other technical factors.

Provocative testing can be performed during esophageal manometry for selected indications. Intravenous administration of edrophonium may increase esophageal contractions and reproduce symptoms in as many as 40% of patients with unexplained chest pain. Ergonovine and bethanechol also may reproduce chest pain; however, side effects are common with these agents.

An acid reflux test can be performed to assist in the diagnosis of gastroesophageal reflux. This provocation involves measuring esophageal pH 5 cm above the LES before and after maneuvers that increase intraabdominal pressure. The Bernstein test is performed by means of alternate infusion of hydrochloric acid and saline solution in the esophagus with the patient blinded. This test can be used to determine whether unexplained chest pain or heartburn is caused by acidification of the esophagus.

Clinical Findings

Lack of esophageal body peristalsis is a requirement for the diagnosis of achalasia, although low-amplitude simultaneous contractions often are present ([Fig 129.1](#)). Vigorous achalasia is a variant with high-amplitude (>80 mm Hg) nonperistaltic contractions. Incomplete LES relaxation is usually (>80% of cases) but not always present in achalasia; some early presentations have complete relaxations of very short duration. Some patients with achalasia may have elevated LES or intraesophageal pressure. The presence of simultaneous esophageal body contractions at more than two recording sites more than 10% of the time with normal LES relaxation is found with diffuse esophageal spasm. Nutcracker esophagus is characterized by high-amplitude (>180 mm Hg) peristaltic body contractions of long duration (>6 seconds). These conditions cause chest pain more often than they do dysphagia. Hypertensive LES is defined by an LES pressure >45 mm Hg. Low LES pressures are common among patients with scleroderma.

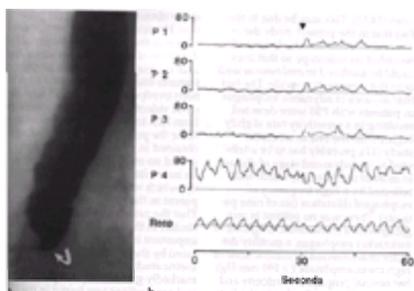

FIGURE 129.1. Videofluoroscopic and manometric findings for a patient with achalasia. **A:** Radiographic image shows a typical bird's beak appearance. **B:** Manometric tracing of the esophageal body (P1-3) shows a lack of peristalsis with swallowing water (arrow). There also is incomplete relaxation of the LES (P4). (From Schima W, Stacher G, Pokieser P, et al. Esophageal motor disorders: videofluoroscopic and manometric evaluation--prospective study in 88 symptomatic patients. *Radiology* 1992;185:487-491.)

Impaired UES relaxation occurs with primary UES disorders such as cricopharyngeal achalasia and diffuse neuromuscular diseases such as central nervous system lymphoma, oculopharyngeal muscular dystrophy, and familial dysautonomia. UES hypertension may occur with gastroesophageal reflux. Low UES pressures occur with amyotrophic lateral sclerosis, myotonic dystrophy, and myasthenia gravis. Among patients with gastroesophageal reflux, a low LES pressure is associated with a high rate of failure of medication therapy. Thus manometry may be useful in determining which patients might benefit from antireflux surgery. Preoperatively manometric assessment of esophageal body peristalsis also is important, because the presence of uncoordinated peristalsis can influence the type of surgical

procedure chosen.

Twenty-four-hour pH Monitoring

Indications

Twenty-four-hour ambulatory esophageal pH monitoring is most commonly indicated to determine whether gastroesophageal reflux of acid is responsible for atypical symptoms, such as chest pain, cervical dysphagia, cough, pharyngitis, or pulmonary disorders such as asthma or bronchitis. The procedure also is performed to confirm that acid is the source of esophageal symptoms among patients being considered for antireflux surgery. Monitoring of pH may be performed during therapy with acid-suppressing medications to determine the adequacy of antireflux treatment among patients with persistent or atypical symptoms.

Methods

After topical anesthesia of the nasal cavity and throat, the catheter is passed through the nose until the pH electrode is determined to be 5 cm above the LES. Intraesophageal pH is recorded continuously with an electronic device worn on the belt or over the shoulder while the patient performs normal daily activities, including ingestion of meals, exertion, and sleep. An event recorder is included to correlate episodes of chest pain, heartburn, cough, or dysphagia with periods of gastroesophageal reflux of acid.

Clinical Findings

The maximal sensitivity and specificity of 24-hour pH monitoring are obtained by means of quantifying the percentage of time pH is greater than 4 and the number of episodes longer than 5 minutes in duration. Temporal correlation of specific symptoms on the event recorder with periods in which esophageal pH is greater than 4 enhances the accuracy of the test.

Cineradiography

Indications

Cineradiographic assessment of swallowing is indicated to determine whether impaired pharyngoesophageal coordination is the cause of cervical dysphagia, meal-related coughing, or pulmonary aspiration.

Methods

Cineradiography is performed to record the motor events in the mouth, pharynx, and upper esophagus that are associated with swallowing. Dynamic recordings are obtained in the lateral and posteroanterior projections after ingestion of thin and thick liquid barium and barium cookies.

Clinical Findings

Dysphagia among patients with neuromuscular disease may be caused by delayed initiation of bolus transfer or prolonged retention of the swallowed bolus in a pharyngeal recess. Delayed UES relaxation, as occurs with familial dysautonomia, also may produce dysphagia. Cricopharyngeal bars may be caused by muscular hypertrophy of the UES. Misdirected swallows with laryngeal or nasal penetration or tracheal aspiration are important abnormalities that may mandate initiation of enteral tube feedings for patients with symptoms of pulmonary aspiration.

ASSESSMENT OF GASTRODUODENAL MOTOR FUNCTION

Gastric motor dysfunction most commonly produces nausea, vomiting, early satiety, bloating, fullness, and abdominal discomfort. Gastric motor dysfunction also may be a predisposing factor for development of gastroesophageal reflux of acid. Symptomatic manifestations of small-intestinal dysmotility may be similar. When severe, small-intestinal motor dysfunction also may be a predisposing factor for the development of small-intestinal bacterial overgrowth, which can cause diarrhea, malabsorption of vitamins and nutrients, electrolyte disturbances, and weight loss.

Measurement of Gastric Emptying

Indications

Quantification of the rate of gastric emptying is most commonly indicated for the diagnosis of gastroparesis among patients with unexplained nausea and vomiting. Gastric emptying testing also is performed on patients with dysmotility-like functional dyspepsia, diabetes, and poor glycemic control. These disorders may be caused by gastroparesis, postgastrectomy syndrome, medically refractory gastroesophageal reflux, and chronic intestinal pseudoobstruction.

Methods

Scintigraphic assessment of gastric emptying of a solid meal is the most widely accepted test for the diagnosis of gastroparesis. Solid-phase scintigraphy is performed with a technetium Tc 99m sulfur colloid label mixed with a solid meal such as scrambled eggs, oatmeal, or chicken liver. Solid emptying shows a biphasic curve with an initial lag phase during which food is mixed in the stomach but not emptied. The lag phase is followed by a linear emptying phase that persists until the stomach is emptied. In general, 40% to 80% of a solid meal is emptied within 2 hours of ingestion. Liquid-phase gastric scintigraphy also may be performed after ingestion of water with an aqueous phase isotope such as indium In 111 diethylenetriamine pentaacetic acid (DTPA). Liquid emptying is rapid; the half-time is 8 to 28 minutes.

Other methods of quantification of gastric emptying are gaining favor. Breath tests after ingestion of octanoate or acetate preparations have been developed to assess emptying of both solids and liquids. The results correlate well with scintigraphic findings. With such tests, the nonradioactive isotope carbon C 13 is incorporated to provide the capability to study emptying among patients in whose care a radioactive tracer would be contraindicated, such as pregnant women. As the carbon C 13-labeled meal is delivered to the duodenum, the ligand is digested and liberates carbon dioxide C 13, which is absorbed into the bloodstream and exhaled in the breath. Ultrasonography and magnetic resonance imaging have been used to measure gastric emptying of liquids, but these techniques are poorly standardized. Ultrasonography depends heavily on the skill of the operator. Thus these modalities have not achieved widespread acceptance.

Clinical Findings

Gastroparesis is diagnosed when the time for emptying of either solids or liquids exceeds the maximal normal value ([Fig 129.2](#)). In general, solid-phase tests are more sensitive for the diagnosis of gastroparesis than are liquid-phase tests. However, liquid-phase emptying may be selectively accelerated among patients with postvagotomy dumping syndrome. The utility of gastric emptying testing in clinical decision making is unproved. Gastric symptoms often correlate poorly with delays in gastric emptying. Symptoms also may show drastic improvement during therapy with prokinetic drugs without acceleration of emptying. In the only study to date of the utility of gastric scintigraphy, emptying results did not influence clinical management.

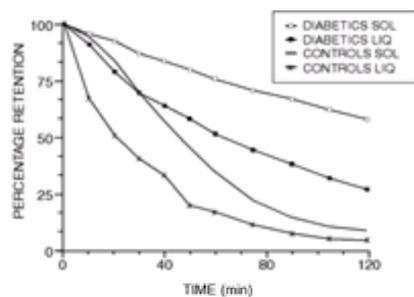

FIGURE 129.2. Gastric emptying profiles of solids and liquids measured by means of scintigraphy. Emptying is slower among patients with diabetes and gastroparesis than it is among healthy volunteers. (From Urbain JL, Vantrappen G, Janssens J, et al. Intravenous erythromycin dramatically accelerates gastric emptying in gastroparesis diabetorum and normals and abolishes the emptying discrimination between solids and liquids. *J Nucl Med* 1990;31:1490–1493.)

Gastroduodenal Manometry

Indications

Gastroduodenal manometry is performed to detect gastric or small-intestinal dysmotility among patients with unexplained nausea, vomiting, or abdominal discomfort. Patients usually have normal gastric emptying results or delayed emptying but do not respond to prokinetic agents. Manometry also may reveal specific motor patterns that can be used to differentiate myopathic and neuropathic intestinal pseudoobstruction and to detect a generalized dysmotility syndrome among patients with localized symptoms such as severe constipation. Intestinal manometry can be used to predict ability to tolerate enteral feeding.

Methods

Gastroduodenal manometry involves fluoroscopic placement of a water-perfused or solid-state catheter so that pressure ports span the antrum and duodenum (and in specialized cases, the pylorus, jejunum, and ileum). In the initial 4 to 6 hours fasting motility is recorded. During this time one or more cycles of the migrating motor complex (MMC) usually are observed. The MMC consists of three phases that cycle every 90 to 120 minutes, beginning in the stomach and propagating into the small intestine (Fig 129.3). Afterward the first phase, motor activity is measured for 2 hours after a solid meal, which should induce a fed pattern. Calculation of an antral motility index from the summed fed contractions has been shown to correlate with scintigraphic measurements of gastric emptying. Manometry affords the option of testing the effects of prokinetic drugs during recording. Advances in miniaturization have made it possible to record 24 hours of motor activity while the patient undertakes normal activity.

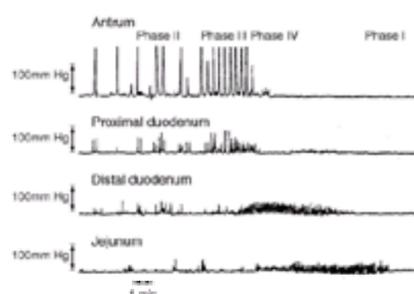

FIGURE 129.3. The migrating motor complex of a healthy person consistently shows three phases. Phase I is a period of motor quiescence. Phase II is a period of irregular contractions. Phase III is a brief complex of intense contractions that propagates from the stomach through the small intestine. Some studies show a transitional period, phase IV. (From Rees WDW, Malagelada JR, Miller LJ, et al. Human interdigestive and postprandial gastrointestinal motor and gastrointestinal hormone patterns. *Dig Dis Sci* 1982;27:321–329.)

Clinical Findings

Absence of the MMC or a reduction in fed contractions in the antrum indicates gastroparesis. Some patients with gastroparesis have prolonged periods of increased tonic and phasic motor activity in the pylorus, known as *pylorospasm*. Decreases in gastroduodenal contractile amplitude occur with myopathic disorders such as scleroderma, amyloidosis, and familial visceral myopathy. In contrast, intense uncoordinated intestinal bursts suggest familial visceral neuropathy, neuropathic forms of scleroderma or amyloidosis, or paraneoplastic intestinal pseudoobstruction. The minute rhythm, a regular pattern of intestinal bursts occurring every 1 to 3 minutes, occurs with mechanical obstruction, visceral neuropathy, and some cases of irritable bowel syndrome. In a study of the clinical utility of gastroduodenal manometry, management decisions were influenced by test results in 19% of cases, most commonly directing the choice of prokinetic drugs and feeding options.

Electrogastrography

Indications

The most common indication for electrogastrography is unexplained nausea and vomiting. Most patients have normal gastric emptying or delayed gastric emptying that has not responded to prokinetic medication. Electrogastrography has been proposed as a noninvasive test to predict gastroparesis among patients such as pregnant women in whose care use of a radioactive tracer would be contraindicated. Electrogastrography can be used to detect evidence of functional gastric impairment among patients with localized dysmotility syndromes such as severe gastroesophageal reflux or constipation.

Methods

Electrogastrography is used to measure gastric slow-wave activity acquired from cutaneous electrodes placed over the stomach for 15 to 60 minutes before and 60 to 120 minutes after a meal. The signal is carefully filtered to exclude cardiac (60 to 100 cycles per minute [cpm]), respiratory (10 to 25 cpm), and intestinal (10 to 12 cpm) electrical activity. The raw signal is analyzed with a computer program to produce a frequency spectrum of the dominant frequencies as a function of time (Fig 129.4). A normal gastric slow wave cycles at 2 to 4 cpm. Meal ingestion produces a physiologic increase in signal amplitude.

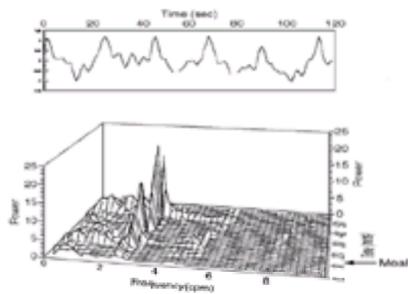

FIGURE 129.4. Electrogastrographic results of a healthy volunteer. *Top*, Raw slow wave signal exhibits rhythmic oscillation that cycles every 20 seconds. *Bottom*, Frequency spectral analysis of the slow wave. Throughout the recording, the dominant frequency is 3 cycles per minute. There is a physiologic increase in signal amplitude after eating. (From Kohagen KR, Kim MS, McDonnell WM, et al. Nicotine effects on prostaglandin-dependent gastric slow wave rhythmicity and antral motility in nonsmokers and smokers. *Gastroenterology* 1996;110:3–11.)

Clinical Findings

Tachygastric is diagnosed when a substantial fraction of the recording has a dominant frequency of >4 cpm. Bradygastric is diagnosed when the signal is <2 cpm. Such dysrhythmias are prevalent among patients with gastroparesis, dyspepsia, motion sickness, and the nausea of pregnancy. Some patients have no change or have a decrease in electrogastric amplitude after eating. This finding correlates with delays in gastric emptying.

ASSESSMENT OF COLORECTAL AND ANAL MOTOR FUNCTION

Impairment of colonic motility can cause inertia, a condition in which transit of feces is markedly delayed. The result is severe constipation. Contractile abnormalities of the rectum, anus, and pelvic floor also may produce constipation. Other dysfunctional motor patterns in this region may promote development of fecal incontinence.

Colonic Transit Testing

Indications

Colonic transit testing is performed on patients with severe constipation to quantify the degree of colonic inertia. The most common indication is to determine whether inertia is so severe as to necessitate subtotal colectomy.

Methods

The most common method for assessing colonic transit is to obtain serial abdominal radiographs after ingestion of radiopaque markers. Calculation of markers remaining on each radiograph can generate a total colonic transit time (normal <68 hours). The radiopaque marker technique also can be used to estimate regional transit in the right, left, and rectosigmoid portions of the colon with use of bony landmarks on the radiographs. More detailed analysis of colonic transit can be performed with colonic scintigraphy. With this technique, a radioisotope is given orally or through an intestinal perfusion tube. The geometric center of the radioactive bolus is assessed as a function of time to calculate regional and total colonic transit times.

Clinical Findings

Some patients with severe colonic inertia respond poorly to laxative therapy. Demonstration of marked prolongation of colonic transit is predictive of a good response to subtotal colectomy. In selected instances, lesser resection can be performed for regional delays in colonic transit. Some patients who report severe constipation have normal colonic transit. Many of these patients have abnormal psychometric profiles and should not be considered for surgical treatment.

Anorectal Manometry

Indications

Anorectal manometry is indicated to exclude neuromuscular dysfunction of the defecation process among patients with fecal incontinence or with constipation caused by Hirschsprung's disease, reduced rectal sensitivity, or anismus (also known as *pelvic floor dyssynergia*) (see [Chapter 100](#)). Results of anorectal manometry also can be used to direct biofeedback therapy for defecation disorders.

Methods

A manometric catheter with a balloon on the tip and with anal-pressure recording sites is passed into the rectum. The catheter is slowly withdrawn to assess resting anal tone, a function of the internal anal sphincter. The patient is asked to squeeze maximally against the catheter to provide a measure of external anal sphincter pressure. The rectoanal inhibitory reflex is assessed by means of measuring relaxation of the internal anal sphincter during inflation of the rectal balloon ([Fig 129.5](#)). The rectal balloon is gradually inflated with concurrent recording of rectal pressure to quantify rectal perception and compliance. With the balloon partly inflated, the patient may be asked to attempt to defecate the balloon.

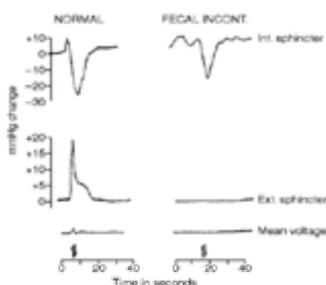

FIGURE 129.5. The rectoanal inhibitory reflex in response to rectal balloon inflation is demonstrated for a healthy volunteer (*left*) and a patient with fecal incontinence. For the healthy volunteer, rectal distention evokes relaxation of the internal anal sphincter with a compensatory increase in external pressure. In the patient with fecal incontinence, the rectoanal inhibitory reflex is preserved but the compensatory increase in external sphincter pressure does not occur. *Bottom*, Electromyographic recordings from the external sphincter that correlate with the contractile responses. (From Alva J, Mendeloff AI, Schuster MM. Reflex and electromyographic abnormalities associated with fecal incontinence. *Gastroenterology* 1967;53:101–106.)

Clinical Findings

Anorectal manometry can assist in the diagnosis of Hirschsprung's disease, a rare cause of constipation among adults, with the demonstration of a loss of the rectoanal inhibitory reflex. For confirmation of this disorder, however, a deep rectal biopsy specimen with a lack of ganglion cells is required. Patients with anismus may have a failure of relaxation of the external sphincter during attempts at defecation with an inability to expel the inflated balloon. Megarectum and megacolon may be characterized by impaired perception of rectal distention. Patients with fecal incontinence may have low resting anal tone or a failure of external sphincter pressure to increase with inflation of a rectal balloon ([Fig 129.5](#)). Patients with anismus can use biofeedback to retrain the external anal sphincter to relax during defecation. In biofeedback training for fecal incontinence, the patient is instructed learn to contract the external sphincter when a rectal stimulus is present.

Defecography

Indications

Defecography is a dynamic radiographic technique performed on patients with constipation to exclude structural abnormalities such as rectocele or rectal prolapse or functional disturbances such as anismus (pelvic floor dyssynergia) (see [Chapter 100](#)).

Methods

A paste made from 200 mL barium mixed with a thickening agent is inserted into the rectum with a syringe. The patient is asked to sit on an evacuation receptacle, and the resting anorectal angle is measured at rest. The patient is asked to strain and expel the barium paste. With normal defecation, the anorectal angle should show an increase from the normal resting value of 84 to 110 degrees ([Fig 129.6](#)).

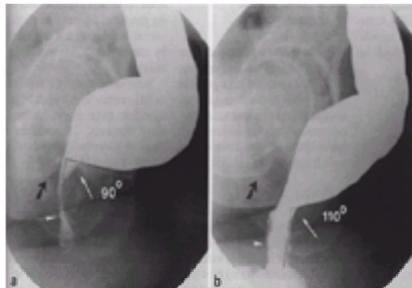

FIGURE 129.6. Normal results of defecography are shown at rest (**A**) and with defecation (**B**). At rest, the anorectal angle is 90 degrees. With defecation, there is an increase in the anorectal angle to 110 degrees, which facilitates evacuation of the barium paste. (From Goei R. Defecography: principles of technique and interpretation. *Radiologe* 1993;33:356–360.)

Clinical Findings

A rectocele, or anterior bulging of the rectal wall, may be found during attempts at defecation. Prolapse or intussusception within the rectum also may impair rectal evacuation. Pelvic floor dyssynergia is associated with a paradoxical decrease in anorectal angle with attempted defecation.

BREATH TESTING IN GASTROENTEROLOGY

A variety of breath tests can be performed for the diagnosis of a broad range of gastrointestinal disorders, including gastroparesis, *Helicobacter pylori* infection (see [Chapter 108](#)), milk intolerance, and small-intestinal bacterial overgrowth. Each of these tests requires normal small-intestinal mucosal integrity and pulmonary gas transfer. Unreliable results may be obtained in the presence of certain malabsorptive disorders and lung diseases.

DIAGNOSIS OF LACTASE DEFICIENCY

Indications

Hydrogen breath testing for lactase deficiency is performed on patients with unexplained gas, bloating, abdominal discomfort, or diarrhea believed to be caused by intolerance of dairy products.

Methods

After overnight fasting, the patient ingests 25 g lactose in water. Serial breath samples are obtained over 2 hours and analyzed for production of hydrogen. Patients should not smoke before testing. Mouthwash is given before lactose ingestion to prevent false-positive results caused by the presence of bacteria in the oral cavity.

Clinical Findings

Lactase deficiency is diagnosed when the breath hydrogen level rises to >20 ppm. The magnitude of the increase in hydrogen correlates semiquantitatively with the degree of malabsorption. False-positive test results occur with bacterial overgrowth. False-negative results may occur when a patient has colonic bacteria that do not produce hydrogen.

DIAGNOSIS OF SMALL-INTESTINAL BACTERIAL OVERGROWTH

Indications

Breath testing is performed to exclude small-intestinal bacterial overgrowth among patients with unexplained gas, bloating, discomfort, diarrhea, or malabsorption. Evaluation usually is considered for persons at risk for the condition, including those with intestinal dysmotility, hypochlorhydria, and small-intestinal diverticula, fistulas, or narrowing.

Methods

After overnight fasting, the patient ingests a carbohydrate solution in water. For ingested substrates such as lactulose or glucose, exhaled breath obtained serially over 2 hours is analyzed for hydrogen production. In some centers, carbon C 14 D-xylose is used as a substrate because of its minimal metabolism by the host. For this test, carbon dioxide C 14 is quantified in the exhaled breath. Radiolabeled bile acid breath tests are no longer used because of poor sensitivity and specificity.

Clinical Findings

Increases in breath hydrogen level after glucose or lactulose ingestion provide 62% to 68% sensitivity and 44% to 83% specificity for the diagnosis of bacterial overgrowth, whereas the carbon C 14 D-xylose test has 30% to 100% sensitivity and 89% to 100% specificity compared with quantitative intestinal fluid culture. Elevations in fasting breath hydrogen level occur among some patients with bacterial overgrowth. False-negative results occur among patients who have colonic flora that do not produce hydrogen. The most common reason for a false-positive test result is rapid small-intestinal transit, which delivers the ingested carbohydrate

substrate to the colon before intestinal absorption.

SECRETORY TESTING IN GASTROENTEROLOGY

In some instances, assessment of secretory function can complement the findings of structural testing. Quantification of gastric acid production may be needed for the diagnosis of hypersecretory conditions and to ascertain vagal integrity among patients with unexplained ulcer disease. Determination of pancreatic output of bicarbonate or enzymes may be used in the diagnosis or direct management of chronic pancreatic insufficiency.

GASTRIC ACID ANALYSIS

Indications

Gastric acid analysis may be performed in the diagnosis of Zollinger–Ellison syndrome (ZES) to monitor the effectiveness of medication therapy for some patients with ZES that cannot be corrected with surgical resection, to provide important diagnostic information about unexplained hypergastrinemia, and to test for completeness of vagotomy among patients with recurrent ulceration who have undergone surgery for peptic ulcer disease (see [Chapter 107](#)).

Methods

After overnight fasting, a double-lumen perfusion catheter is passed into the stomach. Four 15-minute fasting gastric samples are withdrawn with perfusion of a nonabsorbable marker to ensure adequate recovery. Basal acid output (BAO) is determined by means of measuring the titratable acidity. Pentagastrin is administered intravenously, and four or more 15-minute acid samples are obtained and titrated to determine maximal acid output (MAO). To test for vagal integrity, acid output is measured after sham feeding, during which the patient chews and spits a meat meal without swallowing.

Clinical Findings

A BAO greater than 15 mEq per hour is found among more than 90% of patients with ZES, but 12% of duodenal ulcer patients also have this finding. A BAO/MAO ratio greater than 0.6 is highly specific for ZES, but many patients with ZES have lower ratios. Reduction in BAO to less than 10 mEq per hour with medical therapy for ZES confirms the adequacy of acid suppression. The presence of normal acid production in a patient with hypergastrinemia excludes pernicious anemia and atrophic gastritis. If a patient has undergone previous surgery for peptic ulcer disease, a BAO greater than 5 mEq per hour or a marked increase in acid output with sham feeding suggests that the vagotomy was incomplete.

TESTING OF PANCREATIC FUNCTION

Indications

Quantification of exocrine pancreatic secretion is indicated to document pancreatic insufficiency when structural evaluation with computed tomography, endoscopic retrograde pancreatography, and endoscopic ultrasound does not provide enough information for diagnosis. Assessment of exocrine function also is useful in the search for a pancreatic source of unexplained malabsorption or diarrhea. Pancreatic function testing also has been used to direct medication therapy for chronic pancreatic insufficiency.

Methods

After overnight fasting, a double-lumen perfusion tube is placed fluoroscopically in the descending duodenum. A gastric aspiration tube is placed to continuously aspirate gastric acid, which can stimulate duodenal secretion of bicarbonate and inactivate pancreatic enzymes. Pancreatic juice is aspirated from the duodenal tube during perfusion of a nonabsorbable marker to ensure adequate recovery. Duodenal fluid is collected for assay. Exocrine function is commonly measured in response to either secretin or cholecystokinin. With secretin stimulation, fasting and stimulated outputs of bicarbonate are measured. With cholecystokinin stimulation, fasting and stimulated outputs of trypsin and lipase are quantified.

Clinical Findings

Pancreatic function testing is 90% sensitive and 90% specific for the diagnosis of pancreatic insufficiency. It cannot, however, be used to determine the cause of impaired exocrine output. Quantification of exocrine output has been used to predict responses to medication therapy for pancreatic insufficiency. Patients with chronic pancreatitis with mild to moderate impairment of function have greater reductions in pain with administration of exogenous pancreatic enzyme supplements than do those with severe insufficiency.

NUTRITIONAL SUPPORT

WHO NEEDS NUTRITIONAL SUPPORT?

Protein-calorie malnutrition impairs wound healing, is a predisposing factor for infection, and diminishes the functional capacity of every organ system. Patients who are not meeting their protein and calorie requirements through oral intake need nutritional support. Previously well-nourished patients who are at risk of protein-calorie malnutrition because of acute medical problems such as severe trauma or major surgery also need nutritional support. Nutrients can be provided through the veins (parenteral nutrition) or through the gastrointestinal tract (enteral nutrition). Nutrition provided through the gastrointestinal tract can be administered by means of oral supplementation or feeding tubes (forced enteral nutrition).

The need for nutritional support is determined by means of comparing nutritional intake and protein and calorie requirements. If protein and calorie requirements exceed intake, nutritional needs are not being met. Intake can be estimated from a calorie count. As part of the determination of nutritional intake, remediable causes of diminished intake are assessed. Many patients have diminished nutritional intake as a result of oral and upper gastrointestinal problems such as poorly fitting dentures, esophagitis, and peptic ulcer disease. Medications can diminish nutritional intake by suppressing appetite or inducing nausea and dyspepsia. Depression is another common and remediable cause of diminished nutritional intake. Protein requirements for a healthy adult are 0.8 g per kilogram per day (56 g for a 70-kg person). Minimal energy requirements for a healthy adult are 25 kcal per kilogram per day (1750 kcal for a 70-kg person). Increased activity raises the calorie requirement; metabolic stress such as trauma or severe infection increases protein and calorie requirements (see [Chapter 8](#)).

If protein and calorie requirements exceed nutrient intake for a long time, protein and fat are depleted. The greater the degree of protein and fat depletion, the greater is the need for intensive nutritional support. A thorough patient history, including changes in weight, nutritional intake, functional capacity, and the presence and activity of disease, provides useful information regarding nutritional status. Loss of more than 15% of total weight suggests severe malnutrition. Interpretation of weight changes can be impeded by the development of edema. The physical examination also is useful for assessing malnutrition. Signs of muscle wasting, such as temporal wasting, and edema are especially important in evaluating nutritional status. Laboratory tests have a role in assessing nutritional status. Low levels of albumin, prealbumin, or transferrin raise the possibility of malnutrition. However, these test results also are affected by other factors, such as liver disease, the presence of infection, and urinary protein losses.

If protein-calorie malnutrition already is established, the patient needs nutritional support. If the patient is well nourished but is about to enter a period of decreased nutrient intake or increased protein and calorie requirements, the need for nutritional support is determined by the expected duration of decreased intake or increased requirements. The longer the expected duration of decreased intake or increased requirements, the more pressing is the need to initiate nutritional support. Surgical procedures of moderate scope, such as appendectomy, cholecystectomy, or hysterectomy, are associated with predictable but relatively short periods of negative protein and calorie balance. An otherwise healthy person with normal protein and fat stores should not need intensive nutritional support when undergoing these procedures. However, the same person would be considered for intensive nutritional support if he or she had a condition that would cause negative protein and calorie balance. A patient with extensive burns or severe trauma needs to be considered for nutritional support even if baseline nutritional status is normal.

The last question to be addressed is whether nutritional support will markedly affect the patient's outcome. Some patients qualify for nutritional support on the basis of protein and calorie status, but intensive nutritional support would have no effect on clinical outcome. A patient in the last stages of AIDS or cancer may be in this group. The morbidity and expense of total parenteral nutrition (TPN) cannot be justified if the therapy will have no appreciable effect on longevity or clinical outcome.

DECIDING BETWEEN ENTERAL AND PARENTERAL NUTRITION

Most patients whose nutritional needs can be met orally should receive enteral nutrition rather than parenteral nutrition. Parenteral nutrition is much more expensive and is associated with a high incidence of major complications, including pneumothorax at central catheter insertion and line sepsis. Enteral nutrition provides nutrients directly to the epithelium of the gastrointestinal tract to support epithelial health and maintain barrier function. Glutamine, short-chain fatty acids, and nucleotides provided through the intestinal lumen support epithelial integrity. Enteral nutrition and parenteral nutrition are not mutually exclusive. Many patients can meet only some of their nutritional needs with enteral feeding. To help preserve the integrity of the gastrointestinal epithelium, those patients should receive a mixture of enteral and parenteral nutrition, rather than parenteral nutrition alone.

Some gastrointestinal disorders, such as ileus or obstructing small-bowel lesions, make any form of enteral nutrition impossible. Other disorders, such as impaired swallowing, make oral feeding impossible but have no effect on the feasibility of tube feeding. Other conditions, such as multiple small-intestinal strictures from radiation enteritis, make enteral administration of a regular diet impossible but allow the use of oral liquid supplements. The availability or lack of availability of the gastrointestinal tract usually is obvious, but in some cases, a trial of enteral feeding is necessary to determine whether this is a practical approach to nutritional support of a particular patient.

PARENTERAL NUTRITION

Parenteral nutrition is the process by which nutrients are administered to a patient through an intravenous catheter. By means of parenteral nutrition, it is possible to deliver part of a patient's macronutrient and micronutrient requirements (partial parenteral nutrition) or all of them (TPN). Nutrients can be delivered through a catheter into a peripheral vein (peripheral parenteral nutrition) or into a central vein, typically the superior vena cava (central parenteral nutrition). Most patients who receive TPN have protein-calorie malnutrition, and their nutritional needs cannot be met with enteral nutrition. A few patients receive TPN as primary therapy for gastrointestinal disease. In these cases, TPN is given to provide nutrients and to rest the gastrointestinal tract.

PARENTERAL NUTRITION AS PRIMARY THERAPY

In a few clinical conditions, prolonged complete bowel rest is considered therapeutic. In these conditions, TPN is used to provide nutrients while the bowel is at rest. The two diseases in which complete bowel rest is used most commonly as a component of therapy are Crohn's disease and pancreatitis.

In Crohn's disease (see [Chapter 111](#)), the use of complete bowel rest is based on the theory that reducing the antigen load in the intestinal lumen reduces the level of immune activation in the affected bowel. Complete bowel rest eliminates introduction of dietary antigens into the intestine. Moreover, complete bowel rest reduces the amount of nutrients available for bacteria, decreasing the number of colonic bacteria and the load of bacterial antigens. TPN is more successful in inducing remission in small-bowel Crohn's disease than in colonic disease. Remission can be achieved in most patients with small-bowel Crohn's disease by treating them in the hospital with complete bowel rest and TPN. However, this approach does not appear to affect long-term remission rates. TPN also has proved useful in treating patients with fistulas from Crohn's disease. The reported success rate is 30% to 60%. Growth retardation, an important complication of Crohn's disease among children, can be reversed with TPN. Forced enteral nutrition often is successful and with far less cost and morbidity than TPN. Besides allowing complete bowel rest, TPN can reverse the nutritional deficiencies common with Crohn's disease. Enteral nutrition with an elemental diet has been used in the management of Crohn's disease for the same indications as has TPN.

In pancreatitis (see [Chapter 117](#)), complete bowel rest is used to prevent stimulation of pancreatic secretion by the presence of nutrients in the intestinal lumen. A

regimen of complete bowel rest and TPN can reduce the duration and severity of pain and speed normalization of the serum amylase levels of persons with pancreatitis. This approach is most useful in the management of pancreatitis among patients with abscesses, fistulas, and other complications. When hypertriglyceridemia is part of the clinical presentation of pancreatitis, lipids should not be included in the TPN formula.

CENTRAL PARENTERAL NUTRITION AND PERIPHERAL PARENTERAL NUTRITION

Parenteral nutrition can be given centrally into the superior vena cava or peripherally into an arm vein. The amount of glucose and amino acids required to meet individual needs constitutes a massive osmotic load. To deliver this load in a reasonable volume, the formula must be hypertonic. Central administration of a hypertonic solution is possible because the solution is diluted rapidly in the high blood flow of the superior vena cava. However, in peripheral veins, which have low blood flow, hypertonic solutions cannot be diluted easily.

The limiting factor for peripheral parenteral nutrition is phlebitis induced by hypertonic solutions. Successful use of peripheral parenteral nutrition requires that osmolarity be kept at less than 800 to 900 mOsm per liter and glucose at less than 10%. Lipid emulsions, which have a high caloric density without a large osmotic load, allow delivery of a large number of calories through a peripheral vein without induction of phlebitis. However, an attempt to deliver all required nutrients through a peripheral vein would necessitate that about 70% of nonprotein calories be delivered in the form of lipids. Parenteral formulas with high lipid content have immunosuppressive effects and are associated with development of hyperlipidemia. For these reasons, the only practical route of delivery of parenteral nutrition among patients who must take all their nutrients parenterally is through a centrally placed catheter. Peripheral parenteral nutrition is useful, however, when only a fraction of a patient's total nutritional needs must be given parenterally. When applicable, peripheral parenteral nutrition has considerable advantages over central parenteral nutrition. Chief among them is reduced exposure to the risks of pneumothorax and other complications associated with placement of a central catheter.

NUTRIENT REQUIREMENTS AND SOURCES IN TOTAL PARENTERAL NUTRITION

CALORIES

A reasonable estimate of the minimal calorie needs for a healthy adult is 25 kcal per kilogram per day. With the stress of disease or surgery, the calorie requirement increases to 30 to 40 kcal per kilogram per day. Administration of the formula in [Table 130.1](#) to a 50-kg person would yield 40 kcal per kilogram per day. The main calorie sources in TPN solutions are carbohydrate in the form of glucose and lipid in the form of soybean and safflower oils emulsified with egg phospholipids. Glucose monohydrate has 3.4 kcal per gram, 10% lipid emulsion has 1.1 kcal per milliliter, and 20% lipid emulsion has 2 kcal per milliliter. Glucose can be the sole calorie source, but the large load required can cause hyperglycemia, fatty liver, and fluid overload. The use of glucose as the only source of calories also leads to essential fatty acid deficiency. This condition can be prevented by means of providing 2% to 4% of nonprotein calories as linoleic acid. The triglycerides from soybean oil and safflower oil in TPN lipid emulsions are rich in linoleic acid. Almost all patients given TPN receive both glucose and lipid emulsion as calorie sources. In most TPN formulas, 25% to 50% of nonprotein calories are from lipids and the rest are from glucose. Lipids contribute 28% to 30% of nonprotein calories in standard formulas. Almost all patients can be treated with the standard distribution of lipids and carbohydrates. The metabolism of carbohydrates yields more carbon dioxide than does the metabolism of a calorically equivalent amount of lipids. For this reason, it has been suggested that patients with respiratory failure be given a high-lipid, low-carbohydrate formula. However, the total calorie load is more important than the lipid-carbohydrate distribution as a determinant of carbon dioxide production, so the first therapeutic approach to carbon dioxide retention among patients receiving TPN is to decrease the caloric load.

Macronutrient	Amount	Form (20% Lipid Emulsion)
Carbohydrates	350 g	350 mL
Proteins	100 g	100 mL
Lipids	100 g	100 mL
Electrolytes	See text	
Vitamins/Minerals	See text	

TABLE 130.1. STANDARD 24-HOUR TOTAL PARENTERAL NUTRITION FORMULA

Risks are associated with administration of large amounts of carbohydrates or lipids. The more glucose administered in a given period, the more probable it is that hyperglycemia will develop, necessitating use of insulin. Fatty liver also develops when glucose is given in excessive amounts. The amount of glucose given per unit of time is enhanced by means of increasing the total caloric load, increasing the proportion of calories from carbohydrates, or using cycling to compress the time of administration. A reasonable guideline for glucose administration is to limit the infusion to 7 mg per kilogram per minute or less. If a 50-kg patient receiving the formula in [Table 130.1](#) (350 g glucose) were given cycled TPN, he or she would have to receive TPN at least 16 hours each day to stay within the recommended guidelines.

Risks of administration of excessive amounts of lipid include impairment of neutrophil function and increased risk of infection. Limiting the rate of lipid infusion to no more than 0.03 to 0.05 g per kilogram per hour has been recommended. Administration of the formula described in [Table 130.1](#) (in which lipids provide 24% of total calories and 28% of nonprotein calories) to a 50-kg patient over 24 hours would necessitate a rate of lipid administration of 0.04 g per kilogram per hour.

PROTEIN

For nonstressed patients, the recommended dietary protein allowance is 0.8 g per kilogram per day. The recommendation increases to 1.5 g per kilogram per day for catabolic patients, such as those with burns or severe trauma or recovering from major surgery. Protein requirements also are increased among patients who lose protein, such as those with large open wounds or protein-losing intestinal diseases such as inflammatory bowel disease. Many standard TPN formulas deliver more protein than recommended. For example, administration of the standard formula in [Table 130.1](#) to a 50-kg person would deliver protein at a rate of 1.6 g per kilogram per day.

The protein source in all TPN solutions is free amino acids. The standard amino acid mixture is formulated to achieve the same proportions of the various amino acids as are found in serum. The amino acids in TPN solutions have two metabolic fates. They can be incorporated into protein, or they can be converted to glucose and used for energy. How much of the administered amino acid load causes protein synthesis or is used for energy is determined by the patient's needs and the number of nonprotein calories administered. Positive caloric balance is necessary to establish positive nitrogen balance. For administered amino acids to be incorporated into new protein rather than undergo catabolism, the ratio of nonprotein calories to grams of nitrogen should approach 150:1. This ratio is based on the fact that 10% to 15% or more of caloric need during catabolism is derived from protein breakdown. One gram of nitrogen is the equivalent of 6.25 g of amino acids. Positive nitrogen balance can be established when the ratio of calories to nitrogen is less than 150:1; however, best use of the delivered amino acids occurs with the higher ratios of nonprotein calories to nitrogen. Almost all patients catabolize at least some of the administered amino acids, and many patients catabolize most of them. However, the exact amount catabolized is difficult to predict, so the contribution of amino acids to calorie expenditure also is difficult to predict.

Special amino acid formulas are available for patients with renal and hepatic diseases. The renal disease formulas contain high levels of essential amino acids and little or no nonessential amino acids. Use of these formulas allows patients to receive adequate amounts of essential amino acids without a large nitrogen load. These formulas are useful only to patients who have severe renal failure but are not yet undergoing dialysis. The amino acid formulas for patients with hepatic disease are high in branched-chain amino acids (leucine, isoleucine, valine). Branched-chain amino acids are oxidized outside the liver and serve as a fuel source for muscle. They also block protein breakdown in liver and muscle. These special hepatic amino acid formulas are most useful to patients who have encephalopathy when given conventional TPN formulas. The renal and hepatic amino acid formulas are expensive and should be reserved for those who clearly need them.

VITAMINS AND MINERALS

Vitamin requirements for most patients are met by adding a multivitamin preparation to the TPN formula ([Table 130.1](#)). Vitamin K is not included in standard commercial multivitamin preparations because of the individual needs of patients receiving warfarin and must be ordered separately. Some trace minerals (zinc, copper, chromium, manganese, and selenium) are given every day. Iodine is of concern only for patients receiving long-term TPN. Iron is not given routinely and is not compatible with the lipids in three-in-one formulas. Iron–dextran solution can be given intramuscularly or intravenously at a dosage of 50 to 100 mg iron once a month. More iron should be given if there is a deficiency or excess loss.

FLUIDS AND ELECTROLYTES

Water requirements vary depending on the capability of the patient to excrete an osmotic load. The usual requirement is 30 to 35 mL per kilogram for a healthy adult, or about 1 mL per kilocalorie delivered. Additional water and electrolytes must be given to patients with increased losses, such as those with diarrhea, vomiting, or nasogastric suction. An additional 360 mL per day is recommended for each degree centigrade of temperature elevation. In addition, 300 to 400 mL of water per day may be necessary for new intracellular fluid if anabolism is being induced. Restriction of water is necessary during volume overload and in the presence of hyponatremia. Patients who become hyperosmotic may need additional free water every day. Regular laboratory monitoring and daily weight measurement help to detect abnormalities in water balance.

Electrolyte requirements are highly variable and are affected greatly by renal losses and losses from diarrhea, vomiting, and nasogastric suction. Potassium and phosphate requirements may be large when TPN is initiated because these electrolytes are driven into cells by infusion of glucose and reversal of the catabolic state. Electrolyte requirements also are affected by the underlying disease. For example, sodium may have to be restricted for patients with congestive heart failure, renal disease, or portal hypertension with ascites. For patients with renal disease, the potassium, phosphate, and magnesium content of the formula should be reduced.

The two major anions in TPN solutions are chloride and bicarbonate. The relative amounts of these two anions can be adjusted to accommodate the patient's acid–base balance. Acetate can be metabolized to bicarbonate; therefore, the acetate content of the TPN formula should be increased for patients with metabolic acidosis and reduced for patients with metabolic alkalosis.

MECHANICS OF TOTAL PARENTERAL NUTRITION

FORMULAS

In many institutions, TPN formulas are given with all the components in one bag. This form of administration is termed a *total nutrient admixture* or *three-in-one formula*, named for the three macronutrients (carbohydrates, protein, and lipids). The relative simplicity of administering a total nutrient admixture makes it a practical system for use in the hospital and at home. However, preparation of total nutrient admixture solutions requires expensive equipment, and this system is economically feasible only for institutions with many patients receiving TPN. Total nutrient admixtures are relatively unstable because the lipid droplets tend to coalesce into large particles, especially in the presence of vitamins and trace minerals. These formulas should be used within 24 hours of preparation. These admixtures are stable for longer periods if vitamins and minerals are withheld.

The alternative to use of a total nutrient admixture is a system in which the lipid emulsion is in one bag and all the other components are in a second bag. The two bags are connected with Y tubing, and the contents are combined just before they enter the patient. This system is easier for the pharmacy to prepare than are the three-in-one formulas, but administration requires more nursing time, more bags, and more tubing. These more stable formulas can be stored for up to 4 weeks before use.

CHOOSING A DELIVERY SYSTEM

TPN should be administered through a catheter placed directly into the central venous circulation because the formulas are hypertonic and would be damaging if administered through a small vessel. The type of central catheter selected depends on the expected duration of TPN. Catheters used to administer TPN for 6 to 8 weeks are relatively inexpensive and can be inserted percutaneously directly into the vein. When TPN is to be administered for more than 6 to 8 weeks, the catheter should be placed surgically and tunneled subcutaneously between the site of entrance through the skin and the site of entrance into the vein. Many of these catheters have a cuff at the point at which the catheter exits the vessel to promote stability. Subcutaneously placed catheters are less likely to be pulled out accidentally and allow the patient or caregiver to assume more responsibility and independence in daily care of the catheter. The subcutaneous tracking of these catheters serves as a barrier to the passage of skin bacteria, and the incidence of sepsis is reduced.

Another type of catheter is an implantable intravascular access device. The infusion site is implanted subcutaneously and accessed with a percutaneously inserted needle. This catheter allows even greater freedom of activity, because the patient has no tubing to manage when TPN is not being given. However, many patients object to the repeated needle sticks.

CATHETER CARE

The catheter should be flushed with heparin or normal saline solution on a routine schedule based on the recommendations of the manufacturer. The volume of the flush ranges from 0.5 to 5 mL and depends on the internal diameter of the catheter. Positive pressure is obtained by means of exerting pressure on the plunger in the syringe while closing the clamp on the lumen. This method is used to prevent reflux of blood into the tip of the catheter. The catheter insertion site should be inspected daily for early signs of catheter-related infection, such as erythema or drainage. The occlusive sterile dressing and catheter caps should be changed according to strict protocol to prevent or reduce catheter-related infections. With multilumen catheters, selection of the lumen to be used for TPN may be based on the policy of the institution or the recommendations of the manufacturer. The lumen through which TPN is administered should not be used for administration of drugs or blood products or for sampling of blood.

INITIATION, CYCLING, AND DISCONTINUATION

The first bag of TPN formula should be infused at an hourly rate determined by means of dividing the volume by 24 hours. The infusion rate is recalculated each day because the total volume of the formula varies with the volume of added electrolytes, medications, vitamins, and minerals. The formula can be administered at a slower rate and advanced to the calculated hourly infusion rate to allow adaptation to higher blood glucose levels. Gradual adjustment in the rate of administration is especially appropriate in the care of patients in unstable hemodynamic condition and those with type I diabetes.

Administration of a full day's TPN in less than 24 hours is called *cycling*, a practice that allows the patient freedom of movement for a portion of each day. Persons receiving TPN at home often are treated with shorter infusion schedules to allow greater independence. The shorter infusion schedule should be initiated before discharge from the hospital to determine whether blood glucose levels are controlled adequately during the accelerated infusion. The duration of infusion is limited by the amount of carbohydrates the liver can metabolize.

When TPN is interrupted unexpectedly, blood glucose level should be measured to determine whether hypoglycemia has developed as a result of continued secretion of insulin despite cessation of the glucose infusion. If the serum glucose level is 60 mg per deciliter or less, infusion with 5% or 10% glucose should be initiated. Hypoglycemia after abrupt discontinuation of TPN is especially likely to occur in a patient in unstable hemodynamic condition or with type I diabetes.

TPN can be discontinued when the patient's caloric needs can be met with oral or enteral feedings. TPN solutions, especially the lipid component, suppress appetite and promote a feeling of fullness. Reducing or withholding the lipid component for 1 to 2 days before discontinuing TPN often increases appetite and oral intake among patients who experience early satiety. Hypoglycemia should not occur with abrupt discontinuation of TPN after the initiation of oral or enteral intake because serum glucose level is maintained. Adequate intake of calories should be assessed with a calorie count. Identification of food preferences and use of oral supplements or enteral nutrition may be necessary to maintain caloric intake once TPN is stopped.

ADDING MEDICATION TO TOTAL PARENTERAL NUTRITION

Medication can be added to a TPN formula, but it is essential that the stability and activity of the medication in the formula be determined from the time of mixing to

the completion of the infusion. Most of the data on drug stability are limited to two-in-one formulas (protein and carbohydrates) rather than three-in-one formulas (protein, carbohydrates, and lipids). Histamine 2 receptor antagonists, regular insulin, and heparin are stable in three-in-one TPN formulas. Iron–dextran can be added to two-in-one formulas but not to three-in-one formulas.

MONITORING TOTAL PARENTERAL NUTRITION

Administration of TPN initially induces shifts in electrolytes, especially potassium and phosphate, from the extracellular to the intracellular compartments. The magnitude of these shifts depends on the degree of starvation before the initiation of TPN. Frequent monitoring of electrolytes is recommended during the first few days of TPN until these shifts stabilize. The frequency of monitoring can be reduced as the body adapts to TPN ([Table 130.2](#)). Bedside blood glucose monitoring should be conducted every 4 to 6 hours until the glucose level is consistently less than 200 g per deciliter. Even after stable levels are achieved, daily glucose monitoring should be continued because an increase in glucose level may be the first indication of infection. Vital signs, including temperature, pulse, respiration, and blood pressure, should be assessed every 4 hours when TPN is initiated. The frequency can be reduced as the body adapts to TPN.

Before Initiation	Daily for 1-2 Days	Weekly for 2-3 Wk	Short-term (up to 6 mo) Every 1-2 wk	Long-term (1-6 mo) Every 3-6 mo

Phosphate, total bilirubin, albumin	Phosphate, total bilirubin, albumin	Phosphate, total bilirubin, albumin	Phosphate, total bilirubin, albumin	Phosphate, total bilirubin, albumin
Weight	Weight	Weight	Weight	Weight

TABLE 130.2. MONITORING DURING TOTAL PARENTERAL NUTRITION

COMPLICATIONS OF TOTAL PARENTERAL NUTRITION

METABOLIC COMPLICATIONS

Metabolic complications associated with TPN are common and can occur immediately or after prolonged use ([Table 130.3](#)). Administration of glucose, especially at high rates of infusion, can produce hyperglycemia, which should be controlled promptly to prevent osmotic diuresis and dehydration. For patients with hyperglycemia, blood glucose level should be assessed every 4 hours with a bedside monitor until the level returns to normal. Insulin can be administered according to a sliding scale to control glucose level, and the daily insulin needs of individual patients can be determined by means of calculating the cumulative dose over 24 hours. When insulin is administered subcutaneously to patients with low oncotic pressures as a result of a decrease in albumin, absorption may be erratic. Therefore, blood glucose level is best controlled by means of intravenous administration of insulin as an infusion or a bolus. The use of intravenous insulin may necessitate more frequent bedside glucose monitoring (every 1 to 2 hours). Hypoglycemia can be caused by administration of too much insulin or by abrupt discontinuation of a TPN infusion in the care of a patient receiving insulin. Hypoglycemia also can occur with certain bacterial infections or severe hepatic disease.

TABLE 130.3. METABOLIC COMPLICATIONS ASSOCIATED WITH TOTAL PARENTERAL NUTRITION

Refeeding syndrome occurs among severely malnourished persons when protein, carbohydrates, fats, electrolytes, vitamins, and minerals are reintroduced. When patients chronically adapted to starvation are challenged with carbohydrate feedings, there are rapid shifts of electrolytes, especially phosphorus, magnesium, potassium, and calcium, from the extracellular to the intracellular compartment. This can induce arrhythmia, cardiopulmonary dysfunction, neurologic symptoms, or death. When a patient is believed to have severe malnutrition, electrolyte monitoring should be performed every 4 to 6 hours for the first 24 to 48 hours of TPN. Aggressive intravenous replacement of electrolytes should be initiated for deficits when they are present.

Patients with impaired myocardial or renal function can have fluid overload during TPN. The volume administered can be minimized through use of TPN formulas with concentrated nutrients. Most TPN formulas can be mixed in 1.5 to 2 L, depending on the concentrations of the nutrients used. Restriction of fluids obtained from other sources, such as intravenous medications or oral and enteral intake, may reduce the incidence of cardiopulmonary complications, including congestive heart failure. Electrolyte levels, body weight, and total intake and output should be monitored to prevent these complications.

The calcium loss from bone that occurs with severe malnutrition causes metabolic bone disease. TPN also produces a negative calcium balance caused by hypercalciuria. Rapid weight gain associated with nutritional replacement in a patient with metabolic bone disease may cause vertebral compression or stress fractures of weight-bearing long bones.

NONMETABOLIC COMPLICATIONS

Nonmetabolic complications are related primarily to catheter placement or catheter-related infection ([Table 130.4](#)). The most common serious complication of insertion of a central venous catheter is pneumothorax. Other complications are caused by incorrect positioning of the catheter. The catheter can be displaced into the jugular vein or positioned outside the intravascular space. For these reasons, catheter position must be confirmed with radiography before TPN is initiated. Catheter thrombosis is a common complication, especially if blood is withdrawn through the catheter. Venous thrombosis at the site of catheter entrance is a serious complication that can be associated with infection.

The incidence of catheter-related infection should not exceed 5% of the total number of catheters used annually for TPN. The organisms most commonly associated with catheter-related infection are listed in [Table 130.4](#). The signs and symptoms of a catheter-related infection include fever, chills, increased blood glucose level, leukocytosis with a shift to the left, and the growth of organisms in blood cultures aspirated through the catheter, particularly if culture results from other sites, such as sputum, urine, and other drain sites, are negative. Catheter-related infection can be caused by infection at the insertion site or by translocation of organisms to the catheter from other sites in the body, such as infected surgical wounds or infected urine. Contamination of the central catheter dressing with pulmonary secretions can cause local catheter site infection, which can progress to bacteremia. When bacteremia develops among patients with central catheters, potential secondary sources of infection always must be considered. Specimens for blood cultures should be obtained from the lumen of the central venous catheter and from a peripheral site. Cultures of the TPN solution and of other intravenous solutions can be obtained to rule out bacterial contamination. When other sources of infection are not present,

removal of the catheter may be necessary. The skin wound should be cleaned thoroughly with bactericidal cleansers, and the tip of the catheter should be sent for culture. Catheters used for long-term TPN should be evaluated carefully before removal because of the limited venous access of these patients.

Complications Related to Central Catheter Placement	Other Complications
Pneumothorax	Catheter thrombosis
Hematoma	Venous thrombosis
Undesirable catheter direction	Catheter-related infection (common organisms)
Arterial puncture	<i>Staphylococcus aureus</i>
Thoracic duct puncture	<i>Candida</i> species
Subcutaneous emphysema	<i>Klebsiella pneumoniae</i>
Air embolus	<i>Pseudomonas aeruginosa</i>
Pulmonary embolus	<i>Staphylococcus albus</i>
Hydrothorax	<i>Enterobacter</i> species
Hydromediastinum	
Hemothorax	
Brachial plexus injury	
Chylothorax	
Catheter fragment embolus	

TABLE 130.4. NONMETABOLIC COMPLICATIONS ASSOCIATED WITH TOTAL PARENTERAL NUTRITION

ENTERAL NUTRITION

DELIVERING ENTERAL NUTRITION

Oral Supplementation

Oral supplementation can be implemented by means of increasing portion sizes, adding high-calorie foods to the diet, or giving commercial nutritional supplements. If the patient can eat and has an adequate appetite, oral supplementation can be an effective approach. Instituting multiple small meals, adding snacks, spreading nutrient intake throughout the day, and paying attention to taste and patient preference can help make this approach successful. Milk-based supplements such as Carnation Instant Breakfast are useful in the care of lactose-tolerant patients. Lactose-free supplements such as Ensure are available in a variety of flavors. Careful monitoring of calorie intake and periodic weight checks are needed to make sure that the food offered actually is consumed.

Forced Enteral Nutrition

If the gastrointestinal tract is available and functioning, and if the patient is not achieving adequate caloric intake even with oral supplementation, forced enteral nutrition is indicated. The choice of method of delivery of forced enteral nutrition is determined by the expected duration of nutritional support, the patient's clinical condition, and the availability of nursing support and equipment ([Table 130.5](#)).

TABLE 130.5. APPROACHES TO FORCED ENTERAL NUTRITION

For short-term nutritional support (less than 6 weeks), a nasogastric or nasointestinal tube commonly is used. Nasogastric tubes have large diameters that allow feeding without a pump and with an intermittent schedule. Although clogging is less of a problem than with smaller-diameter tubes, nasogastric tubes need to be irrigated regularly. The most common serious problem with nasogastric feeding is aspiration. The risk of aspiration can be reduced by means of elevating the patient's head during and after feeding and by monitoring residual volumes carefully before each feeding. Nasointestinal tubes are narrower than nasogastric tubes and require a pump with continuous infusion of formula. They clog easily, and replacement is more difficult than that of nasogastric tubes. Aspiration is less common with nasointestinal tubes but only if the tube is positioned properly. If a nasointestinal tube is displaced into the stomach, as commonly happens, the risk of aspiration is as high as with a nasogastric tube. Nasogastric and nasointestinal tubes are removed easily by uncooperative patients.

If nutritional support is needed for more than 6 weeks, a gastrostomy tube or, less commonly, a jejunostomy tube is the feeding method of choice. Gastrostomy tubes can be placed by a surgeon, endoscopist, or radiologist. Gastrostomy tubes allow intermittent feeding without a pump. Aspiration is a common problem with gastrostomy tubes. The patient's head should be elevated during and after feedings, and residual volumes should be monitored. The complication rate with placement of gastrostomy tubes is high because of the advanced age and debility of most patients who need them. Oversedation during the placement procedure and wound infections are common problems. Jejunostomy tubes are used when gastrostomy tubes are not practical, as in the care of patients undergoing gastric surgery or with duodenal obstruction, or when aspiration is a major problem. Jejunostomy tube feedings require continuous infusion with a pump. These tubes clog easily because of their small diameter, and they can be displaced into the peritoneal cavity.

Choosing an Enteral Formula

There are many commercial enteral formulas, and new formulas are introduced often. The rapid turnover of commercial formulas soon will make the list of products in [Table 130.6](#) out of date. The most suitable formula for any patient is the one that provides the desired allowances of macronutrients and micronutrients and has appropriate restrictions for the patient's medical disorders. All the products listed in [Table 130.6](#) can be used for tube feeding, although some are not suitable for small-diameter tubes. Many of the formulas also can be used as oral supplements. Products that are marketed as oral supplements are flavored, and many come in a variety of flavors. All the formulas in [Table 130.6](#) include protein, carbohydrates, and lipids. In most of these products, the protein source is intact protein, often casein. The carbohydrate source can be a complex carbohydrate or an oligosaccharide. The fat source typically is vegetable oil. Almost all these formulas also contain electrolytes, trace metals, and vitamins. Many commercial formulas have similar features with minor variations. [Table 130.6](#) groups commercial formulas into classes based on the main features. The following is a series of descriptions of these classes of enteral products.

following:

Medications such as antibiotics, elixirs containing sorbitol, laxatives, antacids, and electrolyte replacements

Infection of the gastrointestinal tract, such as pseudomembranous colitis

The presence of lactose in the formula (most commercially prepared formulas are lactose-free, but many homemade feedings contain lactose)

Infusion of the formula at too rapid a rate

Use of hypertonic formulas, which can cause an increase in stool output (switching to an isotonic formula may decrease the amount of diarrhea)

Ingestion of high-fat formulas by patients with pancreatic insufficiency, bile salt deficiency, or ileal resection

Bacterial contamination of the enteral formula or bag

The presence of hypoalbuminemia, which is associated with a higher incidence of diarrhea

Intermittent feedings into the small intestine (patients are more likely to tolerate the osmotic load of tube feedings introduced directly into the intestine if the feedings are spread throughout the day in a continuous infusion)

Underlying disease such as Crohn's disease or ulcerative colitis

Treatment of patients with diarrhea should begin with a review of all medications, formulas, infusion methods, infusion rates, handling techniques, and the potential for causing diarrhea. Stool cultures and tests for *Clostridium difficile* toxin should be obtained when indicated. Switching to a formula containing fiber or administering bulk-forming medications may reduce stool frequency but also may clog the tube.

Tracheobronchial Aspiration

Aspiration can occur when regurgitated stomach contents or food or secretions from the oropharynx enter the trachea. A decreased gag reflex, a swallowing disorder, or an altered level of consciousness increases the risk of aspiration. The presence of a nasogastric tube can increase the incidence of reflux and aspiration by interfering with the competence of the upper and lower esophageal sphincters. Although less common, aspiration also occurs when tubes are placed in the jejunum. The presence of a cuff on an endotracheal or tracheostomy tube does not necessarily protect a patient breathing with a ventilator from aspiration into the lungs, especially during tracheal suctioning. If aspiration is suspected or the patient is at high risk, testing of the sputum for glucose is indicated. The sputum also should be tested for blood, because the presence of blood in the sputum produces a positive test result for glucose.

Measures to reduce the incidence of aspiration include the following:

Verification of tube location in the stomach or small intestine

Elevation of the head of the bed to 30 degrees during feeding and for 2 hours after completion of feeding

In nasogastric tube feeding, monitoring the residual volume before each intermittent feeding (tube feeding should be withheld if the volume exceeds 50% of the previous feeding)

Assessment for delayed gastric emptying (this complication should be managed with erythromycin, metoclopramide, or cisapride)

Assessment for the presence of fever, tachycardia, tachypnea, or respiratory distress

Conversion of a temporary nasogastric tube to a gastrostomy to increase the competence of the upper and lower esophageal sphincters

Clogging of the Tube

Clogging of the tube is caused most often by administration of medications or the lack of routine flushing. Medications are more likely to cause clogging if they are poorly crushed or if they interact chemically with the formula residuals on the inner surface of the tube. Examples of medications that can react with formulas are calcium and magnesium supplements. The tube should be flushed every 4 to 6 hours with 20 to 30 mL water or sugar-free carbonated dark soda for both intermittent and continuous feedings. The tube also should be flushed before and after administration of each medication. Another cause of clogging is administration of a viscous formula through a small-bore tube.

PARAESOPHAGEAL HERNIA

Through the use of laparoscopic approaches to GERD, surgeons have become more comfortable using laparoscopy to manage other esophageal conditions. Because of the risk of incarceration, bleeding, and respiratory compromise of some paraesophageal hernias, a laparoscopic approach is a natural extension of laparoscopic antireflux surgery. Laparoscopic paraesophageal herniorrhaphy has become the preferred approach to all but the largest of these hernias. Some physicians argue that the unmasking of GERD among patients with these hernias warrants a fundoplication in all cases.

MOTILITY DISORDERS

Primary motor disorders of the esophagus are being diagnosed with increasing frequency (see [Chapter 108](#)). Management of achalasia centers on ablation of the LES. The ineffectiveness and associated side effects of pharmacotherapy leaves only primarily mechanical means of disruption of the LES. Although pneumatic balloon dilation is effective, high rates of perforation have left many clinicians afraid to use this therapy. The newer approach of injection of botulinum toxin into the LES, while effective, does not often provide long-lasting relief of dysphagia. Operative myotomy is the standard of care. Laparoscopic esophagomyotomy has matured and is now routinely performed for the management of achalasia. Increasing numbers of patients are being referred for laparoscopic treatment soon after diagnosis. As many as 90% of patients have complete resolution of dysphagia and 98% have dramatic improvement in swallowing after laparoscopic esophagomyotomy. Postoperative recovery involves a 1 to 2 day hospital stay, rapid return to usual activity, and immediate improvement in quality of life.

Who should undergo operative myotomy? Long-term relief of symptoms by means of pneumatic dilation is clearly less effective in the treatment of younger patients, and the effect of injection of botulinum toxin is of short duration. These approaches therefore are less desirable in the care of young patients. After failing, pneumatic dilation or injection of botulinum toxin can be repeated with an increase in response with successive treatments. It seems reasonable, however, to offer laparoscopic myotomy to patients who have had two unsuccessful trials of either nonoperative therapy.

Previous nonoperative therapy complicates myotomy because of scarring of the tissue planes; thus some surgeons recommend myotomy as initial therapy if the patient is a good candidate for surgical treatment. Patients at excessive risk of esophageal perforation during pneumatic dilation, including those with a tortuous esophagus, esophageal diverticula, or previous operation on the gastroesophageal junction, may be best treated by means of laparoscopic myotomy. An increasing number of patients want to avoid multiple interventions and seek out minimally invasive therapies that have a low complication rate, fast recovery, and lasting results.

Motor disorders of the esophagus such as diffuse esophageal spasm and nutcracker esophagus can be managed with laparoscopic myotomy or an antireflux procedure. However, the rarity of the conditions and controversy surrounding the best treatment limit the use of laparoscopic techniques to centers with medical and surgical expertise in this area.

ESOPHAGEAL DIVERTICULA

Laparoscopic approaches to esophageal diverticula are limited to centers with programs in the management of esophageal diseases and minimally invasive surgery. Technical issues are related to the immaturity of instruments for these procedures, limitations in videoimaging (two-dimensional visual field), and concerns regarding the physiologic effect of laparoscopy on the mediastinum.

ESOPHAGEAL TUMORS

Laparoscopic techniques are not yet routine for curative resection of malignant tumors of the esophagus. However, the 10% of esophageal neoplasms that are benign, such as leiomyoma, may be amenable to laparoscopic resection. An endoscope often is needed for intraoperative location of the lesion. Most leiomyomas enucleate after longitudinal myotomy. If recent biopsy has induced inflammation, resection and closure may be necessary.

STOMACH AND DUODENUM

Laparoscopic procedures rarely are used to manage gastroduodenal disorders, mainly because most surgical disorders of the stomach necessitate some form of excision and reconstruction ([Table 131.2](#)). Management of peptic ulcer disease once was the most common indication for operations on the stomach and duodenum. The identification of *Helicobacter pylori* as the etiologic agent in peptic ulcer disease and the success of medical eradication of *H. pylori* have changed the spectrum of operations performed on the stomach and duodenum (see [Chapter 107](#)).

Indication	Accepted Procedure	Procedure in Development
Ischemia	Wedge-type resection	—
Intractable duodenal ulcer disease	Parietal cell vagotomy	—
Complicated duodenal or gastric ulcer with perforation	Closure of perforation	Gastrectomy (partial)
Pyloric obstruction	Gastrojejunostomy bypass	—
Gastric cancer	—	Gastrectomy (partial, total)
Weight obesity	Laparoscopic gastric banding	Non- <i>en</i> - <i>ty</i> gastric bypass or vertical banded gastroplasty

*Performed at selected centers with special interest or expertise; not widely available.

TABLE 131.2. LAPAROSCOPIC SURGERY OF THE STOMACH

PEPTIC ULCER DISEASE

Although optimal management of peptic ulcer disease involves antisecretory therapy and antibacterial control of *H. pylori* infection, some patients do not respond to medical therapy or have complications of the disease, such as perforation, bleeding, gastric outlet obstruction, or recurrence. In these situations, an attractive concept is laparoscopic management of gastroduodenal ulcer disease. Early enthusiasm was devoted to laparoscopic vagotomy for intractable ulcer diathesis by means of parietal cell vagotomy (highly selective vagotomy) or thoracoscopic transthoracic vagotomy for recurrent ulcers after incomplete previous surgical vagotomy. However, surgical vagotomy rarely is indicated in this era of medical management of *H. pylori* infection.

More relevant to surgical management of peptic ulcer disease are the complications of perforation and pyloric obstruction. Perforated duodenal ulcers are almost always on the anterior surface of the postpyloric duodenum or within the pyloric channel and are thus readily accessible by a laparoscopic approach. Classic teaching in the management of perforated peptic ulcer disease dictated closure of the perforation and performance of a definitive antisecretory procedure (vagotomy). In the era of eradication of *H. pylori* and management of ulcers induced by nonsteroidal anti-inflammatory drugs, laparoscopic therapy to manage the acute complication (close the perforation) and deal later with the cause of the ulcer is appealing. The site of perforation can either be patched by means of sewing a piece of vascularized omentum over the hole or be closed by means of suture approximation and buttressing the closure with an omental patch. The extravasated duodenal secretions can be aspirated or irrigated from the peritoneal cavity laparoscopically. Patients with large, complex perforations typically are not good candidates for laparoscopic treatment. Perforated gastric ulcers, when easily accessible, may be amenable to a laparoscopic approach if gastric cancer can be excluded.

Bleeding gastric or duodenal lesions are difficult to approach laparoscopically. Laparoscopic endoluminal techniques (placement of trocars in the lumen of the stomach for direct visualization and oversewing of the bleeding site) have been used successfully but rarely. Endoscopically guided laparoscopic wedge resection of a bleeding area in the stomach may be successful. Laparoscopic duodenotomy and oversewing of a bleeding vessel in a duodenal ulcer can be performed by a surgeon expert in laparoscopic technique, but the advantages of such an approach are unproved.

Gastric outlet obstruction due to antropyloric ulcer disease is amenable to a laparoscopic approach. Considerations include classic pyloroplasty, although this requires extensive experience with laparoscopic suturing, or constructing a gastrojejunostomy accompanied by a truncal or highly selective vagotomy should a protecting vagotomy be deemed necessary to minimize the chance of a stomal ulcer.

GASTRIC TUMORS

Probably the most common gastric disorder managed laparoscopically is gastric stromal tumor (leiomyoma). Because they usually require only limited resection or when small and benign can be managed by means of simple enucleation, these neoplasms lend themselves to a laparoscopic approach. Large neoplasms (2 to 5 cm in greatest dimension) along the greater curvature or in the corpus or proximal antrum often can be wedged out with a laparoscopic stapling device without functional narrowing of the gastric lumen. Leiomyoma at the ends of the stomach (cardia or distal antrum) are best managed by means of enucleation with suture closure of the defect. When the stromal tumor exceeds 5 cm, the risk of sarcoma increases markedly, making a laparoscopic procedure less attractive, especially if more complex resection is needed.

Laparoscopic gastrectomy for gastric cancer or for gastric or duodenal ulcer disease (antrectomy with gastroduodenostomy [Billroth I] or gastrojejunostomy [Billroth II]) is in development. Although performed at some centers of expertise, this approach is certainly not generally available, experience is limited, and the use of this type of approach for gastric adenocarcinoma can be seriously questioned. Gastrectomy thus awaits further development.

MORBID OBESITY

Laparoscopic technique is under active development in the field of bariatric surgery—operations for clinically severe obesity. Severe obesity, defined as a body mass index (weight in kilograms divided by the square of height in meters) greater than 40 affects more than four million persons in the United States. Patients who do not respond to medical and behavioral weight control programs and have comorbid conditions such as hypertension, diabetes, atherosclerotic cardiovascular disease, pulmonary insufficiency, and osteoarthritis are candidates for bariatric operations. These procedures performed as open operations carry increased risk of incisional hernia (approximately 15%), wound infection (5% to 7%), and respiratory complications. A minimally invasive approach helps avoid these problems. One might find it difficult to believe that any major upper gastrointestinal procedure can be performed laparoscopically on patients weighing more than 250 to 300 pounds (114 to 136 kg), but it is possible.

There are two NIH-sanctioned bariatric procedures—vertical banded gastroplasty and Roux-en-Y gastric bypass. In the former a gastrointestinal stapler is used to perform a gastroplasty to separate the stomach into a small upper compartment, which communicates with the rest of the stomach through a narrow channel, without any formal anastomosis. Technical developments in design and use of internal laparoscopic stapling devices make this procedure feasible with laparoscopy. A modification of the concept of gastroplasty has been introduced: an adjustable silicone gastric band is placed around the cardia for external induction of a form of gastroplasty similar to vertical banded gastroplasty. This technique is ideally suited to a laparoscopic approach because no anatomic rearrangement or anastomosis is necessary. This minimally invasive procedure has been used extensively in Europe with encouraging short-term results.

A minimally invasive approach to Roux-en-Y gastric bypass has been developed. This operation entails transection of the proximal stomach with construction of a gastrojejunostomy to the cardia of the stomach and a jejunojunctionostomy to the Roux limb. Although preliminary experience is encouraging, whether this procedure will become widely performed remains to be seen.

SMALL BOWEL AND APPENDIX

APPENDICITIS

Laparoscopic approaches to diseases of the small (and large) intestine started with laparoscopic appendectomy ([Table 131.3](#)). The concept of laparoscopic appendectomy is attractive for the following reasons: (a) the procedure is technically easy, (b) it avoids the morbidity of a 4 to 10 cm right lower quadrant incision, (c) the incidence of wound infection should be low, (d) the pelvic adnexa of women of childbearing age can be examined should the appendix not prove to be inflamed, (e) the procedure and visualization are facilitated in operations on obese patients, and (f) disorders masquerading as appendicitis, such as Meckel's diverticulitis or ovarian cyst, can be found and managed laparoscopically, or formal celiotomy can be avoided if the disorder is a nonsurgical inflammatory condition such as simple acute diverticulitis, regional enteritis (Crohn's disease), or mesenteric adenitis.

Indication	Accepted Procedure
Appendicitis	Appendectomy
Meckel's diverticulum	Diverticulectomy
Small-bowel obstruction	Adhesiolysis
Colonic diversion	Diverting loop ileostomy
Crohn's disease	Small-bowel resection with or without colectomy, stricturoplasty
Neoplasm	Resection

TABLE 131.3. LAPAROSCOPIC SURGERY OF THE SMALL BOWEL AND APPENDIX

Despite these theoretical advantages, numerous feasibility studies followed by prospective, randomized studies have shown remarkably few clinically important objective benefits of laparoscopic appendectomy. The technique appears most beneficial when the diagnosis of acute appendicitis remains obscure, especially if the patient is a young woman with right lower quadrant or pelvic pain. Less clear benefit may be realized by patients sensitive to the presence of a right lower quadrant scar or by athletes who play rough sports and want an early return to full physical activity.

The indications for laparoscopic appendectomy depend on the surgeon's confidence in the diagnosis and the stage of appendicitis. If uncomplicated appendicitis is found, laparoscopic appendectomy is straightforward. If a normal appendix and no other pathologic condition are detected, or if the pathologic condition detected is likely to cause recurrent pain, such as terminal ileitis, the appendix is easily removed. Appendectomy is not performed if another surgical problem, such as acute cholecystitis, is apparent. If unsuspected advanced inflammatory conditions of the appendix (gangrene, phlegmon, and abscess) are found, conversion to laparotomy or antibiotic therapy and interval appendectomy is indicated. Perforation of the appendix can be managed laparoscopically if the inflammatory reaction is minimal and the base of the appendix is normal.

BOWEL OBSTRUCTION

The full length of the small bowel is available to laparoscopic assessment. Adhesive small-bowel obstruction sometimes can be managed by means of laparoscopic lysis of adhesions. If the patient has undergone a previous abdominal operation, achieving pneumoperitoneum and placing ports is challenging. If multiple dilated loops of bowel are present, as in distal obstruction, visualization may be impaired. Results with a laparoscopic adhesiolysis are better in operations on patients with early acute small-bowel obstruction (before marked abdominal distention occurs), nonacute, partial obstruction, or recurrent, intermittent obstruction. The offending adhesive band often represents a single, easily lysed adhesion readily accessible and visualized at laparoscopy. Complex adhesions fixing one segment of the small bowel to the abdominal wall, pelvis, or retroperitoneum, the presence of an internal hernia, or even an unrecognized abdominal wall hernia such as a femoral hernia also can be repaired. In general, success rates with a laparoscopic approach are better for intermittent partial obstruction, nonresolving partial obstruction, or chronic obstruction (60% to 80%) than they are for acute complete obstruction (approximately 50%).

SMALL-BOWEL TUMORS

Whether a primary neoplasm of the small intestine is amenable to a laparoscopic approach depends on the extent of mesenteric resection or lymphadenectomy needed. Stromal tumors, early adenocarcinoma, and primary small-bowel lymphoma seem to be amenable. Carcinoid tumors with known or highly suspected nodal metastases probably are best approached by means of open exploration because of a propensity for nodal metastases and mesenteric sclerosis or fibrosis. Small-bowel metastases to the intestine from extraintestinal neoplasms (carcinoma of the breast, lung, or kidney and melanoma) are ideal lesions for a laparoscopic approach. The lesion may be brought through a trocar site, the incision for which is enlarged to allow evisceration of the lesion. This allows resection of the lesion and extracorporeal anastomosis.

CROHN'S DISEASE

Many patients with small-bowel Crohn's disease are candidates for laparoscopic surgery. The involved segment often is quite mobile, even after previous resection, and lends itself well to directed exteriorization and resection or stricturoplasty. Ileocolonic Crohn's disease also allows relatively easy mobilization of the cecum and proximal ascending colon.

MISCELLANEOUS CONDITIONS OF THE SMALL BOWEL

Although rarely indicated, laparoscopic transmural biopsy of the small bowel is easy. A segment of jejunum or ileum can be exteriorized through one of the ports, the biopsy specimen obtained, the enterotomy closed by means of external hand suturing, and the segment placed back into the abdomen. When colonic or rectal diversion is necessary, as for distal colonic fistula or colonic dysmotility, loop ileostomy is easily performed with basic laparoscopic techniques. Less common situations in which laparoscopy might be performed include management of radiation enteropathy, inability to differentiate a primary small-bowel motility disorder from mechanical obstruction, or treatment of a patient younger than 40 years with chronic occult gastrointestinal bleeding when it is likely the cause can be found at exploration, for example, Meckel's diverticulum, leiomyoma, or a small carcinoid.

COLON AND RECTUM

Introduction of laparoscopic techniques to colorectal surgery has met with unique challenges that distinguish these procedures from other laparoscopic applications (Table 131.4). Use of laparoscopic colonic procedures has lagged behind other specialties for the following reasons: (a) resection of the colon requires advanced laparoscopic experience, (b) maintenance of oncologic principles may be difficult during resection of colorectal cancer, and (c) evidence of objective benefits of the approach are not obvious.

Indication	Accepted Procedure	Procedures in Development
Diverticulitis	Colectomy (segmental)	--
Large analte polyp or mass	Transcolonic polypectomy or colectomy (segmental)	--
Colonic carcinoma (especially right-sided, left-sided, high rectum)	Colectomy (oncologic resection)	Colectomy (oncologic resection)
Colectomy	Laparoscopic colonic diversion or stoma of proximal stoma	--
Inflammatory bowel disease (chronic ulcerative colitis, Crohn's disease)	--	Colectomy (partial, total abdominal)
Rectal prolapse	Colectomy, rectopexy	--
Hirschsprung's disease	Colectomy, anastomosis	--

*Performed at selected centers with special interest or expertise; not widely available.

TABLE 131.4. LAPAROSCOPIC SURGERY OF THE LARGE INTESTINE

DIVERTICULITIS

Diverticulitis is a common benign indication for colectomy. The chief difficulty of laparoscopic resection is residual inflammation or scarring, which obliterates normal tissue planes, impedes identification of the left ureter, and often produces a bulky specimen that is difficult to manipulate. Laparoscopic techniques are most successful when used to treat patients with resolving or mild inflammation or contained perforation (abscess) without extensive surrounding inflammation. The degree of inflammation is difficult to predict preoperatively and explains the often higher rate of conversion to open laparotomy for diverticulitis. However, because patient-related benefits have been demonstrated in terms of shorter ileus and reduced analgesic requirements and lengths of stay, a laparoscopic approach should be considered in nearly all cases.

COLON CANCER

Because colorectal cancer is the most common intra-abdominal malignant tumor and the most common indication for colectomy, it is not surprising that colorectal cancer is one of the few malignant tumors resected with laparoscopic techniques. Issues surrounding the oncologic adequacy of a laparoscopic procedure have prompted caution in its use and led to performance of well-designed, randomized, prospective trials on a scale rare for evaluation of surgical procedures.

The primary issue in management of colorectal cancer is whether survival after treatment with a laparoscopic approach is equivalent to that after treatment with an open approach. Although the length of margins, number of lymph nodes removed, and ability to perform proximal ligation of the vascular pedicle are the same for the two approaches, the true oncologic end point is survival. Concerns have been raised through anecdotal reports of unexpected tumor recurrence in both the incision made to extract the specimen and in laparoscopic trocar sites. Results for large series of patients suggest that the rate of tumor recurrence is about 1%, which compares favorably with that for open colectomy. Current recommendations are that laparoscopic resection for cancer be performed in a clinical trial or with an equivalent form of follow-up study.

When colon or rectal polyps cannot be removed endoscopically, surgical resection is indicated. The procedure is performed most commonly on the right colon, where the thinner bowel wall precludes aggressive attempts at polypectomy. The extent of resection must not be compromised by the approach; the very indication for operation (size of the polyp) is also a risk factor for malignant growth within the polyp.

MISCELLANEOUS DISORDERS OF THE COLON AND RECTUM

Laparoscopy has been used for construction and reversal of stomas. Often only two trocar sites are needed, one becoming the stoma site. Such a minor procedure causes little interruption of bowel function. Colostomy closure can be performed laparoscopically. Success depends on the preceding operation and extent of adhesions. Laparoscopic management of ulcerative colitis requires proctocolectomy and either Brooke ileostomy or ileal pouch–anal anastomosis. These procedures require advanced laparoscopic skill. Anterior resection and rectopexy for rectal prolapse have been shown to be feasible laparoscopic procedures. Difficulties of the procedures lie in the complete rectal dissection necessary for full reduction of the prolapse. Current instrumentation does not fully address the challenges of working within the confines of the bony pelvis.

BILIARY TREE

Although gynecologic surgeons had been using laparoscopic techniques for years, an explosion in minimally invasive techniques in gastrointestinal circles occurred when the first laparoscopic cholecystectomy was reported (Table 131.5). Laparoscopic approaches to the biliary tree continue to be the most commonly performed laparoscopic operations.

Indication	Accepted Procedure	Procedures in Development
Biliary tree		
Cholelithiasis	Cholecystectomy	--
Acute cholecystitis	Cholecystectomy	--
Cholelithiasis	Common duct exploration	--
Liver		
Directed or high-risk liver biopsy	Liver biopsy	--
Peripheral mass	Limited wedge resection	--
Single hepatic cyst	Partial cystectomy or fenestration	--
Multiple cysts	--	Resection
Pancreas		
Relief of pancreatic cancer	Cholecystectomy with or without gastrojejunostomy	--
Distal gland disease	--	Distal pancreatectomy
Mediastinal	--	Resection
Recurrent pancreatitis	--	Cholecystectomy*
Localized, organized pancreatic necrosis	--	Resection, drainage
Chronic pancreatitis	Therapeutic splenopancreatectomy	--

*Formerly in selected cases with general interest or expertise, not widely available.
 -- Limited endoscopic/laparoscopic approach.

TABLE 131.5. LAPAROSCOPIC SURGERY OF THE HEPATOBILIARY-PANCREATIC AXIS

CHOLELITHIASIS

The standard of care for elective cholecystectomy is a laparoscopic approach. Indeed, it is against the law not to mention a laparoscopic approach to a patient as an option. Hospitalization is minimized, usually less than 36 hours, and at some centers these operations are outpatient procedures. Pain is decreased, return to work is expedited, and overall cost, including convalescence and return to work, is decreased.

The laparoscopic approach initially was limited to elective surgery for biliary colic, unless the patient had acute cholecystitis. Now even acute cholecystitis is managed laparoscopically approximately 75% of the time. It would be difficult to argue a case for approaching cholecystectomy with a primary open incision without first performing a laparoscopic examination to assess the feasibility of a minimal access approach.

More than 95% of patients undergoing elective cholecystectomy should be able to undergo a successful laparoscopic procedure. Exceptions include rare patients with serious biliary anomalies not evident or clearly definable intraoperatively or patients with a stone impacted in the distal cystic duct with surrounding inflammation deemed too dangerous or too scarred to dissect. Early in the history (1990–1994) of laparoscopic cholecystectomy, serious biliary injuries were all too common whether the operation was performed by an experienced or an inexperienced surgeon. Some of the injuries were extremely serious and caused a plethora of problems that necessitated reconstruction of the biliary tree. This led to exponential growth in the number of lawsuits, many settled for large sums. These situations stimulated numerous teaching seminars and courses with hands-on laboratories designed to re-educate older surgeons in laparoscopic techniques of cholecystectomy. Since then, all general surgical residency programs have incorporated laparoscopy into the curriculum, and today open cholecystectomy is a rare operation.

With increasing experience and an intense nationwide educational program to highlight situations that predispose a patient to serious biliary complications, most tertiary referral centers are seeing fewer serious biliary injuries caused by laparoscopic cholecystectomy than in the first 5 years of the 1990s. Today patients should expect a success rate of laparoscopic cholecystectomy under elective conditions of approximately 95% with a risk of serious bile duct injury of 0.5% or less. However, the risk of bile duct injury is not zero, and preoperative discussion with the patient should emphasize the importance and possibility of conversion to an open procedure if the surgeon is unsure of the anatomic features. Such conversion should not be considered a failure by the patient or by the surgeon and should be acknowledged as such preoperatively. Conversion to open cholecystectomy or development of a complication, however serious, should be discussed immediately with the patient and family to minimize the chances of medicolegal confrontation.

A pregnant woman with cholecystitis presents a not uncommon problem. Pregnancy once was considered a contraindication to laparoscopic cholecystectomy because of unknown consequences of pneumoperitoneum for the woman and the fetus. Most surgeons now believe that an attempt at laparoscopic cholecystectomy may be warranted in the third trimester if necessary. Every reasonable attempt should be made to delay the procedure to the postpartum period.

CHOLEDOCHOLITHIASIS

Stones in the biliary tree (common bile duct, common hepatic duct, or intrahepatic ducts) have come under the technical realm of the laparoscopic surgeon. Common bile duct stones once were removed by an interventional endoscopist either before surgical exploration if the presence of the stones was known or suspected, or after exploration if the stones were found during intraoperative cholangiography. The technical development of a laparoscopic choledochoscope allows visualization of common bile duct stones and facilitates capture of stones with baskets introduced into the duct through the choledochoscope. Laparoscopic exploration of the common duct can be performed through the cystic duct if the ductal diameter is large enough after intraoperative dilation or even by means of direct choledochotomy and laparoscopic suture closure of the choledochotomy. If the laparoscopic procedure is technically unsuccessful, most patients can be treated with an endoscopic procedure the following day, avoiding open celiotomy and a long convalescence. Although the technical ability to perform laparoscopic common bile duct exploration is not yet widespread, many gastrointestinal surgeons are gaining the necessary experience and interest. Most laparoscopic surgeons soon should be able to perform common bile duct exploration.

LIVER AND PANCREAS

The bulkiness of the liver and pancreas, the rich and varied blood supply, the retroperitoneal and dorsal location in the abdomen, and the preponderance of malignant disease of these organs make laparoscopic approaches to the liver and pancreas limited at best ([Table 131.5](#)). Laparoscopic instruments and equipment are largely inadequate for laparoscopic management of diseases of these organs.

STAGING MALIGNANT TUMORS

With many forms of malignant gastrointestinal tumors, the surgeon operates with the intent to perform a curative procedure only to find small metastatic lesions in the peritoneum or liver or direct local extension of the tumor to another structure that either precludes curability or necessitates a much different approach. Laparoscopy and new evaluative procedures such as laparoscopic ultrasonography have fostered a more aggressive concept of staging of some malignant gastrointestinal tumors.

Preoperative staging laparoscopic examination of the intraperitoneal cavity has been suggested for adenocarcinoma of the esophagus, stomach, pancreas, liver, and biliary tree. In certain situations, the laparoscopic procedure should be performed as a separate, staged procedure one or more days before the proposed resection. In other instances, laparoscopy immediately precedes the proposed resection. The former approach may be used if the laparoscopist is not the surgeon performing the resection.

Performance of staging laparoscopy implies that treatment will be changed on the basis of the laparoscopic findings. Optimal use of this procedure would be in the care of a patient with what appears to be resectable pancreatic or liver cancer. The patient undergoes staging laparoscopy, which reveals unappreciated hepatic or peritoneal metastases, and cannot undergo resection for cure. The patient is spared the discomfort and requisite convalescence of a celiotomy to reveal such incurability. This approach allows the patient to proceed with palliative therapy if indicated and limit the time spent in the hospital.

LIVER TUMORS AND CYSTS

Resection of hepatic tumors is in the developmental stage. Although they have been performed in highly specialized centers, more development of technique, hemostasis, and exposure is needed. Peripherally based, small lesions amenable to classic wedge hepatic resection are readily removed, but centrally situated masses within the hepatic parenchyma should be managed with open resection. One exception may be a neoplasm in the left lateral segment (Couinaud segments 2 and 3), for which laparoscopic excision may be attempted by a highly experienced laparoscopic surgeon. Anatomic or nonanatomic segmental resection is fraught with the risk of hemorrhage and bile leak.

Symptomatic benign hepatic cyst is a hepatic disorder readily amenable to a laparoscopic approach. Most simple cysts that cause symptoms are quite large (more

than 10 cm) and are not likely to be controlled with percutaneous sclerosis. Because they are so large, these cysts are present at the liver periphery and thus are easily accessible to a laparoscope. If these cysts meet the criteria for being a simple cyst (round, smooth internal wall, no associated eccentric mass component, lack of internal septa, and nonbilious content) and thus are differentiated from neoplastic or infectious cystic lesions, laparoscopic excision of the external wall is fairly easy and effective. The excised cyst wall should always be subjected to histologic review to exclude the rare unilocular cystic neoplasm of the liver (cystadenoma). Symptomatic polycystic liver disease can be managed with laparoscopy. All accessible cysts are unroofed and drained.

PANCREAS

Aside from staging of pancreatic cancer before open exploration, almost all laparoscopic operations directed at the pancreas itself, aside from simple biopsy, are in the developmental stage or are performed only at highly specialized centers.

Tumors

Although formal pancreatic resection for tumors has been accomplished successfully, such procedures remain in the developmental stage even at highly proficient laparoscopic centers. Of the resective techniques performed, distal pancreatectomy is the most realistic for a laparoscopic approach because no formal reconstruction (anastomosis) is needed, and closure of the proximal pancreatic stump and ligation of the splenic artery and vein can be accomplished with laparoscopic stapling devices. However, there are few indications for distal pancreatectomy, and few centers have sufficient experience in performing this procedure.

Another suggested pancreas-directed laparoscopic procedure is enucleation of insulinoma or other selected small, benign islet cell tumors. When the lesion is readily identifiable and accessible, a minimally invasive approach is reasonable if the lesion is not near the main pancreatic duct, which warrants formal pancreatectomy. In contrast, inability to palpate the pancreas of a patient without an obvious tumor or a patient with multiple endocrine neoplasia syndrome (risk of multiple tumors) is a limitation of the laparoscopic approach and may be a relative contraindication. Use of laparoscopic ultrasonography may play an important role in this situation.

Chronic Pancreatitis

Inflammatory disorders of the pancreas have been targeted with laparoscopic techniques. Laparoscopic internal drainage of pancreatic pseudocysts includes endoscopic cystogastrostomy and cystojejunostomy. In rare instances, when access to the gastric or duodenal region necessary for internal drainage is impossible with oral endoscopy, a combined laparoendoscopic approach may be possible. This technique allows laparoscopically directed insertion of trocars into the gastric and duodenal lumens to allow the laparoendoscopic procedure to be accomplished. This approach has been used for endoscopic excisions of polyps.

The visceral pain of chronic pancreatitis is amenable to a promising procedure that is yet to be established as a durable procedure—thoracoscopic splanchnicectomy. This minimal access thoracoscopic approach is designed to transect the greater splanchnic nerves believed to transmit visceral pain fibers from the pancreas to the central nervous system. Surgical history does not recall neurolytic procedures for chronic pancreatitis kindly, but this procedure has its advocates, especially when patients are selected with an epidural technique designed to differentiate visceral from nonvisceral pain. Whether a simultaneous bilateral procedure or unilateral left splanchnicectomy followed by staged right splanchnicectomy is optimal remains to be determined, as do the true success rate and duration of benefit.

HISTORICAL PERSPECTIVE

Surgical removal of a diseased liver and replacement with a donor organ in the same anatomic location is called *orthotopic liver transplantation* (OLT). The formidable complexities of the surgical technique, poor allograft quality, frequent rejection of transplanted organs, and a 1-year survival rate of only 30% produced a sense of skepticism about liver transplantation in the 1970s. Acceptance of the concept of brain-stem death in the 1970s and 1980s led to retrieval of organs from heart-beating donors, improving the viability of cadaveric livers offered for transplantation. The introduction of cyclosporin A in the early 1980s revolutionized immunosuppressant therapy of transplant recipients, which resulted in greater safety and efficacy in the prevention of rejection. In 1983, the National Institutes of Health Consensus Development Conference on Liver Transplantation declared that liver transplantation was a therapy that deserved broader application rather than experimental use. The introduction of the University of Wisconsin (UW) preservation solution in 1986 allowed longer cold ischemia time for donor allografts and resulted in improved outcomes.

LIVER TRANSPLANTATION: AN OVERVIEW

Liver transplantation has become the preferred therapeutic approach to irreversible acute or chronic liver failure. More than 4,000 liver transplants are performed annually in the United States. Fifteen percent of recipients are younger than 18 years. The overall survival rate after liver transplantation currently approaches 80% to 90% at 1 year and 65% to 70% at 5 years.

Liver transplantation should be considered in the treatment of all patients (children and adults) with advanced acute or chronic hepatic failure or severe liver disease for which there are no satisfactory medical or surgical therapeutic options. Although many of the indications for liver transplantation for acute and chronic end-stage liver disease (ESLD) are now well established ([Table 132.1](#)), the list continues to expand and generate controversy. More than 12,000 patients are awaiting liver transplantation in the United States alone, fueling debate over how best to allocate the limited number of suitable cadaveric livers available each year. The growing imbalance between the number of cadaveric donors and suitable recipients has led to innovative approaches to expand the supply of donor organs, including dividing a cadaveric donor liver between two recipients and the use of partial grafts from living donors. Reduction in the size of donor allografts, use of living-related donor allografts, and split-liver transplantation have dramatically reduced waiting list mortality and improved overall survival among pediatric patients.

TABLE 132.1. INDICATIONS FOR LIVER TRANSPLANTATION

DONOR AND RECIPIENT FACTORS AFFECTING OUTCOME OF LIVER TRANSPLANTATION

Donor factors that reduce graft survival include donor age, transplantation of a liver allograft from a female donor into a male recipient, and total ischemia time. Steatosis of the donor liver influences early graft function, perhaps by facilitating the generation of reactive oxidative species.

Several recipient factors have been identified as independent predictors of outcome. The cause of the underlying liver disease affects graft survival after OLT. Survival rates after OLT are best for chronic cholestatic liver diseases and slightly better than those for chronic hepatocellular disorders that cause cirrhosis. The outcome is somewhat worse among patients who undergo transplantation because of fulminant hepatic failure and markedly worse among patients with cancer. Retransplantation is less successful than primary grafting, especially among patients undergoing second OLT soon after the initial graft attempt. The outcome of liver transplantation is influenced by the severity of illness of the recipient before surgery. Patient and graft survival rates are markedly reduced among recipients cared for in intensive care units, those undergoing mechanical ventilation, and those with multisystem organ failure before transplantation.

TIMING OF LIVER TRANSPLANTATION

The minimal criterion for being placed on a waiting list is a predicted 1-year likelihood of survival without transplantation of less than 90, that is, the 1-year survival rate with OLT is better than without OLT. The prognosis among patients with cirrhosis is assessed with the Child–Pugh classification (see [Chapter 105](#)). This empiric scoring scheme is a compilation of five features of chronic liver failure (ascites, encephalopathy, prothrombin time, serum bilirubin level, and serum albumin level). Likelihood of survival among patients with cirrhosis declines with worsening Child class. The Child–Pugh classification system is useful in the setting of evaluation for liver transplantation because a patient in Child–Pugh class B has crossed the threshold of probability of 1-year survival less than 90%.

A complementary approach is to consider end-stage liver disease as either compensated (stable) or decompensated cirrhosis. Stable cirrhosis is defined as cirrhosis without variceal hemorrhage, ascites, jaundice, or encephalopathy. Cirrhosis with at least one of these clinical phenomena is decompensated disease. The onset of decompensation in a patient with previously stable cirrhosis is associated with a significantly reduced likelihood of survival and indicates the need for evaluation for OLT. Other life-threatening complications of end-stage liver disease, such as hepatorenal syndrome and spontaneous bacterial peritonitis, or an unacceptable quality of life because of hepatic disease, also warrant consideration of OLT ([Table 132.2](#)).

Recurrent gastroesophageal variceal hemorrhage
 Refractory ascites
 Spontaneous bacterial peritonitis
 Severe hepatic encephalopathy
 Hepatorenal syndrome
 Profound pruritis of cholestatic liver disease
 Severe hepatic osteopathy
 Progressive rise in serum α -fetoprotein without mass
 Refractory bacterial cholangitis
 Intractable coagulopathy
 Severe fatigue and weakness
 Severe malnutrition

TABLE 132.2. SPECIFIC CLINICAL INDICATIONS FOR CONSIDERATION OF LIVER TRANSPLANTATION IN PATIENTS WITH CHRONIC LIVER DISEASE

SPECIFIC INDICATIONS FOR LIVER TRANSPLANTATION

Cirrhosis due to viral hepatitis or alcohol-induced liver injury, is the leading indication for OLT among adults. Chronic hepatitis B virus infection historically was viewed as a relative contraindication to hepatic transplantation because of the reduced overall survival rate, particularly due to the development of a rapidly progressive form of recurrent hepatitis B virus infection known as fibrosing cholestatic hepatitis. In recent years, long-term administration of hepatitis B immune globulin has been shown to be effective in controlling recurrence of hepatitis B after liver transplantation, and outcomes are excellent. Lamivudine and famciclovir, antiviral agents with activity against hepatitis B, further expand the potential for control of post-transplantation hepatitis B infection and are undergoing clinical trials.

Chronic hepatitis C virus infection has become the most common underlying diagnosis among persons undergoing liver transplantation in the United States. The effect of chronic hepatitis C on the allograft is discussed later.

In North America and Europe, approximately 20% of all hepatic transplantation procedures are performed on patients with alcoholic liver disease. In addition to meeting minimal listing criteria, alcoholic patients being evaluated for liver transplantation should undergo formal psychosocial assessment and when feasible participate in alcoholism rehabilitation and counseling. Many transplantation programs and third-party payers demand abstinence for a specified time (6 months at most centers) before approving transplantation for candidates with alcoholism. Interesting is that the primary benefit of a mandated period of abstinence before transplantation is that it allows recovery from acute alcoholic hepatitis, which may obviate hepatic replacement. Alcoholic patients need careful assessment of other sites of alcoholic end-organ damage. Among selected alcoholic patients, rates of graft and patient survival after liver transplantation are similar to those for other causes of end-stage liver disease.

Large hepatocellular carcinomas almost invariably recur after transplantation. Patients with this disease cannot be placed on the transplantation list, except within defined study protocols. Resection remains the treatment of choice among patients with small tumors without evidence of spread beyond the liver and with well-preserved hepatic synthetic function. Small hepatocellular carcinomas confined to the liver are amenable to transplantation, and the patients have excellent outcomes.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are good indications for OLT. Together they account for approximately 20% of all liver transplantation procedures in the United States and Europe. Prognostic models of the natural history of PBC and PSC are a guide for the timing of transplantation. The Mayo mathematical model of PBC identified five independent variables from which a prognostic equation is derived (total bilirubin level, albumin level, age, prothrombin time, and amount of edema). The Mayo model is not time dependent and has not been validated for serial measurements. In contrast to models of PBC, prognostic models of PSC among patients with advanced disease are probably no better than Child–Pugh scores. Cholangiocarcinoma occurs among approximately 5% to 15% of patients with preexisting PSC. The prognosis among patients in whom cholangiocarcinoma develops is poor even with transplantation. The presence of cholangiocarcinoma usually is considered a contraindication to OLT. Patients with either PBC or PSC should be referred for formal evaluation for OLT when they meet minimal listing criteria for cholestatic liver disease (Child–Pugh score greater than 6), have life-threatening complications of cirrhosis, or have quality-of-life indications such as severe pruritus, severe hepatic osteopathy, profound fatigue, and recurrent cholangitis.

Fulminant hepatic failure, a term traditionally used to describe the condition of patients with hepatic encephalopathy that develops within 8 weeks of acute liver failure, and its clinical variant, submassive hepatic necrosis, are characterized by massive hepatocyte necrosis often resulting in dysfunction of multiple organ systems. The outcome with medical management is determined by the course of encephalopathy. Acute hepatic encephalopathy can progress rapidly. [Table 132.3](#) lists the prognostic criteria developed at King's College Hospital, London, England, to assist in determining the necessity for liver transplantation for fulminant hepatic failure. The decision to place a patient with fulminant hepatic failure on the transplantation list is confounded by the difficulty of procuring a suitable donor organ quickly. Even when listed at the highest emergency status, it is not unusual for a patient in North America to wait 72 hours or longer. During this time further deterioration, especially worsening cerebral edema, may make transplantation impossible. The outcome of liver transplantation for fulminant hepatic failure is somewhat worse than that of liver transplantation for other causes. One-year survival rates of 50% to 60% are common.

Cause of Liver Failure	Criteria
Acetaminophen poisoning	pH < 7.3 irrespective of grade of hepatic encephalopathy or International Normalized Ratio (INR) > 6.5 and serum creatinine > 3.0 mg/dL (260 μ mol/L) in patients with grade 3 or 4 hepatic encephalopathy
All other causes	INR > 6.5 irrespective of grade of hepatic encephalopathy or Any three of the following variables irrespective of grade of hepatic encephalopathy: Age < 10 y or > 40 y Fulminant hepatic failure caused by non-A, non-B hepatitis, fulminant drug reactions, or idiosyncratic drug reactions Duration of jaundice before onset of encephalopathy > 7 days INR > 2.5 Bilirubin > 17.5 mg/dL (300 μ mol/L)

* Transplantation was considered if the likelihood of survival without it was less than 50%. Adapted from O'Grady JP, Alexander RL, Hayler MG, et al. Early indicators of prognosis in fulminant hepatic failure. *Gastroenterology* 1988;94:187-193, with permission.

TABLE 132.3. CRITERIA FOR PREDICTING DEATH AND THE NEED FOR LIVER TRANSPLANTATION, KING'S COLLEGE HOSPITAL, LONDON^a

Biliary atresia is the most common indication for OLT among children. It represents more than 50% of cases in most series. Metabolic liver disease is the second most common indication for pediatric OLT, accounting for 21% of all hepatic transplantation procedures among children.

CONTRAINDICATIONS

The absolute and relative contraindications to OLT are listed in [Table 132.4](#). Advanced age (greater than 65 years) is no longer considered to be a relative contraindication to OLT at many centers, but it necessitates more extensive preoperative cardiac evaluation.

Absolute contraindications
 Severe, uncontrolled infection outside the hepatobiliary system
 Metastatic cancer
 Extrahepatic cancer other than local skin cancer
 Advanced cardiopulmonary disease
 AIDS
 Severe pulmonary hypertension

Relative contraindications
 Active drug or alcohol abuse
 Age older than 70 y
 HIV infection
 Inability to comply with immunosuppression protocol or participate in routine posttransplant medical follow-up care
 Advanced chronic renal disease
 Moderate pulmonary hypertension

TABLE 132.4. CONTRAINDICATIONS TO LIVER TRANSPLANTATION

COMPONENTS OF THE EVALUATION FOR LIVER TRANSPLANTATION

CARDIOPULMONARY EVALUATION

Prevention of life-threatening cardiac events in the perioperative period is one of the main objectives of the pre-OLT cardiac evaluation. All patients must undergo a complete history interview with special attention to risk factors for coronary artery disease, a thorough physical examination, baseline electrocardiography, and chest radiography. A history of systemic hypertension, angina pectoris, or myocardial infarction or age greater than 45 years necessitates a formal investigation of cardiac functional status that includes stress cardiography, echocardiography, and in selected cases coronary angiography. Perfusion imaging with pharmacologic stress testing is a reasonable alternative to exercise stress testing for debilitated patients.

Cardiac tolerance of hemodynamic stress, irrespective of the presence or absence of coronary artery atherosclerosis, is important in the evaluation and treatment of candidates for OLT. Patients with known valvular, hypertensive, or myopathic heart disease, as in alcoholic cardiomyopathy, must undergo estimation of left ventricular function. These data may be difficult to interpret because of reduced peripheral resistance and hyperdynamic circulation, which occur with advanced chronic liver disease.

Pulmonary hypertension, otherwise known as portopulmonary hypertension, occurs among 2% to 4% of patients with end-stage liver disease. Patients with symptoms of marked dyspnea, vascular abnormalities on chest radiographs, or electrocardiographic evidence of right ventricular strain or hypertrophy should undergo echocardiography. A possible diagnosis of pulmonary hypertension necessitates right heart catheterization for pressure measurements and assessment of reversibility. Patients with markedly elevated systolic pulmonary arterial pressure or irreversible portopulmonary hypertension have a high perioperative mortality and should not undergo hepatic transplantation.

The triad of liver disease, increased alveolar-arterial gradient on room air, and intrapulmonary shunting defines the hepatopulmonary syndrome. Although mild hypoxemia affects nearly one-third of patients with cirrhosis, severe hypoxemia in the absence of parenchymal lung disease is uncommon and suggests hepatopulmonary syndrome. The hepatopulmonary syndrome occurs among approximately 5% of patients with cirrhosis. Pulmonary symptoms should be evaluated with arterial blood gas measurements and either contrast-enhanced echocardiography or perfusion lung scanning. This syndrome is reversible in some patients after liver transplantation, but the process is often quite slow.

ASSESSMENT FOR MALIGNANT GROWTH

All candidates for OLT should undergo a careful evaluation for hepatocellular carcinoma that includes measurement of serum α -fetoprotein level and imaging of the hepatic parenchyma. Biopsy confirmation of a small tumor rarely is necessary, especially because there is a risk of spreading the tumor along the biopsy track. Patients with cholangiocarcinoma identified at evaluation before OLT are at high risk of recurrent disease after the operation. Malignant disease metastatic to the liver is considered an absolute contraindication to OLT with the possible exception of slowly growing neuroendocrine tumors.

A history of extrahepatic malignant disease is a difficult challenge for the OLT evaluation team. In general, patients with known recurrent disease are not candidates for OLT. Patients who have completed a curative treatment protocol should be considered on a case by case basis.

All patients older than 40 years should be screened for occult colorectal cancer by means of stool Hemoccult testing. Colonoscopy should be performed if the screening test result is positive. Digital rectal examination and testing for prostate-specific antigen should be included in the assessment of all men older than 45 years. All women need a gynecologic evaluation, including a Papanicolaou cervical cytologic smear. Women older than 40 years should undergo mammography.

ASSESSMENT FOR INFECTION

A standard screening protocol includes a chest radiograph and placement of purified protein derivative (PPD). Candidates who have a positive PPD result but have no evidence of active disease may be treated with antituberculosis monotherapy (isoniazid for 6 months) before transplantation, or treatment can be postponed until after OLT. Antibodies to cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes simplex virus are routinely measured in baseline studies. In the case of CMV, the viral status of the donor and the recipient predicts the risk of CMV disease after transplantation. Candidates without circulating antibodies to hepatitis A or hepatitis B virus should receive appropriate vaccination. All patients should be screened for antibodies to HIV. HIV infection without AIDS is a relative contraindication to OLT; a diagnosis of AIDS is an absolute contraindication.

NUTRITIONAL ASSESSMENT

Many patients evaluated for liver transplantation are malnourished. The causes of poor nutritional status among patients with end-stage liver disease include reduced intake, metabolic alterations, malabsorption or maldigestion, effects of medications, and iatrogenic protein losses due to large-volume paracentesis. Severe malnutrition complicates OLT and results in higher perioperative morbidity and mortality. An aggressive approach to nutritional repletion is appropriate to improve metabolic reserves, potentially stabilize hepatic function, and improve outcome after OLT. Most patients with cirrhosis, even those with intermittent hepatic encephalopathy, can tolerate 80 g of protein daily.

SURGICAL ASSESSMENT

The presence of a surgical portacaval shunt, transjugular intrahepatic portosystemic shunt (TIPS), or previous surgical procedure on the right upper quadrant increase the surgical complexity of OLT but do not preclude liver transplantation. Extensive thrombosis of the portal venous system involving the confluence of the superior mesenteric vein and splenic vein and previous complex upper abdominal surgery may make transplantation technically impossible.

PSYCHIATRIC EVALUATION

Psychiatric symptoms are common among patients with advanced liver disease and must be sought in the pretransplantation evaluation. When informed that a liver transplant will be necessary, patients often have feelings of anger, grief, anxiety, and depression. Adjustment disorders occur among 20% to 25% of patients. Management of these symptoms should be initiated in the preoperative period. The preoperative evaluation also helps identify patients with psychiatric risk factors such as psychotic disorders and severe personality disorders, which may be predictive of postoperative difficulty with compliance or impulse control. The psychiatric evaluation is perhaps most important to patients with a history of illicit drug use or alcoholism. Assessing the prognosis for long-term abstinence from addictive substances both before and after transplantation is paramount. This assessment evaluates the patient's acceptance of the diagnosis of addiction, availability of social support to assist in maintaining abstinence, and use of behavior-modifying alcoholism treatment programs.

ASSESSING THE WISHES OF THE CANDIDATE

Prospective recipients and their families should be informed of the risks and benefits of liver transplantation. This includes providing the patient with the opportunity to withdraw from transplantation assessment. Patients considered unsuitable candidates should be given access to a second opinion regarding suitability for liver transplantation.

THE TRANSPLANTATION OPERATION

Donor and recipient are matched for ABO blood group compatibility and liver volume. The surgical approach to OLT consists of three steps first, removal of the allograft from the heart-beating, brain-dead donor; second, perfusion and storage of the liver in cold UW preservation solution (cold ischemia) for transport to the transplantation center; and third, the recipient operation. The donor liver is inspected at the time of procurement. Cold ischemia times less than 12 hours are ideal. After 12 hours the risk of primary graft nonfunction and biliary complications increases. Younger allografts typically tolerate long cold ischemia times better than do older livers.

The recipient operation can be divided into three separate phases: recipient hepatectomy, the anhepatic phase, and reperfusion. Recipient hepatectomy is the most technically challenging part of the operation. The use of venovenous bypass allows decompression of the venous system below the diaphragm and less splanchnic congestion. The next phase is the anhepatic phase, during which the new graft is sewn into the recipient. Five anastomoses are needed: the suprahepatic inferior vena cava, the infrahepatic inferior vena cava, the portal vein, the hepatic artery, and the biliary anastomosis, most commonly a choledochocholedochostomy. In many centers, a percutaneous biliary drainage tube (T tube) is placed across the biliary anastomosis. This technique reduces bile leakage from the anastomosis, may reduce anastomotic stricturing, and allows monitoring of bile production in the immediately postoperative period. A choledochojejunostomy incorporating a Roux-en-Y loop is used to treat patients with an abnormal native common bile duct (as in PSC or biliary atresia) or patients with very small donor ducts. The third phase of the transplantation operation begins after the portal venous anastomosis. Hepatic reperfusion is a critical phase of the procedure and demands careful circulatory monitoring. Because of a sudden release of cold, hyperkalemic fluid, reperfusion syndrome may occur. This syndrome consists of hypotension, bradycardia, arrhythmias, and rarely, cardiac arrest.

POSTOPERATIVE CARE

NO COMPLICATIONS

The typical recipient of an orthotopic liver transplant remains in the intensive care unit for 24 to 48 hours. If the patient's hemodynamic condition is stable, the endotracheal tube can be removed within the first 24 hours. Doppler ultrasonography often is performed on the first postoperative day to confirm patency of vascular anastomoses. Early signs of satisfactory allograft function include correction of acidosis, improving urine output, normoglycemia without intravenous dextrose solutions, stable hemodynamic values, correction of coagulopathy without additional blood products, quality bile output if a T tube is present, and improving mental status. Daily liver enzyme studies are performed to assist in the monitoring of hepatic function. Serum transaminase levels peak 24 to 48 hours after transplantation and then decline as the ischemia and reperfusion injury resolves. No pattern of liver function abnormalities indicates a specific cause of allograft injury. Reperfusion injury, acute cellular rejection, and recurrent viral hepatitis produce overlapping biochemical profiles.

Recipients typically stay in the hospital for 10 to 14 days. Frequent office visits and serial measurements of liver enzymes and drug levels are needed. All patients receive immunosuppressive medications, initially in high doses and in gradually decreasing doses thereafter. Either cyclosporine or tacrolimus is the mainstay calcineurin inhibitor. The drug is used in combination with glucocorticoids and other immunosuppressive agents. There is no consensus on the best immunosuppressant regimen. Glucocorticoids typically are reduced to 5 mg per day or withdrawn within the first 6 months. All patients receive trimethoprim-sulfamethoxazole prophylaxis against *Pneumocystis carini* pneumonia. Selected patients receive prophylaxis against CMV infection.

IMMEDIATE AND EARLY POSTOPERATIVE COMPLICATIONS

Unexplained failure of the allograft to function in the first 24 to 72 hours is called primary nonfunction. It is related to pre-existing donor organ characteristics such as high fat content, poor graft preservation or prolonged cold ischemia time, or reperfusion injury. Primary nonfunction occurs among 5% to 10% of OLT operations on adults. The condition may mimic acute liver failure and is characterized by renal insufficiency, encephalopathy, coagulopathy, and jaundice. It is important to exclude technical problems such as intraperitoneal hemorrhage, vascular occlusion, or biliary anastomotic leak. Patients should be returned to the list for OLT when a diagnosis of primary nonfunction is made. A lesser degree of preservation injury is common after OLT and may cause a marked increase in transaminase levels and a delay in improvement. Intrahepatic cholestasis develops later and can be diagnosed by liver biopsy. Hepatic arterial thrombosis can cause a similar clinical and histologic appearance and must be excluded with Doppler ultrasonography.

After OLT, early infections are most commonly bacterial and often represent residual infection from the pretransplantation period or complications of mechanical ventilation. Biliary infections are common but must be differentiated from simple colonization of the biliary tract. The seronegative recipient of an allograft from a CMV-positive donor is at greatest risk of post-transplantation CMV infection. Prophylaxis with ganciclovir reduces both the frequency and the severity of CMV among liver allograft recipients. Invasive fungal infection is a serious development in the post-transplantation recovery period and frequently portends death.

Biliary problems are common after transplant, complicating 10% to 25% of cases. Anastomotic leakage usually occurs early in the postoperative course. The diagnosis is suggested by right upper quadrant abdominal pain, fever, and a biloma found at ultrasonography or computed tomography. Anastomotic stenosis and nonanastomotic strictures manifest as cholestasis and occasionally cholangitis. Biliary leaks or strictures may be caused by occlusion of the hepatic artery. Effective therapy for biliary leaks or strictures is dilation, stent placement, or surgical revision. The formation of biliary casts is a rare but devastating problem. Hepatic arterial thrombosis also may lead to the development of sterile hepatic abscesses. Hepatic arterial thrombosis usually necessitates retransplantation.

Failure of restoration of normal neurologic function in the first 24 to 48 hours is a particularly ominous development. The differential diagnosis includes primary nonfunction, cerebral injury due to intracranial hemorrhage in a patient with coagulopathy, or the consequences of cerebral edema in a patient with fulminant hepatic failure. Seizure activity in the first 7 to 14 days after transplantation may be caused by electrolyte disturbances, typically of calcium or magnesium, toxicity from cyclosporine or tacrolimus, or fungal infection of the central nervous system. Central pontine myelinolysis due to a rapid change in serum sodium concentration is recognized as a later event after OLT.

Some patients have congestive heart failure in the early postoperative period. This is probably caused by occult cardiomyopathy previously masked by the hyperdynamic circulation and reduced systemic vascular resistance of end-stage liver disease.

ACUTE AND CHRONIC REJECTION

Despite immunosuppression, 50 of recipients of orthotopic liver transplants have at least one episode of acute cellular rejection that necessitates adjustment of immunosuppressive medications. Eighty percent of episodes of acute cellular rejection of liver allografts occur in the first 10 postoperative weeks. Curious is that an episode of acute cellular rejection that responds to adjustment in immunosuppression does not increase the risk of graft loss and may even protect the graft. In contrast, severe acute cellular rejection that does not respond to increased immunosuppression or recurs once immunosuppression is tapered may cause chronic ductopenic rejection and graft loss.

Acute cellular rejection is manifested by a disturbance in liver enzyme levels that sometimes is accompanied by a systemic illness with fever and malaise. It can be difficult to differentiate from other disorders, such as graft ischemia or viral hepatitis, such as hepatitis C or CMV infection. The diagnosis should be confirmed with a liver biopsy that demonstrates a mixed, predominately lymphocytic portal infiltrate, lymphocytic cholangitis (ductitis), and lymphocytic injury to the vascular endothelium (endotheliitis). The infiltrate often contains eosinophils. Standard therapy for acute cellular rejection is a short course of high-dose glucocorticoids, although patients with mild cases may not be treated. Clinical resolution of the elevated transaminase levels in response to increased corticosteroids supports the diagnosis. Failure of liver enzymes to respond to corticosteroids is called *steroid-resistant rejection*. Steroid-resistant rejection may be managed with conversion from cyclosporine to tacrolimus and the use of anti-CD3 monoclonal antibodies or agents such as mycophenolate mofetil.

Chronic ductopenic rejection (also known as chronic rejection or vanishing bile duct syndrome) is a serious sequela of acute cellular rejection. It consists of arteriopathy and bile duct loss. A liver biopsy shows loss of bile ducts. The clinical syndrome is cholestatic, consisting of elevated bilirubin and alkaline phosphatase levels, jaundice, and pruritus. It rarely responds to incremental immunosuppression and necessitates retransplantation. Fortunately, the incidence of chronic ductopenic rejection appears to be declining.

LONG-TERM MANAGEMENT

RESTORATION OF LIFESTYLE

Recipients of a transplants should plan a return to work, school, and leisure activities as their condition allows. There should be no restrictions on sexual activity. Patients should be encouraged to eat a well-balanced diet. Moderate use of alcohol is permitted except for patients with a history of alcoholism. Annual health evaluations for adult recipients include cervical smears for all women, mammography for women 40 years or older, and measurement of prostate-specific antigen for all male recipients older than 45 years. All patients older than 45 years should perform annual screening for colorectal cancer using Hemoccult cards. Patients with a history of PSC or chronic ulcerative colitis (with the colon in situ) should undergo annual colonoscopy. Evidence of mucosal dysplasia is an indication for colectomy.

Most premenopausal female patients, even those who had prolonged amenorrhea before transplantation, menstruate within 3 months of successful OLT. Pregnancy should be avoided for at least 1 year after transplantation. Pharmacologic contraceptives and barrier contraceptives may be used. Use of intrauterine contraceptive devices, however, carries an unacceptable risk of infection. Successful pregnancy is possible after liver transplantation but should be considered a high-risk pregnancy and managed accordingly.

Live or attenuated vaccines such as bacille Calmette-Guérin, measles, mumps, rubella (MMR), varicella-zoster, yellow fever, oral typhoid, and oral polio vaccine (OPV) are not safe after transplantation and should be avoided. MMR is safe to administer to siblings or other household contacts of recipients, but OPV is not, and household contacts should receive inactivated polio vaccine (IPV) if immunization is necessary. Inactivated vaccines, capsular antigens, and toxoids are safe. These include immunization against hepatitis A, hepatitis B, *Haemophilus influenzae*, pneumococcus, and influenza. All older recipients should receive annual influenza vaccinations.

MEDICAL COMPLICATIONS OF IMMUNOSUPPRESSIVE THERAPY

Post-transplantation lymphoproliferative disorder (PTLD) is proliferation of lymphoid cells among patients taking high doses of immunosuppressants. The affected lymphocytes are infected with Epstein-Barr virus. PTLD manifests as a spectrum of features from a lymphocytic infiltrate that which resolves when immunosuppression is reduced to aggressive monoclonal non-Hodgkin's lymphoma. PTLD may manifest as a mass in the liver or an extrahepatic mass in the brain, intestine, or other solid organ. PTLD may occur soon after transplantation or be delayed for months or years of apparently successful graft survival. PTLD is more common among children than adults and among patients who have received high doses of immunosuppressive agents, especially anti-CD3 monoclonal antibody than patients who have not. These patients at high risk should undergo routine screening with an Epstein-Barr virus polymerase chain reaction. PTLD is managed by means of reducing immunosuppressant medications. When the disorder resembles lymphoma, PTLD is managed by means of chemotherapy. The outlook depends on the aggression of the tumor and the degree of improvement when immunosuppression is reduced or withdrawn.

Headache is the most common neurologic toxicity of immunosuppressive therapy and is most severe among patients with a history of migraine. It is equally common with cyclosporine- and tacrolimus-based treatment protocols. Tremor occurs with both cyclosporine and tacrolimus therapy and usually is a clinical manifestation of drug levels above the therapeutic range.

Many patients, especially those with a pretransplantation history of hypertension experience hypertension that necessitates medication. Cyclosporine, tacrolimus, and glucocorticoids are the main causes of hypertension. Post-transplantation hypertension should be controlled pharmacologically whenever immunosuppressants have been judiciously reduced. The calcineurin inhibitors (cyclosporine, tacrolimus) are the main causes of renal failure, which often accompanies hypertension and is in part dose dependent.

Insulin-dependent diabetes mellitus is related to use of glucocorticoids. There is a suggestion, that tacrolimus is more diabetogenic than cyclosporine. Weight gain is one of the most troubling metabolic complications of immunosuppression. Gout is another metabolic complication of immunosuppressants. Cyclosporine may cause hirsutism, gingival hyperplasia, and changes in facies. These phenomena may be sufficiently disabling to warrant conversion to tacrolimus-based immunosuppression. Hyperlipidemia complicates the use of cyclosporine and corticosteroids. Hypercholesterolemia may necessitate use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors.

Many patients, especially women, are osteopenic before transplantation. Bone loss is exacerbated by glucocorticoids in the first 6 to 12 months after transplantation. Thereafter bone density increases in concert with good allograft function. The desire to protect already thin bones is an indication to withdraw or reduce corticosteroids after transplantation. Calcium supplements, vitamin D repletion, hormone replacement therapy, and bisphosphonates all have a role in treating selected patients with osteopenia.

RECURRENCE OF THE UNDERLYING DISEASE

All patients with hepatitis B virus infection should undergo long-term administration of hepatitis B immune globulin after liver transplantation. With this regimen, fibrosing cholestatic hepatitis is very infrequent. Lamivudine or famciclovir or both may be used as additional agents.

Hepatitis C virus infection of the allograft is almost universal when patients with hepatitis C undergo liver transplantation. After transplantation hepatitis C is associated with a marked rise in circulating viral copy number. The clinical course of liver transplant recipients with hepatitis C is quite variable. Some data suggest that the circulating viral load before transplantation predicts the risk of post-transplantation graft injury. Aggressive hepatitis C, which rapidly leads to death or retransplantation, occurs among approximately 10% of patients. Perhaps another 50% of patients have moderately active chronic hepatitis with a natural history that is truncated compared with that of hepatitis C in the native liver. The remaining 40% of patients appear to have mild disease. Interferon alfa alone is ineffective. Combination therapy with interferon alfa and ribavirin is under study. It is probable that hepatitis C infection causes markedly higher rates of allograft loss, mortality, and retransplantation.

The grafted liver is the most common site of recurrence of hepatocellular carcinoma. No antitumor regimen, including systemic chemotherapy, chemoembolization, direct injection of alcohol, external beam radiation, or a combination of these treatments has been shown to control recurrent tumor after liver transplantation. Recurrence of alcoholism after liver transplantation occurs among 5% to 10% of transplant recipients who have alcoholism. Another 30% admit to "slips" defined as occasional drinking episodes. Alcoholic liver injury is rare in the first 5 years after transplantation. Recurrence of autoimmune liver disease, including PBC, PSC, and autoimmune hepatitis sometimes occurs after transplantation but is rarely clinically significant.

CHAPTER 133: THE PATIENT WITH RENAL DISEASE

H. DAVID HUMES

[Diagnostic Approach to Renal Disease](#)
[Glomerular Disease](#)
[Nonglomerular Diseases](#)

A patient with renal disease may have various initial signs and symptoms: symptoms directly referable to the kidneys, such as flank pain or gross hematuria; extrarenal signs and symptoms not directly related to the kidneys, such as hypertension or generalized edema; or no symptoms at all, but abnormal results on urinalysis or an elevated serum creatinine value discovered during a routine medical evaluation or in the diagnostic workup of another disorder.

Once renal disease is documented, the approach to the patient is twofold—to assess the severity of the renal process and to establish the correct diagnosis. The history and physical examination are useful, but the clinical evaluation of renal function primarily depends on laboratory data, especially the estimation of the glomerular filtration rate (GFR), the quantitation of urinary protein excretion, a careful urinalysis, and the assessment of urine electrolyte concentrations and osmolality. Radiologic studies and a renal biopsy may also aid in the diagnostic evaluation. These diagnostic tools are discussed in [Chapter 163](#) and [Chapter 164](#).

DIAGNOSTIC APPROACH TO RENAL DISEASE

Renal disease is often detected by abnormal urinalysis findings or an elevated plasma creatinine concentration (P_{cr}). Renal disease is always suggested if hematuria or abnormal amounts of protein are present on urinalysis. The diagnostic approach and pathophysiologic mechanisms responsible for hematuria and proteinuria differ substantially and are discussed in [Chapter 134](#) and [Chapter 135](#). The finding of an elevated P_{cr} should be confirmed by repeating the laboratory measurement. If it is verified and the history or physical examination suggests the presence of kidney disease, the laboratory evaluation should begin with an estimation of the GFR through a 24-hour urine collection for creatinine as a reasonable index of functioning renal tissue and of disease severity.

The first important assessment of structural renal disease is the determination of the duration of disease. This assessment is easiest to make if serial P_{cr} measurements rise during observation in the hospital, thus suggesting that the renal disorder is most likely acute. If previous data are unavailable, several clues can be helpful in determining the duration of disease. The presence of oliguria with a urine output less than 500 mL per day suggests an acute process, because prolonged oliguria rapidly results in renal failure and symptoms of uremia. Anemia is more common in advanced chronic renal disease than it is in acute disease of similar magnitude. The anemia of renal failure is due to diminished renal production of erythropoietin, which stimulates the production of red blood cells (RBCs) by the bone marrow. Because less than 1% of circulating RBCs turn over each day, in the absence of bleeding, hemolysis, or hemodilution stemming from fluid retention, the hematocrit in a patient with acute renal failure is usually normal or nearly normal because there has not been enough time for anemia to develop.

The second important assessment in the diagnosis of renal disease is the determination of whether the decline in GFR is due to prerenal, postrenal, or intrarenal disease ([Table 133.1](#)). The clinical and laboratory evaluations to diagnose the presence of prerenal functional or postrenal obstructive processes as the cause of a rise in blood urea nitrogen and P_{cr} are discussed in [Chapter 138](#) and [Chapter 140](#). If prerenal disease due to a decline in renal blood flow, with a concomitant reduction in GFR and urinary tract obstruction, has been excluded, some form of intrarenal structural disease must be present. Intrinsic renal disease is then best approached by categorizing the primary pathologic process into glomerular or nonglomerular disorders. The urinalysis is especially helpful in distinguishing between these two categories ([Table 133.2](#)).

Urinary Findings	Etiology
Hematuria with red blood cell casts	Any of these findings, singly or in combination, is virtually diagnostic of glomerular disease or vasculitis. The absence of these changes, however, does not exclude these diagnoses.
Mass proteinuria (>15 g/d or >100 mg/dl)	
Rapidly progressive glomerular disease with glomerular and epithelial cell casts	In acute renal failure, strongly suggests acute tubular necrosis, although marked hyperkalemia alone can produce similar findings.
Proteinuria with white blood cell casts, granules, or many casts and no or mild proteinuria	Suggestive of tubular or interstitial disease or obstruction.
Hematuria and proteinuria with no or variable casts (including red blood cell casts)	May be seen in glomerular disease, vasculitis, obstruction, renal infarction, acute interstitial nephritis, or infection.
Hematuria alone	Suggestive of vasculitis or obstruction in acute renal failure; may also be found with acute glomerular disease, polycystic kidney disease, or extrarenal problems, such as prostatic disease, tumor, or trauma.
Normal or near-normal flow casts with few or no casts or proteinuria (hyaline casts are not an abnormal finding)	Acute: May be found in prerenal disease, obstruction, hypotension, nephritis, acute casts of acute tubular necrosis, or tubular disease with glomerular sclerosis but not infection (glomerulonephritis, glomerulonephritis). Chronic: May be seen in prerenal disease, obstruction, tubular or interstitial disease, and nephrotic syndrome.
Protein alone	Usually indicative of urinary tract infection (including tuberculosis); may occur with tubulointerstitial disease.

TABLE 133.1. MOST COMMON CAUSES OF RENAL DISEASE

Urinary Findings	Etiology
Hematuria with red blood cell casts	Any of these findings, singly or in combination, is virtually diagnostic of glomerular disease or vasculitis. The absence of these changes, however, does not exclude these diagnoses.
Mass proteinuria (>15 g/d or >100 mg/dl)	
Rapidly progressive glomerular disease with glomerular and epithelial cell casts	In acute renal failure, strongly suggests acute tubular necrosis, although marked hyperkalemia alone can produce similar findings.
Proteinuria with white blood cell casts, granules, or many casts and no or mild proteinuria	Suggestive of tubular or interstitial disease or obstruction.
Hematuria and proteinuria with no or variable casts (including red blood cell casts)	May be seen in glomerular disease, vasculitis, obstruction, renal infarction, acute interstitial nephritis, or infection.
Hematuria alone	Suggestive of vasculitis or obstruction in acute renal failure; may also be found with acute glomerular disease, polycystic kidney disease, or extrarenal problems, such as prostatic disease, tumor, or trauma.
Normal or near-normal flow casts with few or no casts or proteinuria (hyaline casts are not an abnormal finding)	Acute: May be found in prerenal disease, obstruction, hypotension, nephritis, acute casts of acute tubular necrosis, or tubular disease with glomerular sclerosis but not infection (glomerulonephritis, glomerulonephritis). Chronic: May be seen in prerenal disease, obstruction, tubular or interstitial disease, and nephrotic syndrome.
Protein alone	Usually indicative of urinary tract infection (including tuberculosis); may occur with tubulointerstitial disease.

TABLE 133.2. URINARY FINDINGS AND CAUSES OF RENAL DISEASE

Careful examination of the urine is the most important noninvasive diagnostic aid in the evaluation of renal disease. Measurements of electrolyte concentration, pH, and osmolality of the urine are common tests to assess renal tubular function and to evaluate fluid and electrolyte disorders; they are discussed in [Chapter 163](#). Less quantitative analysis of the urine can be performed easily in the clinical setting, along with the urinalysis, and can provide substantial information as to the presence and type of renal disease.

GLOMERULAR DISEASE

Glomerular disease can appear as three distinctly different, but not mutually exclusive, clinical syndromes: the acute nephritic syndrome, the nephrotic syndrome, or chronic glomerulonephritis. The full diagnostic approach to glomerular disease is discussed in [Chapter 150](#) and [Chapter 164](#).

ACUTE NEPHRITIC SYNDROME

The acute nephritic syndrome complex reflects an acute inflammatory response within the kidney and is characterized by hematuria and RBC casts in the urine sediment along with other signs of acute inflammatory renal injury, including proteinuria, peripheral edema, hypertension, or renal insufficiency with or without oliguria. Hematuria alone is not sufficient to define this syndrome. Urinary bleeding may arise from various extrarenal and intrarenal disorders distinct from acute inflammatory processes. The finding of RBC casts in the urinary sediment clearly suggests a nephronal origin of bleeding and is thus of great importance. Because glomerular bleeding can originate from chronic as well as acute processes, it is important to look for other signs of acute inflammatory renal injury before diagnosing the syndrome of acute nephritis.

The hallmark of the acute nephritic syndrome is the finding of RBCs and RBC (as well as other) casts in the urine sediment. The finding of RBC casts in a patient with hematuria virtually ensures that the patient has a glomerular pathologic process. The urinary findings in acute glomerular disease vary, ranging from normal (usually seen in subclinical disease) to signs of proteinuria, hematuria, pyuria, lipiduria, and RBC and other casts. The severity of these abnormalities also varies, since hematuria can be either microscopic or grossly visible. The degree of proteinuria can range from just above the upper limit of normal to the nephrotic range.

The manner in which RBCs pass into the urine in glomerular disease has not been definitively clarified, but transit is probably due to focal disruptions in the glomerular capillary wall produced by the underlying inflammatory process. These focal disruptions along the glomerular capillary wall may contribute to proteinuria and may allow plasma proteins larger than albumin to escape into the urine.

Renal sodium and water retention resulting in generalized edema is common in the acute nephritic syndrome and develops because of poor renal perfusion stemming from a decline in renal blood flow and proteinuria, with resulting hypoalbuminemia and a decline in intravascular volume. Elevated blood pressure is an additional common clinical component of the acute nephritic syndrome. Both volume overload from inappropriate renal fluid retention and enhanced renin secretion from renal injury and resulting vasoconstrictor tone play important roles in this process.

The GFR is often reduced in the acute nephritic syndrome, resulting in a rise in blood urea nitrogen and P_{cr} . This reduction is a result of declines in glomerular blood flow, glomerular transcapillary hydraulic pressure gradients, and the glomerular permeability coefficient, which is a function of both porosity and surface area available for filtration of the glomerular capillary.

Often in this syndrome, renal insufficiency is transient, but it also can be progressive, leading to chronic glomerulonephritis and renal failure. Most patients with acute nephritis have a form of proliferative glomerulonephritis and, occasionally, acute tubulointerstitial nephritis; for this reason, renal biopsy is generally performed to determine the final diagnosis.

NEPHROTIC SYNDROME

Proteinuria above 3.5 g per day is usually classified as being in the nephrotic range, but the nephrotic syndrome complex usually refers to the clinical triad of massive proteinuria, hypoalbuminemia, and edema. Hyperlipidemia and hypercoagulability may also be present. The nephrotic syndrome occurs in association with various primary renal diseases and systemic diseases, as discussed in [Chapter 135](#).

Proteinuria in the nephrotic syndrome is due to an increase in glomerular permeability of serum albumin and arises in response to alterations in both the size and charge barriers of the glomerular filtration apparatus. As a consequence of proteinuria, the serum albumin concentration and therefore the plasma oncotic pressure fall. The generalized edematous state common to the nephrotic syndrome is largely caused by this drop in plasma oncotic pressure and the movement of fluid from the vascular to the interstitial fluid compartment, producing a decline in plasma volume that signals the kidney to retain sodium and water. Other sensing mechanisms may play a role in renal sodium retention, because many patients with this disorder have been reported to have normal rather than diminished plasma volumes.

Hyperlipidemia stemming from increased hepatic synthesis, along with lipiduria, also frequently occurs in this disorder. Two-thirds of patients have type IIa or IIb hyperlipoproteinemia; most others have type V. The nephrotic syndrome may accompany such systemic diseases as diabetes or amyloidosis or idiopathic processes. If no systemic disease is present and the P_{cr} value is not dramatically elevated, renal biopsy is often necessary to reach a final diagnosis.

CHRONIC GLOMERULONEPHRITIS

Many forms of glomerular disease can progress to chronic renal failure. On morphologic examination, this progression is characterized by scarring of most of the glomeruli. Consequently, the urinalysis results are more benign, with less proteinuria and hematuria and with broad, waxy casts in the urine sediment. Occasionally, the urine may have characteristics of nephritic, nephrotic, and chronic patterns. This urinary finding has been called a "telescoped" sediment and is usually seen in severe glomerulonephritis or vasculitis.

NONGLOMERULAR DISEASES

When intrarenal disease processes are present and the laboratory evaluation does not suggest a glomerular disorder, nonglomerular disease processes should be considered in the differential diagnosis. Tubulointerstitial disease, the foremost cause of nonglomerular disease, is discussed in [Chapter 151](#). Acute pyelonephritis, papillary necrosis, and hypersensitivity interstitial nephritis are the major causes of acute tubulointerstitial disease. The causes of chronic tubulointerstitial disease are numerous. It may be associated with essentially normal urinalysis results, although mild degrees of pyuria and proteinuria (less than 2 g per day) may be present. Vascular diseases are other major sources of nonglomerular disorders. Acute vascular intrarenal processes include vasculitis, scleroderma, coagulopathies, and renal infarction; chronic vascular processes include nephrosclerosis and renal artery stenosis. These disorders are discussed in [Chapter 152](#).

CHAPTER 134: APPROACH TO THE PATIENT WITH HEMATURIA

JOHN H. GALLA

[Differential Diagnosis](#)
[Evaluation](#)
[Management](#)

Hematuria, the presence of an excessive number of red blood cells (RBCs) in the urine, may manifest dramatically as painful, gross hematuria or occultly as asymptomatic microscopic hematuria. Whatever the initial signs and symptoms, it can signal a process as ominous as an advanced malignancy or as innocuous as vigorous exercise. Because of its potentially grave implications, hematuria must always be thoroughly evaluated.

First, the presence of hematuria should be confirmed. Proper microscopic examination of the urine requires a freshly voided midstream specimen, preferably collected in the early morning. Contamination of the urine specimen with vaginal blood should be carefully avoided. Ten milliliters of urine is centrifuged at 2,000 rpm for 5 minutes in a conical centrifuge tube, about 9.5 ml of supernatant is decanted, and the infranant is resuspended in the remaining 0.5 ml. A drop of this concentrated urine is placed on a clean glass slide and examined under a coverslip with a ×40 objective. More than two to four RBCs per high-power field (hpf) is considered abnormal and corresponds to about 5,000 RBCs per milliliter of urine or between 500,000 and 600,000 RBC per 12 hours.

Gross hematuria can be confused with pigmenturia of hues from brown to red ([Table 134.1](#)). Except for the heme proteins, all of these pigments can be excluded by testing the urine with orthotolidine and peroxidase-impregnated paper strips, which have a high level of sensitivity (91% to 100%) and specificity (65% to 95%) and result in a positive test for blood for as few as three RBCs per hpf. A positive test in the absence of increased numbers of RBCs per hpf should prompt an investigation for intravascular hemolysis (hemoglobinuria) and rhabdomyolysis (myoglobinuria) (see [Chapter 140](#)). After confirming the presence of either gross or microscopic hematuria, clinical and laboratory evaluations should be carried out.

- Drugs: Rifampin, sulfamethoxazole, phenazopyridine, ibuprofen, phenytoin, levodopa, nitrofurantoin, quinine
- Foods: Beets, various food dyes
- Bile pigments
- Porphyryns
- Hemoglobin or myoglobin
- Ascorbic acid in high urinary concentration (heme false-negative result on dipstick)
- Bacteriuria (heme false-positive result on dipstick)

TABLE 134.1. PIGMENTURIA AND OTHER SUBSTANCES THAT MAY CONFUSE THE DIAGNOSIS OF HEMATURIA

DIFFERENTIAL DIAGNOSIS

The etiologic considerations for hematuria are myriad and most easily considered in an anatomical construct. This listing of the possibilities in differential diagnosis is not intended to be exhaustive; rather, broad categories provide a framework and then a focus for subsequent evaluation ([Table 134.2](#)). A specific etiologic diagnosis will frequently require tissue confirmation. Estimated rates of frequency of causes vary considerably, depending on age and whether the survey separates gross from microscopic hematuria or hematuria from concurrent proteinuria ([Table 134.3](#)). In adults between the ages of 20 and 40 years, the rates lie between these patterns. Urothelial tumors are rare before the age of 40 years.

(This section contains a list of causes of hematuria, which is mostly illegible due to small font size and low contrast. It appears to be a list of medical terms related to the differential diagnosis.)

TABLE 134.2. CAUSES OF HEMATURIA

Cause	Adults	Children	
		Microscopic	Gross
Infection	30%		26%
Calculi/hypercalciuria	20%	26%	2%
Prostatic hypertrophy/obstruction	10%		1%
Cancer	15%		<1%
Glomerulonephritis		13%	4%
Idiopathic		46%	14%
Perineal/penile irritation			18%
Trauma			7%
Coagulopathy			3%

^a Categories do not sum to 100%.

TABLE 134.3. ESTIMATED FREQUENCY RATES OF SOME CAUSES OF HEMATURIA^a

EVALUATION

HISTORY AND PHYSICAL EXAMINATION

Important clues to a likely diagnosis will often be obtained from a thorough history and a physical examination and may direct subsequent testing. A number of elements in the history merit particular attention. The duration, timing, associations, and nature of hematuria should be established. Hematuria coincident with menses

suggests endometriosis. Clots are more often seen with nonglomerular lesions. The presence of frequency, urgency, dysuria, or urethral discharge suggests bladder or urethral involvement. Rectal or perineal pain or discomfort may occur in the context of prostatitis. Flank pain or colic may be seen with stones, acute obstruction, infarction, or polycystic kidneys; even if it is unilateral, severe and persistent flank pain may also be associated with intrinsic renal diseases, such as IgA nephropathy or sickle cell nephropathy. Weight loss may signal a malignancy.

Upper-respiratory-tract infections or gastroenteritis may trigger an exacerbation of IgA or mesangiocapillary glomerulopathy, in particular. Hemoptysis may indicate the presence of antiglomerular basement membrane or lupus glomerulonephritis. Environmental toxins or infectious exposures may be associated with glomerulonephritides and interstitial nephritides. Systemic symptoms, such as fever, arthralgias, easy bruising, and a host of indications of other organ system involvement, suggest lupus erythematosus, Henoch–Schönlein purpura, or vasculitis. All medications should be noted; the loin pain–hematuria syndrome has been associated with oral contraceptives, and cystitis and bladder cancer have been noted with cyclophosphamide. Family history should focus on hematuria, such traits as deafness or ocular defects (Alport syndrome), urinary tract diseases, and bleeding disorders. Travel or residence in countries where such parasitic infections as malaria and schistosomiasis may be encountered is pertinent.

In view of the myriad possible causes, a complete, not a limited, physical examination should be performed, even though the urogenital tract is the major focus. Elevated blood pressure and peripheral edema may indicate a renal lesion. Fever, rash (lupus erythematosus), mucosal lesions, purpura (Henoch-Schönlein purpura, vasculitis), petechiae, cardiac murmur or rub (endocarditis, uremia), lymphadenopathy, or hepatosplenomegaly may direct the evaluation along a particular avenue toward the diagnosis of a systemic illness with or without a specific renal lesion. The kidneys and bladder should be carefully palpated for size and tenderness; the prostate examined for size, consistency, tenderness, and masses; and the external genitalia inspected and palpated for discharge, bleeding, or masses.

LABORATORY STUDIES

A complete urinalysis, the initial laboratory test, includes other important elements. RBC casts and heavy proteinuria point to a glomerular lesion; pyuria and bacteria or fungi indicate infection. Any significant proteinuria suggests other intrinsic renal diseases.

Additional maneuvers can enhance the diagnostic power of the urinalysis. In the “three-glass” test, the initial and final 15 ml of urine are examined separately from the midstream sample. Blood in the initial urine sample suggests bleeding in the urethra or male genital system; terminal hematuria is associated with bladder lesions. Second, examination of the urine by phase-contrast microscopy permits the determination of the proportion of dysmorphic RBCs, which, in contrast to the uniform size and shape of normal RBCs, show irregular outlines, blebs, and granular cytoplasm. When more than 75% of RBCs (at least 100 should be counted) are dysmorphic, renal (not solely glomerular) lesions are a possibility.

Initial blood studies should include a complete blood count (hemoglobin and white blood cell and platelet counts), prothrombin time, partial thromboplastin time, serum creatinine concentration, and hemoglobin electrophoresis or sickle cell screening in appropriate patients. Urinary calcium and uric acid excretion should be determined, particularly in children.

DIAGNOSTIC APPROACH

When the initial evaluation suggests a probable cause, that cause should be pursued until the diagnosis is either confirmed or excluded. Several approaches have been proposed to distinguish the etiologic possibilities in various subsets of patients or associated problems. The following approach for the adult seeks to balance the likely probabilities against the risks and costs of the evaluation (Fig. 134.1). This approach assumes a single cause, although hematuria may be multifactorial. If benign prostatic hypertrophy or a coagulopathy is identified, further evaluation is mandatory to exclude alternative urinary tract lesions. Certain diseases may be associated with more than one cause, for example, analgesic nephropathy is associated with both papillary necrosis and urothelial tumors.

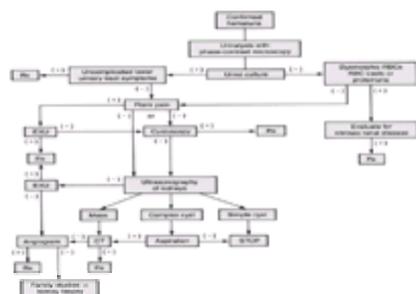

FIGURE 134.1. Approach to the evaluation of hematuria in the adult. Rx indicates the points at which appropriate therapy should be initiated, as discussed elsewhere. Cystoscopy can be deferred in children and young adults. EXU, excretory urogram; CT, computerized tomography; RBC, red blood cell.

For a female patient with an uncomplicated urinary tract infection (a woman of childbearing age with her first episode of lower-urinary-tract symptoms and a urine culture positive for bacteria), specific treatment is initiated; all other urinary tract infections should be considered complicated and evaluated further. If the routine urine culture shows negative results in the context of lower-tract symptoms, special cultures (e.g., tuberculosis, chlamydia) should be obtained, as appropriate, and a tuberculin skin test performed. If lower-urinary-tract symptoms are absent and flank pain is present, an excretory urogram should be performed.

When the urinalysis or initial clinical and laboratory examination suggests intrinsic renal disease, the appropriate diagnostic evaluation, as outlined in Fig. 134.1, should be initiated; this evaluation may include some of the tests outlined. It is anticipated that an abundance of dysmorphic RBCs will be seen with IgA nephropathy and other mesangiopathic glomerular lesions in which asymptomatic or occasionally symptomatic gross hematuria occurs without significant proteinuria or an abnormal serum creatinine concentration. The decision to proceed to kidney biopsy is discussed in Chapter 164.

In the absence of flank pain, the problem is essentially asymptomatic hematuria; cystoscopy is preferable to the excretory urogram as a diagnostic tool. A decision to perform retrograde pyelography can then be entertained, particularly if blood is emanating from the ureters. Ureteral bleeding can be unilateral in intrinsic renal diseases involving both kidneys, such as IgA nephropathy or sickle cell nephropathy.

If cystoscopy shows negative results, ultrasonography of the kidney and its vessels begins a search for a renal mass, which, if found, is evaluated as shown in Fig. 134.1. The diagnosis of the “nutcracker” phenomenon (entrapment of the left renal vein between the aorta and the superior mesenteric artery) can be made with this technique. A negative ultrasound test result leads to an excretory urogram. If all of the tests are normal to this point, the decision to elect an angiogram or computerized tomography study with radiocontrast material is based on the clinical symptoms. In the young patient, benign or recurrent or familial hematuria is a more logical direction for the evaluation. Blood typing of the patient's peripheral blood and urinary RBC may assist in the diagnosis of factitious hematuria.

MANAGEMENT

The management of hematuria is directed at the identified cause, as indicated in other sections. When specific treatment is available and the disease can be cured, the resolution of hematuria should be confirmed; if hematuria persists, reconsider the diagnosis. If no specific treatment is available for the identified cause of hematuria, the decision to pursue additional explanations is a matter of clinical judgment. For example, new gross hematuria in a patient with known renal disease should be evaluated. If no cause is uncovered, reassurance and continued follow-up may be sufficient. On occasion, when essential hematuria has been recurrent, profuse, painful, or associated with iron-deficiency anemia, partial or complete nephrectomy has been performed, and small hemangiomas or patent venous sinuses have been found. Most of these reports antedate the description of IgA nephropathy. In these instances, when hematuria per se becomes the focus of treatment, thorough histologic examination of the kidney is mandatory before considering nephrectomy. Renal autotransplantation has been successfully employed for the loin pain–hematuria syndrome, but bilateral nephrectomy for this syndrome is to be decried.

PRESENTATION

Proteinuria is often the first evidence of renal disease and is usually discovered on routine screening urinalysis. Less commonly, patients with undiagnosed glomerular disease and proteinuria that has caused hypoalbuminemia (i.e., nephrotic syndrome—see later discussion) seek medical care for new-onset ankle or periorbital edema. Patients with coexisting left ventricular dysfunction and nephrotic syndrome can show initial signs and symptoms of new-onset or worsening congestive heart failure.

The incidence of proteinuria identified on routine urinalysis screening varies in population-based studies from 0.6% to 10.7%. Careful evaluation of patients with proteinuria is necessary, since the underlying renal disease may be amenable to therapy. The quantity of urinary protein has both diagnostic and prognostic significance. Nephrotic proteinuria, defined as urinary protein excretion greater than 3.5 g per 24 hours, usually results from glomerular disease. If it is persistent and severe, nephrotic proteinuria is an independent risk factor for progression of the underlying renal disease. However, most proteinuric patients will have non-nephrotic proteinuria (less than 3.5 g per 24 hours), which is more typically associated with tubulointerstitial or glomerular diseases that do not progress, remit, or have an indolent clinical course. Proteinuria that is below the detection limits of standard reagent strips used for screening urinalysis, but which represents abnormally increased albumin excretion, is defined as microalbuminuria.

Both immunoassays and special reagent strips are available for detection of microalbuminuria. The prevalence of microalbuminuria varies in the population, ranging from 4% in healthy individuals to as high as 20% to 30% in diabetic and hypertensive patients. Microalbuminuria appears to be a marker of patients at risk of cardiovascular disease. Screening for microalbuminuria in the clinic is used most commonly in patients with diabetes mellitus, in whom this test has been validated to identify individuals at risk of nephropathy.

PATHOPHYSIOLOGY OF PROTEINURIA

Glomerular cells, matrix, and basement membrane are assembled to generate a highly selective filter that permits passage of water, electrolytes, and solutes with molecular weights of 10 kd or less but prevents movement of larger molecules into the urinary space. This property of the glomerular capillary wall, termed *glomerular permselectivity*, restricts solute filtration on the basis of both molecular size and ionic charge. Glomerular ultrafiltrate must pass through (a) negatively charged, fenestrated endothelial cells; (b) the glomerular basement membrane, which is composed primarily of anionic extracellular matrix components; and (c) slit diaphragms, which bridge negatively charged glomerular epithelial cell foot processes. Under normal circumstances, the net anionic charge of these three layers of the glomerular capillary membrane creates a barrier to passage of anionic proteins, such as albumin. The restrained filtration of larger molecules is also prevented by size constraints of the pores in the filtration barrier.

The molecular basis of glomerular permselectivity is beginning to be understood. Several glomerular epithelial cell proteins (podocalyxin, GLEPP1, and nephrin) have been cloned and appear to regulate glomerular permselectivity by as yet unknown mechanisms. Despite efficient restriction of protein from Bowman's space, small quantities of protein are filtered by the glomerulus in healthy individuals, but almost all of the filtered proteins are reabsorbed and catabolized by proximal tubule cells, so that the amount of protein measured in the urine is only a very small fraction of the amount filtered (less than 150 mg per day).

Increased proteinuria occurs in both glomerular and tubulointerstitial disease. Glomerular damage from disease eliminates both the charge and size barriers and results in loss of glomerular permselectivity. The ensuing leakage of plasma proteins into the glomerular ultrafiltrate in large amounts overwhelms tubular capacity for reabsorption and produces glomerular proteinuria. Interestingly, kidney biopsy samples from patients with many types of glomerular disease often also indicate significant tubulointerstitial disease. Several studies demonstrate that proteinuria can cause tubular epithelial cell injury by several mechanisms of action, which contributes to renal disease progression.

The composition of proteins lost in the urine reflects the extent of damage to the filtration barrier. Loss of glomerular basement membrane charge selectivity typically results in albuminuria, with little loss of larger proteins, such as globulins. This type of selective proteinuria occurs usually, but not exclusively, in patients with minimal-change nephropathy. Other glomerular diseases are characterized by more profound structural damage that destroys both size and charge barriers. Proteinuria in patients with these diseases tends to be nonselective (excretion of both albumin and larger-molecular-weight proteins). A subset of multiple myeloma patients have glomerular proteinuria composed of immunoglobulin light chains. Because of their relatively small size (less than 25 kd) and neutral or cationic charge, these light chains, termed Bence Jones proteins, are freely filtered across the glomerular capillary wall with normal permselectivity. The quantity of filtered Bence Jones proteins frequently exceeds maximal tubular resorptive capacity. Unless glomeruli or tubules have undergone light chain–induced injury, albuminuria is absent, and screening with the urinary dipstick therefore will not identify these patients (see later discussion, Measurement of Urinary Protein Excretion and Urinalysis).

Primary or secondary tubular disorders, in the absence of glomerular disease, may cause tubular proteinuria by reducing the tubular capacity to reabsorb filtered proteins. Tubular proteinuria may result in urinary losses of albumin, low-molecular-weight globulins, and enzymes. Proteinuria in the context of inflammatory tubulointerstitial diseases may be due to decreased protein resorption, as well as secretion of IgA and uroepithelial mucoproteins. Tubular proteinuria rarely exceeds 2 g per 24 hours and usually is less than 1 g per 24 hours.

Mechanisms of microalbuminuria are less well understood and have been primarily explored in patients with diabetes. Careful morphologic analysis shows a diminished number of podocytes and increased glomerular volumes in diabetic Native Americans of the Pima tribe who have microalbuminuria. Since podocytes do not replicate, the remaining podocytes, though normal on ultrastructural examination, appear inadequate to maintain a normal filtration barrier. Microalbuminuria may also result from endothelial cell dysfunction, with leakage of protein across diseased glomerular capillary basement membranes.

HISTORY AND PHYSICAL EXAMINATION

After proteinuria is discovered, the patient should be carefully questioned for history or symptoms characteristic of systemic diseases that cause proteinuria ([Table 135.1](#)). Diabetes is the most common cause of proteinuria, and proteinuria rarely is the first indication of this disease in a patient with type II diabetes. While they are nonspecific symptoms, malaise, anorexia, and weight loss point to systemic illness or uremia. The patient's use of both prescribed and over-the-counter medications and street drugs should also be determined. Blood pressure levels may suggest the underlying disease source. For example, patients with minimal-change disease or membranous nephropathy less commonly are hypertensive. In contrast, hypertension is often associated with focal segmental glomerulosclerosis and proliferative glomerulonephritides. Orthostatic changes in blood pressure and other signs of extracellular fluid volume status should be assessed, because some patients with nephrotic syndrome exhibit intravascular volume depletion despite marked peripheral edema, findings that can alter subsequent management. Dependent or periorbital edema indicates the possibility of hypoalbuminemia from nephrotic syndrome. Lower-extremity skin rashes are characteristic of certain vasculitides, and a malar rash suggests systemic lupus erythematosus.

Angiotensin-Converting-Enzyme Inhibitor and Progressive Renal Disease Study Group. *Ann Int Med* 1997;127:337–345.

NON-NEPHROTIC PROTEINURIA

Non-nephrotic proteinuria is diagnosed in patients who excrete 150 mg to 3.5 g urinary protein per 24 hours, although non-nephrotic urine protein excretion characteristically is less than 1 g per 24 hours. In contrast to nephrotic proteinuria, a patient with non-nephrotic proteinuria is more likely to have a normal GFR, a normal urinalysis result, and absence of an associated systemic disease. Non-nephrotic proteinuria can reflect serious systemic disease, however, such as vasculitis or incipient diabetic nephropathy. Patients with non-nephrotic proteinuria, especially of more than 1 g per 24 hours, should be carefully screened for both glomerular and tubular diseases with detailed history, physical exam, and appropriate laboratory studies. In patients without serious systemic disease, non-nephrotic proteinuria can be classified as either benign (transient or orthostatic) or persistent (glomerular or tubular).

Benign Proteinuria

Transient proteinuria is defined as proteinuria that ultimately resolves with no identifiable harmful effects. Functional transient proteinuria is associated with fever, strenuous exercise, emotional stress, congestive heart failure, or other acute medical illnesses, whereas idiopathic transient proteinuria is proteinuria present in an otherwise healthy person. Orthostatic proteinuria occurs only when the patient is in the upright position and is diagnosed by quantitating proteinuria in daytime and nighttime urine collections. Approximately 90% of young men with proteinuria will have orthostatic proteinuria, which is usually associated with urinary protein excretion of less than 2 g per 24 hours. Orthostatic proteinuria spontaneously resolves in over 80% of cases.

Persistent Proteinuria

Persistent non-nephrotic proteinuria occurs in patients with either glomerular or tubulointerstitial disease. Glomerular diseases that cause non-nephrotic proteinuria can spontaneously remit, remain indolent, or rapidly progress from associated inflammation (see [Chapter 150](#)). Patients in the latter group usually have signs and symptoms of significant illness, and urinalysis generally shows hematuria and, occasionally, red blood cell casts. Patients with persistent proteinuria, but otherwise normal urinalysis results may eventually experience progressive renal failure and hypertension, although many patients' disease follows an indolent course. For this reason, follow-up investigation for renal disease may be warranted for at least some patients with persistent proteinuria. Many patients with persistent proteinuria without evidence of glomerular disease have tubulointerstitial disease as a primary disorder or as a result of a systemic illness (see [Chapter 151](#)).

NEPHROTIC SYNDROME

The nephrotic syndrome is a constellation of clinical and laboratory abnormalities common to a variety of primary and secondary kidney diseases, each characterized by increased permeability of the glomerular capillary wall to circulating plasma proteins. The defining clinical manifestation of filtration barrier dysfunction caused by these disorders is heavy proteinuria (more than 3.5 g per 24 hours) that leads to hypoalbuminemia. Secondary manifestations, such as edema, hyperlipidemia, and lipiduria, are common.

Proteinuria and Hypoalbuminemia

In the nephrotic syndrome, proteinuria results from a combination of defects in the size-selective and charge-selective sieving properties of the glomerular capillary membrane. Albumin is the predominant protein that is excreted, since it is the most abundant protein in plasma, but there may also be increased urinary loss of other proteins. Proteinuria and hypoalbuminemia are not necessarily directly related, since the serum albumin concentration reflects the composite effects of urinary protein loss, dietary protein intake, hepatic protein synthesis, protein catabolism, and the distribution of albumin between vascular and extravascular compartments. In the nephrotic syndrome, some or all of these regulatory factors may be altered. In the absence of coexisting liver disease or a systemic illness or malnutrition, hepatic synthesis of albumin is either normal or moderately high in nephrotic patients. The predominant cause of hypoalbuminemia appears to be a failure to enhance hepatic synthesis sufficiently to compensate for increased urinary losses and renal catabolism of albumin.

Edema

The mechanisms of edema formation in the nephrotic syndrome can vary and depend on the underlying glomerular abnormality. The classic view of edema formation is that hypoalbuminemia reduces plasma oncotic pressure, thereby promoting fluid transudation from the intravascular to the interstitial space. This theory may apply to some patients with minimal-change disease who exhibit signs of intravascular volume depletion. However, the observation that blood volume is increased in many other patients with nephrotic syndrome suggests that elevated hydrostatic pressure due to sodium and water retention mediated by intrarenal mechanisms (e.g., decreased GFR or enhanced tubular sodium reabsorption) may be a primary mechanism of edema formation. Patients with the nephrotic syndrome typically show signs of "pitting" edema in dependent areas where the imbalance of Starling forces is greatest, such as the lower extremities and periorbital and scrotal tissues. Transudative pleural effusions and ascites also may be present, but pulmonary edema is unusual in the absence of concomitant heart or renal failure.

Hyperlipidemia and Lipiduria

An increase in the serum concentrations of cholesterol and phospholipids is often a striking finding associated with nephrotic proteinuria. Reduction in plasma albumin concentration leads to enhanced hepatic synthesis of the cholesterol-transporting protein and apolipoprotein B, resulting in a higher serum concentration of very-low-density lipoproteins (VLDLs). The exact way in which apolipoprotein B synthesis is linked to hypoalbuminemia is unknown. Increasing oncotic pressure by infusion of albumin or dextran, however, causes a decrease in plasma lipid levels, suggesting that the reduction of serum oncotic pressure from hypoalbuminemia may be the primary signal for hyperlipidemia in a nephrotic patient. Increases in VLDLs are also caused by decreased VLDL clearance in the nephrotic syndrome.

In general, plasma concentrations of lipids are related inversely to the serum albumin concentration, but the specific plasma lipoprotein fractions that are elevated tend to vary with the severity of hypoalbuminemia. Early in the course of nephrotic syndrome, triglycerides of VLDL are hydrolyzed rapidly by lipoprotein lipase, causing low-density lipoproteins (LDLs) to form in excess without a rise in VLDL concentration. Thus, an increase in plasma LDL cholesterol levels is the first lipid abnormality to appear in nephrotic patients. Total serum high-density lipoprotein (HDL) levels vary, but the cardioprotective HDL₂ subfraction tends to be decreased. As the nephrotic syndrome progresses in severity, lipoprotein lipase activity diminishes in some patients, and hypertriglyceridemia results from overproduction of VLDL and defective lipolysis of triglyceride-rich lipoproteins. Lipiduria is common in the nephrotic syndrome and results from increased glomerular permeability to low-molecular-weight proteins, thus correlating better with the degree of proteinuria than with the degree of hyperlipidemia.

Other Metabolic Derangements

Patients with the nephrotic syndrome tend to experience arterial and venous thrombosis, especially renal vein thrombosis. Several mechanisms of action have been proposed for this hypercoagulable state. Minor elevations of the platelet count and plasma concentrations of fibrinogen and factors V, VII, VIII, and X have been reported. Urinary loss of antithrombin III, a potent anticoagulant protein with a molecular weight similar to that of albumin, may play a role in the thrombotic tendency of some patients. Decreased activity of protein S, a plasma protein that serves as a cofactor for the anticoagulant effects of activated protein C, also has been described in patients with nephrotic syndrome. Nephrotic patients exhibit platelet hyperaggregability that is related inversely to the serum albumin concentration and reverses with infusion of albumin. Albumin binds arachidonic acid and limits its conversion to thromboxane, a potent stimulator of platelet aggregation. In addition, enhanced production of thromboxane in nephrotic patients with hypoalbuminemia may contribute to increased platelet aggregation.

In nephrotic patients with nonselective proteinuria, the serum concentrations of proteins other than albumin may be reduced through urinary losses. Loss of vitamin D-binding globulin may result in vitamin D deficiency, leading to hypocalcemia, osteomalacia, and secondary hyperparathyroidism. Loss of immunoglobulins may contribute to the increased rate of infections observed in nephrotic patients. Depletion of transferrin may lead to iron-deficiency anemia. Loss of thyroxine-binding globulin may affect certain thyroid function tests, but free thyroxine, triiodothyroxine, and thyroid-stimulating hormone levels are normal.

Etiology

The nephrotic syndrome either results from a primary glomerulopathy or is a manifestation of a systemic disorder. A partial list of such disorders is shown in [Table 135.1](#), and they are discussed in [Chapter 150](#). Most (50% to 70%) adult patients who show signs of the nephrotic syndrome have a related systemic illness. The most common multisystem diseases found in conjunction with this syndrome are diabetes mellitus, systemic lupus erythematosus and other collagen vascular diseases, and primary or secondary amyloidosis. Bacterial, viral, protozoan, and helminthic infections have been found to be related to the nephrotic syndrome, most often resulting in proliferative or membranous glomerulopathy. Chronic hepatitis C infection has been associated with cryoglobulinemia and proliferative glomerulonephritis and may be the most common infectious cause of nephrotic syndrome. Immunologic and virologic studies suggest that renal disease results from intraglomerular deposition of immune complexes containing hepatitis C. Infection with human immunodeficiency virus can cause a glomerular lesion that resembles focal segmental glomerulosclerosis, which usually leads to nephrotic syndrome and can cause rapidly progressive renal failure.

Neoplasms also are associated with the nephrotic syndrome. In the case of carcinomas, the histologic features are typical of membranous glomerulopathy, implicating an immune response to tumor antigens in the pathogenesis of this disease. Lymphomas and leukemias more often are associated with minimal-change disease. A variety of medications, particularly penicillamine and gold, have been linked to membranous glomerulopathy. Nonsteroidal anti-inflammatory drugs cause a syndrome of nephrotic proteinuria and acute renal failure. Pathologic examination in these cases usually reveals acute interstitial nephritis with minimal glomerular changes other than glomerular epithelial cell foot process fusion. Focal segmental glomerulosclerosis is a common lesion in nephrotic syndrome as a complication of intravenous heroin use. Subcutaneous drug abuse (“skin popping”) more often is associated with amyloidosis.

Between 30% and 50% of adult patients with nephrotic syndrome do not show evidence of a systemic disorder and are identified as having idiopathic nephrotic syndrome. Histopathologic examination of biopsy material usually shows one of four pathologic entities: membranous glomerulopathy (30% to 40% of cases), focal segmental glomerulosclerosis (20% to 30%), minimal-change disease (10% to 20%), or membranoproliferative glomerulonephritis (10% to 20%). Focal segmental glomerulosclerosis is the most common lesion identified in biopsy specimens obtained from African Americans with nephrotic syndrome, and studies suggest that it is increasingly common in the general population. In contrast to the findings among adult patients, minimal-change disease accounts for more than 80% of all cases of nephrotic syndrome in children (less than 10 years of age).

STRATEGIES FOR OPTIMAL CARE

Specific management approaches to both glomerular and tubulointerstitial conditions related to proteinuria are discussed in [Chapter 151](#) and [Chapter 164](#). Supportive treatment of the patient with proteinuria is discussed here. Blood pressure should be optimally controlled in all patients, in an effort to slow progression of the underlying renal disease. A randomized, multicenter trial has shown that reduction of mean arterial blood pressure (MAP) to less than 92 mm Hg in patients with proteinuria and azotemia lowers the rate of decline in GFR compared with a control group of patients whose hypertension was treated to standard levels (MAP of 107 mm Hg). The benefit of blood pressure reduction is greatest in nephrotic patients and moderate in patients with protein excretions of 1 to 3 g per day.

Several classes of antihypertensives have been termed “renal protective” and may have beneficial effects on the rate of renal disease progression that are independent of blood pressure lowering. The renal-protective effects of angiotensin-converting enzyme (ACE) inhibitors are the best studied and most compelling, and a limited number of human studies have suggested that non-dihydropyridine calcium channel blockers (e.g., diltiazem and verapamil) and b-blockers may also belong in this category. Several multicenter trials, in diabetics and nondiabetics, have shown that treatment of both hypertensive and normotensive proteinuric patients with ACE inhibitors results in slower deterioration in renal function compared with control groups with equivalent blood pressure using a regimen that did not contain an ACE inhibitor. The greatest benefit has been confirmed in patients with nephrotic proteinuria, but use of these drugs in patients with lesser levels of proteinuria also appears to be warranted. Smaller trials similarly have suggested beneficial effects of angiotensin II receptor blockers on the rate of progression of renal disease and the level of proteinuria.

The renal protective effect of ACE inhibitors and other antihypertensive drugs seems to result from their “antiproteinuric” effects, which is in agreement with observations that proteinuria confers an independent risk of progressive kidney disease. ACE inhibitors are the most efficacious agents available to reduce proteinuria and are increasingly used in normotensive, nondiabetic nephrotic patients to prevent progression of the underlying nephropathy. Nonsteroidal anti-inflammatory drugs also have been administered in conjunction with sodium restriction (50 mEq per day) to limit protein excretion in patients with intractable hypoalbuminemia and edema, although the benefit on progression of renal disease has not been studied. The hemodynamic changes, which are induced by nonsteroidal anti-inflammatory agents and which contribute to the diminution of proteinuria, usually cause a stable but reversible decrease in GFR but also can precipitate ischemic acute renal failure in some nephrotic patients. Renal function and serum electrolytes of patients must therefore be carefully monitored if treatment with nonsteroidal anti-inflammatory agents or ACE inhibitors is initiated, particularly if the clinical status of the patient changes.

Management of diabetic proteinuria, the most common cause of the nephrotic syndrome, merits special comment. In addition to obtaining adequate blood pressure control, studies have demonstrated that aggressive blood glucose control delays progression of proteinuria in nonazotemic patients with type 1 diabetes and microalbuminuria. In one study, intensified insulin treatment regimens also prevented development of proteinuria in patients who entered the study with normal daily protein excretion rates. Studies to evaluate the advantage of tight glycemic control for end-organ complications in the context of type 2 diabetes are ongoing; most investigators believe that achieving normal serum glucose levels also should be a goal in this group of patients.

Nutritional therapy for all patients with chronic renal disease, including patients with the nephrotic syndrome, has generated great interest in the nephrology community for two reasons. First, adequate nutrition reduces morbidity and mortality in patients on dialysis. Patients with the nephrotic syndrome are at risk of malnutrition, particularly if urinary protein losses are persistent and appetite becomes suppressed owing to uremia. Adequate protein and calorie intake should be maintained to avoid malnutrition, and dietary management may require consultation with a dietician. Second, dietary protein restriction has been shown to delay the progression of renal disease in animal models. However, the applicability of these data to management of human disease remains controversial. In the multicenter Management of Diet in Renal Disease study, dietary protein restriction had no conclusive benefit on the decline in GFR, although progression in some subsets of patients may have minimally slowed. Protein restriction to slow progression in all patients with renal disease should be attempted only with adequate support from a dietician.

Other supportive therapies are directed primarily at alleviating edema. Dietary sodium restriction should be the initial maneuver to reduce edema. Usually, limiting a patient's sodium intake to 2 to 3 g per day is sufficient to lessen fluid retention, although patients with severe hypoalbuminemia may require further restriction of sodium intake. Diuretics can be added later, but they must be used judiciously to limit extracellular fluid volume while preserving intravascular volume. Although nephrotic patients usually have expanded extracellular fluid volumes, intravascular volume depletion also can be present in some patients if oncotic pressure becomes sufficiently low. Aggressive diuresis in these patients may precipitate acute renal failure as the result of further intravascular volume depletion. Bed rest alone or, more commonly, hospital admission for administration of intravenous albumin followed by a loop diuretic usually elicits diuresis in these patients. Low doses of dopamine (1 to 6 µg per kilogram per minute) increase renal blood flow and may be a useful adjunct to diuretics in the therapy of severe edema in the hospitalized patient. Finally, hemofiltration or continuous loop diuretic infusion can be employed to reduce extracellular fluid volume in the rare patient who is refractory to other therapies. In all cases, patients undergoing diuresis must be closely monitored for evidence of volume depletion.

Safe and effective modes of therapy are now available to lower serum lipid levels in nephrotic patients, but the association between hyperlipidemia, which often

accompanies the nephrotic syndrome, and accelerated atherosclerosis has not been proved conclusively. Given the pro-atherogenic lipid profiles of most nephrotic patients, most nephrologists initiate appropriate lipid-lowering therapy in patients with persistent nephrotic proteinuria or other vascular risk factors. If lipid-lowering treatment is initiated, drug therapy will be required, because dietary modification is ineffective owing to the severity of hyperlipidemia in the nephrotic syndrome. Inhibitors of the rate-limiting enzyme in cholesterol synthesis (3-hydroxy-3-methylglutaryl coenzyme A reductase) are the most effective therapy for hypercholesterolemia. Fibric acids (e.g., clofibrate) lower triglyceride but not cholesterol levels in nephrotic patients. Combinations of lipid-lowering drugs from different categories also can be used if additive toxicities are avoided. Experimental evidence from animal studies has suggested that hyperlipidemia may hasten the progression of all types of renal disease, including those associated with the nephrotic syndrome, but further confirmation in human trials is warranted.

As described previously, the nephrotic syndrome is a hypercoagulable state, although estimates of the evidence of thromboembolic phenomena (most commonly renal vein thrombosis) vary widely. Anticoagulant therapy should be initiated if a thromboembolic complication is documented, but patients with the nephrotic syndrome may be relatively resistant to the effects of heparin as the result of losses of antithrombin III (the heparin substrate) in the urine. The duration of anticoagulation that is required after a thromboembolic event is unclear. In theory, anticoagulant therapy may need to be continued as long as nephrotic-range proteinuria persists, although the risk/benefit ratio of long-term anticoagulation in the nephrotic syndrome has not been established. Finally, doses of all drugs tightly bound to albumin may need to be reduced to avoid toxicities, because diminished albumin concentrations in nephrotic patients can lead to accumulation of the unbound fraction.

Indications for HOSPITALIZATION

Hospitalization is rarely necessary for evaluation of the patient with proteinuria. Renal biopsy can be performed in the outpatient setting if the patient can be monitored for at least 8 to 12 hours after the procedure. Several studies that analyzed biopsy complications suggest that major bleeding generally occurs within that time period. Diuresis of the nephrotic patient with edema can generally be done in the clinic if the patient's weight is monitored daily. To prevent skin breakdown or anasarca, some patients with refractory edema will require hospitalization for intravenous diuretic therapy with or without intravenous albumin or low doses of dopamine. Finally, patients who require cytotoxic therapy may need hospitalization.

CHAPTER 136: APPROACH TO THE PATIENT WITH DYSURIA AND PYURIA

ERIC W. YOUNG

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION

Dysuria and pyuria are common clinical problems and cardinal manifestations of diseases of the genitourinary tract. *Dysuria* refers to pain, burning, or other discomfort associated with urination and is often accompanied by urinary frequency, urgency, and suprapubic discomfort. *Pyuria* is the presence of abnormal numbers of white blood cells in the urine. Patients often present with both dysuria and pyuria. Infection is the most common cause of dysuria and pyuria, but other etiologies may need to be considered.

PATHOPHYSIOLOGY

In general, dysuria and pyuria indicate inflammation or irritation within the urinary bladder, urethra, or surrounding tissues. The specific cause of the inflammation depends on the cause, as detailed in the section Differential Diagnosis.

HISTORY AND PHYSICAL EXAMINATION

A patient with dysuria or pyuria should be asked about urinary frequency, urgency, cloudy or malodorous urine, urethral discharge, fever, and flank pain. Women should be asked about vaginal discharge or itching. It may be appropriate to inquire about recent sexual activity in the context of possible cystitis or a sexually transmitted disease. Pertinent aspects of the physical examination include the presence or absence of fever, suprapubic tenderness, and flank tenderness. If indicated by the clinical history, men should be examined for a urethral discharge and women should undergo a pelvic examination to detect vaginal discharge and inflammation.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A urinalysis should be done on patients with dysuria or other symptoms of lower-urinary-tract irritation. Quantitative measurements have established that pyuria is characterized by a leukocyte excretion rate of more than 200,000 cells per hour. For practical clinical purposes, however, pyuria is defined by the presence of at least five leukocytes per high-power field on the microscopic portion of a standard urinalysis. The leukocyte esterase dipstick test is quite specific (95%) for detecting pyuria, although its sensitivity is only fair (false-negative rate as high as 26%). The nitrite dipstick test detects the presence of bacteria, which reduce urinary nitrates to nitrites. Infection is unlikely if the leukocyte esterase and nitrite dipstick test results are both negative.

One reasonable cost-saving strategy is to screen urine with a dipstick and perform a microscopic examination only if the test for leukocyte esterase, nitrite, hemoglobin, or protein yields positive results. However, urine microscopy should be done for symptomatic patients regardless of the screening dipstick results. Finding bacteruria on a urinalysis further supports a diagnosis of infection, whereas proteinuria or casts indicate renal disease. If acute renal interstitial nephritis is suspected, a Wright or Hansel stain of the urine should be done to detect eosinophils.

A urine culture may be ordered to establish or confirm a diagnosis of infection. Culture is mandatory for complicated, recurrent, or unclear cases, but it may be optional or even unnecessary for straightforward cases of cystitis. Vaginal or urethral cultures or smears should be done for suspected vaginitis or urethritis, as detailed later. Specific situations may call for more specialized tests, such as cystoscopy or kidney biopsy.

DIFFERENTIAL DIAGNOSIS

The major causes of dysuria (often accompanied by pyuria) are listed in [Table 136.1](#) and the causes of pyuria in [Table 136.2](#).

Acute cystitis
Acute urethral syndrome
Acute cystitis with pyelonephritis
Acute vulvovaginitis with or without urethritis
Idiopathic interstitial cystitis
Genitourinary trauma
Urethral irritants
Allergic reaction
Autoimmune diseases

TABLE 136.1. CAUSES OF DYSURIA

Infection of the urinary tract
Acute interstitial nephritis
Chronic interstitial nephritis
Acute glomerulonephritis or vasculitis

TABLE 136.2. CAUSES OF PYURIA

DYSURIA

Acute cystitis is the most common cause of dysuria in clinical practice. Women are particularly prone to cystitis, apparently owing to the ease with which the urethra

can become contaminated with perineal flora. The risk of cystitis seems to be amplified with delayed bladder emptying following intercourse. Dysuria due to cystitis may also be seen in immunocompromised hosts. Cystitis in children or men might indicate an underlying structural urologic problem, particularly if infections are recurrent.

Coliform bacteria are the most common cause of infectious cystitis. *Escherichia coli* is the causative organism in approximately 85% of community-acquired infections; the rest are accounted for by *Proteus* and *Klebsiella* species and *Staphylococcus saprophyticus*. A much broader spectrum of resistant and unusual organisms are encountered in hospitalized patients and those with other complications.

A diagnosis of bacterial cystitis should be made in a patient with dysuria if pyuria is found on urinalysis. Other rapid laboratory indicators of cystitis include bacteruria, the presence of bacteria on a Gram stain of the urine, and a positive dipstick reaction for leukocyte esterase or nitrite. The urine culture is usually considered positive with a bacterial density of more than 100,000 colony-forming units (CFU) per milliliter. Lower levels of growth, however, can occasionally indicate infection. A clean-catch urine culture specimen can be considered positive with as few as 100 CFU per milliliter in symptomatic women and 1,000 CFU per milliliter in symptomatic men.

Acute urethral syndrome refers to dysuria and frequency in the absence of significant bacteruria. Many patients with this clinical picture have true bacterial cystitis with low bacterial counts on culture. Other patients have infections with chlamydia, *Ureaplasma*, or other fastidious organisms. Rarely, patients have no defined cause of dysuria.

Occasionally, a patient with subclinical pyelonephritis and cystitis may have isolated dysuria in the absence of fever and flank pain, which usually signals upper-urinary-tract infection. Various infectious sources are possible, as for cystitis. Silent pyelonephritis may be a reason for failure of short-term or oral antibiotic therapy directed at cystitis.

Vulvovaginitis is an important cause of dysuria in women. Dysuria may stem from accompanying urethritis or may be due to the contact of urine with inflamed external tissues. Burning toward the end of urination indicates the latter. If queried, patients with vaginitis usually complain of vaginal itching and discharge that may smell foul. On physical examination, there is inflammation and tenderness of the external genitalia and discharge. Urinalysis may show pyuria if there is coexistent urethral inflammation. The most common causes of vaginitis are *Candida albicans* and *Trichomonas vaginalis*. Candida vaginitis produces a thick white discharge. Candida infection may occur in any woman, but patients with diabetes or those who have recently undergone antibiotic treatment are particularly vulnerable. The diagnosis is made by finding fungal elements on a potassium hydroxide stain of vaginal secretions. Trichomonas vaginitis is characterized by a thin, watery discharge. Diagnosis is made by seeing trichomonads on a wet mount of vaginal fluid.

Urethritis may cause dysuria in women and men. Important causes of urethritis include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and herpes simplex virus. In addition, *C. albicans* and *T. vaginalis* sometimes cause urethritis in women in the absence of symptoms of vaginitis. Urinalysis often shows pyuria without bacteruria. Specific cultures must be obtained if these entities are suspected on clinical grounds.

Idiopathic interstitial cystitis appears to be a noninfectious cause of lower-urinary-tract symptoms, including dysuria, frequency, urgency, and nocturia. The origin of this condition is not well understood. Urinalysis often reveals pyuria without bacteruria. The urine cultures are sterile. Cystoscopic examination classically documents very small petechial hemorrhages of the bladder wall. Dysuria may also arise from trauma, chemical or mechanical irritants, and autoimmune diseases.

PYURIA

Pyuria is most often caused by infection within the urinary tract, as detailed previously. Urine sediment showing white cells and white cell casts strongly suggests pyelonephritis. Pyuria usually resolves with successful treatment of urinary tract infections. Infectious agents that may require special efforts to culture and identify include chlamydia and *Mycobacterium tuberculosis*. The presence of "sterile pyuria" (as determined by standard culture techniques) should prompt the clinician to request multiple urine culture specimens for acid-fast bacilli. Sterile pyuria or isolated pyuria may also indicate renal parenchymal disease, particularly in patients with proteinuria or an elevated serum creatinine concentration.

Acute interstitial nephritis is a well-recognized cause of acute renal failure. The inflammatory response can be induced by drugs, autoimmune diseases, or infection (see [Chapter 151](#)). Drug-induced interstitial nephritis is characterized by eosinophilic pyuria in approximately 80% of cases. Other features can include hematuria, eosinophilia, fever, and rash. Many drugs have been reported to provoke acute interstitial nephritis, but the most common include penicillin and sulfa antibiotics, rifampin, allopurinol, loop diuretics, and cimetidine. The diagnosis is usually based on clinical findings and the presence of eosinophils in the blood or urine. A kidney biopsy may be needed to establish the diagnosis.

Chronic interstitial nephritis connotes chronic irreversible scarring of the renal interstitial space. Pyuria may be present, as well as increased serum creatinine concentration, renal tubular defects (diminished concentrating ability, renal tubular acidosis), hypertension, and papillary necrosis with sloughing of tissue into the urine. Prolonged exposure to analgesic agents has been implicated in this disease.

Pyuria may be seen in patients with acute glomerulonephritis or vasculitis, reflecting inflammation within the kidney. Usually, pyuria is eclipsed by other manifestations of renal disease, such as hematuria, red cell casts, proteinuria, azotemia, and hypertension. However, it is not uncommon for patients who are evaluated in the early stages of glomerulonephritis (e.g., Wegener's granulomatosis, Goodpasture's syndrome) to be mistakenly diagnosed as having urinary tract infection on the basis of pyuria and hematuria on urinalysis.

STRATEGIES FOR OPTIMAL CARE

Specific aspects of treatment are described in the chapters on specific entities. Usually, a patient with dysuria and pyuria should be started on antibiotics. A urine culture is unnecessary for uncomplicated cystitis, and treatment should not be delayed while awaiting the results of a urine culture. Uncomplicated infections are defined as those in adult, nonpregnant women without an accompanying condition that increases the risk or persistence of infection (e.g., diabetes, immunosuppression, and abnormalities of the urinary tract). Urinary infections in men, children, pregnant women, and hospitalized patients should be considered complicated. Short-course therapy (i.e., 1 or 3 days, as opposed to the traditional 7-day regimens) may be appropriate for uncomplicated cases. Appropriate antibiotic regimens include amoxicillin, trimethoprim-sulfamethoxazole, and quinolones (e.g., ciprofloxacin or norfloxacin). Specific antimicrobial therapy should be administered to patients with vulvovaginitis or urethritis, as guided by the diagnostic evaluation. Drug-induced interstitial nephritis is treated by withdrawing the putative agent. A short course of steroids is sometimes administered to dampen the inflammatory response.

CHAPTER 137: APPROACH TO THE PATIENT WITH POLYURIA OR NOCTURIA

ROBERT M. A. RICHARDSON AND SHELDON TOBE

Polyuria
Nocturia

POLYURIA

PRESENTATION

Polyuria is defined as the excretion of more than 2.5 to 3 L of urine per day. This definition is arbitrary and is based on the likelihood of a patient's being inconvenienced by the need to void frequently. It should be noted that much lower urine flow rates may be inappropriately high for a given clinical context but may not qualify as polyuria. Polyuria as a primary disorder stimulates thirst, leading to polydipsia. Because some patients have a primary increase in thirst or water intake, it may be difficult to determine whether polyuria is the cause or the effect of polydipsia.

PATHOPHYSIOLOGY

Polyuria may be caused by either water or solute diuresis. *Water diuresis* refers to the excretion of a large volume of dilute urine, with normal solute excretion. This may stem from a lack of antidiuretic hormone (ADH, vasopressin) or to failure of the kidney to respond to ADH. *Solute diuresis* is caused either by an excess of filtered solute, such as glucose, which disrupts the concentrating mechanism, or by impaired tubular function, resulting in the excretion of large amounts of electrolytes, such as sodium chloride.

WATER DIURESIS

Water diuresis has three sources: failure of the posterior pituitary to secrete ADH (central or neurogenic diabetes insipidus), failure of the kidney to concentrate the urine despite the presence of adequate levels of ADH (nephrogenic diabetes insipidus), and excessive fluid intake, which includes psychogenic polydipsia and administration of fluids by physicians. When the lesions of nephrogenic diabetes insipidus (NDI) and central diabetes insipidus (CDI) are complete (total absence of ADH secretion or effect), they are easily recognizable in a patient with copious dilute urine. They may be incomplete, however, and have a more subtle clinical expression, making diagnosis much more difficult.

Central Diabetes Insipidus

CDI is caused by inadequate release of ADH from the posterior pituitary, resulting in the excretion of excessive urine volume (see [Chapter 404](#)). This loss of water leads to an increase in serum osmolality, triggering thirst and increased water intake to defend the normal limits of serum osmolality (285 to 295 mOsm per kilogram). A complete absence of ADH may lead to the daily excretion of 20 L or more of urine having an osmolality as low as 50 mOsm per kilogram. Incomplete CDI is a milder form of the condition; ADH secretion is present but still inappropriately low, causing less severe polyuria and a urine osmolality higher than minimum.

The causes of CDI are listed in [Table 137.1](#). Congenital CDI is autosomal dominant, but rare. Acquired CDI most commonly arises from idiopathic causes, pituitary surgery, and hypothalamic-pituitary damage from neoplasia or infection. Pregnancy-induced CDI provoked by a vasopressinase responds to synthetic desmopressin (DDAVP).

TABLE 137.1. CAUSES OF POLYURIA

TABLE 137.1. CAUSES OF POLYURIA

ADH acts on V_1 and V_2 receptors present in different tissues. V_2 receptors mediate water resorption in the kidney and are present on the antiluminal surface (blood side) of cells lining the collecting ducts. ADH binding to V_2 receptors leads to activation of adenylate cyclase and production of cyclic AMP, which ultimately brings about an increase in permeability of the luminal membrane of the collecting duct to water by insertion of water channels into that membrane. The ADH-sensitive water channel in the collecting duct is called aquaporin 2; it is stored in the cytoplasm just beneath the luminal membrane in vesicles that merge with the luminal membrane on exposure of the cell to ADH. ADH receptors on endothelial cells mediate release of von Willebrand complexes, and infusion of the ADH analogue DDAVP can improve the defect in bleeding time found in patients with chronic renal failure.

Nephrogenic Diabetes Insipidus

NDI can be caused by resistance to ADH at the level of the collecting duct cell or by loss of ability to concentrate the renal interstitium due to tubulointerstitial disease. The most common cause of resistance to the renal tubular effect of ADH is therapy of bipolar affective disorders with lithium, which causes polyuria in 20% to 30% of patients who take this drug. Lithium enters collecting duct cells from the lumen through amiloride-sensitive sodium channels and interferes with cyclic AMP formation. Hypercalcemia can induce NDI by blocking cyclic AMP production as well as through interstitial damage caused by chronic nephrocalcinosis.

Tubulointerstitial diseases lead to a loss of concentrating ability through the loss of the countercurrent mechanism responsible for producing a hypertonic renal interstitium. Most of these disorders are characterized by only modest degrees of polyuria (usually less than 4 L per day) and by urine that is roughly isotonic to plasma.

NDI is usually acquired, but there are congenital hereditary forms. The most common exhibits X-linked transmission with full penetrance in males and partial penetrance in females. The gene coding for the V_2 receptor has been localized to the X chromosome and has been shown to be defective in families with this rare congenital form of NDI. A less common form of hereditary NDI is an autosomal recessive disorder due to defects in the gene coding for aquaporin 2, causing failure of insertion of functional water channels into the lumen of the collecting duct cells. In both types of hereditary NDI, polyuria is present from birth.

Excessive Fluid Intake

Primary polydipsia results from the intake of large volumes of fluid. The most common form is psychogenic polydipsia, seen in many patients with chronic schizophrenia. The reason for the increased drinking behavior is unknown. Some of these patients experience recurrent episodes of severe hyponatremia that can result in serious acute and chronic neurologic dysfunction. Although it is not usually a diagnostic problem, inadvertent or unrecognized excess fluid therapy in a

Dehydration Test

Patients who have water diuresis but are not hyperosmolar need to undergo a dehydration test to differentiate primary polydipsia from CDI or NDI. The idea behind a dehydration test is to restrict the water intake of the polyuric patient until the serum sodium has risen sufficiently to cause endogenous release of ADH; if the urine osmolality increases to a normal high value, the cause of polyuria is polydipsia. If there is no response, the possibilities are either CDI or NDI, which can be differentiated by the administration of ADH or DDAVP. Patients with CDI who have inadequate ADH secretion respond to ADH with an increase in urine osmolality, whereas patients with NDI, who already have endogenous release of ADH, do not.

Two important principles must guide the administration and interpretation of a dehydration test. The first is that patients with polyuria can become severely dehydrated if water deprivation is carried out for too long, particularly if they do not respond with a reduction in urine volume. The second is that anyone with polyuria will have washed out the renal interstitial osmotic gradient, which may take days to regenerate.

With these principles in mind, the dehydration test is performed as follows. The duration of water deprivation before measurement of urine osmolality must be tailored to the patient and may range from only 4 to 6 hours in a patient with severe polyuria to the more usual 12 to 18 hours. Serum sodium, osmolality, and body weight should be measured frequently to assess the degree of water depletion, and no more than 3% of body weight should be lost. After the initial period of water deprivation, urine osmolality should be measured hourly; when the urine osmolality is no longer increasing by more than 30 mOsm per kilogram per hour, ADH (5 units of aqueous vasopressin subcutaneously) is given. Urine osmolality is again measured at 1 and 2 hours.

Characteristic responses to the dehydration test are shown in [Fig. 137.2](#). A large increase in urine osmolality suggests CDI, whereas patients with either NDI or polydipsia have little increase. The urine osmolality does not rise to values seen in normal persons after water deprivation (more than 800 mOsm per kilogram) because of the time required to regenerate the interstitial osmotic gradient. This test clearly determines the diagnosis in most patients, but some are misdiagnosed; in ambiguous cases, measurement of plasma ADH levels may be required.

TREATMENT OF POLYURIA

Treatment of polyuria begins with diagnosing the underlying disorder and instituting both supportive and specific treatment. DDAVP is a V_2 receptor agonist that eliminates polyuria and polydipsia in CDI with few adverse effects. The dose required must be titrated to the individual but is given two or three times daily. The usual dose is 1 to 5 μg (0.03 to 0.15 μg per kilogram) intramuscularly or intravenously, 5 to 25 μg (0.15 to 0.75 μg per kilogram) intranasally, or 100 to 500 μg (3 to 15 μg per kilogram) orally. The main complication of DDAVP is water intoxication, manifesting as hyponatremia. If this occurs, DDAVP can be used at night to prevent nocturia and to allow polyuria and appropriate drinking during the daytime. Patients who are maintained on ADH therapy and who are admitted to the hospital should be continued on the same dose; their fluid intake needs to be adjusted to prevent erratic oscillations in urine output and plasma sodium concentration.

Partial CDI may be treated with DDAVP or chlorpropamide, which augments ADH release and its action on the collecting duct. The dose of chlorpropamide is 250 to 500 mg per day. The limiting side effect is hypoglycemia, and use of chlorpropamide should be avoided in patients with renal failure.

NDI is usually more difficult to treat but is often relatively mild and transient. Lithium-induced polyuria has been successfully treated with amiloride, which blocks lithium entry into collecting duct cells, and with indomethacin, which reduces prostaglandin inhibition of ADH action. Thiazide diuretics paradoxically improve many types of NDI, probably by lessening extracellular fluid volume and thereby limiting distal delivery of fluid by lowering the glomerular filtration rate and stimulating increased proximal resorption of salt and water. The treatment of polyuria in the recovery from acute renal failure or obstructive uropathy is to provide enough water and electrolyte solution until tubular function recovers.

NOCTURIA

Nocturia may be defined as urination at night with interruption of sleep. While it may occur at any age due to a variety of medical or surgical conditions affecting the kidney or lower urinary tract ([Table 137.2](#)), it is particularly common in the elderly. The prevalence may be as high as 80% by age 80. Nocturia in the elderly may be associated with impaired sleep quality, incontinence, and an increased risk of falls.

Nephrologic disorders
Polyuria
Nocturnal polyuria
Chronic renal insufficiency
Edematous state
Congestive heart failure, cirrhosis, nephrotic syndrome
Urologic disorders
Bladder outlet obstruction
Urethral stricture, bladder or prostate carcinoma, benign prostatic hypertrophy
Urinary tract infection
Bladder calculi
Bladder tumors

TABLE 137.2. CAUSES OF NOCTURIA

In normal adults, nocturia is avoided by an increase in ADH secretion at night, resulting in a lower urine flow rate. Nocturia arises as a result of either an increase in flow rate at night or reduced bladder capacity. Up to one-half of elderly patients with nocturia have an increase in nocturnal urine flow (without an increase in 24-hour urine flow), which has been attributed to loss of the normal circadian rhythm of ADH secretion and low ADH concentrations at night. In these patients, administration of DDAVP before bedtime may be successful in reducing nocturnal urine flow rates and alleviating nocturia.

CHAPTER 138: APPROACH TO THE PATIENT WITH URINARY RETENTION AND OBSTRUCTION

NELSON LEUNG, AMIT K. GHOSH AND KARL A. NATH

[Differential Diagnosis](#)
[History and Physical Examination](#)
[Laboratory Studies](#)
[Diagnostic Tests](#)
[Management](#)

The presence of urinary tract obstruction, as for any disease process, is intimated by symptoms elicited from the medical history, signs detected during the physical examination, clues offered by laboratory and radiologic tests, and the appearance of syndromes of which urinary tract obstruction may be a contributing cause. [Table 138.1](#) summarizes such varied signs and symptoms of urinary tract obstruction. These findings should lead the clinician to suspect the presence of underlying obstruction. By expeditiously securing the diagnosis, the condition can be effectively treated, thereby avoiding potentially irreversible renal failure and other complications. [Chapter 158](#) provides further details regarding obstructive nephropathy.

TABLE 138.1. PRESENTING FEATURES AND SYNDROMES OF URINARY TRACT OBSTRUCTION

DIFFERENTIAL DIAGNOSIS

Obstructive uropathy is caused by lesions that impede the flow of urine at any site along the tract, beginning at the renal calyces and ending at the external urethral meatus. Congenital or developmental lesions account for the overwhelming majority of cases in children; however, a small percentage of such lesions escape detection in early life and may appear in the form of chronic renal insufficiency in adolescents or adults. Obstructive uropathy in adults, on the other hand, arises mainly from acquired lesions.

Obstruction of the upper tract can stem from lesions that are intrinsic or extrinsic to the urinary tract. Intrinsic lesions are further divided into intraluminal or intramural types (see [Table 158.2](#)). Intraluminal lesions may be located at either intrarenal or extrarenal sites. Causes of intraluminal obstruction include deposition of crystalline materials and proteinaceous casts. Medications can lead to obstruction either by intratubular precipitation (e.g., sulfonamide, acyclovir, indinavir, methotrexate) or by promotion of nephrolithiasis (e.g., acetazolamide, allopurinol, triamterene). Metabolic end products, such as uric acid, generated in excess, can provoke intraluminal obstruction, as occurs in acute uric acid nephropathy. Intraluminal renal obstruction may also be produced by casts due to paraproteins from plasma cell dyscrasias and casts formed from heme proteins and tubular epithelial cellular debris, as is seen in rhabdomyolysis.

Intraluminal causes in the upper tract include urinary calculi, blood clots, sloughed renal papillae, and fungus balls. Urinary calculi of a wide variety, including struvite, calcium oxalate, calcium phosphate, and cystine, can bring about urinary obstruction. Blood clots can arise from bleeding caused by trauma, calculi, tumors, or cysts or may develop as a complication of kidney biopsy. Sloughing of the renal papilla is a complication of analgesic abuse, diabetes mellitus, sickle cell disease, amyloid disease, tuberculosis, and acute pyelonephritis.

Intramural lesions may be functional, as in motility disorders affecting the ureteropelvic or the ureterovesical junctions, or structural, anchored within the walls (e.g., valves or strictures). Ureteropelvic junction obstruction originates from abnormalities in the architecture of the smooth muscle in the upper ureter and is a common cause of bilateral hydronephrosis in infants; this condition is usually unilateral when detected beyond the first year of life. This disorder should be considered in adults with obstruction, because many cases escape detection in childhood. Uncommon causes of obstructive uropathy in children are ureteral valves and strictures, conditions that usually affect the proximal and middle ureter, and ureterocele that cause obstruction in the distal ureter. Ureteral strictures in adults are uncommon; they arise as a complication of radiation therapy, previous instrumentation, or surgery.

The ureterovesical junction is susceptible to a functional defect that causes obstructive uropathy infrequently in children. More common is vesicoureteral reflux, which may arise as either a primary or a secondary abnormality. In this disorder, there is reflux of urine from the bladder into the ureter during micturition. Such reflux does not normally occur, because of the oblique orientation of the ureter through the detrusor muscle and the arrangement of the muscle fibers of the ureterotrigoal unit. The primary disorder is congenital, and many cases resolve with age. Patients with vesicoureteral reflux are predisposed to recurrent infections; repeated episodes of infections involving the kidney in this context can lead to renal scarring. For unclear reasons, however, vesicoureteral reflux may also be associated with glomerulosclerosis and progressive renal insufficiency, despite treatment of infection and surgical correction of reflux.

Extrinsic lesions obstructing the upper tract can occur through five major mechanisms. *Vascular system* lesions include aberrant blood vessels at the ureteropelvic junction, perianeurysmal scarring from an abdominal aortic aneurysm, assorted vasculitides, and congenital “retrocaval” ureter obstructed by the vena cava. Lesions arising in the *female reproductive system* as a group are the most common causes of ureteric obstruction. By the end of the second trimester of pregnancy, most pregnant women show signs of dilatation of the collecting system. It usually involves the right ureter, generally does not perturb renal function, and abates in the postpartum period. Renal insufficiency due to urinary tract obstruction during pregnancy occurs very infrequently as a complication of such conditions as twin pregnancies and polyhydramnios. Cervical cancer is the most common malignant cause for obstructive uropathy in women; other uterine lesions that can obstruct the ureter include benign fibroids, malignancies, and uterine prolapse. Ureteral obstruction may also arise from ovarian tumors, ovarian abscesses, and endometriosis.

Lesions and pathologic conditions in the *gastrointestinal tract*, such as inflammatory bowel disease, diverticular disease, and malignancies, can also compress the ureters. Inflammatory bowel disease may predispose to obstruction because of associated nephrolithiasis. Crohn's disease and appendicular abscess may provoke right-sided hydronephrosis, whereas diverticular disease can obstruct the left ureter. Obstruction to the ureter also can originate in the *retroperitoneum*, as exemplified by idiopathic retroperitoneal fibrosis and assorted retroperitoneal tumors that develop de novo or as a consequence of metastatic disease. Retroperitoneal fibrosis can arise as a complication of radiation, malignancy, infection, perianeurysmal scarring, or scarring triggered by inflammatory processes in the intestinal tract. It also can come about as an adverse effect of medications such as methysergide, methyl dopa, sotalol, and other β -adrenergic antagonist agents. Extrinsic compression of the ureters can develop as a result of inadvertent ligatures and other complications of *surgery*.

Obstruction of the lower tract can arise from such bladder lesions as blood clots, stones, tumors, foreign bodies, or infections or from neurogenic bladder. In males, lesions affecting this site include strictures, valves, stones, meatal stenosis, and phimosis. The bladder neck and urethra are constricted in older men by prostatic hypertrophy or carcinoma. Benign prostatic hyperplasia is a common and significant disorder because it provokes bladder outlet obstruction in more than 75% of men older than 50 years, necessitating surgery in 10% of these symptomatic patients. Prostate cancer can cause obstructive uropathy by occluding such sites as the bladder neck or the ureters as they enter the bladder.

A wide variety of neurogenic bladders can predispose to urinary tract obstruction. Reflex neurogenic bladder is found in patients with spinal cord injury or multiple

sclerosis and is attended by high intravesical pressure, vesicoureteral reflux, and obstructive nephropathy. Patients with diabetes are often devoid of bladder sensation; this, in turn, leads to large bladder volumes before the micturition reflex is triggered and predisposes these patients to vesicoureteral reflux. Infrascral neurogenic bladder arises from motor and sensory neural deficits and is seen as a complication of pelvic surgery.

Obstruction to the urethra occurs virtually exclusively in males and stems from posterior urethral valves or strictures as a result of complication from trauma, gonorrhea, or previous instrumentation. Bladder dysfunction can be an adverse effect of a number of medications, including anticholinergics, antihistamines, narcotic analgesics, and α -adrenergic agonists. In the transplanted kidney, urinary tract obstruction in the early postoperative period reflects blood clots, mechanical problems (e.g., twisting of the ureter), ischemia of the ureter, and extrinsic compression by a lymphocele. Later, obstruction may be due to ureteric fibrosis from ischemia or rejection.

HISTORY AND PHYSICAL EXAMINATION

The first step in evaluation is a detailed history and physical examination. A common initial complaint is pain. Acute obstruction arising from calculi and blood clots is often associated with severe flank and abdominal pain radiating into the groin. During these episodes, the patient is never pain-free and experiences intense paroxysms superimposed on a background of unremitting pain. Acute flank pain, low-grade fever, hematuria, and the passage of tissue in the urine are features of papillary necrosis. In contrast, chronic hydronephrosis may be associated with a dull ache or may be asymptomatic. Flank pain during micturition is characteristic of vesicoureteral reflux. Flank pain exacerbated by a large oral fluid intake or diuretics suggests ureteropelvic obstruction. Abnormalities in the urine, such as unusual discoloration or the presence of blood, stones, or tissue, should raise the suspicion of urinary tract obstruction.

Altered urine output may also be an initial feature. Complete obstruction leads to anuria, whereas partial obstruction can impose polyuria and nocturia; intermittent obstruction may appear as fluctuating urinary output. A single episode of urinary tract infection in males or recurrent urinary tract infections in females can also be a manifestation of underlying urinary tract obstruction. Patients should be asked about symptoms pointing to abnormalities of the lower urinary tract, including urgency, frequency, hesitancy, a poor urinary stream, terminal dribbling, dysuria, strangury, and nocturia.

Particular attention should be given to a personal or family history of kidney stones and cystic or other kidney diseases. Medications relevant to obstructive uropathy should also be carefully reviewed, including those that cause crystal formation in the urine, those that impair bladder function, and analgesics. Diseases that can predispose to obstructive uropathy, such as diabetes mellitus, multiple sclerosis, inflammatory bowel disease, and sickle cell disease, should be noted or specific inquiries made as to their presence. A history of recurrent urinary tract infections, sexually transmitted infections, AIDS, and tuberculosis may also be relevant, since urinary tract obstruction can develop as complications of these disorders or their treatment.

A careful physical examination should be performed to ascertain the presence, cause, and complications of obstruction to the urinary tract. A general examination may uncover such features of the uremic syndrome as fetor, uremic pigmentation, and pallor of the mucous membranes or cachexia arising from an underlying malignancy. Systemic hypertension and signs of volume overload may reflect underlying high-grade obstructions, whereas signs of dehydration and orthostatic hypotension may develop in patients with postobstructive diuresis. Fever and rigors suggest a superimposed infection. Obstructive uropathy may be a complication of previous surgical procedures, and, for this reason, abdominal incisions should be noted.

The abdomen should be palpated for tenderness, guarding, bladder distention, enlargement and tenderness of the kidney, organomegaly, masses, and ascites. Abdominal aortic pulsations or abdominal bruits suggest an aortic aneurysm. Bowel sounds should be carefully auscultated, because several causes of obstructive uropathy can predispose to ileus. Rectal and pelvic examinations are essential components of the physical examination, since they can uncover pathologic conditions that lead to obstructive uropathy. The rectal examination may find an enlarged prostate, nodularity of the prostate, and rectal masses. During the pelvic examination, attention should be paid to any vaginal, pelvic, or rectal mass or prolapse. Examination of the penis can disclose evidence of meatal stenosis or phimosis. Lymphadenopathy in the inguinal or other areas or tenderness over the bony skeleton raises the possibility of an underlying malignancy. A careful neurologic examination is also indicated, since neurogenic bladder can cause obstructive uropathy. Special attention should be paid to possible signs of diabetic neuropathy, spinal cord injuries, or multiple sclerosis, because these diseases can contribute to the development of neurogenic bladder.

LABORATORY STUDIES

Measurements of serum electrolytes and renal function must be obtained. Blood urea nitrogen (BUN) and serum creatinine levels may be elevated if there is bilateral obstruction, obstruction in a solitary kidney, or obstruction in one kidney with intrinsic disease in the other or both kidneys. In the absence of volume contraction or other conditions that disproportionately elevate the BUN, the ratio of BUN to serum creatinine is approximately 10:1. Serum electrolyte measurements can show evidence of hyperchloremic metabolic acidosis accompanied by hyperkalemia, which usually bespeaks type IV renal tubular acidosis. Less commonly, hyperchloremic metabolic acidosis arises from a type I acidification defect in which the serum potassium level is normal or low.

Hyponatremia may be present and may reflect excess free water intake in the context of renal insufficiency; rarely, it may be due to renal salt wasting. Alternatively, hypernatremia may be present as the result of polyuria and excess free water loss. Acute obstruction may lead the fractional excretion of sodium to be less than 1 and cause urine osmolality to be more than 400 mOsm per kilogram of water, spuriously suggesting prerenal causes of renal failure. With chronic obstruction, the loss of concentrating ability leads to reduced specific gravity and osmolality of urine.

The urinary sediment is usually nondescript, showing trace to 1+ proteinuria and hyaline casts. Proteinuria of greater severity may accompany chronic renal insufficiency due to obstruction, and nephrotic-range proteinuria may occur in the context of vesicoureteral reflux and accompanying glomerulosclerosis. The presence of leukocytes and bacteria points to urinary tract infection. Red cells suggest bleeding, stones, malignancy, or papillary necrosis. Urinary crystals may indicate the presence and type of urinary calculi.

DIAGNOSTIC TESTS

Figure 138.1 shows an approach that can be used to evaluate patients in whom obstructive uropathy is suspected. The presence of symptoms and signs pointing to obstruction of the lower tract should lead to the assessment of the postvoid residual. A postvoid residual urine volume should be determined by catheterization of the urinary bladder; a volume above 100 ml suggests lower-tract obstruction. If insertion of a Foley catheter into the urinary bladder proves difficult or obstruction is encountered, repeated attempts may traumatize the urethra or bladder. The expertise of urologists should be sought in such cases to catheterize the bladder or establish drainage of the urinary tract by a suprapubic catheter. If a large residual of urine is encountered, the bladder can be freely decompressed, because rapid decompression of the bladder does not predispose to hypotension or bladder hemorrhage.

FIGURE 138.1. Approach to the patient with suspected urinary obstruction.
EVIDENCE LEVEL: C. Expert Opinion.

Several visualization procedures are available. Each has its advantages and drawbacks. A plain film of the abdomen is usually obtained, because it can detect calculi

(in approximately 80% to 90% of cases) and may provide information as to the size and shape of the kidneys and the presence of soft-tissue masses or bony metastatic disease. While it is inexpensive, a plain abdominal film is limited by its low sensitivity and specificity.

Ultrasonography is the recommended screening test for urinary tract obstruction. It relies on detecting dilatation of the urinary tract. It is noninvasive and does not require the use of intravenous contrast, making it particularly useful for patients with acute and chronic renal failure. The absence of radiation makes ultrasonography safe for pregnant patients. This method has 90% sensitivity and 80% specificity in the diagnosis of obstructive uropathy. Nonobstructive dilatation of the upper tract can occur in several conditions, however; conversely, obstruction is not always detected by ultrasonography ([Table 158.1](#) in Chapter 158).

An intravenous pyelogram (IVP) makes visible the kidney, calyces, pelvis, and ureter and may localize the level of obstruction. It is the initial test of choice in examining the pyelocalyceal system and ureter in patients with normal renal function. The findings of an IVP depend on the degree and the duration of obstruction. In acute cases, the nephrogram is delayed but eventually attains a higher density than the normal kidney; the kidney is enlarged, and the collecting system is dilated above the obstruction. With chronic obstruction, the cortex is thin, the calyces are dilated, the papilla is flattened and may be frankly concave, and the calyces may have a clubbed appearance. In bladder outlet obstruction, both ureters are usually dilated, and bladder trabeculation or diverticula may also be present. An IVP may also suggest the presence of retroperitoneal fibrosis if there is medial deviation of the ureters. The adverse effects of IVP include allergic reactions to contrast dye and the nephrotoxicity of these agents. The latter is more likely to occur in patients with renal insufficiency, multiple myeloma, and diabetic nephropathy.

While intravenous pyelography and ultrasonography are typically employed as initial radiologic tests for urinary tract obstruction, computed tomography (CT) is increasingly utilized in this context. Improved anatomic imaging and lack of intravenous contrast are appealing features of CT scans, especially in patients with contrast dye allergy or poor renal function. Noncontrast CT scans can uncover calculi, dilatation of the collecting system, atrophy, and other changes of the renal parenchyma, and delayed excretion of contrast can be detected with contrast enhancement. CT scans can detect other abnormalities that impose urinary tract obstruction, including malignancies, abdominal lymphadenopathy, retroperitoneal fibrosis, hematomas, and calculi. Magnetic resonance imaging provides remarkable anatomic detail and renal functional measurements and does not require the use of contrast agents. Its expense and its inability to detect stones and parenchymal changes limit its uses, however. This imaging technique is not currently part of the routine evaluation of patients with suspected urinary tract obstruction.

Although diuretic scintigraphy is inferior to IVP in terms of anatomic detail, it is helpful in differentiating a dilated nonobstructed collecting system from true obstruction. In this test, renal scintigraphy is performed before and after the administration of a loop diuretic, such as furosemide. Diuresis facilitates washout of the isotope that accumulates in the dilated, nonobstructed renal pelvis but not in the pelvis with true anatomic obstruction.

Retrograde and antegrade pyelography calls for direct injection of contrast dye into the collecting system and may be indicated for patients suspected of having obstructive uropathy. It is particularly useful for patients with contrast dye allergy or those with renal insufficiency, in whom the administration of contrast dye can exacerbate renal dysfunction. These procedures usually allow identification of the site of obstruction and the presence of intraluminal and intramural lesions. Retrograde pyelography necessitates catheterization of the ureter after cystoscopy and may require general anesthesia. Antegrade pyelography allows entry into the renal pelvis via a percutaneous route under ultrasonographic guidance and local anesthesia. These tests also have therapeutic value, since they allow the placement of stents during a retrograde study or a percutaneous nephrostomy tube during an antegrade study.

The Whitaker test may be used to diagnose obstruction of the upper urinary tract when its presence is deemed uncertain using other diagnostic maneuvers. In this test, hydrostatic pressure differences between the renal pelvis and bladder are determined at ambient urinary flow and after the infusion of fluid into the renal pelvis at a defined rate. With significant ureteral obstruction, a pressure differential of more than 20 cm water usually indicates ureteral obstruction.

Lower-tract obstruction can be evaluated by cystoscopy and radiologic and urodynamic tests. Cystoscopy makes visible the entire urethra and bladder. The anterior urethra is assessed by retrograde urethrography. The posterior urethra can be seen by excretory or antegrade cystography. A voiding cystourethrogram is used to detect the presence of vesicoureteral reflux, the function of the bladder, and the presence of bladder neck and urethral abnormalities. Urodynamic evaluation is used in the diagnosis of neurogenic bladder dysfunction; this evaluation includes cystometrography, electromyography, a urethral pressure profile, and urine flowmetry.

MANAGEMENT

The aims of treatment of patients with obstructive uropathy include the relief of symptoms, the correction of fluid and electrolyte abnormalities, the restoration and preservation of renal function, and the prevention or effective treatment of complications, such as infection or stone formation. The therapeutic approach varies with the clinical circumstance: it may be conservative or may include the use of instrumentation, endourologic techniques, or surgical procedures. High-grade or total obstruction affecting both kidneys or high-grade obstruction in a solitary kidney must be relieved as soon as possible. Relief of obstruction of any severity should be promptly undertaken if there is concomitant urosepsis. In patients with renal failure as a complication of bilateral obstruction, dialysis may be indicated for fluid and electrolyte abnormalities. Severe volume overload, hyperkalemia, and acidosis mandate acute dialysis before relief of the obstruction. Surgical intervention for chronic partial low-grade obstruction can be delayed for several weeks, but such an obstruction should be expeditiously decompressed if there are repeated episodes of urinary tract infection, urinary retention, significant flank pain, and progressive renal insufficiency.

Decompression may be effected by percutaneous nephrostomy tubes or retrograde ureteral catheters. For lower-tract obstruction, relief is afforded by bladder catheterization or, rarely, suprapubic cystostomy. Complications of nephrostomy tubes include perirenal hematomas, acute obstruction due to blood clots, infection, and dislodgment of the tube. Indwelling stents may ensure patency of the collecting system for months, but their use can be complicated by blockage, migration into the bladder, urinary reflux, pain, hematuria, and infection. Indwelling ureteral stents minimize uremic symptoms and may be used instead of an ileal conduit in such poor-risk patients as those with advanced or incurable malignancy.

The prognosis after the relief of obstruction to the urinary tract depends on its underlying cause, severity, and duration and the development of complications during the obstructive and postobstructive phases. A remarkable recovery of the glomerular filtration rate, often to normal values, may take place in kidneys subjected to obstruction lasting several days. The longer the period of obstruction, the more attenuated is the regaining of renal function after decompression. As demonstrated by studies of experimental obstructive uropathy, however, obstruction of only 24 hours' duration in the rat leads to irreversible loss of a fraction of nephrons; thus, functional recovery does not reflect the irreversible damage inflicted on the kidney even with relatively short periods of obstruction. Defects in the concentrating ability and acidification mechanisms may persist for protracted periods after relief of obstruction.

The relief of bilateral obstruction or obstruction of a solitary kidney gives rise to a postobstructive diuresis characterized by polyuria and natriuresis and the loss of solutes, including potassium, magnesium, phosphate, and calcium. Natriuresis and diuresis may lead to marked contraction of the extracellular fluid and, depending on the relative losses, hyponatremia or hypernatremia; hypokalemia, hypomagnesemia, and hypophosphatemia may be present. This syndrome does not develop after the relief of unilateral obstruction. Postobstructive diuresis is multifactorial in origin and reflects the excretion of salt and water retained during the phase of obstruction, the renal effects of natriuretic factors, osmotic diuresis from retained urea, renal resistance to vasopressin, and defective tubular sodium absorption. If patients are euvoletic, half-normal saline should be infused at 50 to 75 ml per hour, with careful assessment of orthostatic changes in blood pressure and pulse, plasma electrolytes, and renal function. This regimen allows the excretion of salt and water retained during the obstructive phase and avoids excessive fluid administration that may sustain continued diuresis and natriuresis. If extracellular fluid volume contraction develops on this regimen such that orthostatic changes occur, additional amounts of fluid should be provided to repair the loss. Excessive administration of salt and water should also be avoided, however, since this will perpetuate diuresis. Serum potassium, calcium, magnesium, and phosphate levels should be carefully monitored, because replacement of these solutes may be required.

LOWER-TRACT OBSTRUCTION

Lower-tract obstruction should be relieved if it is complicated by urinary retention, recurrent episodes of urinary tract infection, hematuria, vesicoureteral reflux, or renal parenchymal damage. If such symptoms or complications arise from benign prostatic hyperplasia, transurethral resection of the prostate is the preferred procedure. This procedure has a mortality rate of less than 0.5%. Before prostatectomy, patients with urinary retention or compromised renal function should be treated with clean intermittent catheterization, which reduces the risks of perioperative urinary tract infections. Open prostatectomy may be required in patients with marked enlargement of the prostate.

Medical management of prostatic hyperplasia now includes such classes of drugs as 5 α -reductase inhibitors (e.g., finasteride) and α -1-adrenergic receptor blockers (e.g., terazosin, doxazosin, and tamsulosin). The 5 α -reductase inhibitors block the conversion of testosterone to dihydrotestosterone and thereby attenuate the humoral stimulus for prostatic hyperplasia; prostatic volume is thus reduced. The α -1-adrenergic receptor blockers decrease the tone of the internal urethral sphincter.

Both classes of drugs relieve urinary tract obstruction and attendant symptoms. Cessation of either class of drug may lead to recrudescence of symptoms of lower-tract obstruction. Pharmacologic approaches should not be used in patients with urinary tract dilatation or renal insufficiency. In compromised or debilitated patients or patients with advanced malignancy, long-term indwelling catheters or prostatic stents may be considered. Lower-tract obstruction arising from strictures in males can be treated by urethral dilatation, endoscopic urethrotomy, or an open procedure.

Treatment of patients with neurogenic bladder depends, to some extent, on the cause. Clean intermittent catheterization is the basis of therapy for most forms of neurogenic bladder dysfunction. Reflex neurogenic bladder dysfunction, which occurs in patients with spinal cord injury and multiple sclerosis, is characterized by the release of the sacral reflex arc from inhibitory input, increased detrusor tone, and failure of the internal urethral sphincter to relax. This condition may be treated by clean intermittent catheterization in conjunction with anticholinergic agents. Attempting to decrease the tone of the internal urethral sphincter by using α -adrenergic blockers or skeletal muscle relaxants is another therapeutic approach. Patients with sensory neurogenic bladders experience an increase in bladder volume before contraction occurs; these patients are treated initially by voiding at regular intervals and subsequently by clean intermittent catheterization when they are unable to void. The use of cholinergic agents in these patients is the subject of debate. Clean intermittent catheterization is also used for patients with autonomous neurogenic bladder, a lesion characterized by motor and sensory deficits. Long-term indwelling catheters should be eschewed in patients with neurogenic bladder because of the risks of infection, stone formation, and carcinoma of the bladder. In patients with neurogenic bladder and other forms of lower-tract obstruction, surgical diversion using an ileal conduit may be required if there is progressive loss of renal function, refractory incontinence, or multiple bladder fistulas.

UPPER-TRACT OBSTRUCTION

Acute, high-grade, bilateral obstruction should be promptly decompressed, since delay increases the risk of irreversible loss of function. Acute partial obstruction is commonly caused by calculi in the renal pelvis or ureter. Patients with these stones can be treated as outpatients if they can tolerate large amounts of oral liquids, which are required to facilitate spontaneous passage of the stone. Relief of pain in acute renal colic usually requires intramuscular injection of narcotic analgesics. Stones smaller than 5 mm invariably pass spontaneously; ureteral stones 5 to 7 mm in size may require weeks to do so. Urine should be strained so that any calculi passed can be submitted for analysis. Stones larger than 7 mm usually necessitate intervention.

Extracorporeal shock-wave lithotripsy (ESWL) can be used for most types of kidney stones (except cystine stones) in the renal pelvis, upper ureter, and middle ureter. In this procedure, stones are pulverized by shock waves created by electrohydraulic, electro-acoustic, or ultrasonic means. Patients require anesthesia or sedation. Over subsequent weeks, the remains of the calculi are passed. Calculi distal to the pelvic brim are usually treated by ureteroscopy combined with stone extraction for smaller calculi or stone fragmentation for larger calculi. To secure the patency of the urinary tract and to ensure passage of the stone fragments, ureteral stents are often used in conjunction with ESWL. More details of renal stone disease are found in [Chapter 139](#) and [Chapter 159](#).

A surgical approach is used for several lesions. For example, intramural lesions, such as ureteropelvic junction obstruction, ureteral valves, or ureterovesical junction obstruction, can be surgically repaired; mass lesions of the renal pelvis or ureter are often amenable to resection. Surgical procedures, including ureterolysis, are also required to relieve obstruction caused by idiopathic retroperitoneal fibrosis or fibrosis stemming from such conditions as abdominal aneurysm. Sometimes repair is impossible, and urinary diversion may be necessary.

PRESENTATION

The typical patient with an acute episode of renal colic is not difficult to identify. The discomfort is severe, described by many women as similar to that associated with childbirth. The pain often originates in the flank, radiating anteriorly toward the groin as the stone moves along the ureter toward the bladder. The patient also may experience dysuria, gross hematuria, urgency, and frequency. Stone passage confers almost instant relief of the pain. Associated urinary tract infection or obstruction contributes significantly to morbidity, but death related to nephrolithiasis is rare.

The lifetime risk of stone disease in industrialized nations approaches 20% in men, a rate three to five times greater than in women. The peak age of onset is in the twenties for both sexes. Professionals, despite better working conditions, are affected more often than manual laborers and whites more often than Asian Americans or African Americans.

PATHOPHYSIOLOGY

Stone formation occurs only in the context of urine that is overly saturated with respect to the ionic components of the stone. When this oversaturation, which depends on chemical free-ion activity, reaches the so-called formation product, the relevant ions form clusters or small nuclei by a process termed *homogeneous nucleation*. More often, crystals form around different particles, such as sloughed epithelial cells, casts, or other types of crystals, by *heterogeneous nucleation*. For example, calcium oxalate crystals commonly nucleate around existing uric acid crystals, producing stones composed of both calcium oxalate and uric acid. Thus, when searching for the cause of stones, the urine must be carefully evaluated for concentrations of all relevant constituents, because several different ions may contribute to stone development.

Once nuclei are formed, they rapidly cluster together through a process termed *aggregation*. To prevent the nuclei from washing away in the urine flow before a sizable stone can be produced, the nuclei must anchor to the urothelial surface in a manner that is incompletely understood. Various proteins produced by the kidney (e.g., uropontin, nephrocalcin, Tamm-Horsfall mucoprotein) can inhibit distinct phases of stone formation. Deficiencies in any of these urinary inhibitors can potentiate nephrolithiasis.

Decreasing urinary oversaturation, which is possible through medical management, can prevent stone formation. To lessen the oversaturation of calcium oxalate crystals, for example, the solution volume in which the calcium and oxalate are suspended can be increased by drinking more fluids to expand urine volume or decreased by the concentrations of calcium and oxalate in the urine through dietary modifications or medications. The solubility of calcium also can be augmented by increasing the amount of citrate excreted with it. Manipulation of the urine pH also can affect ionic solubility, especially with respect to uric acid.

HISTORY AND PHYSICAL EXAMINATION

The approach to patients with a single episode of nephrolithiasis is outlined in [Table 139.1](#). Additional studies for children and for patients with a second stone or multiple stones or with calculi that are increasing in size are outlined in [Table 139.2](#). All patients with nephrolithiasis, even first-time stone-formers, should have a thorough history and physical examination to determine the cause of their stone disease and to formulate a management plan. Demographic data, such as age, sex, and race, are useful in determining whether a basic or a more complete evaluation is required. A patient in whom stone disease is unexpected (e.g., a child or an African American) must undergo a complete evaluation to exclude a significant underlying pathologic condition.

TABLE 139.2. APPROACH TO PATIENTS WITH A SECOND OR MULTIPLE STONES OR GROWING STONES AND FOR ALL CHILDREN

A stone history also provides essential data. The age at first stone formation, the number of stones present or passed, the size of calculi, and whether lithotripsy or surgery was required can help determine the severity and sometimes the source of nephrolithiasis. Calcium oxalate stones, for example, tend to grow no larger than 2 cm, whereas struvite and cystine stones can grow very large, forming staghorn calculi. The latter also are distinctive in that they are refractory to fragmentation with extracorporeal shock-wave lithotripsy (ESWL) and often must be removed by percutaneous nephrolithotomy. Symptoms of hematuria and flank pain indicate active stone disease.

Exact chromosomal loci have not yet been discovered, but certain stone disorders exhibit clear hereditary patterns; thus, obtaining a family history is important. Idiopathic hypercalciuria is inherited, though the mechanism of inheritance is unclear. Cystinuria follows an autosomal recessive pattern. Uric acid lithiasis also may be associated with various genetic enzyme defects.

A complete medical history is crucial not only to diagnosing a particular stone type but also to elucidating important secondary causes of nephrolithiasis. In patients in whom hypercalcemia is a potential cause of hypercalciuria, evidence should be sought for systemic disorders that may lead to an elevated serum calcium concentration, such as malignancy, hyperparathyroidism, thyrotoxicosis, granulomatous disease, and immobilization. Uric acid stones may be associated with gout, inflammatory bowel disease, and various inborn errors of metabolism. A history of recurring urinary tract infections should alert one to the possibility of struvite stones. Nephrocalcinosis—the generation of numerous small calcifications within the kidney—often results from calcium phosphate precipitation in the high urinary pH associated with distal renal tubular acidosis.

A complete list of medications, both prescribed and over-the-counter drugs, must be obtained. Antacids and carbonic anhydrase inhibitors, such as acetazolamide, can raise the urinary pH, providing an optimal environment for calcium phosphate stone precipitation. Calcium-containing antacids can worsen stone generation by increasing the amount of calcium ingested and subsequently filtered by the kidneys. Loop diuretics (e.g., furosemide, bumetanide, torsemide) can diminish renal calcium reabsorption, thereby increasing urinary calcium concentration and producing oversaturation. Thiazide diuretics are often used to treat hypercalciuria because they lessen renal calcium excretion. They tend to diminish uric acid excretion, however, which may be detrimental to patients with complications of hyperuricemia. Certain medications can precipitate into crystals or stones. These include triamterene, a potassium-sparing diuretic; acyclovir, when rapidly administered intravenously; and indinavir, an antiretroviral medication used to treat HIV. Large doses of vitamin C (ascorbic acid) can potentially result in hyperoxaluria in some patients, as ascorbic acid is oxidized to oxalate. Excessive vitamin D ingestion can generate hypercalciuria by augmenting both intestinal calcium absorption and bone resorption.

Information on the patient's habits and occupation can provide important clues. For example, people with jobs that require commutes by car or who engage in intensive activity that allows little time for bathroom breaks, such as cardiothoracic surgeons, may limit their fluid intake to avoid having to urinate, resulting in very concentrated urine and marked oversaturation. Patients who exercise or work outdoors may have increased insensible losses that also result in more concentrated urine. Severely disabled, bedridden patients may become hypercalcemic and hypercalciuric as a result of immobilization-induced bone resorption.

Dietary factors have a significant effect on stone formation. Metabolism of animal protein induces mild metabolic acidosis that stimulates bone resorption, leading to an increased filtered load of calcium and a decline in tubular calcium reabsorption and hypercalciuria. Calcium solubility is further reduced by hypocitraturia, which may result from metabolic acidosis. Meats and other purine-containing foods also augment uric acid excretion, increasing the potential for both calcium-based and uric acid stones. A markedly excessive intake of oxalate-containing foods also can contribute to calcium oxalate nephrolithiasis. Foods rich in oxalate include certain leafy green vegetables, such as Swiss chard, kale, spinach, and mustard greens, as well as tea, chocolate, nuts, and rhubarb.

Calcium consumption should be assessed in hypercalciuric patients but should not be restricted unless intake is exorbitant. Diminished calcium intake in hypercalciuric patients can result in a net negative calcium balance, with ensuing bone resorption. A recent study also suggests that the rate of stone formation may be higher in patients with lower calcium intakes, possibly owing to enhanced oxalate absorption. Sodium intake and excretion directly correlate with calcium excretion.

To obtain accurate dietary information, it is useful to ask patients details about the contents of each meal, snacks, how many glasses of fluid they drink, consumption of fast foods or canned foods (both high in sodium), and rare food fetishes. The physical examination in patients with stone disease who are not experiencing renal colic is usually normal. Tophi, abdominal scars, and ileostomies or lymphadenopathy or other evidence of malignancy suggest metabolic abnormalities that can lead to stone formation.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The most common methods for analyzing stone composition are x-ray crystallography and infrared spectroscopy. Information on the constituents of the stone exterior and the core can be obtained, focusing therapy on measures that can lower the levels of those substances in the urine. Urinalysis is simple and inexpensive but often provides critical insights into the mechanisms of stone formation in a particular patient. An elevated urinary pH (more than 7) is associated with the formation of struvite and calcium phosphate stones; uric acid stones tend to form in more acid urine (pH less than 6). On microscopic examination, characteristic crystals may be noted. Bacteria and white blood cells, if present, may indicate the presence of infection stones, and hematuria suggests active stone disease. If pyuria is detected, a urine culture should be obtained, not only for proper antibiotic selection but also to determine whether urease-producing bacteria are responsible for both the calculi and the infection. Fewer than 100,000 colonies of urease-producing bacteria can still be responsible for producing infection stones. If struvite stones are suspected, the microbiology laboratory should be instructed to identify all organisms, regardless of colony count.

In all patients, even those with a single stone, the laboratory evaluation in [Table 139.1](#) is warranted; the blood chemistry profile should include electrolytes, creatinine, calcium, phosphorus, and uric acid levels and, if the serum calcium is high, the parathyroid hormone level. Qualitative cystine screening of the urine should be performed on all patients.

Radiologic evaluation is an important step in determining the location and presence of stones. The size, location, number, and radiopacity of the calculi may be ascertained with a radiograph of the kidney, ureter, and bladder. Intravenous urography can provide additional information, such as the presence of anatomic abnormalities of the urinary tract, medullary sponge kidney, and obstruction. If roentgenographic examination is contraindicated, as in pregnancy, ultrasonography can be used. Although ultrasonography is safe for all patients, it can miss ureteral calculi and cannot distinguish between stones that are radiopaque (e.g., those containing calcium and cystine) and those that are radiolucent (e.g., those containing uric acid).

DIFFERENTIAL DIAGNOSIS

Acute renal colic must be distinguished from other conditions that result in severe pain in either the costovertebral angle (CVA) or the upper or lower quadrants of the abdomen. Pain due to appendicitis often occurs in the right-lower quadrant, but it usually originates in the periumbilical area rather than the CVA. Musculoskeletal pain or pain due to disk disease generally is not as severe as pain due to renal colic and is not associated with dysuria or urinary urgency. The presence of hematuria, crystalluria, or radiologic evidence of a calculus or urinary obstruction can further assist in making the correct diagnosis. Patients with stone disease who do not have severe pain or are not having active renal colic may have hematuria. If no urinary crystals are present, it is important to examine other causes of painless hematuria, such as malignancy, infection, or glomerulonephritis.

STRATEGIES FOR OPTIMAL CARE

Medical management is used to prevent further stone occurrence or growth in patients with nephrolithiasis. Treatment of stones that do not pass spontaneously and require surgical intervention is reviewed later in the chapter. All patients, regardless of stone number or type, can benefit from nonspecific therapy: increasing fluid intake to more than 2 L per day to lower or prevent oversaturation and decreasing dietary sodium and protein intake. Reducing sodium intake lessens sodium and thus calcium excretion. Decreasing protein intake lessens endogenous acid production and calcium excretion and increases citrate excretion. Citrate not only binds calcium, lowering its concentration, but also appears to inhibit crystallization. Calcium intake should not be restricted to less than approximately 1 g per day, to prevent bone demineralization. Specific therapy depends on the variety of stone passed or on the suspected origin of stones, based on the 24-hour urine collection. Computer programs that calculate saturation from measured concentrations can be used to determine the risk of stone formation.

CALCIUM STONES

If calcium stone formation stems from a systemic disorder resulting in oversaturation with respect to calcium salts, treatment of the underlying disease should abolish stone formation. For example, in a patient with primary hyperparathyroidism, parathyroidectomy should prevent further hypercalciuria. Calcium-containing stones can result from several metabolic abnormalities that can be detected by 24-hour urine collection. Therapy is directed by the findings of 24-hour urine collection, in conjunction with the results of stone analysis.

Hypercalciuria

Hypercalciuria is defined as urine calcium excretion greater than 300 mg in men and 250 mg in women (or 4 mg per kilogram per 24 hours in either sex). Several mechanisms of action have been proposed to explain the excessive calcium excretion in so-called idiopathic hypercalciuria. If a precise mechanism could be defined, optimal therapy could be specifically directed. For example, if hypercalciuria is secondary to increased intestinal calcium absorption, a low-calcium diet would be helpful, in theory; if there is a defect in renal calcium reabsorption, a thiazide diuretic should be effective. However, prescribing a low-calcium diet to a patient with a defect in renal calcium reabsorption would lead to a negative calcium balance and bone demineralization. Attempting to determine the source of hypercalciuria in individual patients has not proved helpful in directing treatment and is not recommended except in unusual circumstances.

After instituting nonspecific therapy, such as increasing fluid intake and reducing protein and sodium intake, we prescribe a long-acting thiazide diuretic, such as chlorthalidone, which can be taken once a day, starting at 25 to 50 mg. Indapamide (1.25 to 5.0 mg per day) is a preferable thiazide in patients at risk of coronary artery disease, because it does not tend to increase serum lipids. Since hypokalemia is often severe with long-acting thiazides and can lower the urinary citrate concentration, patients on thiazides should be monitored for hypokalemia and given potassium supplements; alternatively, a potassium-sparing diuretic, such as amiloride, can be added to the regimen. Triamterene should be avoided, because it can precipitate into stones.

Hypocitraturia

Acidosis leads to an increase in proximal renal tubular citrate reabsorption. Metabolic acidosis, often due to renal tubular acidosis or diarrhea, hypokalemia, androgens, strenuous exercise, and animal protein ingestion are common causes of diminished urinary citrate levels. Bacteria responsible for urinary tract infections also may utilize citrate and lower levels in the urine. Treatment with citrate, preferably as the potassium salt, is effective, but the liquid preparations are often not palatable. Patients often prefer tablets (e.g., Urocit-K, a wax matrix preparation, given 10 to 20 mEq two or three times a day). Potassium bicarbonate also is effective in reducing metabolic acidosis and increasing citrate excretion.

Hyperoxaluria

Excessive urinary oxalate excretion (more than 40 mg per day) can result from either increased endogenous production of oxalate or augmented intestinal absorption. The latter, often referred to as enteric oxaluria, can result from such conditions as inflammatory bowel disease, sprue, jejunoileal bypass, ileal resection, and other syndromes that can lead to malabsorption. Intestinal calcium normally combines with oxalate to form an insoluble, nonabsorbable complex that is excreted with the feces. In the context of malabsorption, excess fatty acids bind calcium and create a more permeable colonic membrane for absorption of the available free oxalate. This can result in urinary oxalate levels above 100 mg per day. A low calcium intake combined with excessive dietary oxalate can similarly result in enhanced intestinal oxalate absorption with mildly elevated urinary oxalate levels.

If a malabsorption syndrome is thought to be the cause of hyperoxaluria, a low-fat diet, calcium supplementation with meals to bind oxalate, and dietary oxalate restriction provide the core therapy. Both calcium carbonate (1 to 4 g three times a day in adults) and calcium citrate not only bind oxalate but also provide alkali. The resultant increase in urinary citrate excretion enhances calcium solubility and prevents calcium oxalate precipitation. Cholestyramine chelates bile salts, fatty acids, and oxalate and may further decrease urinary excretion of oxalate. Patients with malabsorptive syndromes typically have chronic diarrhea with pronounced losses of fluids, bicarbonate, potassium, and magnesium. Accordingly, the acidic, concentrated urine may result in other stone types, such as uric acid, and calcium stones may develop from insufficient excretion of inhibitors, such as citrate and magnesium, rather than from hyperoxaluria alone. Therefore, patients must ingest large quantities of fluid and replace losses of alkali, potassium, and magnesium (magnesium gluconate, 500 to 1,000 mg three times a day) as needed.

Primary hyperoxaluria, due to hereditary inborn errors of metabolism, can result in very high urinary oxalate levels in children and young adults. Some forms respond to vitamin B₆ supplementation, since pyridoxine is an important cofactor in the metabolic pathway that causes glyoxylate to form glycine, rather than oxalate. Orthophosphate also may be used to bind dietary oxalate in these patients with severe hyperoxaluria.

Hyperuricosuria

Excess urinary urate can provide nuclei for calcium oxalate aggregation. Urinary uric acid levels above 800 mg per day in men and 750 mg per day in women, urine pH above 5.5, normal serum calcium levels, and normal urinary calcium and oxalate levels are features associated with hyperuricosuric calcium nephrolithiasis. Nonspecific therapy, along with dietary purine restriction, can prevent further stone formation, but some patients require allopurinol (100 to 300 mg per day) to decrease the urinary excretion of uric acid adequately.

URIC ACID STONES

The three cardinal features of pure uric acid nephrolithiasis are low urine volumes, low urinary pH, and elevated urinary uric acid levels. By prescribing oral hydration to increase urine volumes to more than 3 L per day and alkalinizing the urine to pH 6.5 (a higher pH can result in calcium phosphate precipitation and should be avoided), existing uric acid stones may be dissolved and the formation of new ones prevented. In a urine pH of 6.5, even uric acid levels up to 1,000 mg per liter may be soluble. Higher levels of excretion, especially in conjunction with elevated serum levels, require the measures aimed at limiting uric acid formation. Dietary purine and protein restriction are valuable in preventing the production of uric acid and an acidic urine, respectively. Allopurinol effectively reduces the rate of uric acid excretion, but owing to side effects it should be used only if other measures fail. A dose of 100 mg should be used initially, increasing slowly to 300 mg as needed. If high doses of potassium citrate or other sources of alkali are insufficient to raise the urine pH, acetazolamide may be used, especially overnight.

STRUVITE STONES

Struvite stones also are called infection stones or stone cancer. The latter term refers to the high morbidity rate associated with these stones due to their rapid growth, difficult eradication, and large size and the potential need for nephrectomy. They are composed of three cations—magnesium, ammonium, and calcium (the latter as apatite)—complexed to phosphate; thus, they also are referred to as triple phosphate stones. The ammonium ions, trivalent phosphate, and high urine pH required for stone formation can exist simultaneously only in the presence of urease-producing bacteria. *Proteus* is the most common urease-producing bacterium associated with struvite stones, although *Pseudomonas*, *Providencia*, *Klebsiella*, *Serratia*, and *Enterobacter* also have been noted. Although *Escherichia coli* is common in urinary tract infections, it is not a urease producer and is never implicated in struvite stone formation. The presence of urease-producing bacteria, a urine pH above 7, and large stones is virtually pathognomonic.

After appropriate antibiotic therapy is instituted, ESWL or percutaneous nephrolithotomy is usually required, because the stones are large and frequently form staghorns. Chronic suppressive antibiotics are required to prevent stone recurrence because any infected stone particles remaining make eradication of the bacteria difficult. Urease inhibitors, such as acetohydroxamic acid, are theoretically efficacious, but their use is fraught with side effects.

CYSTINE

Cystinuria results from an autosomal recessive defect in proximal tubular reabsorption of certain dibasic amino acids. Because the solubility of cystine is low (300 mg per liter at a neutral pH) and most homozygous patients excrete more than 800 mg cystine per day, large volumes of fluid intake (close to 4 L per day) are required to prevent cystine precipitation. Therapy consists of water intake to match cystine excretion and increasing the solubility of cystine by raising the urinary pH above 7.5, as long as hypercalciuria is not present. If cystine excretion is so great that the required water intake is unmanageable, medications that form soluble complexes with cysteine and decrease the production and excretion of cystine may be required. The most common agents used, D-penicillamine and tiopronin, are associated with numerous side effects. Cystine stones do not crush well with lithotripsy and require percutaneous nephrolithotomy for removal when they are large.

Indications for HOSPITALIZATION

Most stones less than 0.5 cm pass spontaneously. Larger stones, however, rarely advance through the narrow ureters without urologic intervention ([Table 139.3](#)). Although ESWL is associated with lower morbidity rates than percutaneous or open surgical nephrolithotomy, it is a relatively new technique, and the long-term side effects are not yet known. It is usually performed on an inpatient basis, since patients require anesthesia (local or general), intravenous hydration, and pain management for passage of the pulverized stone fragments.

Proximal ureter (upper two-thirds): endoscopic placement of the stone into the renal pelvis, followed by ESWL.
Distal ureter (lower third): endoscopic removal of the stone or in situ ESWL.
Renal stones >0.5 cm, <2 cm: ESWL very effective; not as successful in lower-pole stones >1 cm or multiple stones.
Renal stones >2 cm or lower-pole stones >1 cm: combination of ESWL and percutaneous nephrolithotomy.
Cystine stones: percutaneous nephrolithotomy (poorly responsive to ESWL).
Large, infected stones: ESWL or nephrolithotomy; all stone fragments completely removed to prevent stone recurrence.
Large stones that are not removed or do not pass with ESWL or percutaneous techniques may require open surgical removal.
Complex, large stones are best treated in hospitals with adequate facilities for ESWL, cystoscopy, and open surgery.

ESWL, extracorporeal shock-wave lithotripsy.

TABLE 139.3. GUIDELINES FOR SURGICAL REMOVAL OF KIDNEY STONES

Indications for REFERRAL

Because the rate of stone recurrence in first-time stone-formers varies, the extent of the initial evaluation is the subject of controversy. Do patients with a first episode of nephrolithiasis merit the same workup as those with multiple stones? In 1988, a Consensus Conference on the Prevention and Treatment of Kidney Stones was convened by the National Institutes of Health (NIH) to explore such issues and to determine the direction of future research. The team resolved that all patients, including first-time stone-formers, should undergo the basic evaluation outlined earlier. The combination of this evaluation and the institution of nonspecific therapy, also as outlined previously, can often prevent further stone formation. Patients who form additional stones or whose stones grow and all children require the more extensive, complete evaluation, including 24-hour urine collection. Patients with stones other than calcium oxalate may also have metabolic abnormalities that merit a more extensive examination. Referral to a nephrologist specializing in nephrolithiasis depends on the individual physician's proficiency in treating these patients and the complexity of each case. Surgical referral is warranted in patients who cannot pass stones, either spontaneously or with intravenous hydration.

COST-EFFECTIVENESS

With the advent of less invasive techniques for removal of renal calculi, such as percutaneous nephrolithotomy and ESWL, there is much reflection on the value of medical management. Is a complete metabolic evaluation cost effective? The yearly cost of stone disease in the United States is a staggering \$2.39 billion, which does not include the unquantifiable pain and distress of renal colic. Medical evaluation and treatment, aimed at the prevention of stone recurrence, has been shown to decrease the direct cost of caring for these patients. With proper medical management, there is a \$3,226 per year reduction in procedural costs, which far outweighs the estimated \$1,068 yearly cost of complete medical treatment, resulting in a net saving of \$2,158 per patient per year. Just as the medical evaluation cannot remove obstructing stones, surgical maneuvers cannot prevent further stone formation nor treat the underlying disorder. It is now generally accepted, and asserted by the NIH consensus conference, that medical and surgical interventions are not conflicting treatment strategies but rather valuable complementary approaches that are both required for comprehensive care of the stone-forming patient.

CHAPTER 140: APPROACH TO THE PATIENT WITH OLIGURIA AND ACUTE RENAL FAILURE

H. DAVID HUMES

[Presentation](#)
[Etiology and Pathophysiology](#)
[Clinical Features and Differential Diagnosis](#)
[Strategies for Optimal Care](#)
[Clinical Course and Outcome](#)

PRESENTATION

Acute renal failure (ARF), a common clinical syndrome, is defined as an abrupt decline in renal function. Most nephrologists accept the definition of ARF as a rise in the serum creatinine concentration of 0.5 mg per deciliter per day and a rise in the blood urea nitrogen (BUN) level of 10 mg per deciliter per day over several days. The clinical manifestations of this disorder arise from the decline in glomerular filtration rate (GFR) and the inability of the kidney to excrete the toxic metabolic wastes produced by the body. It is recognized clinically by rising levels of BUN and serum creatinine concentration and may develop dramatically, with a patient progressing from normal renal function to uremia within a week. Most forms of ARF are reversible; correct diagnosis and management are necessary so that renal function can improve with minimal risk to the patient.

ARF is best understood when it is categorized according to the sequential process of urine formation and excretion. ARF may evolve from diminished renal blood flow (RBF), termed *prerenal functional ARF*; from a sudden, severe renal parenchymal insult, termed *intrarenal structural ARF*; or from obstruction to urine flow, termed *postrenal obstructive ARF*. The initial approach to treatment, therefore, is to localize the site of dysfunction (prerenal, intrarenal, or postrenal). If the process is restricted to prerenal or postrenal sites, the specific diagnosis and treatment are readily apparent, even though many diseases can alter renal perfusion or urine flow. If the process is confined to an intrarenal site, it is useful to categorize the pathogenetic process further into vascular, glomerular, interstitial, or tubular disease.

ETIOLOGY AND PATHOPHYSIOLOGY

PRERENAL FUNCTIONAL ACUTE RENAL FAILURE

Prerenal functional ARF, or prerenal azotemia, results from a persistent, significant decline in RBF. Because the GFR is highly dependent on RBF, a decline in RBF results in a decrease in GFR and rising levels of BUN and serum creatinine. It is labeled *functional* because the decline in GFR and renal excretory ability can be reversed rapidly if RBF is improved. A decline in renal perfusion is usually a component of a generalized condition involving poor tissue perfusion, such as myocardial failure, hypotension, and extracellular volume depletion ([Table 140.1](#)). This decline can evolve from true intravascular volume depletion, as in hemorrhage, diarrhea, or overdiuresis, or from redistribution of intravascular volume to a third space, as in the generalized edematous disorders, in which effective arterial volume is reduced because of fluid accumulation in ascites or peripheral edema. A decline in absolute or relative effective arterial blood volume leads to a decline in perfusion of vital tissues. In response to this decline, various vasoactive substances are released locally and systemically to promote arteriolar constriction, primarily in the renal, splanchnic, and musculocutaneous circulatory beds. At the renal level, sympathetic amines and angiotensin II are important hormones released locally for this response, resulting in substantial declines in RBF and thus in GFR.

Hypotension
Extrarenal sodium loss
Gastrointestinal loss (vomiting, diarrhea, nasogastric suction, intestinal fistula, acute bleeding)
Skin loss (heat exposure, burns, inflammatory diseases)
Renal sodium loss
Extrinsic (osmotic diuresis, diuretic administration, mineralocorticoid deficiency)
Intrinsic (salt wasting nephropathy)
Third-space fluid accumulation
Generalized edematous disorders (congestive heart failure, cirrhosis, nephrotic syndrome)
Gastrointestinal (pancreatitis, peritonitis)
Miscellaneous (crush injury, skeletal fracture)
Hepatorenal syndrome
Drug-induced
Nonsteroidal anti-inflammatory drugs or aspirin
Angiotensin-converting enzyme inhibitor
Amphotericin B

TABLE 140.1. CAUSES OF PRERENAL FUNCTIONAL ACUTE RENAL FAILURE

Renal hypoperfusion also may stem from selective processes in which declines in RBF develop out of proportion to changes in blood flow to other tissues, as in the hepatorenal syndrome and drug-induced prostaglandin inhibition. The pathogenesis of the hepatorenal syndrome appears to be due to a functional decline in RBF. The hepatorenal syndrome is a form of ARF that occurs in hepatobiliary disease, in which no clinical, laboratory, or anatomic evidence of any recognized primary cause of renal failure is present. This syndrome most often is the result of alcohol-induced hepatic cirrhosis, but occasionally it complicates the course of fulminant acute viral hepatitis, biliary tract obstruction or surgery, hepatic malignancies, and partial hepatic resection. The basis of this functional secondary decline in renal function is increased renal vascular resistance and reductions in RBF. This severe renal vasoconstrictive response may well be the result of many abnormalities, including hypoalbuminemia, peripheral vasodilatation, arteriovenous shunting, and sequestration of extracellular volume in the peritoneal cavity. All these processes manifest in hepatic cirrhosis and diminish the effective circulating plasma volume, resulting in lowered renal perfusion.

Prostaglandin inhibition by aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) is most likely to produce prerenal ARF in clinical disorders associated with declines in intravascular volume, as in dehydration and the generalized edematous disorders, including congestive heart failure, cirrhosis, and the nephrotic syndrome. In these disorders, the increased effects of vasoconstrictor hormones, including intrarenal angiotensin II, are counterbalanced by the enhanced production of vasodilatory compounds in the kidney, primarily prostaglandin E₂. Intrarenal prostaglandins help maintain GFR despite systemic vasoconstriction and hypoperfusion. Because of the important role renal vasodilatory prostaglandins play in maintaining RBF, and thus GFR, in these states of diminished effective arterial blood volume, prostaglandin inhibitors can significantly lower RBF and GFR and may produce functional ARF on a prerenal basis. Patients with underlying renal disease, such as lupus nephritis and chronic renal insufficiency, are also at higher risk of ARF with prostaglandin inhibitors.

The acute declines in renal excretory function associated with the use of the new immunosuppressant cyclosporine also are related to cyclosporine-induced declines in RBF. Long-term use of cyclosporine is reportedly associated with chronic tubulointerstitial nephritis. The use of angiotensin-converting enzyme inhibitors reportedly produces ARF in patients with bilateral renal artery stenosis, a condition in which intrarenal angiotensin II is required to maintain adequate glomerular capillary hydraulic pressure to drive the glomerular filtration process. Finally, amphotericin B increases renal vascular resistance acutely and results in prerenal azotemia; lowering the dosage ameliorates this effect.

INTRARENAL STRUCTURAL ACUTE RENAL FAILURE

Most cases of hospital-acquired intrarenal ARF result from ischemic or nephrotoxic processes. In many clinical settings, a combination of these two processes may be operating simultaneously to produce ARF. An ischemic insult often potentiates renal damage produced by nephrotoxins. Systemic vasculitis, atheroembolic disease, renal artery occlusion, rapidly progressive glomerulonephritis (RPGN), and acute hypersensitivity interstitial nephritis also can have initial symptoms of intrarenal structural ARF and must be considered in the differential diagnosis ([Table 140.2](#)). The clinicopathologic aspects and approach to diagnosis and treatment of these entities are detailed in [Chapter 151](#), [Chapter 152](#), and [Chapter 164](#).

Ischemic acute tubular necrosis
 Nephrotoxic acute tubular necrosis
 Antibiotics (aminoglycosides, amphotericin B)
 Heavy metals (cisplatin)
 Radiocontrast agents
 Endogenous toxins (myoglobin, hemoglobin, myeloma light chains)
 Vascular processes
 Atheroembolic disease
 Renal artery occlusion
 Vasculitis
 Acute glomerulonephritis
 Acute tubulointerstitial nephritis

TABLE 140.2. CAUSES OF INTRARENAL STRUCTURAL ACUTE RENAL FAILURE

Acute tubular necrosis (ATN) is the most common name given to ARF stemming from either ischemic or toxic processes. Renal failure develops from tubular cell injury that produces necrosis limited to certain nephron segments within the kidney, so that only a patchy distribution of necrotic lesions is observed. Although tubule cell injury is limited to certain nephron segments, substantial renal excretory failure may still develop, since nephrons function as segmental units in series. Truly widespread tubular necrosis is associated with the entirely different entity of renal cortical necrosis, with causes and pathophysiologic signs quite different from those of nephrotoxic or ischemic ARF.

Progressive renal tubular cell injury initiates alterations at the nephron level that ultimately result in renal excretory failure. These alterations include intratubular obstruction, back-leakage of glomerular filtrate through damaged tubular epithelium, and primary reductions in the glomerular filtration of solutes and water. Of these factors, intratubular obstruction and back-leakage of filtrate appear to be major nephron mechanisms of GFR decline in ATN. The intratubular obstruction arises from casts composed of cellular debris from injured or necrotic renal tubular cells; these impede the flow of urine. The necrotic cells that are shed into the tubular lumen reduce renal excretory function by obstructing urine flow and by leaving gaps along the tubular epithelia through which glomerular filtrate can reenter the circulation.

Renal ischemia is a common cause of ATN. The length and severity of ischemic insults that produce ischemic ARF vary widely in clinical settings. In some patients, a period of a few minutes of ischemia leads to ATN; in others, prolonged renal ischemia generates only transient renal dysfunction. Any prerenal cause of renal excretory dysfunction, if prolonged and severe enough, can provoke progression to structural renal damage. Most cases of ischemic ARF, however, are associated with a period of frank hypotension. Postischemic ARF is more common in patients with sepsis or patients undergoing major surgery.

Nearly half of the clinical cases of ischemic ARF arise after surgery. Various processes, including preoperative and intraoperative fluid losses and anesthesia, result in intravascular volume depletion, with subsequent declines in RBF and GFR. If there is an additional hypotensive or hemolytic insult, susceptible patients may experience ATN. Abdominal aortic aneurysmal repair, open-heart surgery, and biliary tract surgery have the highest incidence of ischemic ARF. Each of these procedures is associated with a substantially greater decline in RBF than are other surgical procedures. The higher incidence of ATN in the septic patient may be related to the major hemodynamic effects of endotoxins, which can produce systemic hypotension and secondary renal vasoconstriction.

Because the kidney is a major excretory organ for therapeutic agents, the list of drugs known to induce ARF is long, and as new agents are developed, the list will surely grow. For now, as detailed in [Table 140.2](#), the causes of nephrotoxic ARF can be categorized into four major groups: antibiotics, heavy metals, radiocontrast agents, and endogenous toxins.

Aminoglycoside antibiotics are a mainstay of therapy in the clinical treatment of gram-negative infections. Approximately 10% of patients receiving parenteral therapy with aminoglycosides have significant declines in GFR. The kidney is the principal excretory route for the elimination of the aminoglycoside antibiotics, resulting in the accumulation of these antibiotics in the renal cortex. Aminoglycosides produce tubular cell necrosis, which is confined exclusively to the proximal tubule. Declines in effective GFR and elevations in serum creatinine usually are not seen clinically before 5 to 7 days of aminoglycoside treatment.

Various risk factors predispose to aminoglycoside nephrotoxicity, including the dose, duration, and dosage regimen; recent aminoglycoside therapy; elderly age; preexisting renal insufficiency; concomitant nephrotoxin administration; volume depletion; cirrhosis; potassium and magnesium depletion; and metabolic acidosis. The dose and duration of drug administration are probably the two most important factors in determining clinical nephrotoxicity. It has been suggested that there is a relationship of serum levels, renal parenchymal concentration, and nephrotoxicity for any given aminoglycoside.

Renal toxicity is a major side effect of amphotericin B, an antibiotic used to treat fungal infections. The cardinal features of renal toxicity due to amphotericin B are reduced GFR, distal renal tubular acidosis, renal potassium wasting, and antidiuretic hormone-resistant nephrogenic diabetes insipidus. Rapid declines in GFR are related to its renal vasoconstrictive effect and prerenal azotemia. Long-term declines in GFR with amphotericin B are due to tubulointerstitial injury.

Various heavy metals produce ARF with proximal tubule cell necrosis. Salts of mercury, platinum, arsenic, bismuth, silver, chromium, and uranium are potent nephrotoxins. ATN stemming from these agents is almost completely confined to occupational exposure or ingestion, either accidental or purposeful. Cisplatin, an inorganic antineoplastic compound containing platinum, is the most common heavy-metal agent of nephrotoxicity in the clinical setting. Several risk factors, including the total dose and duration of treatment, simultaneous administration of other nephrotoxic agents, and preexisting renal disease, increase the incidence of nephrotoxicity.

Radiocontrast-induced ARF appears to develop from the combined effects of radiocontrast-induced renal vasoconstriction with resulting ischemia, direct tubular cell toxicity, and intratubular precipitation of the contrast agent with proteins and membrane fragments, resulting in intratubular obstruction. Tubule toxicity of these agents in animal models is potentiated by a modest hypoxic insult. Preexisting renal impairment and long-standing insulin-dependent diabetes mellitus are the most important predisposing factors for radiocontrast-related ARF in humans. Renal insufficiency results in a higher plasma level and a longer plasma half-life of the contrast agent, with a greater exposure time to renal epithelial cells. Diabetes mellitus is a risk factor for this disorder because the common macrovascular and microvascular complications associated with this disease result in more prolonged renal ischemia after contrast administration, adding to the toxic potential of the contrast agent. Dehydration and multiple myeloma are additional important risk factors.

Several endogenous proteins have been associated with the development of ARF, including myoglobin, hemoglobin, and myeloma light chains. Myoglobinuric ARF can develop in the context of traumatic and nontraumatic muscle injury. Traumatic muscle injury occurs from crush syndromes and from postexertional, ischemic, and postseizure events. Nontraumatic rhabdomyolytic ATN has been associated with severe (especially alcohol-related) myopathies, drug overdose with pressure-induced myonecrosis, heat stroke, viral infections, potassium depletion, and phosphate depletion.

Hemolysis and release of free hemoglobin into the circulation appear to result in ATN only when they are associated with other systemic abnormalities, especially dehydration, shock, and acidosis. It is clearly established that hemoglobin-induced ATN is related to hemolysis resulting from exposure to various chemical compounds, snake and spider venoms, malarial infection, and transfusion reactions. Myeloma light chain-associated ARF is detailed in [Chapter 154](#).

The pathophysiologic consequences of myoglobin- and hemoglobin-induced ARF relate both to the potential nephrotoxic effects of these heme pigments and to intratubular obstruction. Both myoglobin and hemoglobin can be filtered and reabsorbed by the proximal tubule epithelia, where toxic effects may manifest. The degree of reabsorption can be enhanced in volume depletion and poor renal perfusion states, so that these conditions can increase the risk of toxic renal cell injury and ATN. Because of its smaller molecular size, myoglobin is more readily filtered at the glomerulus than is hemoglobin. Consequently, in the clinical picture of pigment protein-induced ATN, the urine, but not the plasma, is pigmented during myoglobinuric states; both the urine and plasma are pigmented in hemoglobinuric events. Besides the direct nephrotoxic potential, these heme pigments may produce intratubular obstruction by local precipitation. This process can be promoted by acid urine in the distal segments of the nephron.

POSTRENAL OBSTRUCTIVE ACUTE RENAL FAILURE

ARF from obstructive disease can be the result of intrarenal and extrarenal processes ([Table 140.3](#)). Extrarenal processes leading to urinary tract obstruction are

renal response to diminished perfusion is avid sodium and water reabsorption to protect the circulating blood volume. Accordingly, the urine in prerenal disease is relatively free of sodium and water, the urine sodium concentration is less than 10 mEq per liter, the FE_{Na} is less than 1%, and the urine osmolality is more than 450 mOsm per kilogram of water (Fig. 140.2).

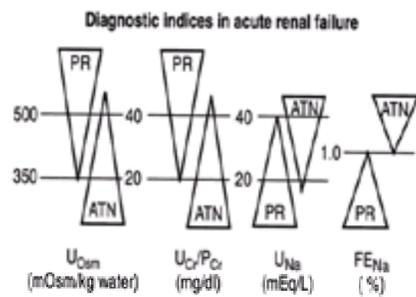

FIGURE 140.2. Common urinary indexes in acute renal failure. The horizontal axis displays four laboratory tests and the units used to differentiate functional prerenal (PR) azotemia from acute tubular necrosis (ATN). The vertical axis depicts values that define the nondiagnostic zones of overlap between the designated values and diagnostic areas of nonoverlap above and below the designated values. The derived urinary index, the fractional excretion of sodium (FE_{Na}), has essentially no nondiagnostic overlap zone. The fraction of the filtered sodium FE_{Na} can be calculated from a urine specimen:

$$FE_{Na}(\%) = (\text{quantity of sodium excreted/quantity of sodium filtered}) \times 100$$

Because the quantity of sodium excreted is equal to the product of the urine sodium concentration (U_{Na}) and the urine volume (V), the quantity of sodium filtered is equal to the product of the plasma sodium concentration (P_{Na}) and the GFR (or creatinine clearance, $C_{Cr} = U_{Cr} \times V/P_{Cr}$):

$$FE_{Na} = \frac{U_{Na} \times V}{P_{Na} \times (U_{Cr} \times V/P_{Cr})} \times 100 = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100 = \left(\frac{U}{P}\right)_{Na} \times \left(\frac{P}{U}\right)_{Cr} \times 100$$

(From Shayman JA, ed. *Renal pathophysiology*. Philadelphia: JB Lippincott, 1995:141, with permission.)

In addition, the ratio of BUN to serum creatinine typically exceeds 20:1. This ratio normally is 10:1 to 15:1, but because urea reabsorption is coupled passively to sodium reabsorption in the kidney, the increase in renal sodium reabsorption in prerenal states is accompanied by an increase in urea reabsorption, a decline in urea clearance disproportionate to GFR alterations, and therefore a rise in BUN. Because creatinine reabsorption is independent of sodium reabsorption, the serum creatinine does not rise by an amount out of proportion to the decline in GFR. These processes lead to an increase in the ratio of BUN to serum creatinine, which often exceeds 20:1. This selective increase in BUN in these functional prerenal disease states is referred to as *prerenal azotemia*.

In several clinical situations, however, these diagnostic laboratory indexes can be misleading. Patients with preexisting renal disease lose the ability to conserve sodium below 10 mEq per liter and to concentrate the urine to levels above 400 mOsm per kilogram of water. Furthermore, if volume depletion is the result of renal salt wasting, the urine sodium concentration may be high. Finally, even in the context of prerenal disorders, the ratio of BUN to creatinine may be normal if urea production is reduced because of low protein intake or severe liver disease. On the other hand, the ratio may exceed 20:1 in obstructive renal disease because of the enhanced urea reabsorption arising from low rates of urine flow.

INTRARENAL ACUTE RENAL FAILURE

Certain acute, severe parenchymal insults can rapidly diminish renal excretory function. These processes include vascular, glomerular, interstitial, and tubular processes. Atheroembolic disorders, vasculitis, RPGN, and acute hypersensitivity interstitial nephritis are specific disorders that often produce ARF. These disorders are detailed in [Chapter 151](#), [Chapter 152](#), and [Chapter 164](#). The combination of hypertension, proteinuria, and hematuria is most suggestive of acute glomerulonephritis, from either idiopathic processes or vasculitis. The absence of significant proteinuria, hematuria, and red blood cell casts virtually excludes this diagnosis. Patients with acute glomerulonephritis usually produce urine with low urine sodium (U_{Na}) and FE_{Na} , similar to prerenal ARF.

Patients with skin rash, fever, eosinophilia, and ARF most likely have acute interstitial nephritis. To establish the diagnosis, it is essential that the patient have a history of exposure to a drug reported to produce this condition. Hematuria, pyuria, and eosinophiluria are common. Urine eosinophiluria also are noted in RPGN and acute prostatitis, but not in ATN. Nephrotic-range proteinuria has been reported in the context of acute interstitial nephritis associated with the use of several NSAIDs. Renal biopsy is the only definitive way to diagnose this condition.

Once other acute parenchymal lesions have been excluded, a detailed investigation for causes of ischemic and nephrotoxic ATN can be made. A careful review of the clinical course before the development of ARF is necessary. Special attention should be paid to the temporal relations of fluid and electrolyte abnormalities, volume status, blood pressure, medication administration, surgical procedures, potential nephrotoxin exposure, and renal function parameters just before the development of ATN. This is particularly true for aminoglycoside, amphotericin B, cisplatin, and radiocontrast nephrotoxicity.

Various urinary findings can help the physician reach the correct diagnosis (Fig. 140.1). Measurement of the daily urine volume excreted from a patient with ARF can be useful. Anuria is the most severe reduction in urine volume (less than 100 mL per 24 hours) and may be the result of reversible urinary tract obstruction or the more ominous consequence of bilateral renal cortical necrosis, bilateral renal arterial or venous occlusion, or overwhelming acute glomerulonephritis. Prolonged anuria is rarely seen in simple, uncomplicated forms of prerenal ARF or ATN. Oliguria, a reduced urine volume of 100 to 400 mL per 24 hours, may be the physiologic response to volume depletion or the pathophysiologic consequence of urinary tract obstruction or ATN. Nonoliguria is a urine volume exceeding 400 mL per 24 hours in the context of ARF. Most forms of ARF can be associated with nonoliguria. Anuria alternating with polyuria is an uncommon but classic occurrence in urinary tract obstruction.

The urine sediment in the early phase of ATN usually contains renal tubular epithelial cells and granular and epithelial cell casts. Because tubular function is impaired, the kidney's ability to conserve sodium and maximally concentrate the urine is diminished. These abnormalities can be of diagnostic value in patients with azotemia in differentiating between prerenal azotemia and ATN (Fig. 140.2). In patients with azotemia due to prerenal causes, the urinary indexes usually show a urinary osmolality greater than 500 mOsm per kilogram of water, a urine sodium concentration less than 20 mEq per liter, and a urine/plasma creatinine ratio above 40. In contrast, patients with ATN usually have urine osmolality less than 350 mOsm per kilogram of water, urinary sodium concentration greater than 40 mEq per liter, and a urine/plasma creatinine ratio less than 20:1. Although these ranges in urinary indexes are discriminating in about 80% of patients, about 20% have indexes in an intermediate, nondiagnostic zone. These two causes of azotemia can be distinguished further by the derived FE_{Na} parameter, which exceeds 1% in patients with ATN but is less than 1% in patients with prerenal ARF. Patients with radiocontrast-induced ARF often have FE_{Na} values less than 1%, even though ATN is present.

Consider the diagnosis of myoglobinuric rhabdomyolytic ARF if the patient has several laboratory findings unique to this disorder. This condition is commonly associated with pigmented granular casts (the pigmentation arises from the presence of myoglobin); a positive orthotolidine (Hematest) reaction in the urine supernatant or positive dipstick for heme in the absence of red blood cells in the spun urinary sediment, indicating the presence of myoglobin; and a marked elevation in the plasma level of creatine phosphokinase due to the release of this enzyme from damaged muscle cells. A definitive diagnosis can be made if there is evidence of

myoglobin in the urine using counterimmunoelectrophoresis.

Because skeletal muscle is rich in creatinine and uric acid precursors, potassium, and phosphate, rhabdomyolysis releases large amounts of these compounds. Consequently, myoglobinuric rhabdomyolysis can result in a rate of rise of the serum creatinine level exceeding 2 mg per deciliter per day. The BUN/serum creatinine ratio is consequently lower than 10. Rhabdomyolytic ARF typically is associated with a serum uric acid concentration above 16 mg per deciliter. This finding should be differentiated from acute uric acid nephropathy. Hyperkalemia is often severe in this disorder; uncontrollable hyperkalemia is a common indication for dialysis. Hyperphosphatemia also results from the release of phosphate from necrotic muscle, and values exceeding 8 mg per deciliter are often seen. Resulting hypocalcemia, due in part to calcium deposition in damaged muscle, may accompany this abnormality. Although hypocalcemia may be present in the oliguric phase of myoglobinuric ARF, hypercalcemia can develop during the diuretic phase of this disorder.

The clinical diagnosis of hemoglobinuric ATN should be considered when a known hemolytic event is followed within minutes to hours by dark urine and a decline in urine output or renal excretory function. Chills and hypotension are common. Radiologic studies, including intravenous pyelography, ultrasonography, and retrograde and antegrade pyelography, are most useful in ruling out postrenal obstructive ARF. These procedures are rarely useful to diagnose intrarenal structural ARF except by exclusion. Similarly, radionuclide scans are infrequently helpful in the diagnosis of parenchymal ARF, but they can assess the possibility of complete renal artery occlusion as a cause of ARF. Renal biopsy is useful only when it is highly likely that patients have acute glomerulonephritis, vasculitis, or acute interstitial nephritis, as discussed in [Chapter 164](#).

ARF is an uncommon but serious complication of pregnancy (see [Chapter 162](#)). Sources include severe preeclampsia, placental hemorrhage, septic abortion, and postpartum hemolytic-uremic syndrome. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) is a severe complication of preeclampsia and has elements similar to the hemolytic-uremic syndrome. ARF also occurs frequently in patients who undergo bone marrow transplantation. Early ARF, within 5 days of transplantation, is due to a tumor lysislike syndrome. A hepatorenal-like ARF presentation stemming from hepatic veno-occlusive disease can develop up to a month after bone marrow transplantation.

POSTRENAL ACUTE RENAL FAILURE

Urine flow may be obstructed at any site along the urinary tract. ARF from obstructive disease can result from both intrarenal and extrarenal processes (see [Chapter 138](#) and [Chapter 158](#)). In general, because extrarenal urinary tract obstruction is a reversible cause of renal failure, it always should be considered as part of the initial differential diagnosis in every patient who shows signs of renal insufficiency.

ARF may arise in the context of intrarenal obstruction from diffuse crystal formation and precipitation occurring within tubular lumina throughout the kidney ([Table 140.1](#)). Because most cases of intrarenal obstructive ARF have initial symptoms similar to those due to other causes of ATN and result from intrarenal rather than extrarenal obstruction, the diagnosis is not made with the commonly used urologic procedures of cystoscopy or retrograde pyelography. Usually the diagnosis is made because of an awareness of the contexts in which intrarenal crystal formation and precipitation can develop.

Acute uric acid nephropathy is characterized by the acute onset of oliguria, often leading to anuria with rapidly rising levels of BUN and creatinine. The level of serum uric acid usually exceeds 20 mg per deciliter. In the early phase, uric acid crystals and hematuria are often found on urinalysis. A uric acid/creatinine concentration ratio greater than 1 on a random urine sample may aid in the diagnosis. Recent exposure to high-dose MTX also must be excluded when intratubular precipitation of crystalline material is implicated as the cause of ARF.

STRATEGIES FOR OPTIMAL CARE

PRERENAL ACUTE RENAL FAILURE

Treatment of prerenal ARF depends on the underlying disorder. When volume depletion is the cause of prerenal azotemia, infusion of saline and plasma volume expanders, preferably albumin-containing solutions, is indicated. In the edematous disorders, prerenal azotemia usually results from excessive diuresis and diminished intravascular volume, even though peripheral edema and elevated total body sodium content persist. In these circumstances, gentle volume repletion improves renal function. In a critically ill patient with hemodynamic instability, more precise estimation of effective intravascular volume is indicated with the measurement of the pulmonary capillary wedge pressure by a Swan-Ganz catheter.

Therapeutic approaches to the hepatorenal syndrome have been relatively discouraging. The prognosis is extremely poor: once this process develops, renal function improves only if hepatic function improves, either spontaneously or after liver transplantation. Treatment therefore is directed toward improvement of liver function. Prevention or amelioration of the various forms of drug-induced prerenal functional ARF involves improvement in renal perfusion by withdrawal of the agent and treatment of the underlying disease. NSAIDs also can produce ARF resulting from acute hypersensitivity interstitial nephritis, with or without accompanying nephrotic-range proteinuria.

INTRARENAL ACUTE RENAL FAILURE

The approaches to management of ARF arising from vascular, glomerular, and interstitial processes are detailed in [Chapter 151](#), [Chapter 152](#), and [Chapter 164](#). The therapy of ATN is to prevent or ameliorate renal injury during the developing phase of ARF and to treat established disease during the maintenance and recovery phases. Once ischemic or nephrotoxic ATN occurs, its treatment is similar to that of ARF that stems from other processes. The basic goals are to maintain fluid and electrolyte balance, to provide adequate nutrition, and to treat any infection and uremia. The use of mannitol or furosemide has been the subject of controversy. There is no good evidence that these diuretics can reverse ATN once it has developed, but it is reasonable to attempt a trial of furosemide (80 to 400 mg) or mannitol (12.5 to 25 g) by intravenous infusion in the early phase of oliguric ARF in the hope of inducing diuresis. This enhanced urine flow may lessen the need for dialysis by limiting hypervolemic and hyperkalemic complications, although that maneuver does not appear to improve renal function or mortality or to speed recovery from ATN. If there is no improvement in urine flow, the use of diuretics and mannitol should be discontinued, because the retention of mannitol in the extracellular space can lead to hyperosmolality, hyponatremia, and extracellular fluid overload; deafness, which can be irreversible, may follow the use of large doses of furosemide or, more often, ethacrynic acid.

Any condition associated with a decline in renal perfusion and functional prerenal azotemia, if prolonged and severe enough, can progress to structural ischemic renal damage. At this stage, return of RBF by hydration and reversal of underlying disease will fail to improve renal function. Mannitol and furosemide improve renal function in ischemic ARF if given before the injurious agent, but these maneuvers are usually no more beneficial than simple volume repletion. Clinical prevention of ischemic ARF is difficult with these interventions, since prophylactic therapy often is impossible.

Low-dose dopamine frequently has been employed to enhance renal perfusion to improve renal function and urine flow in ARF. At present there are no clinical data supporting its efficacy in terms of survival of patients and in obviating the need for dialysis in patients with ARF. Dopamine administration continues to be a valuable agent to support cardiovascular performance in critically ill patients, but its use solely to treat intrarenal ARF is not endorsed by current clinical evidence.

Prevention of nephrotoxic ARF requires a knowledge of the drugs with nephrotoxic side effects and their correct dosage, the careful selection of nephrotoxic agents only for clearly defined clinical indications, and the identification and modulation of the factors that increase the risk of nephrotoxic complications. Specific risk factors that contribute to the development of renal complications from drugs with nephrotoxic potential include preexisting renal disease, volume depletion, advanced age, and concomitant nephrotoxic drug administration. Even with the careful use of nephrotoxic agents, renal toxicity still occurs occasionally. When there is objective evidence of a decline in GFR along with a rising level of serum creatinine and BUN, the drug or drugs that may be responsible for nephrotoxicity should be discontinued if possible. Even after the drug responsible for renal damage is withdrawn, renal dysfunction may progress for several days as the toxic injury continues from the persistence of the toxin within the renal parenchyma. Careful monitoring of renal function is therefore necessary even after recognition of the insult.

The best approach to treatment of aminoglycoside nephrotoxicity is prevention. Because the aminoglycosides have a relatively low toxic therapeutic index, effective therapeutic doses for antibacterial activity are very near potentially toxic doses. Therefore, maintenance of serum antibiotic levels below toxic levels is the most important factor in reducing the clinical risk of nephrotoxicity (see [Chapter 167](#)). The patient receiving an aminoglycoside also should be well hydrated. Electrolyte and acid-base disturbances, such as potassium or magnesium depletion and metabolic acidosis, should be corrected. Finally, if therapy was begun empirically, culture results should be checked as quickly as possible to determine whether aminoglycoside therapy should be continued.

The renal side effects of amphotericin B have important clinical implications, since the degree of azotemia rather than the therapeutic response dictates the daily dosage and the duration of therapy. During therapy, serum electrolyte, BUN, and serum creatinine levels should be followed closely. If hypokalemia and acidosis develop, potassium and bicarbonate repletion is indicated. Most therapeutic regimens advise either discontinuance or alternate-day therapy when BUN exceeds 50 mg per deciliter. Once the BUN and, with it, the GFR improve, reinstitution of larger doses can be attempted.

There are several therapeutic maneuvers that minimize the nephrotoxic effects of cisplatin. Continuous infusion of cisplatin has resulted in much less renal toxicity than similar doses given as a daily intravenous bolus. Hydration with furosemide or mannitol (or both) before and during cisplatin administration has also been successful. Cisplatin should be avoided during treatment with other nephrotoxic agents, such as the aminoglycosides, and if the creatinine clearance rate is below 50 to 60 mL per minute.

Prevention of radiocontrast-induced ARF depends on identification of patients at high risk. Consideration must be given to alternative noninvasive diagnostic studies, including ultrasonography, isotopic scans, retrograde pyelography, and unenhanced computed tomography. If a contrast study cannot be avoided, volume repletion should be undertaken in patients with a serum creatinine level above 1.8 mg per deciliter before the contrast load. The development of new nonionic radiocontrast agents may lessen the incidence of contrast-induced nephrotoxicity and may be particularly useful in patients at high risk, if clinical studies confirm their lower nephrotoxicity.

The most important measure in treating rhabdomyolysis is early, aggressive replacement of the intravascular fluid lost into necrotic muscle. Administration of 4 to 12 L of normal saline solution intravenously in the first 24 hours may be necessary to maintain a high urine output. Administration of a single dose of mannitol (25 g) intravenously early in the course of volume replacement is also recommended. Early clinical trials using atrial natriuretic peptide or growth factors in established ATN have not supported the efficacy of these agents to improve the outcomes of patients with ARF despite evidence in experimental animal models.

POSTRENAL ACUTE RENAL FAILURE

Treatment of acute uric acid nephropathy is directed toward minimizing uric acid crystal formation within the collecting ducts. Raising urine pH by infusion of sodium bicarbonate and concomitant administration of the carbonic anhydrase inhibitor acetazolamide favors solubilization of uric acid. In patients with acute leukemia for whom combination chemotherapy is planned, pretreatment with allopurinol for at least 24 hours, and preferably for 3 days, diminishes the hyperuricemic response and the risk of this disorder. In patients with established renal failure or serum uric acid levels exceeding 25 mg per deciliter, hemodialysis is indicated to lower serum uric acid levels and to reverse ARF.

A similar approach to MTX-induced ARF has been established. Intratubular obstruction and ARF can be avoided by establishing and maintaining alkaline diuresis during and after MTX administration, increasing crystal solubility and thereby lessening the risk of crystal formation and deposition along the terminal segments of the kidney. Therapy of extrarenal obstructive postrenal ARF is detailed in [Chapter 138](#).

CLINICAL COURSE AND OUTCOME

The decline in renal function observed in ATN may begin abruptly after an ischemic event or develop insidiously from nephrotoxic injury. Possible clinical problems during the developing phase of renal failure include volume overload, electrolyte disorders (such as hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, and acidemia), and the signs and symptoms of uremia (including pericarditis, lethargy, vomiting, and infection). Uremic symptoms, volume overload, intractable acidosis, and severe hyperkalemia are typical indications of the need for dialysis therapy in ATN (see [Chapter 165](#)). Peritoneal dialysis, hemodialysis, or continuous hemofiltration can be used. If the patient has oliguria and steadily rising levels of serum creatinine, dialysis or hemofiltration usually is initiated when the serum creatinine level reaches 8 to 10 mg per deciliter, to avoid major uremic problems, which would be immediately life-threatening.

During this maintenance phase of ATN, the patient usually experiences oliguria, but urine output above 500 mL per day or nonoliguria develops in 30% to 40% of patients with ATN. The urine output, therefore, cannot be used as an accurate reflection of GFR in developing ATN. Nonoliguric ATN has a better prognosis than oliguric ATN, perhaps because nonoliguric renal failure reflects lesser degrees of renal damage, with less frequent progression to symptomatic renal failure requiring dialysis.

Renal excretory failure usually persists for an average of 7 to 21 days, but cases lasting several months have been reported. ATN may result in irreversible renal failure, particularly in the clinical setting, where it has arisen from several causes in the critically ill patient. The potential reversibility is the result of the regenerative ability of surviving renal epithelial cells to repopulate the nephron. Renal function, therefore, may return completely, or nearly completely, to baseline levels. As renal function improves, urine output increases, and the serum creatinine level declines.

The prognosis of patients with ATN depends on the causative process. ATN after surgery or trauma has an overall mortality rate of 40% to 75%. The survival rate is much better among patients who do not experience other medical complications, such as infection, bleeding, or respiratory failure. Patients with nephrotoxic ATN have an average mortality rate under 10%. Because dialysis can correct most abnormalities associated with renal excretory failure, the fact that patients' survival depends on extrarenal disturbances is not surprising.

Indications for REFERRAL

Once ARF is diagnosed, an immediate and careful evaluation to rule out prerenal and postrenal causes is necessary. The possibility of a postrenal, obstructive source requires a urologic evaluation. If it appears likely that the culprit is an intrarenal structural process, the patient should be immediately referred to a nephrologist for an evaluation for glomerulonephritis, interstitial disease, renovascular events, and ATN, to clarify appropriate diagnostic and therapeutic approaches.

CHAPTER 141: APPROACH TO THE PATIENT WITH CHRONIC RENAL FAILURE

FUAD N. ZIYADEH

[Progressive Nature of Chronic Renal Failure](#)
[Pathophysiology of the Uremic State](#)
[Alterations in Fluids and Electrolytes](#)
[Metabolic and Endocrine Manifestations of Uremia](#)
[Clinical Features](#)
[Patient Evaluation](#)
[Differential Diagnosis](#)
[Conservative Management](#)
[Follow-Up and Reassessment](#)

Chronic renal failure (CRF) is a slowly progressive and irreversible reduction in glomerular filtration rate (GFR). Chronicity implies that the disease process has been ongoing for a period of months to years. *Chronic renal insufficiency* is a term used to describe a mild to moderate reduction in GFR (usually not below 25 to 30 mL per minute) that has not reached the point at which uremic symptoms appear. The hallmark of uremia is evidence of widespread organ dysfunction, because loss of kidney function impairs metabolism and cell function as a result of abnormal regulation of body fluids, ions, and several hormones. Permanent nephron loss occurs as a consequence of irreversible scarring by any of a number of mechanisms of action and causes ([Table 141.1](#)). In general, whole-kidney GFR may be reduced through a decrease in the number of functioning nephrons, a marked decline in single-nephron GFR, or both.

TABLE 141.1. CAUSES OF CHRONIC RENAL FAILURE

The usual course of chronic renal insufficiency is inexorable progression to end-stage renal disease (ESRD). Sometimes, however, there is an element of reversibility, for one of two reasons. First, there may be ongoing activity of the process responsible for the loss of renal function, which can be treated or suppressed. Second, extrarenal reversible factors, such as hypovolemia, may be superimposed on the chronic process.

This chapter discusses current thoughts concerning the pathogenesis of the uremic syndrome and the causes of progression of renal insufficiency, reviews the clinical signs and symptoms, and describes an approach to the patient. The approach includes consideration of reversible factors or processes, establishment of a diagnosis, and institution of conservative management. Ultimately, a treatment plan requires consideration of the various therapeutic methods available for the long-term management of ESRD.

PROGRESSIVE NATURE OF CHRONIC RENAL FAILURE

A characteristic of most forms of CRF is the inexorable progressive deterioration of kidney function long after the initial insult is no longer present. The rate of loss of GFR is highly variable and depends on the patient, the type of renal lesion, the presence and severity of systemic hypertension, dietary factors, and concomitant complicating illnesses. For example, diabetic nephropathy tends to progress more rapidly and polycystic kidney disease more slowly than the glomerulonephritides or tubulointerstitial diseases. For any individual patient, however, the rate of decline in GFR is constant and can be predicted, in the absence of therapeutic interventions or complicating factors. The reciprocal of the serum creatinine concentration ($1/S_{Cr}$) declines in a linear fashion over a period of observation of months or years, at a rate characteristic of the individual patient.

The pathogenesis of the progressive nature of CRF remains puzzling, but several factors have been suggested. There may be persistent activity of the initiating insult (e.g., glomerulonephritis with ongoing glomerular injury) in some patients, but this does not explain the progression in most patients. Renal parenchymal calcifications (presumably caused by secondary hyperparathyroidism and a high calcium/phosphate product in plasma) may be detected in several forms of advanced renal failure and are thought to contribute to the progression of renal damage. Animal experiments and some human clinical studies have documented that dietary phosphate restriction halts the progression of renal failure and minimizes the severity of nephrocalcinosis. It has also been argued, however, that nephrocalcinosis may be a consequence, not a cause, of renal damage.

In many patients, long-standing, severe, and uncontrolled hypertension is generally believed to contribute significantly to the progression of renal failure. Another potentially important mechanism of action that could explain the inevitable progression of CRF relates to the development of glomerular hypertrophy, intraglomerular hypertension, and hyperfiltration. This last factor has been the subject of considerable investigation. In experimental animal studies, examination of remnant kidneys after subtotal nephrectomy shows compensatory intraglomerular hypertension, hyperperfusion, and hyperfiltration in surviving nephrons. This compensatory process is maladaptive, because it induces glomerulosclerosis and destruction of the surviving nephrons.

Experimental studies have shown that increased strain on the mesangial cells can stimulate them to produce cytokines, such as transforming growth factor- β , which can promote the synthesis and accumulation of extracellular matrix molecules. Mesangial matrix expansion can encroach on the capillary surface area and reduce the single-nephron GFR in surviving nephrons. Intraglomerular hypertension and the associated structural changes, such as glomerulosclerosis and tubulointerstitial fibrosis, can be prevented by feeding a low-protein diet or by administering angiotensin-converting enzyme inhibitors. Through unknown hemodynamic mechanisms of action, a low-protein diet increases afferent arteriolar tone, which leads to decrements in renal blood flow and intraglomerular hydrostatic pressure; this lowers the GFR in the surviving nephrons. Converting enzyme inhibitors diminish the circulating and intrarenal levels of angiotensin II, resulting in dilatation of the efferent arteriole and consequent reduction in glomerular filtration pressure. Both a low-protein diet and converting enzyme inhibitors also lessen the production and prosclerotic activity of transforming growth factor- β .

Both experimental and clinical studies have emphasized that the development of heavy proteinuria is an important risk factor for progression of CRF. Hemodynamic stress in the glomerulus can promote the development of proteinuria. Glomerular hypertension enlarges the radius of the pores of the glomerular membrane by a mechanism that is mediated at least in part by angiotensin II. In glomerular diseases, the excess filtration of proteins into the proximal tubule and their subsequent endocytosis may represent an important pathologic mechanism underlying renal scarring. Lysosomal degradation of proteins by epithelial cells incites a host of reactions, including the release of local vasoactive hormones and inflammatory cytokines, complement activation, and mononuclear cell infiltration. The resulting tubulointerstitial fibrosis and its severity correlate highly with the decline in GFR. A vicious cycle develops in which loss of nephrons leads to further hemodynamic stress in the glomeruli of surviving nephrons, increased proteinuria, and accelerated tubulo-interstitial damage. In this view, heavy proteinuria provides a link between glomerulosclerosis and the development of tubulo-interstitial fibrosis, and a decrease in proteinuria effected by angiotensin-converting enzyme inhibitors leads to an arrest of both glomerulosclerosis and tubulointerstitial fibrosis.

Whether progression of CRF in humans is also mediated by alterations in glomerular hemodynamics cannot be established with certainty. Nevertheless, in several long-term clinical trials, drug intervention to control systemic and intraglomerular hypertension, especially with converting enzyme inhibitors, has been shown to be

effective in slowing the progression of most forms of CRF. Angiotensin-converting enzyme inhibitors are effective antiproteinuric agents, and this property can further protect from progressive renal damage in glomerular diseases characterized by nephrotic-range proteinuria. Also, large prospective clinical trials have confirmed that moderate dietary protein restriction (0.6 g per kilogram of body weight per day) delays the onset of the uremic syndrome and tends to reduce the rate of loss of renal function, at least in some patients.

PATHOPHYSIOLOGY OF THE UREMIC STATE

There are two categories of mechanisms that account for the uremic syndrome: those that have systemic or generalized effects due to accumulation of ill-defined uremic toxins normally eliminated by the kidney and those that stem from defects in a specific organ system.

UREMIC TOXINS

Many nitrogen-containing products of protein and amino acid metabolism accumulate in body fluids and tissues as putative uremic toxins. Although prolonged elevation of the blood urea nitrogen (BUN) concentration is associated with aggravation of the symptoms of uremia, no mechanism of action for this effect has been identified. Urea may be a minor toxin that contributes to some uremic symptoms, such as nausea and vomiting. Nevertheless, BUN can be taken as a surrogate for the true toxins, because urea production is closely related to catabolism of protein (both endogenous and dietary) in normal subjects and uremic patients, and the accumulation of urea reflects the accumulation of all products derived from the catabolism of protein and amino acids, including potential uremic toxins.

Nitrogen-containing uremic toxins include guanidines, polyamines, aliphatic or aromatic amines, some phenols, methylamines, and “middle molecules.” Guanidines have been related to defective platelet function and the bleeding tendency of uremic patients. Spermine, a polyamine, has been shown to inhibit erythropoiesis, and its levels correlate inversely with the hematocrit levels of patients on hemodialysis therapy. The middle-molecule hypothesis states that uremic toxicity is caused by peptides and other nitrogen-containing compounds with molecular weights between 500 and 3,000 daltons. Because protein is the principal source of middle molecules, their concentrations can be reduced by restricting dietary protein or by various dialysis strategies. Most nitrogen-containing compounds are poorly characterized, however, and there is little proof that any particular agent exerts a specific toxicity. Moreover, because virtually none of the putative uremic toxins is measured in clinical laboratories, most physicians rely on the BUN concentration to estimate when uremia will become disabling. In general, a BUN concentration consistently above 100 mg per deciliter is a forerunner of uremic symptoms; however, it is not uncommon to encounter malnourished patients who have a lower BUN but also exhibit overt symptoms of uremia. One example of uremic toxicity due to a middle molecule in patients on long-term dialysis is the development of destructive spondyloarthropathy with β_2 -microglobulin amyloid deposits.

TRADE-OFF HYPOTHESIS

A postulated systemic mechanism of development of many uremic symptoms is the trade-off hypothesis, which proposes that homeostatic factors activated in patients with renal failure permit a balance between intake and excretion, but the same homeostatic factors cause or exacerbate the uremic syndrome. This hypothesis is best illustrated by considering the dynamic effects of progressive renal failure on divalent ion metabolism and the development of secondary hyperparathyroidism (see [Chapter 412](#)). Stated simply, the release of parathyroid hormone is stimulated in an effort to normalize serum phosphate and calcium ion concentrations, but the persistent hyperparathyroid state promotes bone damage ([Fig. 141.1](#)). The details incorporated into this hypothesis have been greatly refined over the past two decades. As GFR decreases, renal excretion of phosphate is impaired.

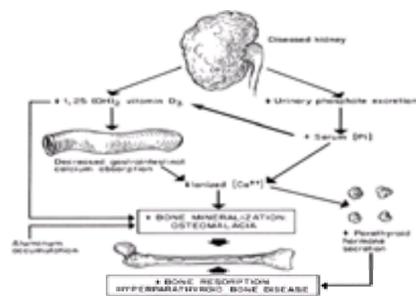

FIGURE 141.1. Evolution of uremic osteodystrophy, showing the roles of calcitriol, parathyroid hormone, and aluminum accumulation.

Besides limiting phosphate excretion, kidney damage also reduces production of the most active form of vitamin D, calcitriol. Hyperphosphatemia directly inhibits the 1 α -hydroxylation of calcifediol, further reducing calcitriol levels. Reduced production of calcitriol by the kidney limits intestinal calcium absorption, so that a higher level of parathyroid hormone is required to achieve a normal ionized calcium level. The mechanism of hyperphosphatemia-induced hypocalcemia involves the intermediary development of calcitriol deficiency. More severe hyperphosphatemia can also lower the serum calcium concentration directly. Experimental evidence indicates that both calcitriol deficiency and hyperphosphatemia can stimulate parathyroid hormone secretion directly, further aggravating hypocalcemia-induced hyperparathyroidism.

Fortunately, parathyroid hormone increases renal phosphate excretion by inhibiting tubular reabsorption of phosphate and also increases the ionized calcium level by promoting bone resorption. Although serum phosphate and calcium concentrations are normalized, a high parathyroid hormone level is maladaptive; it promotes bone damage and renal osteodystrophy. Moreover, a low level of calcitriol leads to osteomalacia (a component of renal osteodystrophy) and also causes resistance of the skeleton to the action of parathyroid hormone, requiring progressively higher levels of the hormone to maintain a normal ionized calcium level. With further reductions in GFR, renal excretion of phosphate may not be augmented further. Thus, further loss of kidney function leads to repetition of the cycle of positive phosphate balance, deficiency of calcitriol, hypocalcemia, and stimulation of parathyroid hormone release that leads to progressively severe osteitis fibrosis cystica. Experimental studies suggest that parathyroid hormone can impair metabolism in many organs, possibly by changing intracellular calcium and cellular signaling pathways. Dysfunction of the skin, skeletal muscle, peripheral nerves, blood vessels, heart, and brain have been linked to secondary hyperparathyroidism.

ALTERATIONS IN FLUIDS AND ELECTROLYTES

SODIUM

The ability to balance sodium excretion with intake is usually maintained even when more than 90% of renal function is lost. This progressive adaptation of the failing kidney is usually attributed to increased function of individual surviving nephrons. Each glomerulus and its tubule are considered a unit (the intact nephron hypothesis), and each nephron increases sodium excretion sharply, either because of a circulating natriuretic hormone or “third factor” (e.g., putative inhibitors of Na,⁺K⁺-ATPase or atrial natriuretic peptide) or because glomerular filtration in each surviving nephron rises sharply with a corresponding adjustment in tubular reabsorption. Typically, patients with CRF maintain sodium balance even when sodium intake is relatively normal (i.e., 2 to 4 g per day or 86 to 172 mEq per day). What they cannot do is to respond rapidly to changes in dietary sodium. Sudden increases in dietary salt cause hypertension and edema (and, when severe, pulmonary edema). On the other hand, when dietary sodium is sharply restricted, sodium excretion continues, causing loss of extracellular volume and, often, loss of renal function.

WATER

The amount of water eliminated by the kidney becomes a greater proportion of the water filtered as the GFR declines. Consequently, the osmolality of the urine becomes relatively fixed at the same osmolality as serum (300 mOsm per liter), that is, the patient has isosthenuria. The limited ability to concentrate urine causes nocturia. Moreover, a limited capacity to excrete water may lead to hyponatremia and water intoxication if patients are given excessive hypotonic fluids or 5% dextrose

in water intravenously.

POTASSIUM

In CRF, the amount of potassium secreted by each nephron is increased, in part through the action of aldosterone as well as an increase in urine flow in each nephron. The adaptation is remarkably efficient, and hyperkalemia is unusual until renal failure is advanced and urine volume falls below about 500 mL per day. This is a serious consequence of renal failure because hyperkalemia impairs cardiac conduction. Some patients may also have hyperkalemia when the serum creatinine concentration is relatively low (3 to 5 mg per deciliter) because of impaired secretion or the action of aldosterone on the collecting duct. Such patients are said to have hyporeninemic hypoaldosteronism or type IV renal tubular acidosis. In patients with advanced renal failure, including patients on dialysis, the capacity of the colon to secrete potassium rises sharply, so that as much as 25% to 40% of the potassium ingested each day is excreted in feces. In such patients, hyperkalemia can occur with constipation.

ACIDOSIS

Acidosis develops in uremic patients because of their inability to excrete the amount of acid generated each day with a normal diet (about 1 mEq hydrogen ion is generated per kilogram of body weight each day). A prominent factor that leads to this dysfunction in renal failure is the production of inadequate amounts of ammonia. Hyperchloremic metabolic acidosis evolves when the GFR is 30 to 60 mL per minute. High anion gap acidosis arises when the GFR falls below about 20 mL per minute, owing to the accumulation of nonvolatile acids generated during metabolism. The unexcreted acid is buffered principally by bone, leading to demineralization, which is characteristic of uremic osteodystrophy. Chronic metabolic acidosis also causes excessive catabolism of protein and amino acids, leading to protein wasting and negative nitrogen balance.

METABOLIC AND ENDOCRINE MANIFESTATIONS OF UREMIA

GLUCOSE AND INSULIN

Uremia is typically associated with impaired glucose metabolism. The sensitivity of muscle to the hypoglycemic action of insulin is reduced in uremic patients. Tissue sensitivity to insulin can be substantially improved by dialysis, which suggests the role of uremic toxins. Hepatic glucose production and uptake are normal in uremia. Other actions of insulin, such as promoting potassium uptake by cells and inhibiting proteolysis, are maintained in uremia. Some patients manifest mild hyperglycemia in response to glucose loading as a result of insulin resistance in skeletal muscle, while others are able to maintain normoglycemia by raising plasma insulin levels. Very rarely, spontaneous hypoglycemia can develop in severely malnourished or alcoholic patients who may also suffer from autonomic neuropathy and impaired release of counterregulatory hormones, such as catecholamines.

The kidney plays a central role in the metabolism of insulin in normal subjects. About 25% of the daily production of insulin by the pancreas is degraded in the kidney; it is also removed by muscle and liver. When the GFR declines to about 40 mL per minute, the half-life of insulin rises, but any benefit of a longer half-life is overcome by insulin resistance. Because the half-life is prolonged, administration of insulin without dose readjustment in diabetic patients with progressive renal insufficiency can lead to dangerous hypoglycemia.

LIPID METABOLISM

The incidence of atherosclerosis is higher in patients with CRF, and this condition is aggravated by hypertension. High-density lipoprotein cholesterol levels are usually reduced, but the levels of very low density and low-density cholesterol are higher in uremic patients.

THYROID METABOLISM

Patients with CRF often have low serum thyroxine levels because of decreased binding to thyroid-binding globulin due to the retention of binding inhibitors. Free thyroxine serum levels (measured by equilibrium dialysis) are usually normal, whereas total and free triiodothyronine serum levels are typically low. These low levels are the result of impaired conversion of thyroxine to triiodothyronine in peripheral tissues. In contrast to other causes of the euthyroid sick syndrome, the serum level of reverse triiodothyronine is normal rather than high. There is a higher incidence of goiter in patients with CRF, possibly owing to accumulation of an unidentified goitrogen. It may be difficult to separate the clinical symptoms of uremia from those of hypothyroidism. Both conditions may be characterized by cold intolerance, a puffy appearance, dry skin, lethargy, constipation, and a higher incidence of goiter. However, the serum concentration of thyroid-stimulating hormone is normal in the majority of patients with CRF. Treatment for hypothyroidism is necessary only for patients with distinct elevations in thyroid-stimulating hormone concentrations (above 10 mU per liter).

SEXUAL DYSFUNCTION

The incidence of impotence in patients with CRF is much greater than expected, compared with other chronic illnesses or states of depression, perhaps because of hormonal derangements and other factors, such as zinc deficiency. Testosterone levels are low because of decreased production; serum levels of dihydrotestosterone are also reduced. Follicle-stimulating hormone levels are usually normal, but this is an inappropriate response when there is a low circulating testosterone level. Luteinizing hormone levels are appropriately elevated; prolactin levels are usually abnormally high.

HEMATOLOGIC MANIFESTATIONS

The anemia of CRF is normochromic and normocytic and is caused principally by suppressed erythropoiesis, although shortened red cell survival may also play a minor role. Erythropoietin deficiency due to renal parenchymal damage is the predominant cause of suppressed erythropoiesis; inhibitors of erythropoiesis have also been implicated as contributory factors. The red cell survival is shortened by 25% to 30% as the result of extracellular factors: red blood cells from uremic patients have a normal life span when transfused into normal persons, but normal red blood cells have a shortened survival time when exposed to uremic serum.

The pathophysiologic cause of the increased tendency to bleeding is related to abnormal platelet function and impaired platelet/vessel wall interactions. There is often prolongation of the bleeding time, and this can be exaggerated by the severity of the anemia. The platelet count is usually normal or slightly low, and there is no prolongation of the prothrombin or partial thromboplastin time. The impairment in platelet adhesiveness may be due to an intrinsic dysfunction of GPIIb-IIIa, a platelet membrane glycoprotein complex that normally plays a role in platelet aggregation and adhesion by binding to von Willebrand's factor. Studies in uremic patients have shown that platelet nitric oxide synthesis is increased and that uremic plasma stimulates nitric oxide production by cultured endothelial cells. Nitric oxide is an inhibitor of platelet aggregation.

Altered membrane arachidonic acid metabolism may also contribute to platelet dysfunction in uremia; there is ineffective synthesis of thromboxane by platelets and excess prostacyclin production by blood vessels. Thromboxane is a potent vasoconstrictor and activator, whereas prostacyclin is a potent vasodilator and antagonist of platelet aggregation. Dialysis can correct the increased tendency to bleeding in part, implying that circulating uremic toxins are a major cause of platelet dysfunction. Desmopressin (DDAVP) has some therapeutic utility in most patients with uremic bleeding and appears to act by increasing the release of factor VIII: von Willebrand's factor multimers from endothelial storage sites. Conjugated estrogens are also of therapeutic benefit because they can increase platelet reactivity, possibly by limiting nitric oxide production. The neurologic, cardiovascular, and musculoskeletal manifestations of uremia are presented in [Table 141.2](#) and are discussed in the subsequent sections.

TABLE 141.2. MANIFESTATIONS OF THE UREMIC SYNDROME

CLINICAL FEATURES

The symptoms of CRF depend on its severity, or the degree of reduction in GFR, and on the rapidity with which the reduction in GFR develops. In slowly progressive states, most patients remain virtually asymptomatic until far-advanced renal failure ensues (the acute discovery of chronic disease). The constellation of uremic symptoms that eventually develop is protean, reflecting malfunction of several organ systems, most notably the neuromuscular, cardiovascular, and gastrointestinal systems (Table 141.2). The initial symptoms may be so insidious that the patient is aware of them only in retrospect, after effective management has been instituted. In general, when uremic symptoms are present, the physician may conclude that the renal failure is advanced (GFR less than 10 to 15 mL per minute). Absence of symptoms, however, still may be associated with equally severe renal failure and may be life-threatening. One must then rely on physical signs and the laboratory evaluation to assess the severity of kidney damage.

HISTORY

In evaluating the chronicity of renal failure, the clinical history should document previous elevations in blood pressure, proteinuria, or hematuria. This information is usually available from school, life insurance, military service, or clinical records. Generalized manifestations of CRF include fatigue, malaise, and lassitude. Gastrointestinal symptoms, such as anorexia, nausea, vomiting, a metallic taste in the mouth, and hiccups, are common. Cardiovascular manifestations are sometimes prominent and consist of dyspnea, orthopnea, edema, and pericardial chest pain. Neuromuscular manifestations are typical and vary in severity; they include impaired mentation, diminished ability to concentrate, insomnia, irritability, headache, muscle cramps, and twitching. Severe encephalopathy can develop and progress to confusion, stupor, seizures, and coma. Peripheral neuropathy may manifest initially as paresthesias, with subsequent disturbances of motor function, including muscle weakness and atrophy. The restless leg syndrome refers to a persistent and extremely uncomfortable sensation in the lower extremities that can be relieved by movements of the legs. Autonomic neuropathy, especially in the diabetic patient, can also develop and result in impaired bladder and bowel function. Skin manifestations include itching and bruising. Genitourinary complaints, such as nocturia, amenorrhea, and erectile dysfunction, also may be present.

PHYSICAL EXAMINATION

The signs of CRF are often multiple and nonspecific, and they usually do not appear until late in the course of the disease. The patient may appear chronically ill, with weight loss and muscle wasting. Dermal manifestations include pallor, yellow-brown discoloration, hyperpigmentation, ecchymosis, and petechiae. Inspection of the head may detect conjunctival or corneal calcifications, retinopathy characteristic of hypertension, and epistaxis. Cardiovascular findings include hypertension, cardiomegaly, edema, and, in the preterminal stages of renal failure, a pericardial friction rub. If they are present, Kussmaul's respirations reflect the severity of an underlying state of metabolic acidosis. Severe renal osteodystrophy can give rise to bone tenderness, fractures, and proximal muscle weakness.

Neuromuscular signs vary in intensity and severity during the course of the disease. Mental status findings include confusion, drowsiness, stupor, or coma. Myoclonic twitches and asterixis (uremic flap) are typical of advanced uremia. Uremic peripheral neuropathy is a distal, symmetric, mixed type of sensorimotor neuropathy. As in other neuropathies, injury is directly related to axon length; longer axons are affected first, resulting in symptoms that are more prominent in the lower extremities. Sensory abnormalities precede motor signs and may include loss of vibratory and position sense. If motor neuropathy develops, deep tendon reflex loss and footdrop may be evident. Mononeuropathies, such as carpal tunnel syndrome or peroneal palsy, will develop occasionally. Autonomic neuropathy can be detected by impaired cardiovascular reflexes, such as the Valsalva maneuver.

LABORATORY DATA

The diagnosis of renal failure is established by documenting an elevation in BUN and serum creatinine concentrations. With stable CRF, the BUN and serum creatinine rise proportionately, and a ratio of BUN to creatinine of 10:1 to 15:1 is typical. The BUN is disproportionately elevated to the creatinine with urinary obstruction, cardiac decompensation, high protein intake, catabolism associated with trauma, sepsis, corticosteroid therapy, or gastrointestinal bleeding. The creatinine is disproportionately elevated with malnutrition, liver disease, or rhabdomyolysis. When the GFR falls below 25 to 30 mL per minute, other laboratory abnormalities may be seen, including anemia (characteristically normochromic normocytic), metabolic acidosis, hyperphosphatemia, hypocalcemia, and hyperuricemia. Hyperkalemia, a late manifestation of CRF, typically occurs when the GFR falls below 10 to 15 mL per minute.

PATIENT EVALUATION

A primary question in the evaluation of the patient with renal failure is whether the failure is chronic or acute. Chronicity implies stability and thus presents less of an immediate threat to the patient than does acute renal failure. Acute renal failure implies reversibility; CRF is typically irreversible, although some specific forms of CRF are remediable or preventable. The approach to acute renal failure takes into account different considerations and is discussed in Chapter 140. A second question is whether there are recognizable factors that contribute to or aggravate renal failure (Table 141.3). Recognition and treatment of these complicating factors often proves valuable in halting the progression of kidney damage and may even result in improvement in renal excretory function.

- Hypovolemia/hypotension
- Hypertension
- Reflux nephropathy
- Congestive heart failure
- Nephrotoxins
- Pericarditis/tamponade
- Hypercalcemia
- Sepsis
- Atheroembolic diseases

TABLE 141.3. POTENTIALLY REVERSIBLE FACTORS PRODUCING ACUTE DECOMPENSATION OF CHRONIC RENAL FAILURE

A definite diagnosis should then be attempted, specifically considering disease processes that could be alleviated (Table 141.4). When the patient with advanced renal failure is first seen, it may be difficult or impossible to identify with certainty, even by histologic examination, the disease process responsible for initiating the damage. Nevertheless, some signs of the primary disease may persist and could be helpful in determining the cause of CRF. When remediable disorders or complicating conditions cannot be found, the physician must decide on a plan of maintenance therapy. Conservative management can be instituted for months or

years and includes measures to slow the progression of CRF, prevention of complications, and therapy to avert or relieve the symptoms of uremia. Eventually, when ESRD ensues, conservative management may not suffice, and the next move is to refer the patient to a consulting nephrologist to institute replacement therapy by long-term dialysis (see [Chapter 165](#)) or renal transplantation (see [Chapter 166](#)).

Malignant hypertensive nephrosclerosis
Renal artery stenosis
Wegener's granulomatosis
Systemic lupus erythematosus
Multiple myeloma
Obstruction
Reflux
Hypercalcemic nephropathy
Interstitial nephritis
Cholesterol embolization
Lead nephropathy

TABLE 141.4. POTENTIALLY REMEDIABLE CAUSES OF CHRONIC RENAL FAILURE

DOCUMENTATION OF CHRONICITY

The best evidence that renal failure is chronic is documentation of a previous sustained reduction in GFR. This information is best obtained from records indicating elevations in BUN, serum creatinine, or both. Equally valuable are ancillary findings that reflect long-standing renal failure, such as small kidneys or renal osteodystrophy. Although radiographic or sonographic determination of shrunken kidneys is almost always associated with chronic rather than acute renal failure, normal-sized or even large kidneys can be associated with CRF caused by adult polycystic kidney disease, diabetic nephropathy, HIV nephropathy, malignant hypertensive nephrosclerosis, multiple myeloma, amyloidosis, and, occasionally, obstructive uropathy or glomerulonephritis. For patients who have normal-sized kidneys, a renal biopsy may be required to clarify the nature of the disease and to determine its chronicity.

Radiographic evidence of renal osteodystrophy, particularly osteitis fibrosa, is a reliable indication of long-standing renal failure, because significant hyperparathyroidism must be present for at least 1 year for diagnostic changes to appear on radiographic film. A long-standing history of nocturia or pruritus also may suggest chronicity. A family history of hereditary renal disease, such as polycystic kidney disease or Alport's syndrome, can be helpful in some patients. Anemia, hyperphosphatemia, hypocalcemia, and acidosis are relatively poor indicators of chronicity and often correlate better with the severity of renal failure; these manifestations frequently develop over a period of 10 days to 2 weeks in most cases of severe acute renal failure.

REVERSIBLE FACTORS COMPLICATING CRF

Recognizing and treating potentially reversible factors that can exacerbate renal failure ([Table 141.3](#)) are important steps in the attempt to delay the development of ESRD. If the information is available, it is useful to plot the relationship between $1/S_{Cr}$ and time. A steep deviation in the slope of the line at the time of initial evaluation of the patient may indicate the presence of reversible factors that are superimposed on the natural progression of the disease.

Hypovolemia

The inability to conserve sodium adequately when sodium intake is decreased and the impairment in maximal urine concentration may lead to excessive urinary losses of salt and water. The ensuing hypovolemia reduces renal perfusion, further worsening renal failure. This may be the most common exacerbating event in the course of CRF. Hypovolemia often develops because of poor salt intake related to uremic symptoms (anorexia and nausea), extrarenal salt losses (diarrhea, laxative intake, gastrointestinal hemorrhage, or vomiting), and renal electrolyte losses (excessive diuretic therapy or osmotic diuresis). Assessment of the patient's hemodynamic status and institution of salt and water replacement are important steps to improving renal function.

Hypertension

Accelerated or malignant hypertension of any origin can impair renal function acutely but often reversibly. Hypertension may be a consequence of renal parenchymal diseases or renovascular disorders, or it may develop from nonrenal causes. The major factor that leads to hypertension in patients with renal disease, who were previously normotensive, is sodium retention. Increased peripheral resistance is another factor that contributes to hypertension, and this may be due to inappropriately high renin and angiotensin II production or activation of the sympathetic nervous system. Plasma levels of catecholamines are elevated primarily as the result of decreased renal clearance and reduced neuronal uptake and degradation. In general, severe hypertension that is poorly controlled can induce arteriolar nephrosclerosis and accelerate the progression of renal failure. Proper control of hypertension has been shown to slow the progression of renal damage and at times can lead to measurable improvement in renal function. Conversely, overzealous lowering of blood pressure using diuretics or vasodilators can compromise renal perfusion and further exacerbate renal failure.

The use of angiotensin-converting enzyme inhibitors or angiotensin II type 1 receptor antagonists to treat hypertension caused by bilateral renal artery stenosis or unilateral renal artery stenosis of a solitary functioning kidney is a well-recognized factor predisposing to the development of reversible acute renal failure. In the context of diminished renal blood flow due to arterial disease, the reduced GFR is maintained by the effect of angiotensin II on constricting the efferent arteriole. When production of angiotensin II is inhibited, efferent arteriolar dilatation results, which reduces glomerular hydraulic pressure and, in turn, glomerular filtration.

Congestive Heart Failure

Because sodium retention is common, congestive heart failure occurs frequently in patients with CRF. In addition to fluid overload, uremic patients can suffer from myocardial dysfunction because of concentric left ventricular hypertrophy from hypertension, an increased incidence of coronary artery disease, or ischemic cardiomyopathy. Finally, myocardial dysfunction can develop in diseases causing renal failure, such as diabetes, hypertension, atherosclerosis, or amyloidosis. Impaired cardiac function can lead to a precipitous decrease in GFR, which can be restored to its initial value if appropriate therapy of cardiac failure is instituted.

Pericarditis

Inflammation of the visceral and parietal pericardium often manifests in patients with slowly progressive severe uremia and may develop into hemorrhagic serositis. Pericarditis can be complicated by cardiac tamponade. This complication further impairs renal perfusion and function and often precipitates uremic symptoms. Pericardiocentesis can be lifesaving, and it improves cardiac output and renal function.

Infections and Catabolism

In the absence of associated obstruction, renal parenchymal infection rarely causes renal failure, except when the infection is fulminant or is complicated by multiple renal abscesses or papillary necrosis, particularly in the diabetic patient. Tuberculosis of the kidney is a well-known cause of renal failure, especially when ureteral constriction ensues. Extrarenal infections with septicemia, especially when they are associated with hypotension, can augment renal vascular resistance and impair renal blood flow, resulting in acute renal failure. Catabolic stresses of infection and surgery, gastrointestinal bleeding, or therapy with corticosteroids or tetracycline can result in marked azotemia and can be associated with the early development of uremic symptoms.

Obstruction

Obstruction of urine flow can contribute to impairment of renal function, particularly if it is associated with infection. The causes, diagnostic approach, and

management of obstructive uropathy are outlined in [Chapter 138](#) and [Chapter 158](#). Relief of obstruction and treatment of any coexisting infection can be rewarding, because variable degrees of renal functional improvement can be achieved.

Reflux

Urine reflux, with or without urinary tract infection, can result in chronic pyelonephritis; it is the most common cause of CRF in children and adolescents. The prognosis is largely determined by the extent of kidney scarring at the time of evaluation. Surgical correction of reflux, especially if it is performed at an early age, can stabilize GFR and delay the development of ESRD.

Nephrotoxins

Various nephrotoxic agents are responsible for exacerbating renal failure in many patients with established chronic renal insufficiency. These agents include drugs (e.g., antibiotics, analgesics, nonsteroidal anti-inflammatory agents, diuretics), heavy metals (e.g., lead and cadmium), and radiographic contrast material. These agents produce renal injury through various mechanisms of action, such as acute interstitial nephritis (see [Chapter 151](#)), renal prostaglandin inhibition, diuretic-induced salt depletion, renal ischemia, or direct tubular injury. Usually, identification of the suspected agent and its early withdrawal can lead to stabilization or significant improvement in renal function.

Hypercalcemia

Sustained or severe hypercalcemia of any origin can result in impaired renal function through any of several mechanisms of action, including acute and reversible renal vasoconstriction leading to decreased GFR, hypovolemia from salt depletion (stemming from anorexia, nausea, vomiting, or diuretic therapy), water depletion (because of impaired concentration), chronic and irreversible renal parenchymal damage from nephrocalcinosis, and urinary obstruction from nephrolithiasis. Prompt reduction of an elevated serum calcium level, therefore, can improve renal hemodynamics, increase GFR, and halt the progression of renal parenchymal damage.

REMIABLE CAUSES OF CHRONIC RENAL FAILURE

When no potentially reversible complication can be identified as a contributor to acute decompensation in renal function, it generally is assumed that the GFR at the time of diagnosis of CRF is permanently and irreversibly depressed. There are a few specific causes of remediable CRF, however. With appropriate intervention in these situations, the GFR can be stabilized for months or years, modifying the need for long-term dialysis. These situations ([Table 141.4](#)) include malignant hypertensive nephrosclerosis (after prolonged, successful control of blood pressure and management of coexisting cardiac failure), bilateral renal artery stenosis (after successful angioplasty or corrective surgery), active Wegener's granulomatosis or lupus nephritis (with proper management using corticosteroids and cytotoxic drugs), multiple myeloma (after control of hypercalcemia and hyperuricemia and institution of effective chemotherapy), analgesic-abuse nephropathy (after withdrawal of analgesics), hypercalcemic nephropathy (with control of the elevated serum calcium level, such as that after parathyroidectomy), obstructive renal disease and reflux nephropathy (after relief of obstruction or antireflux surgery), and some cases of interstitial nephropathy (when drugs or toxins are removed).

In most cases, the diagnosis is made by the history and physical examination and standard diagnostic studies. Because the remediable causes are so important, it is useful to separate this list and to ensure that these diagnoses have been considered. Confirmation of the suspected diagnosis may require interventional studies. Renal biopsy is often of limited value in advanced renal disease, because end-stage histologic findings are relatively nonspecific. Nevertheless, if there is reason to suspect one of the vasculitides and if the kidney size is relatively normal, biopsy is indicated to guide therapy. Kidney biopsy may also provide useful prognostic information. For instance, the presence of severe tubulointerstitial fibrosis, independent of the primary etiologic lesion, implies irreversibility and a tendency toward progression of renal failure.

Renal artery stenosis may require interventional studies for diagnosis and management. This diagnosis can be pursued in a patient with renal insufficiency and in the absence of other definable causes, especially if there is accelerated or difficult-to-control hypertension, abdominal bruits, evidence of significant vascular disease elsewhere, and episodes of sudden-onset or "flash" pulmonary edema. The diagnosis can be established by digital subtraction angiography or magnetic resonance angiography. There are several published series of patients with renovascular disease with initial symptoms of moderate to advanced renal insufficiency in whom balloon angioplasty (often with stenting) or surgical reconstruction produced marked improvement in renal function and blood pressure control.

Another syndrome, lead nephropathy, has been reported to be both common and potentially reversible in patients without other obvious conditions that produce renal insufficiency. The diagnosis is suggested by the coexistence of renal insufficiency, arthritis resulting from gout, and a history of lead exposure and is confirmed by measurement of urinary lead excretion after administration of calcium ethylenediaminetetraacetic acid (EDTA). Treatment involves cessation of lead exposure and a course of EDTA chelation. Anecdotal reports have verified that chelation therapy can halt or partially reverse the course of chronic renal insufficiency. Studies to date are insufficient to warrant the diagnostic use of calcium EDTA infusions in the absence of the described disease characteristics.

DIFFERENTIAL DIAGNOSIS

CRF is the end result of damage to kidneys arising from a multiplicity of causes ([Table 141.1](#)). The initial factors leading to kidney failure are numerous and include immunologic insults, obstruction to urine flow, metabolic disturbances, infections, vascular disorders, hereditary diseases, neoplasia, trauma, and radiation. It is often useful to categorize the renal insult according to anatomic involvement that is predominantly glomerular, tubulointerstitial, obstructive, or vascular. Renal involvement also can be divided into either primary renal diseases (usually glomerular), in which the kidney is the sole afflicted organ, or renal disorders that accompany or complicate systemic illnesses.

The incidence of CRF in the community and the relative distribution of each of its causes remain difficult to establish. Data are available on the comparative importance of the various sources of renal failure in the population of adults with ESRD at the onset of maintenance dialysis. The glomerulopathies are the most important causes; they account for 30% of all cases. Diabetic glomerulosclerosis is the most common cause of renal failure among the systemic disorders and affects an increasing fraction (up to one-third) of the patients currently treated for ESRD. Interstitial renal disease and polycystic kidney disease account for about 20% and 10%, respectively, of cases of CRF among patients with ESRD. The relative contribution of hypertensive arteriolar nephrosclerosis varies with race. In blacks, it may affect a third of all ESRD patients, but it accounts for less than 10% of cases among the white population.

The exact cause of CRF is never established in many patients. This is usually the case even if histologic studies are available, because they may not be diagnostic in the context of far-advanced renal failure with bilaterally shrunken and scarred kidneys (see [Chapter 164](#)). Sometimes clues to the cause can be obtained from the history, physical examination, or specific laboratory studies.

HISTORY

A long-standing history of hypertension may suggest the diagnosis of arteriolar nephrosclerosis. Previous complaints of prostatism, stone passage, or bladder dysfunction may indicate obstructive uropathy. Recurrent urinary tract infection or analgesic abuse may reflect interstitial nephritis. A positive family history is often present in patients with polycystic kidney disease. Symptoms of long-standing diabetes mellitus often accompany the development of diabetic nephropathy. Symptoms of systemic lupus erythematosus or other vasculitides are also indicative in some patients with otherwise unexplained renal failure. HIV-associated nephropathy is typically present in patients with risk factors or symptoms of the infection. Chronic extrarenal infections or inflammation may indicate the presence of amyloidosis. A history of illicit alcohol abuse ("moonshine"), gout, and hypertension may suggest the diagnosis of lead nephropathy.

PHYSICAL EXAMINATION

Funduscopy findings of microaneurysms, exudates, and neovascularization strongly suggest the association of diabetic glomerulosclerosis. Palpable, irregularly enlarged kidneys are indicative of polycystic kidney disease. A large prostate or enlarged urinary bladder may be a sign of bladder outlet obstruction. A facial rash and arthritis can reflect lupus nephritis. Hearing loss and lenticular distortion often indicate the presence of hereditary nephritis (Alport's syndrome). The finding of angiokeratomas strongly supports the diagnosis of Fabry's disease. Dermal manifestations of scleroderma may point to the presence of kidney disease associated with progressive systemic sclerosis.

LABORATORY STUDIES

The urinalysis results are typically abnormal in most stages of renal failure and may show varying degrees of proteinuria, hematuria, pyuria, and casts. Heavy proteinuria and red blood cell casts are helpful in pinpointing glomerulonephritis. Broad and waxy casts are seen in CRF of almost any origin and reflect nonspecific dilatation of the renal tubules. In many forms of CRF (e.g., hypertensive nephrosclerosis, obstructive uropathy, polycystic kidney disease, hypercalcemic nephropathy), the urinalysis results can show minimal abnormalities and thus may be misleading. Other laboratory abnormalities may be more specific, because they can indicate the cause of CRF. Abnormal serum and urine electrophoresis results may suggest multiple myeloma. Urine immunoelectrophoresis is a very sensitive diagnostic test. A positive sickle cell test indicates sickle cell nephropathy, which is confirmed by performing hemoglobin electrophoresis. Renal disease stemming from infective endocarditis requires documentation by positive blood cultures. Positive urine cultures for mycobacteria point to renal tuberculosis. Depressed serum complement levels and positive tests for antinuclear and anti-DNA antibodies are important clues in diagnosing lupus nephritis. Antibodies for glomerular basement membrane are present in Goodpasture's syndrome and antiglomerular basement membrane nephritis; positive antineutrophil cytoplasmic antibodies are helpful in the diagnosis of Wegener's granulomatosis or other systemic vasculitides.

Radiographic studies often help establish the cause of renal failure. Renal ultrasonography, the primary approach for almost all patients, is a noninvasive, cost-effective procedure that provides valuable data, such as the presence of a solitary kidney, small kidneys with cortical atrophy, a dilated pelvicalyceal system, cystic diseases, and renal calculi. It is occasionally useful to include an ultrasonographic examination of the urinary bladder to detect outlet obstruction or other abnormalities. A plain abdominal radiographic film of good quality also may provide helpful clues on renal size and contour and show whether radiopaque calculi and nephrocalcinosis are present. The use of urography to evaluate advanced renal failure has been limited in recent years, partly because of the fear of precipitating contrast-induced acute renal failure in susceptible patients and partly because of the wide use of ultrasonography. It may still be indicated in some situations, however (e.g., establishing evidence of papillary necrosis in analgesic nephropathy). In reflux nephropathy, a voiding cystourethrogram can confirm the diagnosis and avoid intravenous administration of contrast medium. Unfortunately, renal biopsy is of limited value in determining the cause of renal failure, because the histologic findings may be too nonspecific to detect the initial insult. Nevertheless, in some forms of unexplained renal failure associated with normal-sized kidneys, renal histologic studies may be helpful, as discussed earlier.

CONSERVATIVE MANAGEMENT

After ruling out potentially treatable causes of renal failure and after looking for the reversible factors that can produce deterioration of renal function regardless of the underlying cause, it is appropriate to consider prophylactic and therapeutic methods that can improve the patient's quality of life, minimize symptoms, and prevent long-term complications. The following factors should be evaluated to generate a prescription tailored to each patient's needs.

CONTROL OF BLOOD PRESSURE

As renal failure progresses, hypertension, most often due to salt and water accumulation, inexorably develops. Hypertension can accelerate the progression of renal failure and can contribute to atherosclerotic cardiovascular disease. Meticulous blood pressure control, therefore, is an important goal of therapy. In part, this can be accomplished with regulation of sodium balance, as discussed later herein, but it often requires the addition of one or more antihypertensive agents to maintain the blood pressure in the normal range (see [Chapter 30](#)). Care should be taken not to lower the blood pressure too much, which may impair perfusion to vital organs, including the kidneys.

Treatment of hypertension is indicated at any stage of CRF. The superiority of angiotensin-converting enzyme inhibitors in slowing the progression of CRF has been documented in many large-scale studies both in diabetic and nondiabetic patients. The optimal level of blood pressure control is uncertain, but the results of long-term studies have indicated that systolic blood pressures of 125 to 130 mm Hg and diastolic pressures of 80 mm Hg or lower are desirable, particularly in patients excreting more than 2 to 3 g of urinary protein per day. Concurrent diuretic therapy will often be necessary, since fluid overload is present in most patients with CRF. Angiotensin II type 1 receptor antagonists are effective antihypertensive and antiproteinuric agents, but it is still not known whether these agents can slow the progression of CRF. If specific side effects from angiotensin-converting enzyme inhibitors develop, such as cough, a receptor antagonist may be substituted.

PROTEINURIA

Heavy proteinuria can contribute to renal disease progression. For this reason, one aim of therapy is to diminish protein excretion by at least 50%, which may reflect reduced intraglomerular pressure and improved glomerular permselectivity. Even normotensive patients should be treated with antihypertensive agents if they have heavy proteinuria, preferably by angiotensin-converting enzyme inhibitors. Some clinical trials in patients with CRF and heavy proteinuria have established that verapamil, diltiazem, and angiotensin II type 1 receptor antagonists effectively diminish the amount of urinary protein excretion.

MINERAL METABOLISM

Owing to a combination of hyperphosphatemia and decreased production of calcitriol, hypocalcemia and secondary hyperparathyroidism always complicate renal insufficiency. Crippling bone disease in patients with ESRD can be prevented by prophylactic attention at earlier stages of the disease. The therapeutic goal is to maintain near-normal values for serum calcium, phosphate, and parathyroid hormone. This is accomplished in a series of steps. First, phosphate intake must not be excessive (less than 0.8 g per day). Protein restriction, which may be instituted for other reasons, as discussed later, reduces phosphate intake.

Second, when serum phosphate exceeds 5 to 5.5 mg per deciliter, it is appropriate to prescribe phosphate-binding agents with meals, preferably calcium carbonate or calcium acetate. Such therapy can also help maintain a normal level of serum calcium. Magnesium-containing antacids should be avoided by patients with impaired renal function, because of the risk of hypermagnesemia. Aluminum hydroxide is a potent phosphate-binding agent, but its use should be limited to a few days when severe hyperphosphatemia develops, in order to avoid aluminum toxicity. Sevelamer (Renagel®) hydrochloride is a novel non-aluminum- and non-calcium-containing phosphate binder that can be used if a patient shows signs of hypercalcemia (usually because of excess calcium supplements and vitamin D therapy) or if the calcium \times phosphate product in the serum is above 75. Aluminum is absorbed from the gastrointestinal tract; thus, if urinary aluminum excretion is impaired, aluminum accumulates in the bone, brain, and other tissues. The most common toxic effect of aluminum is a type of adynamic osteomalacia that is resistant to treatment with calcitriol. The mechanism of action appears to be accumulation of aluminum in mineralizing bone, causing impaired calcification. Another syndrome linked to aluminum toxicity is dialysis dementia, characterized by seizures, aphasia, facial grimacing, paralysis, and, ultimately, coma. High aluminum levels have been associated with microcytic anemia.

Third, if the serum calcium level falls below 8.5 mg per deciliter despite well-controlled serum phosphate levels, it is reasonable to add calcitriol (0.25 to 1 μ g per day) in conjunction with calcium supplements (more than 1 g per day of elemental calcium), which can be given between meals to optimize gastrointestinal calcium absorption.

SODIUM AND WATER INTAKE

With progression of renal disease, the kidney's capacity to adjust to marked variations in sodium and water intake becomes limited. The patient is at risk of sodium retention with high levels of intake (resulting in edema, congestive heart failure, and increased blood pressure) and is equally at risk of hypovolemia at low levels of intake (leading to hypotension and accelerated renal insufficiency). In general, the asymptomatic patient should be instructed to follow a diet that contains 4 to 6 g of sodium; this amount should be reduced to 2 to 4 g in the context of edema or significant hypertension and should be raised if hypotension, excessive renal or extrarenal salt wasting, or a sudden decline in GFR ensues. A few patients with interstitial nephritides, obstructive uropathy, or medullary cystic disease may excrete large amounts of salt and water. In these cases, dietary salt restriction leads to markedly negative sodium balance and loss of renal function.

The simplest method of avoiding these problems is to monitor body weight daily and to adjust dietary salt to maintain a constant weight. In patients with advanced renal insufficiency, water balance is generally governed by sodium balance, and patients who maintain a normal serum osmolality or sodium concentration can be left to their own instincts regarding water intake. They should be instructed, however, about the loss of adaptability with renal insufficiency and should avoid either severe water restriction or excess intake that is not stimulated by thirst.

POTASSIUM INTAKE

Despite significant loss of function, the kidney retains a remarkable capacity to excrete potassium until the GFR drops below 10 mL per minute. In the absence of iatrogenic manipulation, hyperkalemia is usually not seen before the development of ESRD. Hypokalemia is rare, except in situations of excess potassium losses (diuretics, diarrhea). Many superimposed factors can exacerbate problems with potassium balance, however. The patient may be placed on a low-salt diet with salt substitutes (which contain potassium chloride) or may develop intercurrent illnesses that increase potassium intake (gastrointestinal bleeding). Cellular potassium uptake may be impaired (hyperglycemia with insulin deficiency, β -blockers). Renal potassium excretion may also be limited (volume contraction, triamterene, amiloride, spironolactone, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents). In addition, some renal diseases (diabetes, obstruction, interstitial nephritis) are complicated by hypoaldosteronism (with or without hyporeninism) or an impaired renal response to aldosterone, which can interfere with potassium secretion in the collecting duct. In these instances, avoidance of potassium-rich foods and potassium-sparing diuretics usually suffice; if not, addition of the ion-exchange resin sodium polystyrene sulfonate (Kayexalate) is helpful. As discussed later, the inability to control hyperkalemia in end-stage patients is an indication for dialysis.

ACID-BASE BALANCE

As the GFR falls below 15 to 20 mL per minute, the ability to excrete hydrogen ions becomes significantly limited, owing to the decreasing renal mass and consequent insufficient total renal ammonia production and excretion. At this point, significant metabolic acidosis may ensue. Many authors recommend therapy when the serum bicarbonate level falls below 20 mEq per liter. To the extent that chronic metabolic acidosis with a serum pH of less than 7.3 reduces bone density, increases respiratory work, impairs cardiovascular catecholamine responsiveness, and aggravates muscle protein catabolism, it is reasonable to begin alkali therapy at a bicarbonate level of 18 to 20 mEq per liter, rather than depending on respiratory compensation. Long-term alkali therapy to maintain a near-normal serum bicarbonate concentration may prevent bone resorption and muscle catabolism in patients with CRF. In the absence of edema or significant hypertension, sodium bicarbonate or citrate can be used.

Additionally, calcium carbonate or calcium acetate can be prescribed as adjunct alkali replacement, particularly in patients with a tendency toward hypocalcemia. Sodium citrate should be avoided when a patient is placed on aluminum-containing phosphate binders, because of the enhanced gastrointestinal absorption of aluminum and the increased risk of aluminum toxicity. Patients with advanced renal failure are susceptible to rapid worsening of acidosis when the demand for acid excretion is increased, as in the context of diarrhea. In these situations, larger amounts of alkali may be required to maintain near-normal serum bicarbonate levels.

DRUG DOSAGE

Many drugs depend on renal excretion, and the prescription of usual dosages may result in excessive serum levels and subsequent toxicity. Medications that may require dosage alteration include digoxin, many antibiotics, long-acting barbiturates, and insulin. A detailed listing of the necessary modifications is provided in [Chapter 167](#), and tables published elsewhere should be consulted when reviewing the patient's medication list. Some drugs should be avoided because they are particularly dangerous to the patient with renal insufficiency. These include any magnesium-containing compounds, nonsteroidal anti-inflammatory drugs, potassium-sparing diuretics, and radiographic contrast materials.

PROTEIN INTAKE

Three issues merit consideration in designing the appropriate dietary program for a patient with CRF. The most obvious is the patient's complaint of common symptoms of uremia, which usually develop as the BUN exceeds 90 mg per deciliter. Reducing dietary protein intake improves anorexia, nausea, vomiting, worsening metabolic acidosis, and hyperkalemia. Simple limitation of protein intake, however, is insufficient. The second issue that must be considered is the adequacy of caloric intake and essential amino acids, which can be achieved by providing biologically useful protein mixtures. These issues have led to the development of reasonably palatable diets that provide symptomatic improvement without evidence of malnutrition. The usual protein-restricted diet supplies an intake of 0.6 g per kilogram of body weight of a mixed protein diet.

The third issue that has received considerable attention is the use of a low-protein diet early in the course of renal insufficiency, not to ameliorate uremic symptoms but to retard the progression of renal disease. This approach is based on the hyperfiltration hypothesis discussed earlier. There are scattered reports that dietary manipulation can slow the progression of CRF, including diabetic nephropathy. The results of the Modification of Diet in Renal Disease Study, a recently completed large-scale, randomized trial in nondiabetic patients, suggests that long-term adherence to the low-protein diet is well tolerated and tends to slow the progression of renal failure, although this effect is relatively small, requires at least 2 to 3 years of follow-up to become apparent, and has less of an impact on deterioration of GFR than does tight control of elevated blood pressure with antihypertensive agents that include converting enzyme inhibitors.

Thus, if attention is paid to compliance, palatability, and adequate intake of calories, essential amino acids, and vitamins, the prescription of a low-protein diet early in the course of renal insufficiency, in conjunction with strict control of hypertension, is a relatively safe and beneficial approach to reducing the rate of decline in GFR.

ANEMIA

The introduction of recombinant erythropoietin therapy has dramatically changed our approach to the management of anemia of CRF. This therapy is effective in correcting anemia in virtually all patients, even though red cell survival is shortened. Hormone replacement therapy imparts freedom from the complications of repeated blood transfusions, abatement of symptoms of anemia, and overall improvement in quality-of-life parameters, such as brain and cognitive function, sexual potency, and exercise tolerance. Patients should be screened for other causes of anemia, such as iron deficiency, blood loss, multiple myeloma, and vitamin deficiency. Because iron use is markedly augmented during therapy with erythropoietin, large amounts of iron supplements should also be administered.

FOLLOW-UP AND REASSESSMENT

Because chronic renal insufficiency is almost invariably progressive, it is important to reassess the management program periodically to prevent and detect complications and to plan for eventual replacement therapy. The history and physical examination can provide evidence of uremia, sodium retention, or hypovolemia and the adequacy of blood pressure control. Electrolytes, calcium and phosphate, BUN, and creatinine levels should be assessed at 4- to 6-month intervals to determine when to alter dietary therapy or to add or subtract drugs. Bone roentgenograms and bone biopsy samples may furnish useful information regarding progressive osteodystrophy. A neurologic examination, supplemented by nerve conduction velocity studies, may be required to assess the progression of existing peripheral neuropathy.

Indications for REFERRAL

With progression of renal insufficiency to end stage, conservative management becomes inadequate for the prevention of symptoms and the control of blood pressure. At this point, an end-stage renal program must be designed. Such symptoms as nausea, vomiting, anorexia, or weight loss may herald the need to initiate dialysis replacement therapy. Objective findings that indicate the need for dialysis include progressive peripheral neuropathy, pericarditis, inadequate nutrition, impaired cognitive function, general malaise and weakness that interfere with the ability to work, congestive heart failure, severe hypertension, significant hyperkalemia, and metabolic acidosis. Ideally, maintenance dialysis should be started when there is significant expectation that without dialysis, uremic symptoms would develop in a short time. Long-term dialysis is usually initiated when the creatinine clearance rate falls below 10 mL per minute. It therefore is prudent to begin planning at an earlier time, even in the absence of symptoms. Referral to a nephrologist is indicated to discuss the relative merits and advisability of various dialysis options or renal transplantation and to decide when to establish access to the circulation. Early referral is useful to prevent the development of severe uremic symptoms, to allow time for maturation of an arteriovenous fistula, to prepare the patient for kidney transplantation, and to allow preparation and evaluation of potential kidney donors.

CHAPTER 142: APPROACH TO THE PATIENT WITH VOLUME DEPLETION AND DEHYDRATION

JAMES A. SHAYMAN

[Pathophysiology](#)
[History and Physical Examination](#)
[Differential Diagnosis](#)
[Laboratory Studies](#)
[Strategies for Optimal Care](#)

PATHOPHYSIOLOGY

Total body water comprises 50% to 70% of the total body weight. Fluid within the body distributes into three major compartments: intracellular, extracellular, and transcellular. The intracellular fluid compartment is the largest, accounting for approximately two-thirds of total body water. The extracellular fluid compartment consists of interstitial and intravascular compartments; approximately 75% of extracellular fluid is interstitial, and the rest is intravascular. Transcellular fluid includes cerebrospinal, intraocular, pleural, peritoneal, and synovial fluids. These fluid compartments are separated from the plasma fluid by a capillary endothelium and a specialized layer of epithelial cells.

The regulation of the size and composition of the body's fluid compartments is a primary requirement for survival. Water balance is a critical factor in determining the composition of the fluid compartment. Alterations in water balance manifest as changes in plasma osmolality and are detected as changes in plasma sodium concentration (see [Chapter 144](#) and [Chapter 145](#)). In contrast, sodium balance is the critical factor in determining the size of the fluid compartment. Alterations in sodium balance are detected as changes in extracellular volume.

The regulation of sodium balance is a consequence of physical factors affecting fluid movement across cell membranes, of the renal handling of sodium, and of a complex effector and effector hormonal and neural network that maintains the volume in each fluid compartment (see [Chapter 9](#)). Physical factors that govern the distribution of fluid between the vascular and interstitial compartments can be understood on the basis of the hydrostatic and colloid osmotic pressures in the capillaries (Starling forces). The hydrostatic pressure of blood entering the capillary promotes the movement of fluid across the capillary endothelium into the interstitial space. This fluid movement is opposed by the plasma oncotic pressure and the hydrostatic pressure of the interstitial compartment. Changes in capillary hydrostatic, interstitial hydrostatic, or plasma oncotic pressure can contribute to a clinically significant redistribution of fluid between the interstitial and plasma compartments.

HISTORY AND PHYSICAL EXAMINATION

The intravascular, interstitial, and transcellular fluid compartments may each be evaluated for signs and symptoms of sodium depletion. The presence of signs and symptoms of sodium depletion depends on both the degree of depletion and on the rapidity of its development ([Table 142.1](#)). Acute decreases of less than 5% of the extracellular fluid volume produce minimal signs and symptoms. Losses of up to 10% of extracellular volume manifest as orthostatic changes in pulse and blood pressure. Fluid losses of 20% or more exceed the capacities of an individual's normal homeostatic defense mechanisms and are associated with shock.

Fluid Compartment	Physical Findings
Intravascular	Orthostatic fall in systolic blood pressure of >15 mm Hg Orthostatic rise in pulse rate >15 beats/min Hypotension while recumbent
Interstitial	Decreased skin turgor
Transcellular	Dry mouth, mucous membranes; decreased intraocular pressure

TABLE 142.1. PHYSICAL FINDINGS WITH EXTRACELLULAR VOLUME DEPLETION

The physical examination plays an important role in the assessment of volume depletion. However, a physical examination provides only a rough estimate of the extracellular volume status and may be difficult to interpret. Orthostatic changes in pulse and blood pressure may be absent in the presence of such sympatholytic agents as β -adrenergic receptor blockers or in patients with autonomic insufficiency, as is common in patients with long-standing diabetes mellitus. Skin turgor may be an unreliable sign in the elderly patient who has diminished skin elasticity. The oral mucosa may be dry in patients who respire through their mouths, independent of their volume status.

DIFFERENTIAL DIAGNOSIS

Volume depletion occurs when sodium losses exceed sodium gains. Because the kidneys are very efficient in their ability to conserve sodium, restriction of sodium intake alone is insufficient to produce sodium deficiency in healthy persons. Negative sodium balance develops with excessive extrarenal or renal sodium losses ([Table 142.2](#)).

Extrarenal sodium losses
Gastrointestinal
With metabolic alkalosis (vomiting, nasogastric suctioning)
With metabolic acidosis (diarrhea, intestinal fistulas)
Cutaneous
Burns
Inflammatory disease of the skin
Excessive sweating
Third-space sequestration
Small-bowel obstruction
Pancreatitis
Peritonitis
Renal sodium losses
With normal renal function
Diuretics
Hypoaldosteronism
With renal impairment
Salt-wasting nephropathy (medullary cystic disease, nephrocalcinosis, interstitial nephritis)
Diuretic phase of acute tubular necrosis
Chronic renal failure

TABLE 142.2. CAUSES OF SODIUM DEPLETION

EXTRARENAL LOSSES

Gastrointestinal losses are a major cause of volume depletion due to extrarenal sodium loss. The composition of the fluid secretion varies along the gastrointestinal tract. Gastric secretions have a high hydrogen ion concentration; therefore, excessive sodium loss from vomiting or nasogastric suction tends to be associated with

metabolic alkalosis. Biliary, intestinal, and pancreatic secretions have bicarbonate concentrations in excess of those found in plasma. Excessive fluid loss from these sources results in the net loss of bicarbonate and in metabolic acidosis. Gastrointestinal secretions at all levels are iso-osmotic relative to plasma, so hypo-osmolality (i.e., hyponatremia) does not develop unless hypotonic fluids (e.g., 0.45% sodium chloride) or isotonic glucose are replaced. Gastrointestinal secretions also have higher potassium concentrations than are found in plasma. Hypokalemia is a common feature of excess gastrointestinal fluid loss (see [Chapter 146](#)).

Clinically significant cutaneous sodium loss may accompany diaphoresis and burns. Because sweat is hypotonic, water loss from the skin is proportionately greater than sodium loss. For this reason, excess cutaneous sodium loss from perspiration (as with strenuous exercise) may result in hypernatremia in addition to significant hypovolemia. Burns and other inflammatory disorders of the skin are often associated with an increase in capillary permeability, resulting in the loss of plasma proteins in addition to sodium and water. The decline in plasma oncotic pressure results in contraction of the intravascular compartment in excess of that seen with an equivalent degree of sodium loss alone.

A significant volume of fluid can be sequestered within the body in a compartment where it cannot be exchanged readily with intravascular or interstitial fluid. Such accumulations can occur in the context of bowel obstruction (with fluid in the bowel lumen or wall), peritonitis (with fluid in the peritoneal cavity), or infection or hemorrhage (with fluid in such areas as the retroperitoneum or limbs).

RENAL LOSSES

Sodium depletion from renal losses can occur with a normally functioning kidney or in renal disease. Such diuretics as loop diuretics (furosemide) and thiazides act on the thick ascending limb of Henle's loop or distal tubule, respectively, to decrease sodium reabsorption. When sodium intake is less than sodium excretion, negative sodium balance results. Negative sodium balance is the desired therapeutic effect for hypervolemic patients, such as those with congestive heart failure. When diuretics are abused, are given at doses in excess of therapeutic requirements, or are active when another cause of volume depletion is present (e.g., vomiting or diarrhea), significant sodium depletion may result.

Osmotic diuretics also may produce sodium depletion. These diuretics may represent exogenously administered compounds (e.g., mannitol) or compounds endogenously present (e.g., glucose). In the latter case, a patient with poorly controlled diabetes may filter glucose in excess of his or her tubular capacity for tubular reabsorption. With both exogenously administered and endogenously produced osmotic diuretics, solutes that are not reabsorbed reduce water reabsorption and lower the luminal salt concentration in the tubule, limiting the concentration gradient for salt reabsorption.

Hypoaldosteronism is another cause of sodium depletion in the context of normal renal function. The modest increase in urinary salt excretion observed with hypoaldosteronism is usually compensated by moderate increases in dietary sodium chloride intake. Patients with hypoaldosteronism are susceptible to significant sodium depletion with extrarenal sodium losses, however, owing to lack of adequate renal compensation.

Renal losses of sodium occur in the context of several renal diseases ([Table 142.2](#)). Common to all these conditions is the inability of the renal tubules to reabsorb sodium at a normal level, even when maximally stimulated. In nonoliguric renal failure or during the diuretic phase of recovery from acute tubular necrosis, this inability is due to intrinsic defects in sodium transport. In chronic renal failure, the surviving nephrons may transport sodium efficiently but lack the collective capacity to handle the increased filtered load of sodium. Salt wasting is a feature of several types of renal disease, including medullary cystic disease, nephrocalcinosis, interstitial nephritis, and Bartter's syndrome.

LABORATORY STUDIES

The serum sodium concentration may be normal, low, or high, depending on the concurrent state of water balance; for this reason, it is not a helpful parameter. The blood urea nitrogen (BUN) concentration is usually elevated disproportionately to the serum creatinine concentration. A ratio of BUN to creatinine of more than 20:1 is indicative of prerenal azotemia. In extrarenal sodium losses, the urinary sodium concentration is typically less than 10 mEq per liter. Urinary sodium concentrations are usually higher than 20 mEq per liter in conditions of volume depletion attributable to diuretics, hypoaldosteronism, or intrinsic renal disease with salt wasting.

STRATEGIES FOR OPTIMAL CARE

Regardless of the origin, volume depletion initially should be treated by restoring the vascular volume. Isotonic saline is typically infused so long as any evidence of hemodynamic compromise persists. Coexisting electrolyte abnormalities, such as metabolic acidosis or alkalosis, should be treated to correct the underlying acid-base disorder. When hemorrhage is the basis of the volume depletion, packed red blood cells should be transfused. After the circulatory hemodynamics are stabilized, the basis for the volume depletion must be established and treatment initiated. When the volume depletion is drug-induced (e.g., by diuretics), the offending agent is withheld. If the patient is deficient in aldosterone, mineralocorticoid therapy may be indicated. If volume depletion stems from salt-wasting nephropathy, increased dietary sodium chloride may be initiated.

CHAPTER 143: APPROACH TO THE PATIENT WITH EDEMA

JAMES A. SHAYMAN

[Pathophysiology](#)
[History and Physical Examination](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PATHOPHYSIOLOGY

Edema is the excessive accumulation of fluid within interstitial spaces. Interstitial fluid accumulation is largely determined by the distribution of fluid between intravascular and interstitial compartments or Starling forces. The distribution of fluid between the intracellular and extracellular compartments is determined by the osmotic forces operating across cell membranes, but the distribution of fluid between the intravascular and interstitial compartments is independent of fluid osmolality. This is because crystalloid solutes penetrate the capillary wall completely. In contrast, colloid solutes, such as plasma proteins, are almost completely confined to the vascular space and contribute an oncotic pressure that exerts a net force across the capillary wall. The colloid osmotic pressure (or oncotic pressure) favoring the movement of fluid into the vascular space is 25 to 30 mm Hg.

The distribution of fluid between the intravascular and interstitial compartments is also determined by hydrostatic forces. Blood entering the capillaries has a mean hydrostatic pressure of 40 to 45 mm Hg. At the arteriolar end of the capillaries, there is a net force of approximately 5 mm Hg, favoring movement of fluid into the interstitial space. The dissipation of pressure and the rise in capillary oncotic pressure by the end of the capillary favors the movement of fluid back into the capillary. The amount of intravascular fluid entering the venules from the capillaries is slightly less than that entering the capillary. This excess fluid is returned to the vascular space through the lymphatic circulation.

Based on the factors regulating the distribution of fluid between the intravascular and interstitial spaces, edema may develop as the result of four primary abnormalities: increased mean capillary hydrostatic pressure, decreased capillary oncotic pressure, increased capillary permeability to protein, or obstruction of lymphatic flow. Most disorders associated with edema are initiated by an alteration in the Starling forces and are perpetuated as a result of the retention of sodium by the kidney.

Normally, expansion of the extracellular fluid compartment results in natriuresis. In generalized edematous states, however, there is a stimulus for the retention of sodium by the kidney. This stimulus is a decline in the effective circulating arterial blood volume perfusing the kidney and other tissues. The decrease in effective tissue perfusion leads to increased release of renin, formation of aldosterone, and higher levels of antidiuretic hormone. The result is an increase in sodium and water retention. Three disorders are associated with generalized edema and renal sodium retention: congestive heart failure, the nephrotic syndrome, and cirrhosis. The decline in effective arterial blood volume in congestive heart failure stems from amplified hydrostatic pressure on the venous side and impaired cardiac output. Liver disease and the nephrotic syndrome cause a decrease in effective arterial volume due to a lowering of plasma oncotic pressure and a redistribution of plasma volume from the vascular to the interstitial space.

HISTORY AND PHYSICAL EXAMINATION

Sodium retention resulting in a generalized edematous state may be associated with pulmonary edema, peripheral edema, or ascites. Patients with pulmonary edema often complain of shortness of breath, dyspnea on exertion, or orthopnea. On physical examination, the patient may show signs of tachypnea and rales. A chest radiograph shows changes suggestive of interstitial edema or alveolar fluid accumulation (see [Chapter 386](#)). Peripheral edema is associated with swollen legs or the presacral accumulation of fluid in the patient at bed rest. Pitting edema is the persistence of a depression in the skin after 10 seconds of pressure applied with the fingers and is usually seen when at least 10 pounds of fluid has accumulated. Patients with ascites complain of increasing abdominal girth. The finding of shifting dullness or a fluid wave on physical examination is indicative of ascites. Ascites can be confirmed by abdominal ultrasonography.

DIFFERENTIAL DIAGNOSIS

Common disorders associated with generalized or localized edema can be categorized based on the primary factor affecting the distribution of fluid between the vascular and interstitial compartments ([Table 143.1](#)). Some disorders appear to produce edema as the result of the inappropriate retention of sodium by the kidney, independent of a primary alteration in Starling forces. These include primary aldosteronism, acute glomerulonephritis, and estrogen administration.

Increased hydrostatic pressure
 Generalized: congestive heart failure
 Localized: venous thrombosis
 Decreased plasma oncotic pressure
 Nephrotic syndrome
 Cirrhosis
 Malnutrition
 Increased vascular permeability
 Generalized: angioneurotic edema
 Localized: burns, histamine, pulmonary toxins, respiratory distress syndrome
 Obstructed lymphatic flow
 Tissue irradiation, surgery, lymphatic spread of cancer

TABLE 143.1. PATHOPHYSIOLOGIC BASIS OF EDEMA

Generalized edematous states can be associated with pulmonary edema, ascites, or peripheral edema. Ascites and peripheral edema are common with right-sided ventricular heart failure. Right-sided atrial pressure is elevated; it is detected by distention of the jugular veins and can be confirmed by monitoring central venous pressure. Cirrhosis and the nephrotic syndrome are usually associated with normal or low central venous pressure. Patients with the nephrotic syndrome may have periorbital and peripheral edema; pulmonary edema is absent. These patients have proteinuria, with a 24-hour excretion of more than 3.5 g, and hypercholesterolemia. Diagnostic clues useful in distinguishing between generalized edematous disorders are summarized in [Table 143.2](#).

Disease	Source	Diagnostic Laboratory Values
Pulmonary edema	Left ventricular failure	Elevated pulmonary capillary wedge
	Increased pulmonary capillary permeability	Normal pulmonary capillary wedge pressure
Ascites	Right ventricular failure	Elevated central venous pressure
	Hepatic cirrhosis	Normal central venous pressure
Peripheral edema	Right ventricular failure	Elevated central venous pressure
	Hepatic cirrhosis	Normal central venous pressure
	Nephrotic syndrome	3.5 g proteinuria

TABLE 143.2. DIAGNOSTIC CLUES IN EDEMATOUS DISORDERS

STRATEGIES FOR OPTIMAL CARE

DIURETICS

Diuretics are a potent and useful alternative for the treatment of edema. Several classes of diuretics are available; the choice of agent is based on the degree of diuresis desired and the potential of any particular agent to induce untoward effects. Sulfonamide diuretics consist of two groups, the thiazides, including hydrochlorothiazide, and the nonthiazides, including chlorthalidone and metolazone. These agents act primarily at the distal tubule to inhibit the transport of sodium and chloride. Loop diuretics, including furosemide, bumetanide, and ethacrynic acid, act at the thick ascending limb of the loop of Henle to inhibit the Na-K-2Cl cotransporter. These potent agents may increase the urinary sodium excretion to more than 20% of the filtered sodium load. Potassium-sparing diuretics, including spironolactone, triamterene, and amiloride, act in the distal tubule to induce natriuresis and inhibit potassium excretion. Acetazolamide inhibits carbonic anhydrase in the proximal tubule, reducing bicarbonate reabsorption, and secondarily inhibits the reabsorption of sodium and water. In the absence of other diuretics, the sodium and water unabsorbed in the proximal tubule are reabsorbed more distally. Thus, acetazolamide is not a potent diuretic.

If mild diuresis is required, sulfonamide diuretics are often the agent of choice. These agents have poor efficacy in the context of renal insufficiency with glomerular filtration rates below 50 mL per minute. If more potent diuresis is required, a loop diuretic is chosen. Loop diuretics bind to plasma proteins, and their effectiveness depends on the plasma concentration of the unbound drug. Therefore, a single dose is more likely to be effective than a divided dose of the same total amount of diuretic. Diuretics acting in the proximal tubule are not typically used because of their poor natriuretic effects. Secondary hyperaldosteronism is common in cirrhosis. The diuretic of choice is therefore spironolactone, a competitive antagonist of aldosterone.

Diuretics alone often cannot eliminate generalized edema, owing to the secondary physiologic changes that accompany diuretic-induced diuresis. These changes include a decline in renal perfusion with a reduction in glomerular filtration rate, a stimulation of antidiuretic hormone and renin release and aldosterone production, and an increase in plasma protein concentration and peritubular oncotic pressure. These alterations result in the more avid reabsorption of sodium and water by the kidney. Because diuretics lead to the loss of salt and water from the vascular space, aggressive diuresis can bring about intravascular volume contraction and cardiovascular compromise. Finally, diuretics can produce untoward effects, such as hypokalemia, hyponatremia, and hyperglycemia.

DIETARY SODIUM AND WATER RESTRICTION

Restriction of dietary sodium and water intake is an important component in the treatment of generalized edema. In general, sodium and water restriction limits the further development of edema but has little effect on the resolution of edema. This is because the typical edema-forming patient excretes urine containing less than 10 mEq per liter of sodium, with a daily sodium excretion of less than 20 mEq. Because the most severe sodium-restricted diet may consist of 0.5 g (22 mEq) of sodium, it would take several days to lose even 1 L of excess fluid. Therefore, sodium restriction alone is unlikely to result in the resolution of edema and must be coupled with the use of diuretics or adjunctive therapy.

ADJUNCTIVE THERAPY

Elevation of the lower extremities or bed rest often improves the response to diuretics by increasing blood return to the heart and renal perfusion. The use of elastic stockings or bandages over edematous areas helps mobilize interstitial fluid and often promotes natriuresis and diuresis. Occasionally, patients with refractory edema require dialysis with ultrafiltration.

DISEASE-SPECIFIC TREATMENTS

The use of high-volume paracentesis for the treatment of ascites has become popular for patients with cirrhosis. This procedure can bring about a marked reduction in effective arterial blood volume, so patients should always undergo colloid expansion (usually with albumin) at the time of paracentesis. Patients with preexisting renal impairment may experience acute renal failure after high-volume paracentesis. This procedure should therefore be chosen carefully for patients with elevated creatinine levels.

The goal of diuretic therapy of patients with congestive heart failure is to lower the intravascular volume to the lowest level compatible with optimal cardiac output. This is best accomplished by monitoring cardiac filling pressures in the intensive care unit. In the outpatient setting, the physician must rely on measurements of central venous pressure, as assessed by jugular venous distention or hepatojugular reflux. In the patient on an optimal drug regimen, daily weight measurement is perhaps the best measure of volume status. In the compliant patient, a sliding regimen of loop diuretics can be instituted to maintain the weight within a desired range. Increasing cardiac output with the use of inotropic agents or vasodilators is an important factor in achieving the desired natriuresis and diuresis. Diuretics should be used cautiously in patients with the nephrotic syndrome, to avoid acute renal failure due to intravascular volume depletion. The use of salt-poor albumin in combination with a loop diuretic may initiate diuresis. Low-dose dopamine (1 to 2 µg per kilogram per minute) may also cause a diuretic response by promoting an increase in renal blood flow.

CHAPTER 144: APPROACH TO THE PATIENT WITH HYPONATREMIA

LAWRENCE S. WEISBERG AND MALCOLM COX

[Presentation](#)
[Pathophysiology and Differential Diagnosis](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care](#)

PRESENTATION

Hyponatremia (serum sodium concentration less than 135 mEq per liter) is one of the most common electrolyte disorders—it is found in approximately 3% of hospitalized patients and as many as 30% of patients in intensive care units. Although the exact prevalence is unknown, hyponatremia is also seen often in outpatient practice, especially among patients with underlying disorders of extracellular volume homeostasis. The clinical manifestations of hyponatremia can be attributed largely to intracellular volume expansion (cellular edema). Cellular edema occurs only when hyponatremia is associated with hypotonicity. Intracellular volume expansion is of greatest consequence in the brain, where it is translated into increased intracranial pressure because of the rigid calvarium.

Most cells—especially brain cells—have adaptive mechanisms for mitigating tonicity-related volume changes. Cell volume peaks 1 to 2 hours after the onset of acute hypotonicity. Thereafter, solute and water are lost from cells, and cell volume returns toward normal. Solute loss is initially rapid and consists mainly of electrolytes during the first 6 to 12 hours of adaptation. Over the next 24 to 72 hours, organic solutes (largely amino acids) are more slowly lost. After several days of sustained hypotonicity, cell volume is restored nearly to normal.

The morbidity and mortality associated with hypotonic hyponatremia are influenced by several factors, including the magnitude and rate of development of hypotonicity, the patient's age and gender, and the nature and severity of any underlying diseases. The very young and very old, women, and alcoholics appear to be at particular risk. Volume adaptation to hypotonicity may be deficient in premenopausal women, who suffer more frequent and more severe neurologic consequences than men with equivalent degrees of hypotonicity.

Neurologic symptoms usually do not develop until the serum sodium concentration falls below 125 mEq per liter, at which time the patient may complain of anorexia, nausea, and malaise. At a level between 120 and 110 mEq per liter, the patient experiences headache, lethargy, confusion, agitation, and obtundation. More severe symptoms (seizures, coma) may occur with levels below 110 mEq per liter. Focal neurologic findings are unusual, but they do occur, and transtentorial cerebral herniation has been described in severe cases, especially in young women.

Although symptoms generally resolve with correction of hypotonicity, there may be permanent neurologic deficits, particularly in cases of severe (serum sodium concentration less than 120 mEq per liter), acute hypotonicity, when the brain's volume-regulatory defenses can be overwhelmed. Hypotonicity of this magnitude that develops in less than 24 hours may be associated with residual neurologic deficits and has a 50% mortality rate. In contrast, when hypotonicity evolves more gradually, symptoms are both less common and less severe. Indeed, patients with chronic hyponatremia, even in the range of 115 to 120 mEq per liter, may be completely asymptomatic.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Sodium is the major cation in extracellular fluid and, along with its associated anions, accounts for almost all the osmolality of this body fluid compartment. Consequently, hypotonicity (low effective body fluid osmolality) always implies hyponatremia. In contrast, hyponatremia can coexist with normal (isotonic hyponatremia) or elevated (hypertonic hyponatremia) body fluid tonicity as well as with hypotonicity (hypotonic hyponatremia; [Fig. 144.1](#)).

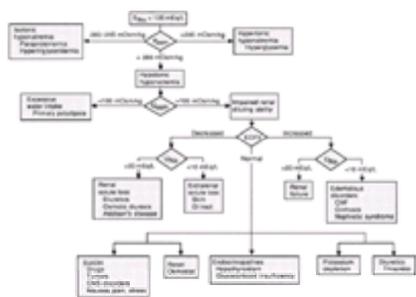

FIGURE 144.1. Approach to the patient with hyponatremia. S_{Na} , serum sodium concentration; U_{Na} , urine sodium concentration; P_{osm} , plasma osmolality; U_{osm} , urine osmolality; ECFV, extracellular fluid volume; GI, gastrointestinal; CHF, congestive heart failure; SIADH, syndrome of inappropriate antidiuretic hormone; CNS, central nervous system.

EVIDENCE LEVEL: C. Expert Opinion.

Isotonic hyponatremia (also known as factitious or pseudohyponatremia) is a laboratory artifact seen with analytic techniques that measure the amount of sodium per unit volume of serum sampled. Normally, water constitutes approximately 93% of serum volume; the remaining 7% consists of solids, mostly lipids and proteins. In the presence of marked hypertriglyceridemia or paraproteinemia, when an increased volume of the serum is nonaqueous, the amount of sodium in the sample volume is reduced. This is reflected as a low serum sodium concentration, even though the concentration of sodium in serum water (and therefore plasma osmolality) is normal. Direct potentiometry (which uses an ion-selective electrode in undiluted serum) avoids this problem and has become the most common method for measuring the serum sodium concentration.

Hypertonic hyponatremia results from the presence in extracellular fluid of abnormal amounts of osmotically effective solutes other than sodium (glucose, mannitol). The osmotic pressure exerted by the nonsodium solute leads to redistribution of water from the intracellular to the extracellular fluid compartment and thereby to cellular dehydration and hyponatremia.

Hypotonic hyponatremia can arise from an isolated increase in total body water; deficits in both total body solute and water, with the water deficit being of lesser magnitude; or increases in both total body solute and water, with the water excess being of greater magnitude. Because water moves freely across cell membranes, hypotonic hyponatremia is always associated with cellular edema.

HYPOTONIC HYPONATREMIA

Hypotonic hyponatremia always reflects an inability of the kidney to excrete sufficient electrolyte-free water to match water intake ([Table 144.1](#)). The normal response to water ingestion (of sufficient magnitude to produce even slight hypotonicity) is the excretion of maximally dilute urine (urine osmolality less than 100 mOsm per kilogram). Hence, a urine osmolality less than 100 mOsm per kilogram in a patient with hypotonic hyponatremia points to excessive water intake as the cause ([Fig. 144.1](#)). In contrast, a urine osmolality above 100 mOsm per kilogram in the face of hypotonic hyponatremia signifies impaired renal electrolyte-free water excretion. In constructing a differential diagnosis, it is helpful to relate the causes of hypotonic hyponatremia to the patient's extracellular fluid volume status, which may be readily

assessed at the bedside. Hypotonic hyponatremia may be associated with normal, decreased, or increased extracellular volume ([Fig. 144.1](#)).

TABLE 144.1. CONCEPT OF ELECTROLYTE-FREE WATER

EUVOLEMIC HYPONATREMIA

Because only one-third of total body water is extracellular in location (and only one-twelfth is intravascular), patients with pure water excess appear euvoletic; the only evidence of the increased total body water is low blood urea nitrogen and serum uric acid concentrations.

Patients with primary polydipsia usually have psychiatric disorders (hence, the use of such terms as psychogenic polydipsia and compulsive water drinking) and occasionally drink such large quantities of water that the kidney's ability to excrete electrolyte-free water is exceeded. The maximal rate of electrolyte-free water generation by the normal kidney is approximately 15 L per day, so that patients with primary polydipsia (and normal renal function) generally must ingest more than 15 L of water daily on an ongoing basis before hyponatremia develops. Because it is difficult to sustain such prodigious consumption for long periods, primary polydipsia is a distinctly unusual cause of hyponatremia in the context of normal renal diluting ability. Most patients with psychogenic polydipsia who experience hyponatremia have concurrent diluting defects, either in association with the underlying mental illness (usually schizophrenia) or perhaps as a side effect of psychotropic or anticonvulsant medications.

The syndrome of inappropriate antidiuretic hormone (SIADH) is characterized by persistently elevated circulating vasopressin levels in the absence of physiologically appropriate (osmotic or hemodynamic) stimuli to vasopressin release ([Fig. 144.2](#)). The development of hypotonic hyponatremia in patients with SIADH depends on water ingestion in excess of that eliminated by insensible, gastrointestinal, and renal routes. Because the normal response to hypotonicity is the elaboration of maximally dilute urine (urine osmolality less than 100 mOsm per kilogram), the urine need only be inappropriately concentrated (i.e., more than 100 mOsm per kilogram in a hypotonic patient) to be compatible with a diagnosis of SIADH.

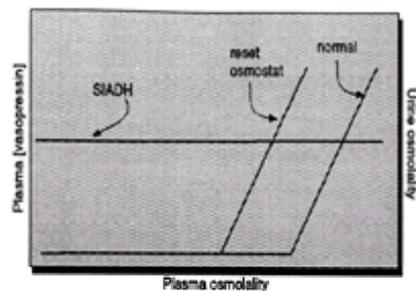

FIGURE 144.2. Relationships of plasma osmolality, plasma vasopressin concentration (plasma [vasopressin]), and urine osmolality in normal subjects, in patients with the reset osmostat variant of the syndrome of inappropriate antidiuretic hormone (SIADH), and in patients with classic SIADH. Patients with a reset osmostat can suppress vasopressin release and excrete dilute urine but only at a lower plasma osmolality than normal. Patients with classic SIADH have persistently elevated, although sometimes variable, vasopressin levels.

Although the diagnosis of SIADH is often entertained in any patient with hypotonic hyponatremia and an inappropriately concentrated urine, certain additional criteria must be met before the diagnosis is confirmed. Most important, the presence of a hemodynamic stimulus to vasopressin secretion must be rigorously excluded. Thus, clinical signs of extracellular volume depletion (tachycardia, hypotension) must be absent. In addition, because the pathologic edema-forming states (congestive heart failure, hepatic cirrhosis, the nephrotic syndrome) are all typically associated with effective arterial hypovolemia, cardiac and hepatic function must be normal, and proteinuria must be excluded. In more subtle cases, effective arterial blood volume is best assessed by measuring the urine sodium concentration. On a liberal sodium intake (more than 2 g per day) and in the absence of diuretic therapy or renal disease, a urine sodium concentration greater than 20 mEq per liter provides good evidence of a normal effective arterial blood volume.

Because hypothyroidism and glucocorticoid insufficiency may impair urinary dilution, patients in whom a diagnosis of SIADH is entertained should also undergo appropriate tests of thyroid and adrenocortical function. SIADH is discussed in more detail in [Chapter 404](#). An important variant of SIADH is the reset osmostat syndrome, in which vasopressin levels are suppressed by hypotonicity but at a lower plasma osmolality than normal ([Fig. 144.2](#)). This syndrome is seen most often in patients who are severely debilitated (e.g., those with malnutrition, metastatic cancer, advanced tuberculosis) and may account for up to one-third of cases of SIADH. The diagnosis of reset osmostat syndrome has important therapeutic implications, as will be discussed later.

HYPVOLEMIC HYPONATREMIA

The coexistence of hypotonic hyponatremia and extracellular volume (salt) depletion implies the presence of both solute and water deficits, with the water deficit being of lesser magnitude. Hypovolemic hyponatremia generally arises when renal or extrarenal solute and water losses are replaced with electrolyte-free water. Because sodium deficits are always associated with intravascular volume contraction, tachycardia, hypotension, decreased central venous pressure, oliguria, and prerenal azotemia frequently accompany hypovolemic hyponatremia. The urinary diluting defect in this situation is mediated both by decreased delivery of fluid to the diluting segments of the nephron and by hemodynamically stimulated vasopressin release. Thus, the patient with volume contraction cannot excrete electrolyte-free water normally and readily becomes hyponatremic even in the face of modest water ingestion.

The cause of volume contraction is usually obvious (vomiting, diarrhea, diuretics). When it is not, the urine sodium concentration can be helpful in distinguishing between renal and extrarenal solute losses. Renal losses are usually reflected by sodium wasting, and extrarenal losses are typically accompanied by sodium conservation ([Fig. 144.1](#)). Exceptions occur in the recovery phase after diuretic therapy (in which solute losses are renal in origin, but the urine sodium concentration is appropriately low once the diuretic is discontinued) and in metabolic alkalosis due to vomiting (in which bicarbonaturia obligates urinary sodium loss). In the latter case, the urine chloride concentration, which is very low, is the best indicator of extracellular volume depletion.

DIURETIC-INDUCED HYPONATREMIA

The hyponatremia associated with diuretic treatment deserves special mention because it is the most common hypotonic state seen in outpatients. Its pathogenesis is multifactorial. Insofar as diuretics produce overt volume depletion, they can cause hyponatremia by the mechanisms of action discussed earlier. In addition, by

blocking sodium reabsorption in the renal diluting segments, thiazide diuretics and loop diuretics, such as furosemide, also directly inhibit electrolyte-free water generation. Thiazides also have been associated with the development of severe, symptomatic hyponatremia in the absence of overt signs of volume depletion. The cause of this often alarming syndrome remains uncertain, but subclinical volume contraction, inhibition of diluting segment function, primary polydipsia in the context of impaired renal diluting ability, SIADH, and potassium depletion have all been implicated.

HYPERVOLEMIC HYPONATREMIA

The coexistence of hypotonic hyponatremia and extracellular volume expansion implies an excess of both salt and water, with the water surfeit being of greater magnitude. Consequently, hypervolemic hyponatremia is generally seen in patients who cannot excrete sodium normally because they have renal insufficiency or one of the pathologic edema-forming states (congestive heart failure, hepatic cirrhosis, the nephrotic syndrome; [Fig. 144.1](#)). These patients are characterized by extracellular volume expansion and impaired renal diluting ability. The effective arterial blood volume and absolute intravascular volume are normal or high in hyponatremic patients with renal insufficiency, whereas the hallmark of the pathologic edematous disorders is effective arterial hypovolemia.

Renal insufficiency, whether acute or chronic, can lead to hyponatremia for two reasons: the decreased glomerular filtration rate may prevent the excretion of sufficient water to match even a modest daily water intake, and the renal disease may directly limit electrolyte-free water generation. Because intrinsic diluting ability is normal in most patients with chronic renal failure, hyponatremia in this case is primarily due to the reduction in glomerular filtration rate. Treatment should be directed at restricting fluid intake to match ongoing losses.

Hyponatremia is common in the pathologic edema-forming states. Although extracellular and interstitial fluid volumes are higher by definition in these disorders, the effective arterial hypovolemia causes intense renal sodium retention. Such patients behave as if their intravascular volumes were low, even though the absolute intravascular volume may be normal or high. Because of the perceived intravascular volume depletion, renal diluting ability is compromised for reasons similar to those in hypovolemic hyponatremia, and hypotonicity may ensue with even modest levels of water ingestion.

Transurethral prostatic resection and hysteroscopic uterine ablation are performed using large volumes of nonelectrolyte (glycine, mannitol, or sorbitol) irrigating solutions. Hydrostatic pressure may force large amounts of these solutions through the surgical field into the systemic circulation during the operation, resulting in rapid intravascular volume expansion accompanied by profound hyponatremia.

HISTORY AND PHYSICAL EXAMINATION

Disorders of water homeostasis produce no specific clinical symptoms or signs and usually become evident only through screening laboratory examinations that find abnormalities in the serum sodium concentration. Otherwise unexplained neurologic abnormalities or a history or clinical findings of disorders commonly associated with hyponatremia, however, will often alert the experienced clinician to check the serum sodium concentration or plasma osmolality.

Given a diagnosis of hyponatremia, the history and physical examination should be guided by the associated alteration in body fluid tonicity. For the patient with isotonic hyponatremia, the history and physical examination generally reveal the telltale signs of severe hyperlipidemia or paraproteinemia, the presence of which then determines the path of further evaluation. The medication history may confirm iatrogenic paraproteinemia from the intravenous administration of immunoglobulin.

For the patient with hypertonic hyponatremia, the history should be directed at discovering the circumstances surrounding the development of the hypertonic state. Patients with hypertonic hyponatremia generally have a history or symptoms of diabetes mellitus, accounting for the hyperglycemia that is by far the most common cause of this disorder. If the patient is not hyperglycemic, documentation should be sought for the administration of an exogenous osmotic agent, usually mannitol.

In the case of hypotonic hyponatremia, the history and physical examination should first be directed at eliciting any neurologic symptoms or signs, the severity and duration of which are paramount in determining the aggressiveness of therapy (see later discussion). Thereafter, the history should be closely scrutinized for symptoms of hypovolemia or volume overload, for disorders of volume (sodium) homeostasis, and for the use of diuretics, the most common iatrogenic cause of salt depletion. Likewise, the physical examination should be directed at establishing the patient's volume status.

Further questioning of the patient with hypotonic hyponatremia is guided by subsequent laboratory results. For the patient with dilute urine, an attempt should be made to discover remediable causes of increased thirst, such as drugs that cause a dry mouth. For the patient with concentrated urine, the history follows directly from the differential diagnosis ([Fig. 144.1](#)). Patients in whom SIADH is suspected should be questioned about the diseases and conditions associated with that syndrome, with particular attention paid to intrathoracic and intracranial processes and to covert adrenal insufficiency and hypothyroidism. A thorough drug history must always be taken because of the many drugs that can cause SIADH (see [Chapter 404](#)).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The laboratory evaluation of hyponatremia is detailed in [Fig. 144.1](#). Although the measurement of plasma osmolality readily segregates hyponatremia by body fluid tonicity, other laboratory tests often provide significant clues as well. For example, paraproteinemia of sufficient magnitude to produce pseudohyponatremia generally causes such significant hyperviscosity that it makes blood collection by standard venipuncture methods difficult. Hyperlipidemia is often suspected because of creamy or opalescent serum. A normal or only mildly elevated blood glucose concentration effectively excludes hypertonic hyponatremia.

Together with the history and physical examination, simple urinary indexes (urine osmolality and sodium concentration) can be used to divide hypotonic hyponatremia into hypovolemic, hypervolemic, and euvolemic categories ([Fig. 144.1](#)). The blood urea nitrogen, serum creatinine, and uric acid concentrations also can be useful in making this distinction. Prerenal azotemia and hyperuricemia often are present in patients with hypovolemic or hypervolemic hyponatremia, and hypouricemia is common in primary polydipsia and SIADH.

Before a diagnosis of SIADH can be made, adrenal insufficiency and hypothyroidism must be excluded (see [Chapter 406](#) and [Chapter 407](#)). Once the diagnosis of SIADH is established, it is important to determine whether the patient has the reset osmostat variant. This diagnosis is often obvious because of the relative stability of the serum sodium concentration (usually 125 to 135 mEq per liter) despite unrestricted water ingestion. If the diagnosis is not apparent, it can be made by stressing the osmoregulatory system with a water load.

The standard oral water loading test is performed as follows. After several days on a liberal salt diet, the patient is instructed to drink tap water (20 mL per kilogram body weight over 15 to 30 minutes). For the next 5 hours, the urine is collected hourly, and its volume and osmolality are measured. Normally, during the peak of water diuresis, the urine osmolality is minimal (less than 100 mOsm per kilogram); in addition, over the 5 hours of the test, a normal subject excretes more than 80% of the administered water. Patients with a reset osmostat eliminate the water load normally once the plasma osmolality drops below their reset threshold for vasopressin release. In contrast, patients with classic SIADH cannot excrete the water load normally: minimal urine osmolality is not achieved, and less than 80% of the water is excreted over the 5 hours. The standard oral water load is designed to decrease the serum sodium concentration by no more than 3%, even if all the water is retained. Nonetheless, patients with severe hyponatremia (less than 120 mEq per liter) should not be water-loaded because of the risk of precipitating neurologic symptoms.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT AND COMPLICATIONS

Because the most important manifestations of disordered osmoregulation relate to alterations in body fluid tonicity rather than to the associated changes in serum sodium concentration, an assessment of plasma osmolality should accompany any diagnosis of clinically significant hyponatremia. Therapy can then be guided by this information. Thus, the treatment of isotonic hyponatremia should be directed at the underlying hyperlipidemia or paraproteinemia. Similarly, in patients with hypertonic hyponatremia, hypertonicity, not hyponatremia, must be addressed. Only when it is associated with hypotonicity, and therefore with cerebral edema, should hyponatremia receive specific attention.

Mild to moderate hypotonic hyponatremia is very common, especially in hospitalized patients. The vast majority of these persons are asymptomatic and should be treated conservatively. Severe hypotonicity (serum sodium concentration less than 120 mEq per liter), although much less common, can be life-threatening, and

immediate therapy may be required.

The therapy of symptomatic hyponatremia, irrespective of cause, is directed at raising extracellular fluid tonicity to shift water out of the intracellular space, thereby ameliorating cerebral edema. The rate of correction, however, must be carefully regulated. Overly rapid correction, particularly in patients with chronic hyponatremia, in whom cell volume adaptations may be complete, can produce central pontine myelinolysis. This so-called osmotic demyelination syndrome is associated with a variety of irreversible neurologic deficits (dysarthria, dysphagia, incoordination, quadriplegia, coma), which typically develop 2 to 6 days after treatment.

Although the exact rate of correction remains the subject of controversy, in most circumstances the serum sodium concentration should be raised by no more than 10 mEq per liter in the first 24 hours and by no more than 20 mEq per liter in the first 48 hours. In grave situations (serum sodium concentration less than 105 mEq per liter), initial therapy can be more aggressive (targeting a change in the serum sodium concentration of 1 to 2 mEq per liter per hour for the first few hours), but the recommended daily target should not be exceeded.

Correction of severe symptomatic hyponatremia, regardless of cause, should be accomplished with hypertonic (3%) saline. The amount of solute required can be estimated as follows. First, calculate the amount of sodium to be administered by multiplying the target change in serum sodium concentration by the patient's total body water. Then calculate the volume of 3% saline that will supply that amount of sodium. For example, in a 70-kg man with a serum sodium concentration of 105 mEq per liter and a total body water of 42 L (60% of body weight), the amount of sodium needed to raise the serum sodium concentration by 10 mEq per liter is 10×42 , or 420 mEq. Three percent saline has a sodium concentration of 513 mEq per liter; therefore, $420/513$, or approximately 820 mL, would be required in the first 24 hours.

This calculation provides only a rough guideline, since it takes no account of ongoing solute and water losses, and the serum sodium concentration must be monitored frequently during treatment to adjust the rate of correction. Rapid extracellular volume expansion with hypertonic saline can precipitate pulmonary edema, particularly in patients with underlying heart disease. Thus, patients receiving 3% saline also should be assessed frequently for evidence of volume overload. A loop diuretic may be administered if necessary, recognizing that this will enhance electrolyte-free water clearance and accelerate the correction.

The treatment of chronic asymptomatic hyponatremia should be directed at correcting the pathophysiologic factors involved in generating the hypotonic state. Because euvolemic hyponatremia represents pure water excess, treatment depends on restricting water intake to less than daily water output. Patients with SIADH excrete little or no electrolyte-free water in the urine. Therefore, if water intake is limited to less than the amount of insensible water losses (approximately 10 mL per kilogram body weight per day), the serum sodium concentration will slowly rise. Progressive hyponatremia does not develop in patients with the reset osmostat variant of SIADH, and such patients rarely require therapy.

If the cause of SIADH cannot be corrected and if water restriction is poorly tolerated or ineffective, demeclocycline (a tetracycline antibiotic that increases electrolyte-free water excretion by inhibiting vasopressin-mediated water reabsorption in the collecting duct) can be used. Demeclocycline is contraindicated for patients with renal disease, hepatic cirrhosis, or congestive heart failure because drug-related renal insufficiency has been described in these situations. Urea (30 to 60 g per day, administered orally) has been used to increase electrolyte-free water clearance, but it is unpalatable, and gastrointestinal side effects limit its usefulness. Specific vasopressin (V_2) receptor antagonists, so-called aquaretic agents, are nearing approval for clinical use and are likely to change the treatment of patients with SIADH in the future.

Therapy of hypovolemic hyponatremia should be directed at restoring intravascular volume with intravenous saline and identifying and correcting the cause of the excessive solute loss. Volume repletion readily elicits water diuresis by increasing the delivery of fluid to the renal diluting segments and suppressing vasopressin release. As with all categories of hypotonic hyponatremia, the rate of correction must be carefully controlled. The treatment of diuretic-induced hyponatremia is straightforward: withdrawing the offending drug, liberalizing salt intake, and replenishing body potassium stores usually correct the disorder.

The treatment of hypervolemic hyponatremia is difficult and frustrating. Resolution of hyponatremia associated with any of the pathologic edematous disorders ultimately depends on effective treatment of the underlying disease. Regardless of the specific therapy of the underlying disorder, the mainstay of therapy for the hyponatremic edematous patient remains salt and water restriction. Diuretics are often a double-edged sword in a patient with hyponatremia and edema. They may be needed to treat pulmonary vascular congestion, peripheral edema, and ascites, but if they are used to excess, they can produce further decrements in effective arterial blood volume and exacerbate water retention. Strategies directed at increasing effective arterial blood volume (e.g., afterload reduction with angiotensin-converting enzyme inhibitors) have had some success in increasing electrolyte-free water excretion and ameliorating hyponatremia in patients with congestive heart failure.

The use of isotonic or hypertonic saline to treat hyponatremia in edematous patients provides at best only a transient increase in effective arterial blood volume. The sodium-containing fluid rapidly equilibrates throughout the extracellular fluid space, and the edema worsens. In addition, pulmonary edema is a serious threat when these solutions are administered to patients with underlying heart disease. Consequently, if hypertonic saline must be used in the emergency therapy of symptomatic hyponatremia in the edematous patient, potent diuretics should be administered simultaneously.

Indications for HOSPITALIZATION

Because neurologic deterioration is unpredictable and can proceed rapidly in patients with hyponatremia, the presence of any neurologic abnormality, irrespective of the degree of hyponatremia, is an absolute indication for immediate hospitalization. For the same reasons, hospitalization is also usually indicated if the serum sodium concentration is below 125 mEq per liter, regardless of signs or symptoms. If hyponatremia is known to be chronic and relatively stable, patients with more moderate, asymptomatic hyponatremia (serum sodium concentration 125 to 135 mEq per liter) can usually be treated as outpatients, but they may require admission for treatment of the underlying disorder.

Indications for REFERRAL

Consultation, usually with a nephrologist or intensivist, is indicated for patients with severe hyponatremia, especially when aggressive therapy with hypertonic saline is contemplated. Consultation with a nephrologist can also be helpful when one is faced with establishing the diagnosis of SIADH or making the distinction between reset osmostat and classic SIADH. Psychiatric consultation may be required for the treatment of patients with primary polydipsia.

COST-EFFECTIVENESS

The evaluation of hyponatremia, for the most part, entails only a thorough history and physical examination and simple and inexpensive laboratory tests. Furthermore, the catastrophic consequences of severe hyponatremia can be prevented in most circumstances by simple prophylactic management (water restriction) or lessened by the judicious use of inexpensive crystalloid solutions in more critical situations. Although no formal cost/benefit analysis is available, common sense dictates the careful assessment and treatment of patients with severe hyponatremia (a serum sodium concentration less than 120 mEq per liter). Cost/benefit considerations would also be expected to favor the evaluation of patients with new-onset (or newly discovered) hyponatremia of any more than trivial magnitude.

CHAPTER 145: APPROACH TO THE PATIENT WITH HYPERNATREMIA

HAROLD M. SZERLIP AND MALCOLM COX

[Presentation](#)
[Pathophysiology and Differential Diagnosis](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care](#)

PRESENTATION

Hypernatremia (serum sodium concentration greater than 145 mEq per L) is found in about 1% of hospitalized patients. Because body fluid tonicity is tightly regulated in healthy persons, hypernatremia is generally a disorder of the very young, the very old, or the very ill, occurring most commonly in infants, debilitated elderly patients in chronic care facilities, and patients of all ages hospitalized with serious illnesses.

Irrespective of cause, hypernatremia always implies coexistent hypertonicity. Because almost all cell membranes are freely permeable to water, hypertonicity is associated with movement of water from the intracellular to the extracellular fluid compartment and intracellular volume contraction (cell shrinkage). Many of the symptoms of hypernatremia are the result of this change in cell volume. Of most significance are the neurologic manifestations associated with shrinkage of the brain.

The presenting symptoms and signs of hypernatremia typically are related to changes in the sensorium. In general, the higher the serum sodium concentration, the greater the depression of the sensorium, although there is considerable variation among individuals. Symptoms can range from agitation, restlessness, confusion, and lethargy to seizures, stupor, and coma. Brain pathology includes intracerebral, subarachnoid, and subdural hemorrhages.

Central pontine myelinolysis, a condition more commonly associated with rapid correction of hyponatremia, has also been reported in patients with hypernatremia. Other presentations of hypernatremia include muscle weakness, nausea, and vomiting.

The brain has well-developed regulatory mechanisms that mitigate tonicity-related changes in cell volume. Brain cells begin to adapt to hypertonicity by promptly increasing intracellular solute shortly after the onset of the disturbance. Extracellular sodium chloride provides some of this new solute, at least acutely. Over time, however, the brain adapts to hypertonic stress by generating organic osmolytes such as glutamine, glutamate, taurine, and myoinositol. Thus, brain cells do not act as true osmometers, as their shrinkage is less than that predicted by the degree of hypertonicity.

Because of this adaptive response, the manifestations of hypernatremia depend on the rapidity of the rise in the serum sodium concentration as well as the magnitude of the hypernatremia. Gradual development of hypertonicity provides time for the adaptive increase in brain solute, and cell shrinkage is less severe. In contrast, the rapid development of hypertonicity does not allow sufficient time for adaptation, and cerebral dehydration is unimpeded. Thus, acute changes in the serum sodium concentration are generally less well tolerated than more chronic changes.

Changes in extracellular fluid volume and the presence of comorbid conditions commonly modify the presentation of patients with hypernatremia and may dominate the clinical picture. For example, hypernatremia secondary to excess salt is often associated with symptoms of volume overload, whereas hypernatremia that results from the loss of hypotonic fluids is associated with signs of volume depletion. These changes in extracellular fluid volume may be of such import that their treatment might have to take priority over that of the hypernatremia.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Hypernatremia can arise from the gain of solute (sodium salts) in excess of water or the loss of water in excess of solute (pure water loss or hypotonic fluid loss). Pure water losses are associated with an isolated decrease in total body water. In contrast, hypotonic fluid losses produce both water and solute deficits, with the water deficit being of greater magnitude. Because hypernatremia is a potent stimulus to thirst, sustained hypernatremia always implies inadequate water intake. This may be due to impaired thirst (hypodipsia) or an inability to obtain adequate amounts of water (e.g., infants or bedridden adults).

HYPODIPSIA

In patients with free access to water, sustained hypernatremia is always associated with impaired thirst. Thirst is first stimulated at a plasma osmolality of approximately 295 mOsm per kg, a level at which urinary concentration has already been maximally stimulated by arginine vasopressin (antidiuretic hormone). Thus, whereas renal water conservation serves as the initial defense against hypernatremia, water intake provides the ultimate guarantee against death from progressive hypertonic dehydration.

Pure hypodipsia (i.e., a defect in thirst sensation in the absence of abnormalities in vasopressin secretion) is uncommon. Although the hypothalamic center responsible for the regulation of thirst appears to be different from that regulating vasopressin release, defects in thirst most often coexist with disturbances in vasopressin secretion. For example, hypodipsia has been described in combination with partial hypothalamic diabetes insipidus; the osmotic thresholds for thirst and vasopressin release in these patients are normal, but the sensitivities of the two systems are depressed. Because of the concomitant defects in thirst and renal water conservation, hypernatremia can be particularly severe in such persons.

Other patients with hypodipsia are characterized by chronic, nonprogressive hypernatremia, euvolesmia, and normal renal concentrating ability (for age). Those patients with so-called essential hypernatremia defend body fluid tonicity around a higher than usual osmolality (upward resetting of the osmolal set point) and have elevated thresholds for both thirst and vasopressin release. Upward resetting of the osmostat may also explain the mild hypernatremia seen in primary hyperaldosteronism.

Many elderly persons have impaired thirst. When dehydrated, even otherwise healthy elderly persons sense less thirst and drink less than younger subjects, putting them at increased risk for hypernatremia should intercurrent illness stress the osmoregulatory system. The cause of so-called geriatric hypodipsia has not been elucidated.

SOLUTE GAIN

The gain of solute in excess of water is a relatively uncommon cause of hypernatremia. However, two situations are typical: the accidental or purposeful ingestion of table salt, and the intravenous administration of hypertonic sodium-containing solutions.

A tablespoon of salt contains approximately 350 mEq of sodium chloride, and the ingestion of as little as one tablespoon can raise the serum sodium concentration by as much as 8 mEq per L in a 70-kg adult. Because of a lower body water content, elderly persons manifest similar increases in the serum sodium concentration with proportionately lesser amounts of salt. Fatal cases of hypernatremia resulting from the intentional ingestion of salt, the use of salt as an emetic, and the inadvertent administration of salt-containing (rather than sugar-containing) infant formula have been documented.

Hypernatremia due to the excessive administration of hypertonic salt solutions is restricted to hospitalized patients, where it usually presents as an iatrogenic complication of the treatment of hyponatremia or metabolic acidosis. The 3% saline solution commonly used in the treatment of severe hyponatremia contains 513 mEq sodium per liter. Even more hypertonic is the 7.5% sodium bicarbonate solution (890 mEq per L) routinely used during cardiopulmonary resuscitation: each 50-mL ampule contains 44.5 mEq sodium.

This type of hypernatremia is associated with expansion of the extracellular space. The magnitude of the increase in extracellular fluid volume depends on the size of the sodium load and the extent of the associated diuresis. With adequate renal function and in the absence of a stimulus for renal sodium retention, extracellular (and

intravascular) fluid volume expansion is mitigated by a brisk diuresis. Edema and ascites may not be evident, but increased central venous pressure is almost invariable. If renal sodium excretion is limited, frank pulmonary edema may be present.

PURE WATER LOSS

Pure water deficits arise from inadequate water intake in the face of ongoing electrolyte-free water losses from skin, respiratory tract, or kidney. Isolated decreases in total body water, unless of very large magnitude, are not associated with significant extracellular (or intravascular) volume depletion. This is because only one third of a pure water deficit is derived from the extracellular fluid and only one twelfth from the intravascular compartment. Thus, patients with pure water deficits generally appear clinically euvolemic.

Cutaneous insensible losses are increased by fever or when the ambient temperature is high. Pulmonary insensible losses are increased in hot, dry environments and by hyperventilation. Excessive renal electrolyte-free water losses are the *sine qua non* of diabetes insipidus; this syndrome is characterized by impaired renal concentrating ability and results from either vasopressin deficiency (hypothalamic diabetes insipidus) or renal unresponsiveness to vasopressin (nephrogenic diabetes insipidus) (see [Chapter 137](#) and [Chapter 404](#)).

HYPOTONIC FLUID LOSS

The most common cause of hypernatremia is the loss of hypotonic body fluids, which may occur through the kidney, gastrointestinal tract, or skin ([Table 145.1](#)). Because of the associated sodium loss, hypotonic fluid deficits lead to greater degrees of extracellular and intravascular volume depletion than do pure water deficits. Thus, patients with hypotonic fluid deficits usually manifest clinical symptoms and signs of intravascular volume depletion.

Renal
Diuretics
Osmotic diuresis
Hyperglycemia
Gastrointestinal
Diarrhea
Vomiting
Nasogastric suction
Skin
Sensible perspiration
Burns

TABLE 145.1. CAUSES OF HYPOTONIC FLUIDS LOSSES

The chronic administration of potent diuretics (such as thiazides, metolazone, or furosemide), and especially combinations of such diuretics, is a notorious cause of excessive renal hypotonic fluid losses. So, too, is the prolonged polyuria that typically accompanies chronic hyperglycemia in patients with poorly controlled diabetes mellitus. In both situations, urinary water losses invariably exceed solute losses, and unless these water losses are counterbalanced by increased water intake, hypernatremia is a predictable consequence.

Gastrointestinal fluid losses are also a common cause of hypernatremia. Except for biliary and pancreatic secretions, most gastrointestinal fluids are hypotonic in composition. Chronic watery diarrhea, extensive vomiting, and prolonged nasogastric suction account for the majority of these cases.

The skin may be a significant site of hypotonic fluid loss. Although only water is lost during insensible perspiration, sensible perspiration contains significant amounts of solute as well. In hot, humid environments, and especially when strenuous exercise produces profuse sweating, hypotonic fluid intake must be sufficient to counteract increased cutaneous water and solute losses. Extensive burns can also be associated with significant hypotonic fluid losses.

HYPERNATREMIA IN THE ELDERLY

Elderly persons are at special risk for developing hypernatremia. Because they have less muscle, total body water as a percentage of body weight is lower. Consequently, for any given degree of solute gain or water loss, hypernatremia is more severe than in young adults ([Fig. 145.1](#)). Furthermore, maximal urinary concentrating ability is lower in the elderly, so that their ability to conserve water is less than that of healthy young adults. In addition, because hypodipsia is relatively common in the elderly, they are less able to defend body fluid tonicity against progressive hypertonic dehydration. Likewise, chronically debilitated adults, especially the institutionalized elderly, depend on others for access to water. All of these factors combine to increase the incidence of hypernatremia in the elderly.

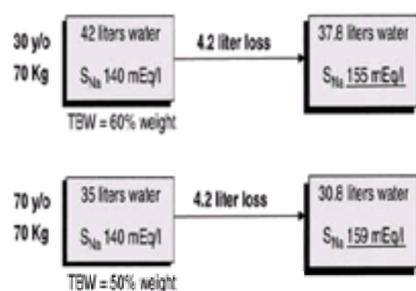

FIGURE 145.1. Differential effect of the same amount of water loss on S_{Na} in a young adult and an elderly subject. Because muscle mass decreases with age, total body water declines. Therefore, for any given water loss, the increase in S_{Na} is greater in the older than in the younger subject.

HISTORY AND PHYSICAL EXAMINATION

Hypernatremia produces no specific clinical symptoms or signs and usually becomes evident only through a screening laboratory examination. However, otherwise unexplained neurologic abnormalities or a history or clinical findings of diseases or disorders commonly associated with hypernatremia often alert the experienced clinician to check the serum sodium concentration.

Once a diagnosis of hypernatremia is established, the history and physical examination assume considerable importance in planning further evaluation and guiding therapy. The initial evaluation should include interviewing the patient (and any caregivers) and reviewing the medical records. Specific information regarding thirst, access to water, water intake, salt intake, urine volume, and medications (especially diuretics) should be sought, as should evidence of neurologic alterations, which are sometimes subtle. A history of fever, vomiting, diarrhea, or polyuria (or, more specifically, diabetes mellitus or diabetes insipidus) is also pertinent.

Extracellular volume status is helpful in segregating hypernatremia into its three main categories ([Fig. 145.2](#)). Moreover, the associated changes in extracellular fluid volume, rather than the hypernatremia itself, often dictate therapy as well, especially initial therapy. Consequently, the history should always be closely scrutinized for symptoms of hypovolemia or volume overload, especially intravascular volume overload. The physical examination should be used to establish volume status. Volume

depletion generally indicates hypotonic fluid losses. In contrast, evidence of intravascular volume expansion is consistent with hypernatremia caused by solute gain.

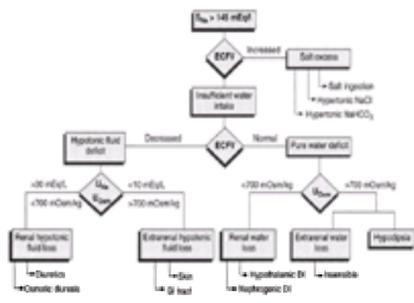

FIGURE 145.2. Approach to the patient with hypernatremia. S_{Na} and U_{Na} , serum and urine sodium concentrations, respectively; U_{Osm} , urine osmolality; ECFV, extracellular fluid volume; GI, gastrointestinal; DI, diabetes insipidus.
EVIDENCE LEVEL: C. Expert Opinion.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory studies are helpful in confirming extracellular volume status and in pinpointing the specific cause of hypernatremia. Prerenal azotemia and hyperuricemia generally imply extracellular volume depletion and therefore suggest hypotonic fluid losses. In contrast, the blood urea nitrogen and serum uric acid concentrations are typically normal or only trivially elevated in patients with pure water deficits.

The laboratory evaluation of hypernatremia is detailed in [Figure 145.2](#). For the most part, simple urinary indexes (urine osmolality and sodium concentration) are used to distinguish between hypotonic and pure water deficits and between renal and extrarenal hypotonic fluid losses. In the absence of a stimulus to renal sodium retention, hypernatremia secondary to salt over-load induces a rapid and marked natriuresis, resulting in very high urinary sodium concentrations (often greater than 100 mEq per L).

More specialized testing depends on the particular situation. Tests that evaluate the integrity of the vasopressin–renal axis (used to establish the diagnosis of diabetes insipidus) are discussed in [Chapter 404](#). Although visual analog scales to quantify thirst are available, they are rarely used; clinicians generally rely on more subjective indexes of thirst.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT AND COMPLICATIONS

The effective management of hypernatremia requires accurate knowledge of extracellular volume status and an appreciation of the cerebral adaptation to hypertonicity. Initial therapy should be directed at normalizing intravascular volume; thereafter, attention can be turned to correcting the hypernatremia itself.

When signs and symptoms of volume depletion are present, the restoration of adequate tissue perfusion is of paramount importance. Isotonic (0.9%) sodium chloride solutions generally provide the best means to this end and should be given intravenously at a rate sufficient to stabilize the blood pressure. Once blood pressure has been stabilized, the water deficit can be addressed.

Incipient or frank pulmonary edema is common in patients with hypernatremia caused by excess salt and may greatly complicate therapy. The rapid administration of large volumes of water to treat the hypernatremia will further expand extracellular volume, worsening pulmonary gas exchange. In this situation, therefore, initial therapy must include removal of the excess sodium as well as water administration. Potent diuretics (such as furosemide) are often effective in patients with intact renal function; otherwise, extracorporeal techniques (such as hemodialysis or hemofiltration) may be required to reduce extracellular volume rapidly.

Once the intravascular volume status has been addressed, attention can be turned to the treatment of the hypernatremia itself. Here consideration of the cerebral adaptation to hypertonicity assumes particular importance. Although the rate of new intracellular solute generation has not been precisely defined—and may vary considerably among persons and in different clinical situations—full adaptation can take several days. Consequently, acute hypertonicity is generally less well tolerated than hypertonicity that develops gradually, and it should be treated more aggressively.

Before a rapid correction regimen is begun, however, the hypertonicity must be determined to be acute in origin. This is usually straightforward in patients with hypernatremia secondary to solute gain (salt poisoning or iatrogenic hypertonic fluid administration) but may be more difficult in other situations. Because of the dangers that accompany the rapid correction of chronic hypertonicity (see below), aggressive therapy should never be used when the duration of the hypernatremia cannot be established with reasonable certainty.

The rate at which new brain solute is removed (or inactivated) during therapy is even less well understood than its rate of generation. In animal models, however, solute dissipation takes more than 24 hours. Because brain cells maintain their volume by an adaptive increase in solute, returning tonicity rapidly to normal may produce cerebral edema and may precipitate seizures, coma, permanent neurologic sequelae, or death. Consequently, the correction of chronic hypernatremia (or hypernatremia of unknown duration) should always proceed over a period of several days.

The treatment of hypernatremia should be directed at repleting total body water, matching ongoing losses with increased water intake, and eliminating any excessive insensible, gastrointestinal, or renal water losses. Calculation of the magnitude of an isolated water deficit is based on the fact that total body solute (or, more conveniently, total body sodium) remains constant, so that the resulting hypernatremia is directly proportional to the deficit in total body water (TBW). Thus:

$$\text{Current TBW} \times S_{Na} = \text{normal TBW} \times \text{normal } S_{Na}$$

In a 60-kg patient with S_{Na} 160 mEq per L:

$$\text{Current TBW} = (0.6 \times 60) \times 140/160 = 31.5 \text{ L}$$

The water deficit is therefore 36 – 31.5, or 4.5 L. Despite inherent inaccuracies in estimating normal total body water (current weight is used because the pre-dehydration or normal weight is rarely known, and it is assumed that total body water is 60% of body weight), this calculation provides an approximate value that can be used in planning therapy.

The same calculation is often used to estimate the water deficit in hypernatremic patients with hypotonic fluid losses, but because of the associated solute losses it may underestimate the true water deficit. However, an accurate reflection of the residual water deficit can be obtained once sodium (and any potassium) deficits have been corrected.

Because the rapid replacement of large water deficits in patients with chronic hypernatremia carries the risk of acute cerebral edema, no more than half of the estimated deficit should be replaced during the first 24 hours, with careful monitoring of the neurologic status and the serum sodium concentration. The rest of the deficit can then be replaced over the ensuing 24 to 48 hours. The oral route is always preferable, provided the patient is alert and there is no risk of pulmonary aspiration. In other cases, 5% dextrose in water should be administered intravenously.

Once water repletion is under way, consideration should be given to estimating and replacing ongoing water losses. Both insensible (cutaneous and pulmonary) and renal water losses must be considered. In addition, therapy for hypodipsia (prescription of an adequate water intake) and specific therapy for hyperthermia, hyperventilation, and diabetes insipidus (see [Chapter 404](#)) should be initiated.

In patients whose hypernatremia is caused by excess salt, the amount of water needed to correct the hypernatremia can be estimated in an analogous fashion. Of course, in this situation, there is no water deficit, and the water administered to correct body fluid tonicity increases total body water above normal. If the hypernatremia is clearly acute (less than 12 hours in duration), correction can be rapid; otherwise, the more conservative recommendations provided for the treatment of chronic hypertonicity should be followed. The rapid administration of electrolyte-free water should continue only until neurologic symptoms improve. Because many of these patients are also receiving potent diuretics, hemodialysis, or hemofiltration (treatment modalities that have their own unique effects on solute and water balance), close monitoring of neurologic status and the serum sodium concentration is mandatory, and frequent adjustments in the rate of water administration might be needed.

Indications for HOSPITALIZATION

Because neurologic deterioration is unpredictable in patients with hypernatremia, the presence of any neurologic abnormality, irrespective of the degree of hypertonicity, is an absolute indication for immediate hospitalization. Likewise, hospitalization for further evaluation is also usually indicated if the serum sodium concentration exceeds 155 mEq per L, regardless of signs or symptoms. If the hypernatremia is known to be chronic and relatively stable (and extracellular fluid volume is neither compromised nor threatened), patients with more moderate, asymptomatic hypernatremia (serum sodium concentration 145 to 155 mEq per L) usually can be handled as outpatients. However, they may require admission for treatment of the underlying disorder.

Indications for REFERRAL

Consultation, most often with a nephrologist or intensivist, is indicated in patients with severe hypernatremia, especially when aggressive therapy is contemplated. Consultation (with a nephrologist, endocrinologist, or neurologist) can also be helpful when one is faced with making the diagnosis of diabetes insipidus—and during the initial treatment of this disorder—or when confronted with otherwise unexplained hypodipsia.

COST EFFECTIVENESS

The evaluation of hypernatremia entails, for the most part, a thorough history and physical examination, as well as simple and inexpensive laboratory tests. Furthermore, in many situations the catastrophic consequences of severe hypernatremia can be prevented by simple and relatively inexpensive means (e.g., prescription of an adequate water intake, adequate enteral or intravenous electrolyte-free water administration in persons who cannot drink, hormone replacement therapy for hypothalamic diabetes insipidus). Thus, although no formal cost/benefit analysis is available, common sense dictates the careful assessment and treatment of patients with severe hypernatremia (serum sodium concentration greater than 155 mEq/L). Cost/benefit considerations would also be expected to favor the evaluation of patients with new onset (or newly discovered) hypernatremia of anything more than trivial magnitude.

CHAPTER 146: APPROACH TO THE PATIENT WITH HYPOKALEMIA

MANUEL MARTINEZ-MALDONADO

[Potassium Redistribution](#)
[Potassium Depletion](#)
[Consequences of K⁺ Depletion](#)
[Diagnostic Approach](#)
[Therapy](#)

The concentration of serum potassium is 3.5 to 5 mEq per L and total body potassium is about 50 mEq per kg, or about 3500 mEq for a 70-kg man. The relative distribution of potassium among various organs and extracellular fluid (ECF) is shown in [Figure 146.1](#). The kidneys are responsible for the excretion of close to 95% of dietary potassium, but in the presence of diarrhea or impairment of renal function the gut may be a primary route of potassium excretion.

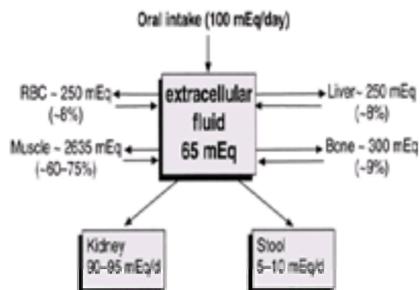

FIGURE 146.1. Internal and external potassium balance in humans.

Several facts about potassium are important in understanding conditions in which serum K⁺ is altered ([Table 146.1](#)). The abundance of intracellular K⁺ (30 times higher than ECF K⁺) should be a tip-off to the possible role of shifts of potassium as a cause of alterations in serum K⁺. This is particularly the case in hyperkalemia (serum K⁺ greater than 5 mEq per L); the fact that cells are a vast deposit for potassium can also lead to the development of hypokalemia.

Normal serum K⁺ is 3.5 to 5 mEq/L.
Intracellular K⁺ is 150 mEq/L.
In young men, total body K⁺ is 60 mEq/kg.
In young women, total body K⁺ is 25% less than in young men.
Total body K⁺ decreases with age.

TABLE 146.1. THINGS TO KNOW ABOUT SERUM, INTRACELLULAR, AND TOTAL BODY POTASSIUM

Hypokalemia is defined as a value of serum K⁺ lower than 3.5 mEq per L. Hypokalemia almost always results from abnormal losses of potassium or, rarely, from potassium shift into cells. Drugs are the most common cause of hypokalemia; therefore, review of the patient's drug record is essential.

POTASSIUM REDISTRIBUTION

Movement of potassium into cells, leading to hypokalemia, can be induced by various factors. Metabolic alkalosis decreases plasma K⁺ by 0.3 mEq per L for each 0.1-unit increase in pH and can lead to a severe degree of hypokalemia. Respiratory alkalosis must be extremely severe (exaggerated and inappropriate mechanical ventilation) to cause substantial degrees of hypokalemia. Bicarbonate administration has only a slight effect on transcellular K⁺ distribution in end-stage renal disease patients.

Exogenously administered insulin or that endogenously released in response to hyperglycemia stimulates K⁺ uptake by muscle and liver cells. Hypokalemia inhibits whereas hyperkalemia stimulates insulin secretion. Drugs such as epinephrine and selective β_2 -agonists (terbutaline, albuterol, salbutamol, ephedrine, and other bronchodilators) and tocolytic agents (ritodrine, nylidrin), can induce marked, if transient, hypokalemia. Endogenous release of catecholamines as a result of myocardial infarction, head injury, cardiac surgery, delirium tremens, and other stress-generating illnesses can lead to transient hypokalemia. Intoxication with several agents such as verapamil, chloroquine, theophylline, barium, and possibly toluene also shifts K⁺ into cells.

A rare hereditary disorder, hypokalemic periodic paralysis, is the result of intracellular shifts of potassium, which may be spontaneous or induced by carbohydrate-rich diets or excessive acute intake of sugars. Most cases are familial, but sporadic cases occur as a complication of thyrotoxicosis, particularly in Asians. Thyroid hormone stimulates cellular uptake of K⁺.

Hypothermia may lower plasma K⁺ to below 3.0 mEq per L by inducing intracellular K⁺ shifts. Potassium administration and rewarming may be associated with overshoot hyperkalemia.

Vitamin B₁₂ therapy of megaloblastic anemia rapidly induces production of new blood cells that avidly extract potassium from the extracellular fluid; severe or lethal hypokalemia may ensue. Administration of washed frozen erythrocytes results in hypokalemia because the rewarmed low K⁺ cells activate their Na⁺,K⁺-ATPase and feast on extracellular potassium. Reduction in plasma K⁺ of as much as 1 mEq per L can be seen in delirium tremens, a phenomenon associated with the level of plasma epinephrine and, presumably, its β_2 -agonist effects.

In circumstances in which cells proliferate and grow rapidly (e.g., acute leukemias, Burkitt's lymphoma), extracellular K⁺ may also be sequestered, and hypokalemia may ensue. In vitro sequestration of potassium may occur in leukocytes rich blood (acute myelogenous leukemia) if sufficient time elapses before analysis. This leads to spurious reductions in K⁺ that obviously need not be replaced.

POTASSIUM DEPLETION

DIETARY CAUSES

Reduced potassium intake (e.g., in the elderly person on a “tea- and-toast” diet and in sufferers of anorexia nervosa or bulimia) and states of protein/calorie malnutrition are associated with significant K^+ losses (3 mEq per gram of nitrogen loss in the latter). Induced vomiting and diuretic or laxative use often compounds the problem. Intravenous feedings of glucose solutions or the use of parenteral nutrition without appropriate potassium supplementation may result in hypokalemia. Geophagia (clay or dirt ingestion) results in hypokalemia if the clay is white (which binds intestinal K^+), but might lead to hyperkalemia, particularly in patients with renal insufficiency, if the clay is red (high K^+ content).

Uncomplicated body K^+ depletion lowers both intra- and extracellular K^+ concentration so that plasma K^+ decreases by 1 mEq for each 300-mEq deficit, up to a depletion of about 700 mEq. If losses exceed 1,000 mEq, plasma K^+ is usually less than 2 mEq/L. This relation between plasma K^+ and K^+ depletion may be altered if the factors determining transcellular distribution are offset simultaneously. For example, patients with diabetic ketoacidosis may have relatively normal K^+ levels as a result of lack of insulin, acidosis, and hyperosmolality (all of which promote extracellular shifts) yet may have marked K^+ depletion.

EXTRARENAL CAUSES

Diarrhea is a common cause of K^+ loss usually associated with metabolic acidosis (normal anion gap), which provides a clue to the underlying problem. Laxative abuse (usually surreptitious) can be uncovered by screening the stool and urine for phenolphthalein-containing compounds, which exhibit a reddish purple color on alkalization. The discovery of melanosis coli on a proctoscopic examination can confirm this diagnosis. For unknown reasons, laxative abusers may present with metabolic alkalosis instead of metabolic acidosis. Two rare conditions, villous adenoma of the rectum and non-b-cell pancreatic islet tumors, lead to watery diarrhea of high K^+ content, hypokalemia, as well as metabolic acidosis.

Loss of gastric fluid from vomiting or drainage (K^+ 10 to 15 mEq/L) associated with renal potassium losses also leads to K^+ deficiency. Sweat losses from vigorous training in hot climates can deplete body stores, but for unknown reasons the kidney does not conserve potassium appropriately despite severe cellular depletion.

RENAL CAUSES

Urine potassium concentration above 20 mEq in the presence of hypokalemia is considered inappropriate. Almost invariably, hypokalemia of nonrenal origin is accompanied by reductions in potassium excretion below 20 mEq per day. Renal potassium wasting is principally found in states of high mineralocorticoid secretion or administration. For diagnostic purposes, the presence or absence of hypertension and the associated acid–base status can be used to classify hypokalemia.

METABOLIC ACIDOSIS

Because hypokalemia is usually associated with metabolic alkalosis or normal acid–base status, the presence of metabolic acidosis is an important diagnostic clue. Metabolic acidosis, renal potassium wastage, and hypokalemia—which may induce severe paralysis—are common in both distal (type I) and proximal (type II) renal tubular acidosis. In the latter, hypokalemia is particularly prominent during therapy with high doses of bicarbonate; in the former, alkali therapy curtails potassium loss. Acetazolamide (Diamox) and other carbonic anhydrase inhibitors can produce a combination of proximal and distal renal tubular acidosis and can lead to K^+ depletion. Metabolic acidosis and potassium deficiency is also found in diabetic ketoacidosis, in which, as already pointed out, the plasma K^+ level may be normal.

NORMOTENSIVE DISORDERS

Hypertension itself has little bearing on the development of alkalosis or hypokalemia, but its presence or absence is extremely helpful in establishing a cause for the disturbance. Chloride depletion is the most common cause of hypokalemic metabolic alkalosis and usually results from gastrointestinal fluid losses caused by vomiting, gastric drainage, or chloride-depleting diarrhea or from renal losses secondary to diuretic therapy.

Chloride depletion leads to contraction of the extracellular fluid and avid chloride retention by the kidney. As a consequence, urine concentration of chloride falls, but that of sodium, potassium, and bicarbonate may increase. The hypochloriduria (Cl^- less than 10 mEq per L) in a persistently alkalotic patient almost always indicates gastric fluid losses because the ion is clearly not wasted in the urine. Persistence of an inappropriate kaliuresis, in which increased aldosterone secretion plays a minor role, is partly responsible for the hypokalemia. Low chloride and high bicarbonate in the distal nephron directly stimulate K^+ secretion, with the former mechanism possibly playing the major role. Hypokalemia inhibits and alkalosis stimulates distal potassium secretion; if the latter predominates, it can perpetuate the kaliuresis.

The use of thiazides and loop diuretics is the most common cause of K^+ depletion and metabolic alkalosis. The increase in urine flow and distal sodium delivery in the presence of volume depletion and excess aldosterone secretion leads to marked kaliuresis. In patients taking prescribed diuretics, it may be easy to identify the cause of the hypokalemic (plasma K^+ rarely less than 3 mEq per L) alkalosis. Surreptitious diuretic use (e.g., weight loss schemes) must be suspected and excluded in normotensive patients in whom hypokalemic alkalosis or renal potassium wasting does not have a clear cause. The concomitant finding of high urine chloride is also suspicious, and proof can come from demonstrating the presence of diuretics by chromatographic analysis of the urine.

Bartter's syndrome is a rare disease characterized by hyperreninemia, hyperaldosteronism, hyperplasia of the juxtaglomerular apparatus, increased prostaglandin secretion, insensitivity to the pressor effect of angiotensin II, and normal blood pressure. The syndrome results from a defect of the loop of Henle's two chloride, sodium-potassium cotransporter, and is attended by hypokalemic alkalosis (see [Chapter 149](#)). Gitelman's syndrome is caused by a defect in the early distal tubule sodium chloride transporter and is characterized by a tendency to hypotension, metabolic alkalosis, hypomagnesemia, and hypokalemia.

Acute myelomonoblastic leukemias may present with renal potassium wastage (25% of cases), often associated with increased urine lysozyme excretion. Magnesium depletion may be accompanied by hypokalemia that is resistant to potassium replacement until the Mg^{2+} deficit is corrected. Drugs such as cisplatin, gentamicin, and levodopa can lead to potassium wasting.

HYPERTENSIVE DISORDERS

Hypertensive conditions usually result from excess mineralocorticoids or, less frequently, glucocorticoids. Extracellular fluid expansion is present so that the urine chloride level exceeds 10 mEq per L. Plasma renin assay can further help to classify these disorders.

Primary hyperaldosteronism (low renin, hypertension) can result from a solitary adenoma (65% of cases), bilateral adrenal hyperplasia, or carcinoma. Increased sodium delivery to the distal tubule in the presence of high aldosterone secretion leads to renal K^+ losses. A high salt intake, by increasing distal sodium for potassium exchange, worsens the kaliuresis. Moreover, salt loading (oral and intravenous) does not suppress aldosterone secretion, which in the presence of a low plasma renin level helps establish the diagnosis and distinguishes it from secondary hyperaldosteronism (edematous states such as heart failure and liver cirrhosis). Secondary hyperaldosteronism states (high renin, normotensive) often result in K^+ depletion, as when edematous patients are treated with diuretics, but in conditions such as renal artery stenosis, malignant hypertension, or rare renin-producing tumors (high renin, hypertensive), hypokalemia may be spontaneous.

Other mineralocorticoid excess conditions presenting with low renin hypertension and hypokalemic alkalosis include ingestion of compounds such as glycyrrhizic acid (present in licorice and some chewing tobacco) and carbenoxalone. Both of these inhibit 11 β -hydroxysteroid dehydrogenase, an enzyme that converts cortisol to cortisone in mineralocorticoid-responsive cells (e.g., renal tubule). Cortisol, but not cortisone, interacts with the mineralocorticoid (aldosterone) receptor. Because cortisol in normal plasma is 100-fold greater than aldosterone, failure of conversion to cortisone permits it to occupy the mineralocorticoid receptor, resulting in salt retention, kaliuresis, and hypokalemia. Hypertension and hypokalemia characterizes a rare genetic abnormality that leads to 11 β -hydroxysteroid dehydrogenase deficiency, also known as apparent mineralocorticoid excess, since plasma aldosterone is low or normal. The use of fludrocortisone acetate (Florinef), intranasal corticosteroid with mineralocorticoid properties, or excessive deoxycorticosterone production as in adrenogenital syndromes (17 α -hydroxylase or 11 β -hydroxylase deficiencies) also are examples of low renin hypertension. In all of the nonaldosterone mineralocorticoid excess conditions, aldosterone secretion is suppressed.

Cushing's syndrome (excess endogenous production or exogenous administration of glucocorticoid) can lead to hypokalemia. Hypokalemia is more common when the

Normal blood pressure and high urine chloride excretion restrict the diagnostic possibilities to Bartter's syndrome and diuretic ingestion. The one caveat is that severe K^+ depletion, regardless of its cause, can promote urine chloride wasting; however, plasma K^+ concentration less than 2 mEq per L with K^+ depletion above 1,000 mEq is needed. In the face of K^+ depletion of this magnitude, partial correction of the deficit may be required before undertaking the differential diagnosis.

Metabolic alkalosis accompanied by intense urine chloride conservation suggests conditions (mostly extrarenal) causing chloride depletion.

Equivocal pH values are common in some hypokalemic conditions, making categorization difficult. Magnesium depletion may be the most elusive, and magnesium should be measured in any patient with K^+ depletion of unclear origin. Other conditions, such as drug-induced K^+ depletion or leukemia, are usually readily apparent.

THERAPY

Treatment of K^+ depletion requires a decision about the specific K^+ salt to be used, and about the route and speed of administration. The magnitude of K^+ depletion can be inferred from the plasma K^+ level and can serve as a guide for the amount of potassium replacement (grossly, 300 mEq per 70 kg body weight leads to a reduction in plasma K^+ of 1 mEq per L). The speed and route of replacement is based on the clinical setting. The presence of a life-threatening emergency such as serious cardiac dysrhythmia or paralysis requires rapid correction. Otherwise, slow intravenous replacement or, if feasible, oral therapy is preferable to avoid induction of hyperkalemia. Because estimates of potassium deficits are inexact, repeat measurements during treatment are wise if not mandatory. As normokalemia is approached, treatment, particularly intravenous, should be cut back.

The cause of K^+ depletion influences the choice of potassium salt. Potassium chloride replacement is effective in all circumstances and is required when chloride depletion accounts for the K^+ depletion. When the depletion is associated with acidosis, treatment with $KHCO_3$ or the potassium salt of a bicarbonate precursor such as citrate, acetate, or gluconate is a rational choice. Coexistence of K^+ and phosphate deficits, as in alcoholics and patients with diabetic ketoacidosis, can be treated with potassium phosphate.

Potassium chloride can be given orally as a liquid or as one of several slow-release tablets. Most patients because of the unpleasant taste of liquid KCl prefer tablets; however, the risk of enteric ulceration, although small, may be greater with slow-release preparations. To maintain a normal serum K^+ concentration, as in patients receiving diuretic therapy, an alternative to K^+ replacement is the use of the K^+ -sparing diuretics such as spironolactone, triamterene, or amiloride. In general, the last two drugs are preferable because spironolactone inhibits only aldosterone-mediated K^+ secretion and, in addition, may induce gynecomastia.

There is considerable debate concerning the appropriate management of diuretic-induced hypokalemia. Many view the degree of depletion as typically mild and asymptomatic, making routine K^+ therapy inappropriate. Others believe that the risk of cardiac abnormalities is sufficient to warrant a more aggressive approach. A reasonable compromise is to recommend K^+ maintenance therapy (i.e., the maintenance of a normal serum K^+ level with either K^+ -sparing diuretics or potassium chloride supplements) in patients treated with cardiac glycosides, those prone to hepatic coma, those whose serum K^+ levels decrease to less than 3 mEq per L, and those with underlying myocardial disease, diuretic-induced glucose intolerance, or symptoms attributable to hypokalemia. It must be understood that the safest way to minimize hypokalemia is to ensure adequate intake of dietary potassium. High potassium content is present in dry figs and molasses. Other K^+ -rich foods include dried fruits, nuts, lima beans, tomatoes, carrots, potatoes, bananas, oranges, ground beef, veal, and lamb, to name some.

The major risk of the treatment of hypokalemia is overzealous therapy, with the development of life-threatening hyperkalemia. Conditions that predispose to this complication are detailed in [Chapter 147](#).

[Therapy](#)

Hyperkalemia, which refers to an elevated serum K⁺ concentration, can result from a spurious laboratory value, redistribution from the intracellular to the extracellular compartment, or K⁺ retention (a surfeit). Chronic hyperkalemia is invariably the result of a defect in renal potassium excretion.

SPURIOUS HYPERKALEMIA

Factitious elevation of serum K⁺ can result from various factors (Fig. 147.1). Hemolysis of the specimen—rarely from an acquired or hereditary defect in the K⁺ permeability of the erythrocyte membrane—can elevate K⁺ concentration. Leukocytosis (white cell count $\geq 70,000/\text{cm}^3$) causes spurious hyperkalemia due to K⁺ leakage from the cells when the specimen is allowed to clot, particularly if preserved in the cold. At room temperature, cellular K⁺ uptake can cause artifactual hypokalemia. Therefore, leukemic blood specimens require rapid separation of cells from plasma or serum to avoid spurious K⁺ determinations. Thrombocytosis (platelet counts $\geq 1,000,000/\text{cm}^3$) can elevate serum K⁺ levels as a result of K⁺ release from the platelets during clotting. Obtaining a heparinized specimen can circumvent this. Excessively tight and prolonged tourniquet application, together with clenching of the fist, can also elevate the K⁺ concentration by 2 mEq/L or more, by release from ischemic exercising muscle.

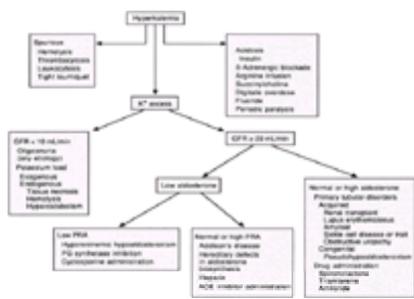

FIGURE 147.1. Diagnostic approach to hyperkalemia. GFR, glomerular filtration rate; PRA, plasma renin activity; PG, prostaglandin; ACE, angiotensin-converting enzyme.

EVIDENCE LEVEL: B. Reference: Weiner ID, Wingo CS. Hyperkalemia: a potential silent killer. *J Am Soc Nephrol* 1998;9:1535–1543.

When spurious hyperkalemia is suspected, a repeat measurement is useful, applying the appropriate precautions. The clinical insignificance of factitious hyperkalemia is rapidly confirmed by normal electrocardiogram (ECG) results; unnecessary treatment should be avoided.

HYPERKALEMIA SECONDARY TO REDISTRIBUTION

Blocking K shifts into cells can result in hyperkalemia. Acidosis, insulin deficiency, and β_2 -blocking agents predispose to hyperkalemia secondary to cellular redistribution. The mechanism of acidosis-induced shifts is complex, as it appears that only mineral acid or hyperchloremic forms of acidosis result in K⁺ shifts; organic forms of acidosis, such as lactic acidosis, do not. Organic acids are incompletely dissociated in solution and as such enter cells where they breakup into protons and the weak bases, thus the membrane potential is mostly unaffected which prevents conductive cellular potassium exit. Organic acidosis also stimulates insulin release, which by shifting K into cells may contribute to the absence of hyperkalemia. Thus, hyperkalemia may be seen in diabetic ketoacidosis as a consequence of insulin deficiency and hypertonicity from hyperglycemia, as high extracellular fluid (ECF) osmolality pulls both water and K⁺ from the intracellular space. The degree of K⁺ alteration is greater with metabolic than with respiratory acidosis, averaging 0.7 mEq/0.1 pH unit with metabolic and 0.1 mEq/0.1 pH unit with respiratory acidosis. Cell shifts are more likely to contribute to hyperkalemia than to hypokalemia, because cellular uptake is easier than cellular release of potassium.

Use of β -blockers predisposes toward hyperkalemia. If other K⁺ regulatory mechanisms are intact, only minimal increases in the serum K⁺ concentration occur; however, serious hyperkalemia can be provoked in patients otherwise prone to K⁺ abnormalities, such as those on chronic hemodialysis.

Redistribution hyperkalemia may be induced by the use of or intoxication with several drugs that can alter K⁺ distribution across cellular membranes, including cardiac glycosides, succinylcholine and other depolarizing muscle relaxants, arginine HCl, and fluoride. K⁺ egress from contracting muscle can produce substantial hyperkalemia with acute, maximal, or very prolonged exercise, such as participation in marathons. Hyperkalemic periodic paralysis is an autosomal dominant hereditary disorder featuring episodic paralytic attacks accompanied by shifts of K from the cellular compartment. The attacks are precipitated by ingestion of small amounts of potassium or other unrelated stimuli (eg, excitement, cold, fasting, stress, infection, and general anesthesia). The attacks may be averted by eating sugar, to cause insulin release, or by using inhalers containing β_2 -adrenergic agonists.

HYPERKALEMIA SECONDARY TO K⁺ RETENTION

K⁺ excretion requires a normal number of functioning nephron units, adequate delivery of sodium and fluid to the distal nephron, an intact aldosterone system, and a distal tubular epithelium with an intact K⁺ secretory mechanism. Abnormalities in any of these parameters can lead to hyperkalemia secondary to K⁺ retention.

ABNORMAL GLOMERULAR FILTRATION RATE

Decreases in the number of functioning nephron units curtails the kidney's capacity to excrete K⁺. So long as K⁺ intake is normal, however, a glomerular filtration rate (GFR) above 5 mL/min can usually sustain normokalemia. Preservation of K⁺ balance occurs because the remaining nephrons adapt their K⁺ secretory capacity, similar to the way normal kidneys do when confronted with an increase in dietary K⁺. On the other hand, dependence on the kidney's adaptive capacity to sustain K⁺ balance with a normal intake limits its ability to handle an increased K⁺ load. Thus, when GFR is decreased significantly (ie, ≤ 20 mL/min), patients are at risk of hyperkalemia in response to an increased K⁺ load. This can result from exogenous sources such as foods high in K⁺, K⁺ replacement therapy, or the use of salt substitutes (which contain K⁺), or it may result from endogenous generation of a K⁺ load. Release of K⁺ from tissue breakdown, as in rhabdomyolysis and tissue trauma, red blood cell degradation in hematomas, or bleeding into the gastrointestinal tract, can produce life-threatening hyperkalemia in patients with a compromised GFR.

Hyperkalemia is a major potential complication of acute renal failure, whether oliguric or nonoliguric. Therefore, all patients with this diagnosis should have an ECG

performed as early as feasible to rule out life-threatening hyperkalemia.

When the number of functioning nephron units is sufficient to sustain K^+ homeostasis (≥ 20 mL/min), renal hyperkalemia results either from aldosterone deficiency or from a primary defect in K^+ secretion by the distal tubular epithelium.

HYPOALDOSTERONISM

Aldosterone deficiency, regardless of the underlying cause, predisposes to the development of hyperkalemia. Patients with low aldosterone levels are not always hyperkalemic if their renal function is normal; however, a decrease in distal salt and water delivery in these persons may induce overt hyperkalemia.

Combined aldosterone (mineralocorticoid) and glucocorticoid deficiencies result in the classical features of Addison's disease. The aldosterone deficiency leads to renal sodium wasting and potassium retention, and the glucocorticoid deficiency results in water retention and many of the constitutional symptoms. The defects lead to hypotension, hyponatremia, and hyperkalemia. Plasma renin levels are high, but plasma cortisol levels are low and unresponsive to adrenocorticotropic hormone (ACTH) stimulation. Addison's disease results from adrenal destruction (autoimmune disease, infection, or hemorrhage) or from bilateral adrenalectomy. Hereditary enzymatic defects in aldosterone biosynthesis, including the syndrome of congenital adrenal hyperplasia (C21 hydroxylase deficiency), or isolated abnormalities in aldosterone production secondary to a deficiency in corticosterone methyl oxidase I or II are less common causes of adrenal hormonal insufficiency. When a low aldosterone level results from a primary defect in adrenal steroid production, plasma renin levels are elevated.

Aldosterone deficiency in association with chronic renal disease has been recognized with increased frequency. These patients generally have tubulointerstitial forms of renal disease and often diabetes mellitus. A few appear to have an isolated defect in adrenal aldosterone production. Most, however, exhibit combined low renin and aldosterone levels, a syndrome referred to as hyporeninemic hypoaldosteronism. A defect in renin secretion seems to be responsible for the low aldosterone levels, although the precise pathophysiology of disordered renin metabolism is unresolved. Many of these patients also exhibit abnormal aldosterone release in response to potassium (usually a potent stimulus for aldosterone release), angiotensin II, or exogenous ACTH, suggesting that a primary defect in adrenal aldosterone production might coexist with the renal defect that causes low renin secretion. In addition to hyperkalemia, about half of these patients exhibit hyperchloremic metabolic acidosis, which appears to be secondary to hyperkalemia-induced suppression of renal ammonia production and perhaps also abnormal H^+ secretion as a result of low aldosterone levels (so-called type IV renal tubular acidosis). In contrast to patients with Addison's disease, persons with hyporeninemic hypoaldosteronism are fluid overloaded; hyponatremia is unusual because cortisol levels are normal.

Several medications can cause aldosterone deficiency that leads to hyperkalemia. Heparin directly impairs adrenal aldosterone biosynthesis. Prostaglandin synthetase inhibitors, such as indomethacin, reduce renin release and produce reversible hyporeninemic hypoaldosteronism, particularly in patients with chronic renal insufficiency. Angiotensin-converting enzyme inhibitors produce hypoaldosteronism by lowering angiotensin II levels, while angiotensin II receptor antagonists can do so through diminished aldosterone secretion. Cyclosporine produces hyperkalemia by suppressing renin levels, but it may also impair aldosterone secretion and directly interfere with tubular K^+ secretion.

In addition to the development of hyporeninemic hypoaldosteronism and acquired immune deficiency syndrome (AIDS)-related adrenal insufficiency, renal potassium excretion is impaired as a result of therapy with pentamidine or trimethoprim, both of which block the principal cell apical sodium channel, and thus potassium excretion, similar to amiloride. Pentamidine-induced hyperkalemia has been almost always observed in the setting of acute renal failure.

NORMAL ADRENAL FUNCTION

Several diseases, all of which can cause hyporeninemic hypoaldosteronism, can also produce hyperkalemia without a concurrent decrease in aldosterone levels. These conditions, which presumably interfere in some direct fashion with K^+ secretion by the distal nephron, include lupus erythematosus, amyloidosis, obstructive uropathy, sickle-cell disease, and postrenal transplantation. Patients with chronic renal failure may have increased levels of plasma aldosterone, suggesting some degree of resistance to mineralocorticoids.

Tubular hyperkalemia occurs in two hereditary conditions. Pseudohypoaldosteronism type I affects infants and presents with salt wasting and hyperkalemia suggestive of aldosterone deficiency. Aldosterone levels are normal or high, however, and a defect in the aldosterone receptor has been found in several aldosterone-responsive tissues. Pseudohypoaldosteronism type II presents in late childhood or in adults, with hypertension rather than salt wasting. Abnormally avid chloride reabsorption by the distal nephron may account for volume expansion, hypertension, and a defect in K^+ secretion.

The K^+ -sparing diuretics all cause hyperkalemia through their effect on the renal tubule. Spironolactone interferes with the action of aldosterone; amiloride and triamterene inhibit K^+ secretion by an aldosterone-independent mechanism.

CONSEQUENCES OF HYPERKALEMIA

Hyperkalemia alters the function of excitable tissues by decreasing the K^+_{i}/K^+_{e} ratio. Because the intracellular K rises minimally or actually falls in hyperkalemia, the intracellular-to-extracellular ratio decreases, causing depolarization of the cell membrane and leading to clinically significant dysfunction of cardiac and skeletal muscle.

Severe hyperkalemia can produce cardiac arrest. The ECG manifestations of hyperkalemia parallel to some extent the severity of the rise in the K^+ level. An early manifestation is peaking or tenting of the T waves, which becomes most prominent with K levels of 6 mEq/L or more. More severe hyperkalemia flattens the P wave, prolongs the PR interval, and widens the QRS complex, with deepening of the S wave. The final event is a sine wave pattern (merging of the widening QRS complex with the T wave), followed by ventricular flutter, fibrillation, and cardiac arrest.

Hyperkalemia produces tingling, paresthesias, weakness, and even flaccid paralysis, particularly of the lower extremities but sparing the respiratory muscles. In most cases, this occurs when the plasma K level exceeds 8 mEq/L; thus, cardiac toxicity usually precedes these neurologic manifestations. Some of these symptoms (eg, weakness, tingling) may mimic hysteria and hyperventilation, which may transiently cloud the possibility of life-threatening hyperkalemia.

Hyperkalemia elevates plasma aldosterone levels by directly stimulating adrenal aldosterone release. A high K^+ level tends to suppress renin levels, but because a high K^+ intake is natriuretic, the volume contraction sometimes overrides the direct K^+ suppressive effects, elevating renin levels. Normal anion gap metabolic acidosis is commonly associated with hyperkalemia. This may be the result of a combination of hydrogen ion displacement from cells and the inhibitory effect of hyperkalemia on renal ammonia production. When aldosterone secretion is reduced, it contributes to the acidosis because renal hydrogen secretion is impaired.

DIAGNOSTIC APPROACH

SPURIOUS AND REDISTRIBUTION HYPERKALEMIA

The first step in the assessment of a hyperkalemic patient is to rule out a spurious laboratory value (see [Fig. 147-1](#)). If the K^+ level is severely elevated, an ECG should be performed promptly: it is helpful diagnostically and also indicates the need for rapid institution of therapy. Next, the possibility of hyperkalemia secondary to redistribution should be considered by reviewing the clinical situation, determining the acid-base status, and considering potential drug-induced conditions.

RENAL DYSFUNCTION

In the presence of oliguria or acute renal failure, the cause of hyperkalemia is usually apparent. On the other hand, in the presence of other renal diseases, it is essential to measure some index of renal function (plasma creatinine, blood urea nitrogen, or creatinine clearance). If the GFR exceeds 5 mL/min, the possibilities of excess K^+ intake and of a defect in tubule K^+ secretion must be considered. A practical approach is to obtain a 24-hour urine collection for K^+ and creatinine and to measure plasma K^+ and creatinine levels simultaneously. The total amount of K^+ in the urine indicates whether a hidden source of K^+ intake not detected in the history explains the hyperkalemia. The calculated fractional excretion of K^+ (FEK⁺) in relation to the GFR indicates whether a defect in K^+ secretion accounts for the

hyperkalemia. If the FEK⁺ is low in relation to GFR, it is useful to measure plasma renin and aldosterone levels.

HORMONAL DEFICIENCIES

Low aldosterone levels and high renin levels suggest adrenal insufficiency, which can be confirmed by measuring plasma cortisol. If both aldosterone and renin are suppressed, the diagnosis of hyporeninemic hypoaldosteronism can be made; if the values are normal, the patient has a primary tubular defect. These two diagnostic possibilities can be confirmed by assessing the plasma K⁺ response to mineralocorticoid replacement (fludrocortisone acetate [Florinef], 0.1 mg/d for 2 wk). This is usually unnecessary and should be carried out with caution, because salt retention with volume overload and hypertension are potential risks in patients with abnormal renal function.

THERAPY

Acute hyperkalemia is a life-threatening abnormality. The higher the plasma K⁺ level and the more severe the ECG alterations and the clinical setting, the more urgent the need for treatment. When the correlation between potassium levels and clinical findings is uncertain, it is preferable to err on the side of overtreatment ([Table 147.1](#)). Calcium antagonizes the effects of hyperkalemia on the heart by stabilizing the myocardium. The effects of hyperkalemia are reversed within seconds and ventricular fibrillation and arrest are averted. Calcium raises the threshold potential, reestablishes the difference between resting and threshold potentials and restores cell excitability, which is dramatically reduced by hyperkalemia.

Medication	Dose	Onset	Duration of Apparent Effect	
Calcium (gluconate 20%)	Membrane antagonist	10–12 mg IV	1–2 min	30–60 min
Albuterol (inhalant)	Redistribution	20 mg in 4 mL saline inhalant over 10 min	15–20 min	1 h
Insulin plus glucose	Redistribution	20 units of regular insulin with 50 g glucose IV over 1 h	30 min	4–6 h
Calcium exchange resin (Kayexalate)	Excretion	2–30 g PO or per rectum with sorbitol	1–2 h	4–6 h
Resonium or hemodialysis	Excretion	—	Within minutes after starting	120 days if continued
Diuretics	Excretion	—	Within minutes of starting	120 days
Furosemide	40 mg IV			48 h
Ethacrynic acid	50 mg IV			48 h

Modified from *Statens Medicinalråd, et al. Handbook of renal therapeutics*. New York: Raven Publishing, 1982, with permission.

TABLE 147.1. ACUTE THERAPY OF HYPERKALEMIA

Bicarbonate and insulin both drive K⁺ into the intracellular compartment. Hyperkalemia is usually associated with a decrease in plasma bicarbonate concentration. Bicarbonate administration is effective in driving potassium into cells but the changes are small and unpredictable. The hypokalemic effects of insulin are dose-related; thus, an intravenous bolus should be given to achieve high plasma levels. Hypoglycemia should be prevented by infusing 50 g glucose per hour to accompany the repeated injections (every 15 min) of 5 units of insulin.

β₂-Adrenergic agonists, given intravenously or by inhalation (nebulized albuterol is particularly effective), also can rapidly induce cellular K⁺ uptake, but they are not uniformly effective in patients with renal failure.

Diltiazem has been shown to reduce the rate of increase in plasma potassium in anuric patients with end-stage renal disease. The effect is independent of plasma aldosterone, cortisol, glucose, or magnesium. Diltiazem and other calcium channel blockers may enhance the cellular uptake of potassium secondary to inhibition of calcium-activated potassium channels in the cell membrane that normally permit diffusion of potassium out of cells.

In general, these maneuvers act rapidly and provide time to eliminate the excess K⁺ burden from the body. The dose of albuterol used is usually too low to effect changes rapidly enough to be a first-line treatment in acute hyperkalemia. More delayed but effective action can be obtained from the cation exchange resin sodium polystyrene sulfonate (Kayexalate). It removes K⁺ from the body most rapidly when given as a retention enema, but is also effective orally in conjunction with a laxative (usually sorbitol). Colonic necrosis has been reported in postoperative patients treated with Kayexalate and sorbitol enemas, and animal studies suggest that sorbitol may be the offending agent.

Sometimes dialysis is necessary for K⁺ removal. Hemodialysis is more efficient than peritoneal dialysis for this purpose.

Patients with hyporeninemic hypoaldosteronism exhibit chronic hyperkalemia. If the K⁺ level is sustained below 5.8 mEq/L, no therapy other than counseling about high-K⁺ foods and the avoidance of medications that can interfere with K⁺ metabolism is required. Specific treatment options to increase K⁺ excretion include the use of exogenous mineralocorticoid replacement, bicarbonate to correct metabolic acidosis, and thiazide or loop diuretics. The risks of mineralocorticoid replacement leading to volume depletion in patients with compromised renal function should be considered. If necessary, Kayexalate can be given on a chronic basis with a mild laxative, but most patients find this medication unpleasant for chronic use.

both sodium and magnesium absorption in the thick ascending limb. Curiously, the thiazide diuretics, which act at a site of minimal magnesium reabsorption, are often associated with hypomagnesemia. Thiazide-induced hyperaldosteronism, hypokalemia, and hypercalcemia might converge to cause renal magnesium wasting. Similarly, Gitelman's syndrome, a familial disease due to mutations in the thiazide-sensitive cotransporter in the distal tubule, leads to hypokalemic alkalosis with hypocalciuria and hypomagnesemia. Drugs toxic to renal tubules, such as aminoglycoside antibiotics and the chemotherapeutic agent cisplatin, commonly lead to excess renal magnesium losses. The effect of cisplatin may persist for months. Pentamidine and foscarnet may also cause magnesium wasting.

Combined causes of hypomagnesemia are common in alcoholism and diabetes. In alcoholics, intake is often impaired by a magnesium-deficient diet, coupled with decreased uptake due to intestinal malabsorption. Cellular magnesium, potassium, and phosphorus are common losses in persons with alcoholics. Finally, renal conservation is compromised by increased urinary lactate excretion. Acute, but not chronic, alcohol ingestion directly increases urinary magnesium losses. Diabetics, especially those in poor metabolic control, tend to have a lower serum magnesium concentration. Both glycosuria and excretion of ketoacids enhance renal magnesium losses. Although uncommon, hypomagnesemia resulting from an acute intracellular shift may be seen after refeeding in the alcoholic or after insulin treatment of the diabetic with ketoacidosis.

PATHOGENESIS

The clinical syndromes seen with magnesium depletion must be differentiated with respect to the pool of magnesium most affected by the loss. For instance, a simple dietary deficiency of magnesium leads quickly to hypomagnesemia and, eventually, to reduced bone content of the cation, but uncommonly to muscle magnesium depletion. Conversely, diseases that lead to cellular wasting of protein, potassium, and phosphorus produce a decreased muscle magnesium content, but the patient may not exhibit hypomagnesemia.

CLINICAL FEATURES

The clinical effects of hypomagnesemia are strongly influenced by the frequent association with hypocalcemia or hypokalemia. Many of the signs and symptoms of hypomagnesemia are thought to be related to those associated electrolyte disturbances. Severe hypomagnesemia itself results in hypocalcemia due to an inhibition of both parathyroid hormone release and its calcemic action at the level of bone. It is postulated that the reduced activity of cellular Na^+ , K^+ -ATPase induced by hypomagnesemia may lead to cellular potassium loss and an associated increase in urine potassium excretion.

Neuromuscular abnormalities are often associated with hypomagnesemia—most commonly, a positive Trousseau's or Chvostek's sign, muscle fasciculations, tremor, muscle spasticity, or tetany. Vertigo, athetoid and choreiform movements, nystagmus, anxiety, delirium, and seizures have also been described. Anorexia, nausea, and apathy are common before the appearance of the peripheral neuromuscular manifestations of hypomagnesemia.

Cardiovascular effects, which include a prolonged QT interval, may predispose to ventricular dysrhythmias. Significant controversy surrounds the association of hypomagnesemia with diuretic therapy. Hypokalemia and the associated hypomagnesemia may enhance the morbidity and mortality of cardiac ischemia or acute myocardial infarction through a dysrhythmogenic effect. An increase in arteriolar tone described in hypomagnesemia may be one basis for essential hypertension.

HYPERMAGNESEMIA

With normal renal function, magnesium excretion can rise by more than fivefold to accommodate increased magnesium intake without changes in its serum concentration. In chronic renal insufficiency, reduced tubular absorption of magnesium maintains normomagnesemia until magnesium delivery becomes limited by the GFR (less than 15 mL per minute). Most cases of hypermagnesemia are seen in the setting of acute or chronic renal insufficiency with severe reductions in GFR. However, hypermagnesemia may occur without severe renal insufficiency in association with bowel disease, especially in elderly patients.

Clinically significant hypermagnesemia in these patients usually occurs as a consequence of ingestion of magnesium-containing antacids (which contain 7 to 14 mEq Mg^{2+} per 5 mL) or magnesium-based cathartics. Bone, but not cellular, magnesium is usually increased in chronic renal insufficiency. Acute hypermagnesemia may follow parenteral magnesium sulfate administration in obstetrics or after excess ingestion of magnesium sulfate (Epsom salt).

Clinical effects of hypermagnesemia are unusual until the serum magnesium exceeds 4 mEq per L. Pharmacologic doses of magnesium have a curare-like effect, increasing the stimulus threshold in nerve fibers and blocking synaptic transmission. Thus, hypermagnesemia may cause initial weakness that can progress to complete paralysis. Earlier, less specific findings include nausea, vomiting, cutaneous flushing, and diminished or absent deep tendon reflexes. Progressive elevations in the serum magnesium level may lead to respiratory muscle paralysis, requiring intubation. Intracardiac conduction abnormalities and hypotension may supervene. At a serum magnesium level above 8 to 10 mEq per L, flaccid quadriplegia, difficulties in talking or swallowing, and respiratory paralysis, coupled with hypotension and dysrhythmias, are imminent hazards. The ECG findings include increased atrioventricular and intraventricular conduction times, evidenced by lengthened PR and QRS intervals.

APPROACHES TO DIAGNOSIS AND MANAGEMENT

HYPOMAGNESEMIA

The severity of hypomagnesemia and the presence of referable symptoms determine the clinical strategy. The degree of magnesium depletion may not be wholly revealed in the serum magnesium concentration, but there is little indication for determining the tissue (bone or muscle) magnesium content. The excretion of less than 1 to 2 mEq of magnesium in a 24-hour urine collection usually indicates a state of deficiency. In less clear cases, as with alcoholics, the renal retention of more than 40 mEq of magnesium during replacement over a 4- to 5-day period indicates a preexisting deficiency. A parenteral magnesium tolerance test has been proposed as the most sensitive method to diagnose magnesium deficiency, which is indicated by increased magnesium retention after an intravenous magnesium load. Measurement of fractional magnesium excretion (FEMg) may also be useful. An FEMg greater than 4% suggests inappropriate urinary magnesium loss.

Generally, oral magnesium administration is safer and, thus, may be preferable in asymptomatic patients. Gastrointestinal absorption of an oral magnesium dose may be erratic, however, and magnesium salts are cathartic. For these reasons, particularly with significant hypomagnesemia, intravenous or intramuscular magnesium administration might be required. In persons with normal renal function, excess magnesium is promptly excreted into the urine. In the face of renal insufficiency, however, great care must be taken and a lower dose of magnesium used. Patients with advanced renal failure should receive magnesium infusions for urgent indications only. Monitoring of deep tendon reflexes (lost at a serum magnesium level greater than 5 mEq per L), the PR interval (prolonged at a serum magnesium level greater than 6 to 7 mEq per L), and blood pressure is critical to prevent serious complications. Simultaneous administration of potassium, phosphorus, and calcium may be needed to accompany magnesium repletion in recovery from diabetic ketoacidosis, in alcoholism, and during parenteral alimentation.

[Figure 148.2](#) outlines an approach to magnesium repletion based on the mechanism of depletion and the magnitude of the existing or expected deficiency. Patients with chronic malabsorption and those on parenteral alimentation should be given magnesium prophylactically to avoid hypomagnesemia and hypocalcemia. In the early hospital stay for both diabetic ketoacidosis and alcoholism, daily requirements of magnesium may reach 30 to 50 mEq, with ongoing urinary losses with organic acids.

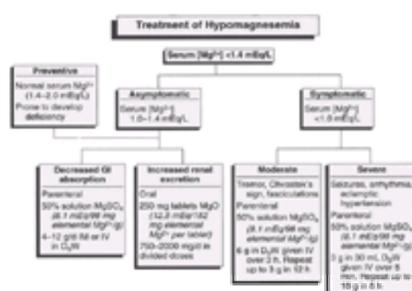

FIGURE 148.2. Treatment of hypomagnesemia.
EVIDENCE LEVEL: C. Expert Opinion.

Magnesium supplementation may be warranted for patients receiving chronic diuretic therapy, particularly for patients given digitalis preparations. The goal is to prevent or reduce the incidence of significant ventricular dysrhythmias due to hypomagnesemia and hypokalemia. Such patients may be refractory to potassium repletion in the face of significant magnesium depletion. Oral magnesium plus potassium supplementation may suffice, but coadministration of potassium-sparing diuretics such as spironolactone or amiloride, which reduce urinary magnesium losses, is equally useful.

In asymptomatic mild hypomagnesemia (1.1 to 1.4 mEq per L), consumption of a normal diet containing adequate magnesium is often sufficient. This can be supplemented by oral magnesium, most effectively given as magnesium oxide, 250 to 500 mg, 3 or 4 times daily. Patients with more severe hypomagnesemia, particularly if symptomatic, should receive 3 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ in 5% dextrose in water given as an intravenous push over 5 minutes. This can be repeated up to a total dose of 10 g in 6 hours, but should be done with close ECG and blood pressure monitoring. In less severe situations, 6 g can be given over 3 hours, followed by another 6 g every 12 hours for 3 to 5 days until the magnesium deficiency is corrected. In general, dosages below 100 mEq per day are tolerated safely in the presence of normal renal function; rarely are more excessive dosages required.

HYPERMAGNESEMIA

Hypermagnesemia requires immediate assessment of neuromuscular and cardiac function, including bedside evaluation of motor and deep tendon reflex functions and performance of an ECG. Because cardiac arrest correlates poorly with blood levels, any serum magnesium level above 6 mEq per L should receive urgent attention.

Cessation of inadvertent magnesium administration is often sufficient in mild (less than 4 mEq per L) and asymptomatic hypermagnesemia. In patients with adequate renal function, the use of intravenous furosemide plus parenteral 0.45% saline replacement of urinary losses can augment magnesium excretion.

In the presence of life-threatening signs, usually at serum levels above 7 to 10 mEq per L, the acute administration of as little as 5 to 10 mEq of calcium can rapidly reverse a potentially lethal depression in respiration or cardiac dysrhythmias. A mild elevation of serum calcium after calcium administration might also enhance urinary magnesium excretion. In the presence of significant renal failure, dialysis using a magnesium-free dialysate is indicated. Hemodialysis is more efficient and is preferred in life-threatening conditions. If respiration is depressed, artificial ventilation may be necessary while the patient is undergoing dialysis for removal of magnesium.

CHAPTER 149: APPROACH TO THE PATIENT WITH ACID–BASE ABNORMALITIES

THOMAS D. DUBOSE, JR.

[Diagnosis of Acid–Base Disorders](#)
[Metabolic Acidosis](#)
[Metabolic Alkalosis](#)
[Respiratory Acidosis](#)
[Respiratory Alkalosis](#)

DIAGNOSIS OF ACID–BASE DISORDERS

Acid–base homeostasis is exemplified by the maintenance of systemic arterial pH between 7.35 and 7.45 pH units. This feat is accomplished by extracellular and intracellular chemical buffering in conjunction with regulatory responses by the respiratory and renal systems in concert. The initial defense of systemic pH is achieved by both extracellular and tissue buffers that serve to blunt changes in pH that would occur as a result of retention of acids or bases. Chemical buffers, in combination with respiration, and renal processes dispose of the physiologic daily load of carbonic acid (as volatile CO₂) and nonvolatile acids. The control of partial arterial CO₂ pressure (PaCO₂) by the central nervous and respiratory systems, as well as control of the plasma bicarbonate by the kidneys, constitutes the regulatory processes that act to stabilize the arterial pH by excretion or retention of acid or alkali.

Metabolic acidosis and alkalosis are disorders characterized by primary disturbances in the concentration of bicarbonate in plasma, whereas respiratory disorders primarily alter PaCO₂. Suspicion that an acid–base disorder exists is usually based on the finding of an abnormal blood pH, PaCO₂, or bicarbonate concentration. Arterial blood gases should be determined simultaneously with plasma electrolytes in all patients with acid–base disturbances. This is necessary since changes in plasma bicarbonate, potassium, and chloride do not allow precise diagnosis of specific acid–base disturbances. Care should be taken when measuring blood gases to obtain the arterial blood sample without using excessive heparin. A careful analysis of the blood gas indexes (pH, PaCO₂) should begin with a check to determine if the concomitantly measured plasma bicarbonates are all consistent. In the determination of arterial blood gases by the clinical laboratory, both pH and PaCO₂ are measured, whereas the reported bicarbonate concentration is calculated from the Henderson–Hasselbach equation:

$$\text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{\text{PaCO}_2 \times 0.03}$$

This calculated value reported with the blood gases with measured bicarbonate concentration within ± 2 mEq per L should agree. After verifying the accuracy of the acid–base values in this manner, one can begin to define the precise acid–base disorder. Diagnosis may be aided by referral to an acid–base map or nomogram ([Fig. 149.1](#)); however, mixed disturbances, which are more common in critically ill patients, may not be diagnosed accurately using this nomogram. Therefore, additional steps to diagnose the acid–base disorder are necessary.

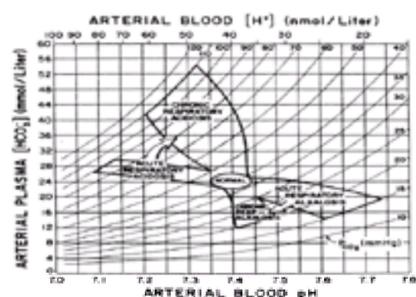

FIGURE 149.1. Nomogram showing 95% confidence intervals for the limits of respiratory and renal compensation in primary “simple” acid–base disturbances. Any two of three values for the pH, PCO₂, or HCO₃⁻ should predict the third value. Failure of all three values to intersect means that either the patient’s buffer systems are not at equilibrium or there is a laboratory error. If a given set of laboratory values falls within a stippled area, it is likely that the type of simple acid–base disturbance as designated in the figure exists. However, mixed acid–base disorders can also fall into these stippled areas, and care must be taken to distinguish a mixed from a simple acid–base disorder as discussed in the text. (From DuBose TD Jr. In: Brenner BM, Rector FC Jr, eds. *The kidney*, Vol. 1, 6th ed. Philadelphia: WB Saunders, 1999.)

SIMPLE VERSUS MIXED ACID–BASE DISORDERS

The most commonly encountered clinical disturbances are *simple* acid–base disorders, that is, one of the four cardinal acid–base disturbances in a pure or simple form: *metabolic acidosis*, *metabolic alkalosis*, *respiratory acidosis*, and *respiratory alkalosis*. More complicated clinical situations, especially in severely ill patients, may give rise to *mixed* acid–base disturbances. The possible combinations of mixed acid–base disturbances are outlined in [Table 149.1](#). In order to appreciate and recognize a mixed acid–base disturbance, it is important to understand the physiologic compensatory responses that occur in the simple acid–base disorders. The limits of the compensatory response to simple acid–base disorders are outlined in [Table 149.2](#). To illustrate, metabolic acidosis, such as may occur from a gain of endogenous acids, will lower the concentration of bicarbonate in extracellular fluid and thus extracellular pH. As a result of the acidemia, medullary chemoreceptors will be stimulated and will invoke an increase in ventilation. In response to the hypocapnic response, the ratio of HCO₃⁻ to PaCO₂ and the subsequent pH will be returned toward, but not completely to, normal. The degree of compensation expected in simple metabolic acidosis can be predicted from the following relationship: PaCO₂ = 1.5 × HCO₃⁻ + 8 ± 2 mm Hg ([Table 149.2](#)). Alternately, in the range of pH from 7.2 to 7.55, the PaCO₂ can be predicted by adding 15 to the patient’s bicarbonate ([Table 149.2](#)). Thus, a patient with metabolic acidosis and a plasma bicarbonate concentration of 12 mEq per L would be *expected* to have a PaCO₂ between 24 and 28 mm Hg. Values of PaCO₂ below 24 or greater than 28 mm Hg define a mixed disturbance (metabolic acidosis and respiratory alkalosis, or metabolic acidosis and respiratory acidosis, respectively). Therefore, by definition, mixed acid–base disturbances exceed the physiologic limits of compensation as predicted by the equations displayed in [Table 149.2](#).

Simple Acid–Base Disorders
Respiratory
Acidosis (acute or chronic)
Alkalosis (acute or chronic)
Metabolic
Acidosis
Alkalosis
Mixed Acid–Base Disorders
Mixed respiratory–metabolic disorders
Respiratory acidosis + metabolic acidosis
Respiratory alkalosis + metabolic alkalosis
Respiratory acidosis + metabolic alkalosis
Respiratory alkalosis + metabolic acidosis
Mixed metabolic disorders
Metabolic acidosis + metabolic alkalosis
Anion gap acidosis + hyperchloremic acidosis
Mixed anion gap acidosis
Mixed hyperchloremic acidosis
“Triple” disorders
Metabolic acidosis + metabolic alkalosis + respiratory acidosis
Metabolic acidosis + metabolic alkalosis + respiratory alkalosis

TABLE 149.1. CATEGORIES OF CLINICAL ACID–BASE DISTURBANCES

Disorder	Prediction of Compensation
Metabolic acidosis	$P_{50}CO_2 = (1.5 \times [HCO_3^-]) + 8$ or $P_{50}CO_2$ will ↓ 1.25 mm Hg per mmol/L ↓ in $[HCO_3^-]$ or $P_{50}CO_2 = [HCO_3^-] + 15$
Metabolic alkalosis	$P_{50}CO_2$ will ↑ 0.75 mm Hg per mmol/L ↑ in $[HCO_3^-]$ or $P_{50}CO_2 [HCO_3^-] + 15$
Respiratory alkalosis	
Acute	$[HCO_3^-]$ will ↓ 2 mmol/L per 10 mm Hg ↓ in $P_{50}CO_2$
Chronic	$[HCO_3^-]$ will ↓ 4 mmol/L per 10 mm Hg ↓ in $P_{50}CO_2$
Respiratory acidosis	
Acute	$[HCO_3^-]$ will ↑ 1 mmol/L per 10 mm Hg ↑ in $P_{50}CO_2$
Chronic	$[HCO_3^-]$ will ↑ 4 mmol/L per 10 mm Hg ↑ in $P_{50}CO_2$

TABLE 149.2. PREDICTION OF COMPENSATORY RESPONSES IN SIMPLE ACID-BASE DISTURBANCES

THE ANION GAP

All evaluations of acid–base disorders should include a simple calculation of the anion gap. The anion gap is defined as $Na^+ - (Cl^- + HCO_3^-)$. The anion gap represents those unmeasured anions normally present in plasma and is equal to 10 to 12 mEq per L. The anions normally present include anionic proteins (principally albumin), phosphate, sulfate, and organic anions. When acid anions, such as acetoacetate or lactate, are produced in excess endogenously, the anion gap increases above the normal value. Assuming that the serum albumin is within the normal range, for each milliequivalent per liter increase in the anion gap there should be an equal decrease in the plasma bicarbonate concentration. An *increase* in the anion gap may occur by a decrease in unmeasured cations or an increase in unmeasured anions. In addition, the anion gap may increase secondary to an increase in anionic albumin as a consequence of either an increased albumin concentration or alkalemia. The increased anion gap in alkalosis can be partially explained by the effect on albumin charge. A *decrease* in the anion gap can be generated by an increase in unmeasured cations or a decrease in the unmeasured anions (Table 149.3). A decrease in the anion gap can result from an increase in unmeasured cations (calcium, magnesium, potassium) or the addition to the blood of abnormal cations, such as lithium (lithium intoxication) or cationic immunoglobulins (IgG) as in plasma cell dyscrasias. The anion gap will also decrease if the quantity of the major plasma anionic substituent, albumin, is low, as in nephrotic syndrome, or if the effective anionic charge on the albumin is decreased by acidosis. Finally, laboratory errors can create a falsely low anion gap. Hyperviscosity and hyperlipidemia lead to an underestimation of the true sodium concentration, and bromide intoxication causes an overestimation of the true chloride concentration.

Anion gap = $Na^+ - (Cl^- + HCO_3^-) = 12$ mEq/L	
Decreased Anion Gap	Increased Anion Gap
Increased cations (not Na^+)	Increased anions (not Cl^- or HCO_3^-)
↓ Ca^{2+} , Mg^{2+}	↓ Albumin concentration
↓ Li^+	Albumin
↓ K^+	↑ Organic anions
Decreased anions (not Cl^- or HCO_3^-)	Phosphate
↓ Albumin concentration	Sulfate
Acidosis	↑ Organic anions
Laboratory error	Lactate
Hyperviscosity	Ketones
Bromides	↑ Exogenously supplied anions
	Toxins: Salicylate
	Paraldehyde
	Ethylene glycol
	Methanol
	↓ Unidentified anions
	Toxins
	Uremic
	Hypomagnesemia, hypokalemia states
	Myoglobinuria, acute renal failure
	Decreased cations (not Na^+)
	↓ Ca^{2+} , Mg^{2+}

TABLE 149.3. CLINICAL APPLICATIONS OF THE ANION GAP

In the face of a normal serum albumin, elevation of the anion gap is usually due to addition to the blood of non-chloride-containing acids. The anions accompanying such acids include inorganic (phosphate, sulfate), organic (ketoacids, lactate, uremic organic anions), exogenous (salicylate or ingested toxins with organic acid production), or unidentified anions. The chloride concentration is not altered when the new acid anion is added to the blood; thus the “gap” increases. If the anion is not excreted by the kidney, the magnitude of the decrement in bicarbonate concentration will equal the increase in the unmeasured anion concentration and the anion gap. If the retained anion can be metabolized back to bicarbonate (e.g., ketones or lactate, after successful treatment), normal acid–base balance will be restored as the anion gap returns toward the normal value of 12 mEq per L.

METABOLIC ACIDOSIS

Metabolic acidosis occurs as a result of a marked increase in endogenous production of acid (such as lactic and ketoacids), loss of bicarbonate stores (diarrhea or renal tubular acidosis), or progressive accumulation of endogenous acids, the excretion of which is impaired because of renal insufficiency. The anion gap serves a useful role in the initial differentiation of metabolic acidoses. A metabolic acidosis with a *normal anion gap* (hyperchloremic) suggests that bicarbonate has been effectively replaced by chloride. This occurs when bicarbonate is lost from body fluids through gastrointestinal or renal mechanisms, or when defective renal acidification results or renal failure impairs the excretion of metabolically produced acid. In contrast, metabolic acidosis with a *high anion gap* indicates addition of an acid other than hydrochloric acid or its equivalent to the extracellular fluid. If the attendant nonchloride acid anion cannot be excreted in relation to the rate of production, and is retained following bicarbonate titration, the anion replaces titrated bicarbonate without disturbing the chloride concentration. Hence, the acidosis is normochloremic and the anion gap increases.

HYPERCHLOREMIC METABOLIC ACIDOSIS

The diverse clinical disorders which may result in a hyperchloremic metabolic acidosis are outlined in Table 149.4. Hyperchloremic metabolic acidosis occurs most often as a result of loss of HCO_3^- from the gastrointestinal tract or as a result of a renal acidification defect. *Diarrhea* causes a loss of large quantities of HCO_3^- and HCO_3^- decomposed by reaction with organic acids. Since diarrheal stools contain a higher concentration of HCO_3^- and decomposed HCO_3^- than plasma, volume depletion and metabolic acidosis will develop. Hypokalemia exists because large quantities of K^+ are lost from stool and because volume depletion causes elaboration of renin and aldosterone, enhancing renal potassium excretion. Instead of an acid urine pH as anticipated with diarrhea, a pH of 6.0 or more may be found. This occurs because metabolic acidosis and hypokalemia increase renal ammonium synthesis and excretion, thus providing more urinary buffer, which allows urine pH to increase above 6.0.

TABLE 149.4. CLINICAL APPLICATIONS OF THE ANION GAP

TABLE 149.4. CAUSES OF HYPERCHLOREMIC METABOLIC ACIDOSIS

Thus, metabolic acidosis due to gastrointestinal losses with a high urine pH must be differentiated from *renal tubular acidosis (RTA)*. Urinary NH_4^+ excretion is typically low in RTA, whereas NH_4^+ excretion is high in patients with diarrhea. The adequacy of urinary ammonium excretion in metabolic acidosis can be assessed by calculating the urine anion gap (UAG): $\text{UAG} = (\text{Na}^+ + \text{K}^+)_{\text{u}} - \text{Cl}_{\text{u}}^-$. Since NH_4^+ can be assumed to be present if the sum of the major cations ($\text{Na}^+ + \text{K}^+$) is less than the sum of major anions in urine, a negative urine net charge is taken as evidence for ammonium in the urine. Urine containing little or no NH_4^+ will have more $\text{Na}^+ + \text{K}^+$ than Cl^- (urine net charge will be positive). This finding suggests a renal mechanism for the hyperchloremic acidosis, such as RTA. Conversely, if the urine $[\text{Cl}^-]$ exceeds the sum of $[\text{Na}^+ + \text{K}^+]$ in the urine, an extrarenal cause of the hyperchloremic acidosis should be considered. This test is only useful in the differential diagnosis of a hyperchloremic metabolic acidosis. If the patient has ketonuria, or drug excreted as anions in large quantity (penicillins or aspirin), the test will not be reliable. Thus, the UAG or net charge allows the estimation of urine $[\text{NH}_4^+]$ on a spot urine and aids in distinguishing extrarenal from renal causes of hyperchloremic acidosis.

Dilutional acidosis (acidosis due to exogenous acid loads and the posthypocapnic state) can usually be excluded by history. When isotonic saline is infused rapidly, particularly in patients with temporary or permanent renal functional impairment, the plasma bicarbonate will decline reciprocally in relation to chloride. Addition of acid or acid equivalents to blood results in metabolic acidosis. Examples include infusion of arginine or lysine HCl during *parenteral hyperalimentation* or ingestion of NH_4Cl .

Loss of functioning renal parenchyma by *progressive renal disease* is known to be associated with metabolic acidosis. Typically, the acidosis is hyperchloremic when the glomerular filtration rate (GFR) is between 20 to 50 mL per minute but may convert to the typical high anion gap acidosis of uremia with more advanced renal failure (i.e., when the GFR is less than 20 to 50 mL per minute).

The majority of cases of *proximal RTA* occur in association with generalized proximal tubular dysfunction manifested by glycosuria, generalized aminoaciduria, hypercitraturia, and phosphaturia and referred to collectively as the Fanconi syndrome. The clinical disorders associated with proximal RTA are outlined in [Table 149.5](#). Patients with proximal RTA generally present in the steady state with a chronic hyperchloremic metabolic acidosis, an acid urine pH, and a small amount of bicarbonate excretion. Upon infusion of NaHCO_3 , and when the plasma HCO_3^- rises above the threshold, bicarbonaturia ensues and the urine becomes alkaline in patients with proximal RTA. The magnitude of the bicarbonaturia (more than 10% of the filtered load) requires that large amounts of bicarbonate be administered to correct the bicarbonate concentration. For example, 10 to 30 mEq per kg per day of bicarbonate or its metabolic equivalent (citrate) may be required to maintain the plasma bicarbonate concentration at normal levels. Supplementation with potassium is also often necessary because of the kaliuresis induced by high distal bicarbonate delivery when the plasma bicarbonate concentration is normalized. Thiazides may be useful in diminishing therapeutic requirements for bicarbonate supplementation by causing extracellular volume (ECV) contraction. Vitamin D and phosphate may be supplemented, and in some patients this might even improve the acidification defect. Fructose should be restricted in patients with fructose intolerance.

TABLE 149.5. DISORDERS ASSOCIATED WITH PROXIMAL RTA

In contrast to proximal RTA, the hallmark finding in *classical hypokalemic distal RTA* is an inability to acidify the urine appropriately during spontaneous or chemically induced metabolic acidosis. The defect in acidification by the collecting duct impairs ammonium and titratable acid excretion, and can be detected easily since the UAG is usually positive (see above). The defect results in positive acid balance, hyperchloremic metabolic acidosis, and volume depletion. Moreover, medullary interstitial disease, which commonly occurs in conjunction with distal RTA, may impair ammonium excretion by interrupting the medullary countercurrent system for ammonium. Hypokalemia and hypercalciuria often accompany this disorder, but proximal tubule reabsorptive function is preserved. The dissolution of bone is the result of chronic positive acid balance, which causes calcium, magnesium, and phosphate wasting. Since chronic metabolic acidosis also decreases renal production of citrate, the resulting hypocitraturia in combination with hypercalciuria creates an environment that is favorable for urinary stone formation and nephrocalcinosis. Nephrocalcinosis is a reliable marker of classical distal RTA since this disorder does not occur in proximal RTA or the generalized dysfunction of the nephron associated with hyperkalemia.

The disorders associated with classical distal RTA are displayed in [Table 149.6](#). The vast majority of patients with distal RTA have distal RTA in association with a systemic illness. Conversely, distal RTA may occur as a part of an inherited defect in which there is no association with systemic disease. This autosomal dominant disorder has been demonstrated recently to be associated with a missense mutation of the *AE-1* gene, which encodes an abnormal $\text{HCO}_3^-/\text{Cl}^-$ exchanger in the collecting duct.

(Table content is illegible due to low resolution)

TABLE 149.6. DISORDERS ASSOCIATED WITH CLASSICAL HYPOKALEMIC DISTAL RTA

In either inherited or acquired forms of distal RTA, the correction of chronic metabolic acidosis can usually be achieved in patients with classical distal RTA by administration of alkali in an amount sufficient to neutralize the production of metabolic acids derived from the diet. In adult patients with distal RTA, this is usually equal to no more than 13 mEq per kg per day. Larger amounts of bicarbonate must be administered to correct the acidosis and maintain normal growth in children. In patients with distal RTA, correction of acidosis with alkali therapy reduces urinary potassium excretion, and hypokalemia and sodium depletion may resolve with

sustained correction of metabolic acidosis.

Generalized distal nephron dysfunction (or *type IV RTA*) is manifest as a hyperchloremic, hyperkalemic metabolic acidosis in which urinary ammonium excretion is invariably depressed and renal function is usually compromised. The UAG is always positive (see above). The transtubular potassium gradient (TTKG) = $K^+_u/K^+_p \div U/P_{osm}$, where “u” is the potassium concentration in the urine and “p” in plasma, and “osm” is the osmolality, is usually low in patients with this disorder, indicating that the collecting tubule is not responding appropriately to the prevailing hyperkalemia. Therefore, in such patients, a unique dysfunction of potassium and acid secretion by the collecting tubule coexists. This dysfunction can be attributed in many cases to hypoaldosteronism and in other cases to a decrease in the effectiveness of aldosterone (aldosterone resistance). A classification of the underlying disorders resulting in a generalized distal tubule dysfunction are outlined in [Table 149.7](#). Hyperchloremic metabolic acidosis occurs in approximately 50% of patients with hyporeninemic hypoaldosteronism. This disorder is a common cause of hyperkalemic hyperchloremic metabolic acidosis and is most typically seen in older adults with diabetes mellitus or tubulointerstitial disease and renal insufficiency. Patients will usually have mild to moderate renal insufficiency and acidosis with modest elevation in plasma potassium (5.5 to 6.0 mEq per L), with concurrent hypertension and congestive heart failure. Drugs are important and common causes of hyperkalemia ([Table 149.8](#)). Although these agents do not cause hyperchloremic metabolic acidosis directly, they are frequently associated with this acid–base disorder in patients with moderate to severe renal insufficiency. The metabolic acidosis is the result of the suppression by hyperkalemia of renal ammonium production and thus a decrease in net acid excretion. The autosomal recessive form of pseudohypoaldosteronism type I (PHA1) occurs because of an inherited loss of function mutation in the gene that encodes the epithelial sodium channel protein (ENaC) of the cortical collecting duct principal cell. This defect impairs sodium absorption and potassium secretion; it also causes salt wasting, hyperkalemia, and acidosis, which are resistant to correction by aldosterone. Rather, these children respond to generous administration of NaCl supplements. This defect is more severe and persists throughout life, whereas, in contrast, the autosomal dominant form of PHA1 is less severe and often resolves by puberty. Recent studies have revealed that autosomal dominant PHA1 is due to a mutation of mineralocorticoid receptor gene (MLR) ([Table 149.7](#)).

TABLE 149.7. DISORDERS ASSOCIATED WITH GENERALIZED ABNORMALITY OF DISTAL NEPHRON WITH HYPERKALEMIA

TABLE 149.8. CAUSES OF HIGH ANION GAP ACIDOSIS

Non-PHA1 forms of type IV RTA are much more common. These patients respond to a cation exchange resin (sodium polystyrene sulfonate) and alkali therapy. Treatment with a loop diuretic (to induce renal potassium and salt excretion) and dietary potassium restriction are also helpful. The correction of the hyperkalemia is often associated with restoration of renal ammonium excretion and, thus, correction of the acidosis. Volume depletion should be avoided unless the patient is volume-overexpanded or hypertensive. Supraphysiologic doses of mineralocorticoids may be necessary but should be administered cautiously, and only in combination with a loop diuretic to avoid volume overexpansion or aggravation of hypertension, and to increase potassium excretion.

HIGH ANION GAP ACIDOSES

Identification of the underlying cause of a high anion gap acidosis is facilitated by consideration of the clinical setting and associated laboratory values. The four most common categories of disorders that cause a high anion gap acidosis are outlined in [Table 149.8](#) and include lactic acidosis, ketoacidosis, the toxin-induced acidoses, and uremic acidosis. Initial screening to differentiate the high anion gap acidoses should include (1) a history or other evidence for drug and toxin ingestion, (2) historical evidence of diabetes (diabetic ketoacidosis); (3) evidence of alcoholism or increased levels of b-hydroxybutyrate (alcoholic ketoacidosis); (4) observation for clinical signs of uremia and determination of the blood urea nitrogen (BUN) and creatinine (uremic acidosis); (5) inspection of the urine for oxalate crystals (ethylene glycol); and finally, (6) the recognition of the numerous settings in which lactate levels may be increased (hypotension, cardiac failure, leukemia, drugs, and cancer).

LACTIC ACIDOSIS

While lactate metabolism bears a close relationship to that of pyruvate, lactate is a metabolic dead-end pathway with pyruvate as its only outlet. The production of lactic acid can be increased with ischemia, during seizures, exercise, in some leukemic conditions, and in alkalosis. This increase in production occurs principally through enhanced phosphofruktokinase activity. Decreased lactate consumption also leads to lactic acidosis. The principal organs for lactate removal are the liver, kidneys, and muscle. Hepatic utilization of lactate can be impeded by several factors: poor blood flow to the liver; defective active transport of lactate into cells; or inadequate metabolic conversion of lactate into pyruvate. Examples of impaired hepatic lactate removal include primary diseases of the liver, enzymatic defects, tissue anoxia or ischemia, severe acidosis, toxic levels of alcohol, fructose, phenformin, or nucleoside analog therapy for human immunodeficiency virus infection. Underutilization of lactate appears to be a more common cause of clinical lactate acidosis than lactate overproduction. *Type A lactic acidosis* is the result of tissue hypoperfusion or acute hypoxia, whereas *type B lactic acidosis* is associated with common diseases, drugs and toxins, and hereditary and miscellaneous disorders ([Table 149.8](#)). A lactate concentration of greater than 4 mEq per L (normal 1 mEq per L) is generally accepted as evidence that the metabolic acidosis is ascribable to net lactic acid accumulation.

D-lactic acidosis has been described in patients with small bowel obstruction or hypomotility associated with overgrowth of abnormal gut flora. Treatment with a low-carbohydrate diet and oral antibiotics is often effective.

The basic principle of therapy for L-lactic acidosis is that the underlying condition initiating the disruption in normal lactate metabolism must first be corrected. Every attempt should be made to restore tissue perfusion when it is inadequate. Vasoconstricting agents are ill advised because they will potentiate the hypoperfused state. Alkali therapy should be provided as either intravenous sodium bicarbonate or Carbicarb (an equimolar solution of sodium bicarbonate and sodium carbonate) for acute, severe acidemia (pH less than 7.1). Use of agents such as tris(hydroxymethyl)-aminomethane (tromethamine; THAM), Tris buffer, or plasma expanders is not recommended. The use of alkali in states of moderate lactic acidemia is controversial, but it is generally agreed that attempts to normalize the pH or bicarbonate concentration by exogenous bicarbonate therapy is deleterious. Fluid overload occurs with bicarbonate therapy because the amount required is often massive when

accumulation of lactic acid is relentless, necessitating diuretics, ultrafiltration, or dialysis against a bicarbonate dialysate. Volume administration is poorly tolerated because of central venoconstriction and decreased cardiac output. Carbicarb may offer potential advantages to sodium bicarbonate alone, since the PaCO₂ may not increase as much. If the underlying cause of the lactic acidosis can be remedied, blood lactate will be reconverted to bicarbonate. Bicarbonate derived from lactate conversion in addition to any new bicarbonate generated by renal mechanisms during acidosis and from exogenous alkali therapy are additive and might result in an overshoot alkalosis. When large doses of bicarbonate are administered, the goal should be to raise the pH to approximately 7.2 to 7.25, not higher. Recent reports suggest that continuous venovenous hemodialysis offers advantages in some patients although lactate-containing dialysate can increase blood lactate levels and remove bicarbonate.

KETOACIDOSIS

Diabetic Ketoacidosis

The pathophysiology of diabetic ketoacidosis is discussed in detail elsewhere in this text. Most, if not all, patients with diabetic ketoacidosis require correction of the volume depletion that almost invariably accompanies the osmotic diuresis and ketoacidosis. Initiate therapy with isotonic saline at a rate of 1,000 mL IV per hour. When the pulse and blood pressure have stabilized and the corrected serum sodium concentration is in the range of 130 to 135 mEq per L, switch to 0.45% NaCl. Ringer's lactate should be avoided. If the blood sugar declines below 300 mg per dL, 0.45% NaCl with 5% dextrose should be administered. Low-dose IV insulin therapy (0.1 unit per kg per hour) smoothly corrects the biochemical abnormalities and minimizes hypoglycemia and hypokalemia. Although regular insulin may also be administered intramuscularly (0.2 mg per kg initially, then 6 units every hour), it should be noted that IM insulin may not be effective in volume-depleted patients, as is often the case in ketoacidosis.

Total body potassium depletion is usually present, although the potassium level on admission may be elevated or normal. Since the plasma potassium concentration should increase by 0.6 mEq per L for each 0.1-unit decline in arterial blood pH, a normal or reduced [K⁺] on admission indicates severe potassium depletion. Administration of fluid, insulin, and alkali might cause the potassium level to decline further. When the urine output has been established, 20 mEq KCl should be administered in each liter of fluid as long as the [K⁺] is less than 4.0 mEq per L. Equal caution should be exercised in the presence of hyperkalemia, especially if the patient has renal insufficiency, since the usual therapy will not always correct hyperkalemia.

The routine administration of phosphate (usually as potassium phosphate) is not advised because of the potential for hyperphosphatemia and hypocalcemia. A significant number of patients with diabetic ketoacidosis will have significant hyperphosphatemia before initiation of therapy. However, in the volume-depleted, malnourished patient, a normal or elevated phosphate concentration on admission may be followed by a rapid fall in plasma phosphate levels within 2 to 6 hours of initiation of therapy.

Alcoholic Ketoacidosis

Chronic alcoholics may develop ketoacidosis when alcohol consumption is abruptly curtailed, usually as a result of vomiting, abdominal pain, starvation, and volume depletion. This disorder, which is more common in women who are binge drinkers, is frequently underdiagnosed and should be suspected in alcoholics presenting with an anion gap acidosis. Often the glucose concentration is low or normal, and the acidosis can be severe. The anion gap is expanded because of elevated ketones, which are predominantly b-hydroxybutyrate. The nitroprusside reaction (Acetest) detects acetoacetic acid preferential to b-hydroxybutyrate. Treatment consists of intravenous volume repletion and glucose administration (5% dextrose in 0.9% NaCl, not saline alone). Hypophosphatemia, hypokalemia, and hypomagnesemia often occur. Hypophosphatemia usually emerges 12 to 24 hours after admission, so that the need for therapy can be overlooked, especially if the serum phosphorus concentration on admission is normal.

RENAL FAILURE

Advanced renal failure (GFR below 15 mL per minute) will eventually convert the hyperchloremic acidosis of progressive chronic renal insufficiency to a high anion gap acidosis. The elevated anion gap is the result of retention of acid anions (e.g., phosphates and sulfates). Classical uremic acidosis is characterized by a reduced rate of ammonium production, primarily due to decreased renal mass. The bicarbonate concentration rarely falls below 15 mEq per L, and the anion gap rarely exceeds 20 mEq per L. Uremic acidosis requires oral alkali therapy to maintain the bicarbonate concentration above 20 mEq per L. This can be accomplished with relatively modest amounts of alkali (1.0 to 1.5 mEq per kg per day). Shohl's solution (sodium citrate) or sodium bicarbonate tablets are equally effective, but Shohl's solution may be better tolerated. Shohl's solution should never be administered to patients receiving aluminum-containing antacids because of the risk of aluminum intoxication.

TOXINS

Under most physiologic conditions, sodium, urea, and glucose together generate the osmotic pressure of plasma. Plasma osmolality (milliosmoles per kilogram) is calculated according to the following expression: $P_{osm} = 2Na^+ + Glu/18 + BUN/2.8$. The calculated and determined osmolality should agree within 10 to 15 mOsm per kg. When the measured osmolality exceeds the calculated osmolality by more than 15 to 20 mOsm per kg, one of two circumstances prevails. First, the serum sodium may be spuriously low, as occurs with hyperlipidemia or hyperproteinemia (pseudohyponatremia). Second, osmolytes other than sodium salts, glucose, or urea have accumulated in plasma. Examples include mannitol infusion, radiocontrast media, or the accumulation of other solutes including the alcohols, ethylene glycol, or acetone. In these examples, the difference between the osmolality as calculated above 40, and the measured osmolality is proportional to the concentration of unmeasured solutes. Such differences in these clinical circumstances have been referred to as the *osmolar gap*. With an appropriate clinical history and index of suspicion, the osmolar gap becomes a reasonable and helpful screening tool in poison-associated anion gap acidosis.

Ingestion of *ethylene glycol* leads to a metabolic acidosis in addition to severe central nervous system, cardiopulmonary, and renal damage. The increased anion and osmolar gaps can be attributed to ethylene glycol metabolites, especially oxalic acid, glycolic acid, and other incompletely identified organic acids. Lactic acid production also increases as a consequence of a toxic depression in the reaction rates of the citric acid cycle and altered intracellular redox state. Diagnosis is facilitated by recognizing oxalate crystals in the urine. Treatment includes prompt institution of osmotic diuresis, thiamine and pyridoxine supplements, ethanol administration, and dialysis. Ethanol serves to lessen toxicity because it competes (through alcohol dehydrogenase) with metabolic conversion with ethylene glycol and alters the cellular redox state.

Methanol ingestion causes metabolic acidosis in addition to severe optic nerve and central nervous system manifestations due to its metabolism to formic acid from formaldehyde. Lactic acids and ketoacids, as well as other unidentified organic acids, may contribute to the acidosis. Due to its low molecular weight, an osmolar gap is usually present. Therapy is generally similar to that for ethylene glycol intoxication, including general supportive measures, ethanol administration, and hemodialysis, as indicated.

The initial step in therapy of *salicylate intoxication* should include vigorous gastric lavage or induced vomiting followed by activated charcoal administration. Salicylate intoxication can result in several acid-base abnormalities: respiratory alkalosis, metabolic acidosis, or mixed metabolic acidosis-respiratory alkalosis. To facilitate removal of salicylate, intravenous sodium bicarbonate administration in amounts adequate to alkalinize the urine and to maintain urine output may be required (urine pH greater than 7.5). While this form of therapy is straightforward in acidotic patients, alkalemia from a respiratory alkalosis may make this approach hazardous. Hypokalemia may occur as a result of an alkaline diuresis from sodium bicarbonate or acetazolamide, and should be treated promptly. Glucose-containing fluids should be administered because of the danger of hypoglycemia. If renal failure prevents rapid clearance of salicylate, hemodialysis may be required against a bicarbonate dialysate.

The treatment of metabolic acidosis is summarized in [Table 149.9](#).

Type of Acidosis	Treatment	
	Specific	Auxiliary
Acute respiratory acidosis	Volume expansion, none	K ⁺ , NaCl ⁺
Chronic respiratory acidosis	Volume expansion, glucose	Na ⁺
Lactic acidosis	Stop underlying cause, NaCl ⁺	Hemodialysis, OBT
Methanol	Folates, NaCl ⁺ , dialysis	NaCl ⁺
Ethylene glycol	Folates, NaCl ⁺ , dialysis	NaCl ⁺ , thiamine
Salicylate intoxication	Dialysis, NaCl ⁺ , folates	Acetazolamide
Chronic renal failure	NaCl ⁺ or dialysis solution	Dialysis
Hyperkalemic acidosis		
C/fos of bicarbonates	Volume, NaCl ⁺ , K ⁺	
Acetazolamide (AZ)	NaCl ⁺ , volume, K ⁺	Thiazide diuretic, vitamin D, K ⁺
Dialysis (DA)	Dialysis solution or NaCl ⁺	K ⁺
Hyperkalemia		NaCl ⁺ , exchange resin
Type III/IV		

OBT, acute renal replacement therapy; K⁺, potassium; NaCl⁺, normal saline solution.

TABLE 149.9. TREATMENT OF METABOLIC ACIDOSIS

METABOLIC ALKALOSIS

Metabolic alkalosis is a common primary acid–base disturbance that is manifest in a pure or “simple” form as alkalemia (elevated arterial pH), and an increase in PaCO₂ as a result of compensatory alveolar hypoventilation. It is often, but not always, accompanied by hypochloremia and hypokalemia. The patient with a high bicarbonate concentration and a low chloride concentration has either metabolic alkalosis or chronic respiratory acidosis. The arterial pH will establish the diagnosis, since the pH will be increased in metabolic alkalosis and decreased or normal in respiratory acidosis. Modest increases in the PaCO₂ are expected in metabolic alkalosis, and the expected increase in PaCO₂ can be approximated by simply adding 15 to the patient's bicarbonate concentration ([Table 149.2](#)). Metabolic alkalosis is also frequently observed, not as a pure or simple acid–base disturbance but in association with other disorders such as respiratory acidosis or alkalosis and even metabolic acidosis.

Under normal circumstances, the kidneys display an impressive capacity to excrete bicarbonate. The development of metabolic alkalosis represents a failure of the kidneys to eliminate bicarbonate in the usual manner. For bicarbonate to be added to the extracellular fluid, bicarbonate must be administered exogenously or gained through endogenously mediated events. The kidneys may be partially or entirely responsible for the generation of new bicarbonate, or the generation may be extrarenal.

The various causes of metabolic alkalosis are listed in [Table 149.10](#). In attempting to establish the cause of metabolic alkalosis, it is necessary to assess the status of the ECV, blood pressure, serum potassium, and renin–aldosterone system. Determination of urine electrolytes (especially the urine Cl[−] concentration), and screening of the urine for diuretics might be helpful. If the urine is alkaline, with high values for sodium and potassium concentration but low values for the chloride concentration, the diagnosis is usually either active (continual) vomiting (overt or surreptitious), or alkali ingestion. If the urine is relatively acidic, with low concentrations of sodium, potassium, and chloride, the most likely possibilities are prior (discontinual) vomiting, the posthypercapnic state, or prior diuretic ingestion. If, on the other hand, neither the urine sodium, potassium, nor chloride concentration is depressed, one must consider magnesium deficiency, Bartter's syndrome, Gitelman's syndrome, or current diuretic ingestion.

Cause of Alkalosis	Treatment	
	Specific	Auxiliary
Chronic administration of alkali	Stop alkali	
Gastrointestinal loss of hydrogen ion	Volume expansion, NaCl ⁺

Administration of large amounts of *non-reabsorbable anions*, such as penicillin or carbenicillin, enhances distal acidification and potassium excretion. *Magnesium deficiency* also results in hypokalemic alkalosis by enhancing distal acidification through stimulation of renin and aldosterone secretion.

Bartter's syndrome is an uncommon cause of metabolic alkalosis associated with hypokalemia, juxtaglomerular apparatus hyperplasia, and hyperreninemic hyperaldosteronism. Young persons are most commonly affected, although the appearance of this syndrome in adults has been reported. Symptoms of the disorder are characteristically those of hypokalemia, including vascular hyporesponsiveness to pressors; a vasopressin-resistant inability to achieve maximal concentration of the urine; increased prostaglandin E₂ excretion; and, in some patients, hypercalciuria and hypomagnesemia. Recently, the defect in Bartter's syndrome has been localized to the thick ascending limb of Henle's loop. Loss of function mutations of both the Na⁺-2Cl⁻-K⁺ cotransporter and the affiliated apical K⁺ channel have been documented. Distinction from surreptitious vomiting, diuretic administration, and laxative abuse is necessary to make the diagnosis of Bartter's syndrome. The urine chloride concentration is elevated in Bartter's syndrome and depressed with vomiting. Treatment is generally focused on the repair of hypokalemia by inhibition of the renin-angiotensin-aldosterone or the prostaglandin-kinin systems. Potassium supplementation, magnesium repletion, propranolol, spironolactone, prostaglandin inhibitors, and angiotensin-converting enzyme inhibitors have all been advocated, but each has met with limited success.

While Bartter's syndrome is usually seen in children, similar findings are present in older children and adults with Gitelman's syndrome. This form of hypokalemic-hypochloremic metabolic alkalosis can be distinguished from Bartter's syndrome by the presence of both hypomagnesemia and hypocalciuria. These latter findings have led to the recent discovery that Gitelman's syndrome is the result of a loss-of-function mutation in the neutral Na⁺-Cl⁻ cotransporter on the apical membrane of the distal tubule.

METABOLIC ALKALOSIS ASSOCIATED WITH HYPERTENSION AND MINERALOCORTICOID EXCESS

High Renin

Aldosterone elaboration by the adrenal gland occurs in response to angiotensin II, which is generated by renin release. States associated with inappropriately high renin levels may be associated with hyperaldosteronism and alkalosis. Renin levels are elevated, since a diminished effective circulating blood volume due to vascular disease is sensed by the kidney. Total ECV may not be diminished. Examples include *renovascular, accelerated, or malignant hypertension*. *Estrogens* increase renin substrate and, hence, angiotensin II formation. Primary *tumor* overproduction of renin is another rare cause of hyperreninemic hyperaldosteronemia-induced metabolic alkalosis.

Low Renin

In these disorders, primary adrenal overproduction of mineralocorticoid suppresses renin elaboration. Hypertension occurs as the result of mineralocorticoid excess with volume overexpansion.

Primary Aldosteronism

Tumor involvement (adenoma or, rarely, carcinoma) or hyperplasia of the adrenal gland is associated with aldosterone overproduction. The circadian pattern of aldosterone elaboration and response to posture is altered (morning aldosterone increases in hyperplasia and falls in adenoma). The diagnosis is made by evaluation of the plasma aldosterone/renin ratio, the clinical and biochemical response to administration of captopril or saline adrenal venography, ¹³¹I-19-iodocholesterol scanning, and computed tomography. The treatment of primary aldosteronism is adrenalectomy or, if adrenalectomy is not indicated, spironolactone.

DIAGNOSIS OF METABOLIC ALKALOSIS

The diagnosis of metabolic alkalosis is summarized in [Table 149.11](#). The diagnostic approach to metabolic alkalosis based on urine Cl⁻ concentration is outlined in [Figure 149.2](#).

Saline-Responsive Alkalosis (Low Urinary [Cl ⁻])	Saline-Unresponsive Alkalosis (High or Normal Urinary [Cl ⁻])
Vomiting, nasogastric aspiration	Hypertensive
Diuretics	Primary aldosteronism
Posthypercapnia	Cushing's syndrome
Bicarbonate therapy of organic acidosis	Renal artery stenosis
K ⁺ deficiency	Renal failure plus alkali therapy
	Normotensive
	Mg ²⁺ deficiency
	Severe K ⁺ deficiency
	Bartter's syndrome
	Gitelman's syndrome
	Diuretics

TABLE 149.11. DIAGNOSIS OF METABOLIC ALKALOSIS

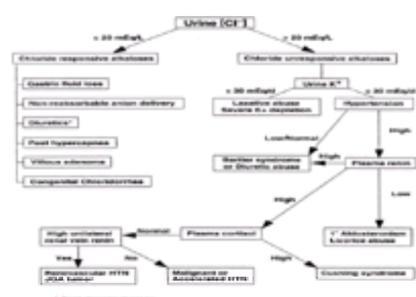

FIGURE 149.2. Diagnostic approach to metabolic alkalosis based on urine chloride and potassium concentrations.
EVIDENCE LEVEL: C. Expert Opinion.

TREATMENT OF METABOLIC ALKALOSIS

Treatment is directed at removing the underlying stimulus for bicarbonate generation. If primary hypermineralocorticoidism is present, correction of the underlying cause will reverse the alkalosis. Stimuli that increase hydrogen ion loss by the stomach or kidneys can be improved by the use of an H₂-receptor antagonist or discontinuation of diuretics. The second aspect of treatment is to eliminate factors that sustain bicarbonate reabsorption, such as ECV contraction or potassium deficiency ([Fig. 149.2](#)). Unusual cases, termed "saline-resistant," are associated with marked potassium deficits, magnesium deficiency, Bartter's syndrome, Gitelman's syndrome, or primary autonomous hypermineralocorticoid states. Therapy in these cases must be directed toward the underlying pathophysiologic problem.

If warranted by associated conditions that preclude infusion of saline, accelerated renal bicarbonate loss can be achieved by administration of acetazolamide, a

carbonic anhydrase inhibitor that is usually very effective in patients with adequate renal function. Dilute hydrochloric acid, while effective, can be dangerous and result in brisk hemolysis. Infusion of acidic amino acids, such as arginine hydrochloride, is safer and as effective. Acidification can also be achieved with oral ammonium chloride, which should be avoided in the presence of liver disease. Finally, hemodialysis against a dialysate that is low in bicarbonate and high in chloride can be effective when renal function is impaired.

RESPIRATORY ACIDOSIS

Respiratory acidosis occurs as the result of severe pulmonary disease, respiratory muscle fatigue, or depression in ventilatory control. The increase in PaCO₂ due to reduced alveolar ventilation is the primary abnormality leading to acidemia. In acute respiratory acidosis, there is an immediate compensatory elevation (due to cellular buffering mechanisms) in HCO₃⁻ that increases by 1 mEq per L for every 10 mm Hg increase in PaCO₂. In chronic respiratory acidosis (duration of more than 24 hours), renal adaptation occurs and the HCO₃⁻ increases by 4 mEq per L for every 10 mm Hg increase in PaCO₂. The serum bicarbonate will usually not increase above 38 mEq per L. Renal compensation (increased reabsorption of HCO₃⁻) requires 12 to 24 hours to take effect and is not fully completed until about 5 days.

The clinical features of respiratory acidosis vary according to severity, duration, the underlying disease, and whether there is accompanying hypoxemia. A rapid increase in PaCO₂ may result in anxiety, dyspnea, confusion, psychosis, hallucinations, and can progress to coma. Lesser degrees of dysfunction in chronic hypercapnia include sleep disturbances, loss of memory, daytime somnolence, and personality changes. Coordination may be impaired, and motor disturbances such as tremor, myoclonic jerks, and asterixis may develop. The sensitivity of the cerebrovasculature to the vasodilating effects of CO₂ helps to explain headaches and other signs that mimic raised intracranial pressure, such as papilledema, abnormal reflexes, and focal muscle weakness.

The causes of respiratory acidosis are displayed in [Table 149.12](#). Reduction in ventilatory drive from depression of the respiratory center by a variety of drugs, injury, or disease can produce respiratory acidosis. Acutely, this may occur with general anesthetics, sedatives, b-adrenergic blockers, or head trauma. Chronic causes of respiratory center depression include the presence of sedatives, alcohol, intracranial tumors, and the syndromes of sleep-disordered breathing, including the primary alveolar and obesity-hypoventilation syndromes. Neuromuscular disorders involving abnormalities or disease in the motor neurons, neuromuscular junction, and skeletal muscle can cause hypoventilation. Although a number of diseases should be considered in the differential diagnosis, drugs and electrolyte disorders should always be ruled out. Mechanical ventilation, when not properly adjusted and supervised, can result in respiratory acidosis. This occurs if carbon dioxide production suddenly rises (because of fever, agitation, sepsis, or overfeeding) or if alveolar ventilation falls because of worsening pulmonary function. High levels of positive end-expiratory pressure in the presence of reduced cardiac output may cause hypercapnia as a result of large increases in alveolar dead space.

Alkalosis	Acidosis
Central nervous system stimulation	Central
PaO ₂	Drug (barbiturates, narcotics, sedatives)
Altering respiratory	Stroke
Center	Intoxication
Central nervous system	Alcohol
depression	Obstruction
Myasthenia gravis	Edema
Stroke	Emphysema
Hypoxemia or blood gases	Emphysema-associated obstructive pulmonary disease
High altitude (PACO ₂)	Neuroleptanalgesia
Pneumonia, pulmonary edema	Barbiturates
Apnea	Adult respiratory distress syndrome
Severe anemia	Barbiturates
Change in breathing	Neuromuscular
Progressing pneumonia	Myasthenia
Tetralogy	Myasthenia
Neuromuscular	Myasthenia
Mitigation of chest expansion	Muscular dystrophies
Respiration	Muscle disease
Full chest	Myasthenia
Carbon failure	Obesity
Pulmonary embolism	Hypoventilation
Myasthenia	
Neuroleptanalgesia	
Barbiturates	
Mechanical hypoventilation	
Fluid exposure	
Recovery from metabolic acidosis	

TABLE 149.12. RESPIRATORY ACID-BASE DISORDERS

Disease and obstruction of the airways when severe or longstanding cause respiratory acidosis. Acute hypercapnia follows sudden occlusion of the upper airway or the more generalized bronchospasm that occurs with severe asthma, anaphylaxis, and inhalational burn, or toxin injury. Chronic hypercapnia and respiratory acidosis occur in end-stage obstructive lung disease.

Restrictive disorders involving both the chest wall and the lungs can cause acute and chronic hypercapnia. Rapidly progressing restrictive processes in the lung can lead to respiratory acidosis because the high cost of breathing causes ventilatory muscle fatigue. Intrapulmonary and extrapulmonary restrictive defects present as chronic respiratory acidosis in their most advanced stages.

The diagnosis of respiratory acidosis requires, by definition, the measurement of arterial PaCO₂ and pH. Detailed history and physical examination often provide important diagnostic clues to the nature and duration of the acidosis. When a diagnosis of respiratory acidosis is made, its cause should be investigated. Pulmonary function studies, including spirometry, diffusing capacity for carbon monoxide, lung volumes, and arterial PaCO₂, and saturation usually provide adequate assessment of whether respiratory acidosis is secondary to lung disease. Workup for nonpulmonary causes should include a detailed drug history, measurement of hematocrit, and assessment of upper airway, chest wall, pleura, and neuromuscular function.

The treatment of respiratory acidosis depends on its severity and rate of onset. Acute respiratory acidosis can be life threatening, and measures to reverse the underlying cause should be simultaneous with restoration of adequate alveolar ventilation to relieve severe hypoxemia and acidemia. Temporarily this may necessitate tracheal intubation and assisted mechanical ventilation. Oxygen should be carefully titrated in patients with severe coronary obstructive pulmonary disease and chronic CO₂ retention who are breathing spontaneously. When oxygen is used injudiciously, these patients may experience progression of the respiratory acidosis. Aggressive and rapid correction of hypercapnia should be avoided because the falling PaCO₂ may provoke the same complications noted with acute respiratory alkalosis (i.e., cardiac dysrhythmias, reduced cerebral perfusion, and seizures). It is advisable to lower the PaCO₂ gradually in chronic respiratory acidosis, with the aim of restoring the PaCO₂ to baseline levels while at the same time providing sufficient chloride and potassium to enhance the renal excretion of bicarbonate.

Chronic respiratory acidosis often is difficult to correct, but general measures aimed at maximizing lung function with cessation of smoking, use of oxygen, bronchodilators, corticosteroids, diuretics, and physiotherapy can help some patients and can forestall further deterioration in most. The use of respiratory stimulants may prove useful in selected cases, particularly if the patient appears to have hypercapnia out of proportion to his or her level of lung function.

RESPIRATORY ALKALOSIS

Alveolar hyperventilation decreases PaCO₂ and increases the HCO₃⁻/PaCO₂ ratio, thus increasing pH (alkalemia). Nonbicarbonate cellular buffers respond by consuming HCO₃⁻. Hypocapnia develops whenever a sufficiently strong ventilatory stimulus causes PaCO₂ output in the lungs to exceed its metabolic production by tissues. Plasma pH and HCO₃⁻ concentration appear to vary proportionately with PaCO₂ over a range from 40 to 15 mm Hg. The relationship between arterial hydrogen ion concentration and PaCO₂ is about 0.7 nEq per L per mm Hg (or 0.01 pH unit per mm Hg), and that for plasma [HCO₃⁻] is 0.2 mEq per L per mm Hg.

Beyond 2 to 6 hours, sustained hypocapnia is further compensated by a decrease in renal ammonium and titratable acid excretion and a reduction in filtered HCO₃⁻ reabsorption. The full expression of renal adaptation may take several days and depends on a normal volume status and renal function. The kidneys appear to respond directly to the lowered PaCO₂ rather than the alkalemia per se. A 1 mm Hg fall in PaCO₂ causes a 0.4 to 0.5 mEq per L drop in HCO₃⁻ and a 0.3 nEq per L fall (or an 0.003-unit rise in pH) in hydrogen ion concentration.

The effects of respiratory alkalosis vary according to its duration and severity, but in general they are primarily those of the underlying disease. A rapid decline in PaCO₂ may cause dizziness, mental confusion, and seizures, even in the absence of hypoxemia, as a consequence of reduced cerebral blood flow. The cardiovascular effects of acute hypocapnia in the awake human are generally minimal; however, in the anesthetized or mechanically ventilated patient, the cardiac output and blood pressure may fall because of the depressant effects of anesthesia and positive-pressure ventilation on heart rate, systemic resistance, and venous

return. Cardiac rhythm disturbances may occur in patients with coronary artery disease as a result of changes in oxygen unloading by blood from a left shift in the hemoglobin–oxygen dissociation curve (Bohr effect). Acute respiratory alkalosis causes minor intracellular shifts of sodium, potassium, and phosphate and reduces serum-free calcium by increasing the protein-bound fraction. Hypocapnia-induced hypokalemia is usually minor.

Respiratory alkalosis is the most common acid–base disturbance encountered in critically ill patients. When severe, it portends a poor prognosis. Many cardiopulmonary disorders manifest respiratory alkalosis in their early to intermediate stages. Hyperventilation usually results in hypocapnia. The finding of normocapnia and hypoxemia may herald the onset of rapid respiratory failure and should prompt an assessment to determine if the patient is becoming fatigued. Respiratory alkalosis is a common occurrence during mechanical ventilation.

The causes of respiratory alkalosis are summarized in [Table 149.12](#). The hyperventilation syndrome may mimic a number of serious conditions and be disabling. Paresthesias, circumoral numbness, chest wall tightness or pain, dizziness, inability to take an adequate breath, and, rarely, tetany may themselves be sufficiently stressful to perpetuate a vicious cycle. Arterial blood gas analysis demonstrates an acute or chronic respiratory alkalosis, often with hypocapnia in the range of 15 to 30 mm Hg and no hypoxemia. Central nervous system diseases or injury can produce several patterns of hyperventilation with sustained arterial PaCO₂ levels of 20 to 30 mm Hg. Conditions such as hyperthyroidism, high caloric loads, and exercise raise the basal metabolic rate, but usually ventilation rises in proportion so that arterial blood gases are unchanged and respiratory alkalosis does not develop. Salicylates, the most common cause of drug-induced respiratory alkalosis, exert their effect by direct stimulation of the medullary chemoreceptor. The methylxanthine drugs, theophylline and aminophylline, stimulate ventilation and increase the ventilatory response to carbon dioxide. Progesterone increases ventilation and lowers arterial PaCO₂ by as much as 5 to 10 mm Hg. As a result of increased progesterone, chronic respiratory alkalosis is an expected feature of pregnancy. Respiratory alkalosis is a prominent feature in liver failure, and its severity correlates well with the degree of hepatic insufficiency and mortality. Respiratory alkalosis is common in patients with gram-negative septicemia, and it is often an early finding, prior to the development of fever, hypoxemia, and hypotension. It is presumed that some bacterial product or toxin acts as a stimulant, but the mechanism remains unknown.

The diagnosis of respiratory alkalosis relies on measurement of arterial pH and PaCO₂. The plasma potassium concentration is often reduced and the serum chloride concentration increased. In the acute phase, respiratory alkalosis is not associated with increased renal bicarbonate excretion, but within hours net acid excretion is reduced. In general, the bicarbonate concentration falls by 2.0 mEq per L for each 10 mm Hg decrease in PaCO₂. Chronic hypocapnia reduces the serum bicarbonate concentration by 5.0 mEq per L for each 10 mm Hg decrease in PaCO₂. It is unusual to observe a plasma bicarbonate concentration below 12 mEq per L as a result of a pure respiratory alkalosis. A detailed history and careful physical examination provide important clues to the nature and duration of any acid–base derangement.

When a diagnosis of hyperventilation or respiratory alkalosis is made, its cause should be investigated. The diagnosis of hyperventilation syndrome is made by exclusion. In difficult cases, it may be important to rule out other conditions such as pulmonary embolism, coronary artery disease, and hyperthyroidism.

The treatment of respiratory alkalosis is primarily directed toward alleviation of the underlying disorder. Since respiratory alkalosis is rarely life threatening, direct measures to correct it will be unsuccessful if the stimulus remains unchecked. If respiratory alkalosis complicates ventilator management, changes in dead space, tidal volume, and frequency can minimize the hypocapnia. Patients with the hyperventilation syndrome may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to underlying psychological stress. Antidepressants and sedatives are not recommended, although in a few patients β -adrenergic blockers may help to ameliorate distressing peripheral manifestations of the hyperadrenergic state.

CHAPTER 150: IMMUNE-MEDIATED GLOMERULOPATHIES

IAN R. RIFKIN AND DAVID J. SALANT

Terminology

Glomerulopathies Presenting with Acute Nephritic Syndrome or Isolated Hematuria
 Glomerulopathies Presenting with the Nephrotic Syndrome or Isolated Proteinuria
 Glomerulopathies Presenting with Both Nephritic and Nephrotic Features

Glomeruli are specialized capillary tufts that produce up to 180 L per day of cell- and protein-free plasma ultrafiltrate. These properties are attributable to the porous glomerular capillary wall composed of fenestrated endothelial cells, the underlying glomerular basement membrane (GBM), and the filtration slits between adjacent visceral epithelial cell foot processes, which allows the bulk flow of water and solutes while preventing the passage of cells and macromolecules based on their size and charge. In addition, the mesangial cells, which occupy the axial region between glomerular capillary loops, synthesize mesangial matrix and regulate the surface area available for glomerular filtration (see [Chapter 164](#)).

The clinical presentation of glomerular diseases in general, and immune-mediated glomerular diseases in particular, is a direct consequence of damage to one or more components of the filtration unit. This can impair glomerular filtration and/or alter permeability to cells or macromolecules. The decreased glomerular filtration rate (GFR) may lead to renal failure with accumulation of metabolic waste products (azotemia) and derangement in fluid and electrolyte balance (see [Chapter 140](#) and [Chapter 141](#)). The alterations in permeability lead to the egress of cells and/or protein into the tubular lumen and then into the urine.

It is implicit in the above that glomerular damage can elicit only a limited number of functional outcomes. Therefore, the clinical presentation in terms of the urine sediment, proteinuria, or renal function is rarely specific for an individual disease. Nevertheless, although there are exceptions, the individual diseases present in a consistent manner, and two broad categories of clinical presentation are recognized: the *acute nephritic syndrome* and the *nephrotic syndrome* ([Table 150.1](#)). From a clinical standpoint, classification of patients into one of these two groups has proven extremely useful as a first step toward identifying the individual underlying disease. However, certain diseases present with features of both the acute nephritic syndrome and the nephrotic syndrome, and some produce only asymptomatic proteinuria and/or hematuria of varying degrees.

Clinical Syndromes and Histology of Primary Glomerulopathy	Examples of Secondary Causes and Associations
Isolated proteinuria or nephritic syndrome	
MCID	Wegener's lymphoma, NSAIDs
PSGN	Nephrotic syndrome, NSAIDs
MPGN	SLE, MALT, cancer, various drugs
Isolated hematuria or acute nephritic syndrome	
Diffuse PGN	Poststreptococcal GN, SLE
Focal or segmental PGN	glomerulonephritis, SLE, SLE
CRESTONIC GN (RPGN)	See Fig. 150.1
Mixed nephritic/nephrotic syndrome	
MPGN type I	HevC, virus, SLE, lymphoma, infection
MPGN type II	CNS? partial lipodystrophy

Note that this table does not include nonimmunologic causes of proteinuria (e.g., diabetic and amyloid nephropathies) or hematuria (e.g., hereditary nephritis syndromes).
 MCID, membranous nephropathy; PSGN, focal segmental glomerulosclerosis; MCID, minimal change disease;
 MPGN, membranoproliferative glomerulonephritis; PGN, proliferative GN; SLE, systemic lupus erythematosus; HevC, hepatitis C; HIV, HIV-associated nephropathy; HevC, hepatitis C; virus, mixed cryoglobulinemia; IgA-MPGN, IgA nephropathy; CNS, central nervous system; SLE, systemic lupus erythematosus;
 CRESTONIC, CRESTONIC; MALT, mucosa-associated lymphoid tissue; MPGN, mixed progressive glomerulonephritis.

TABLE 150.1. CLINICAL SYNDROMES AND HISTOLOGIC LESIONS CAUSED BY IMMUNOLOGIC GLOMERULAR DISEASES

The *acute nephritic syndrome* is defined clinically and includes some or all of the following: hematuria with red blood cell casts, oliguria, azotemia, hypertension, mild to moderate proteinuria (1 to 3 g per day) and moderate edema. Of these, hematuria with red blood cell casts is diagnostically the most important. The underlying glomerular disease is inflammatory in nature and damages the glomerular capillaries allowing the passage of cells into the urinary space. The inflammation is generally accompanied by proliferation of resident cells and infiltration of leukocytes, thus making proliferative glomerulonephritis the histologic counterpart of the acute nephritic syndrome. The rapidity and intensity of the inflammatory response further subdivides the acute nephritic syndrome into clinically useful categories. Acute glomerulonephritis presenting with acute nephritic syndrome may be reversible, either spontaneously or with treatment. A subgroup of patients with rapidly progressive glomerulonephritis (RPGN) have a course that leads to end-stage renal disease in weeks to months unless it is halted with treatment. Others have only microscopic hematuria, sometimes punctuated by episodes of gross hematuria and accompanied by urinary red blood cell casts.

The *nephrotic syndrome* is defined by heavy proteinuria (more than 3 g per day), severe edema, and hypoalbuminemia, often accompanied by hyperlipidemia and hypercoagulability. Many patients have so-called “subnephrotic” proteinuria or heavy proteinuria without other features of the nephrotic syndrome. Hematuria may be present but is not a major feature, and there is frequently only minimal impairment of the GFR at initial presentation. The underlying glomerular pathologic process is generally noninflammatory but the nephrotic syndrome may accompany various inflammatory glomerular diseases (e.g., class IV lupus nephritis; see below). The major abnormality is seen in the visceral epithelial cells and subepithelial aspect of the GBM.

The immune-mediated glomerulopathies are a disparate group of diseases in which glomerular injury is thought to be caused directly by immunologic mechanisms. Glomerular diseases occurring in the context of an immune-mediated disease but where the glomerular disease itself is not due primarily to immunological mechanisms (e.g., diabetic nephropathy in type I diabetes mellitus), are not usually classified as immune-mediated glomerulopathies. The immunologic basis of many glomerular diseases was established by the advent of immunofluorescence microscopy, which documented the presence of immunoglobulins and complement components in the glomeruli of renal biopsy specimens. The pattern of immunofluorescence tends to define the underlying immunopathogenesis, with linear staining of the GBM being characteristic of anti-GBM antibody disease, and granular deposits in the peripheral capillaries or mesangium representing immune complexes. However, not all glomerular diseases with an apparent immune basis are accompanied by glomerular immune deposits. Most notable examples are minimal change disease, the major cause of childhood nephrotic syndrome, and pauci-immune crescentic glomerulonephritis, an important cause of rapidly progressive glomerulonephritis. In addition, some diseases are included among the immune-mediated glomerulopathies by association because of similar clinical and/or pathologic features rather than by direct evidence of an immune basis. Indeed, the only glomerular disease in which the target antigen has been identified with certainty is anti-GBM disease/Goodpasture's syndrome. It is also noteworthy that certain nonimmune glomerulopathies may present with clinical syndromes that are indistinguishable from immune-mediated glomerular diseases. These are discussed elsewhere and include diabetic nephropathy ([Chapter 153](#)), hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura ([Chapter 152](#)), amyloidosis ([Chapter 154](#)), the paraproteinemias ([Chapter 154](#)), human immunodeficiency virus (HIV)-associated nephropathy ([Chapter 164](#)), and hereditary nephritis ([Chapter 157](#)).

TERMINOLOGY

The following is a brief glossary of descriptions used in glomerular pathology. The term *diffuse* implies that all (or most) glomeruli are affected more or less uniformly, whereas *focal* and *segmental* means that some are partly abnormal. A *proliferative* lesion refers to a hypercellular inflammatory process involving infiltrating leukocytes and proliferation of intrinsic glomerular cells. *Sclerosis* describes a degenerative process in which there is an increase in extracellular matrix accompanying the loss of glomerular cells and collapse of capillary loops. Thus, one may see a focal and segmental proliferative lesion give rise to a nephritic clinical presentation or find focal and segmental sclerosis underlying the nephrotic syndrome.

GLOMERULOPATHIES PRESENTING WITH ACUTE NEPHRITIC SYNDROME OR ISOLATED HEMATURIA

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Definition

Poststreptococcal glomerulonephritis (PSGN) follows infection of the skin or pharynx with nephritogenic strains of Lancefield group A β -hemolytic streptococci. It is the classical example of an acute postinfectious glomerulonephritis.

Incidence and Epidemiology

Poststreptococcal glomerulonephritis remains endemic among children over the age of 2 years in certain developing countries where streptococcal pharyngitis and skin infection are common. Although it is now uncommon in developed countries, sporadic cases are still seen among children and younger adults, and occasional epidemics are reported, especially in groups housed in close quarters. Sporadic and epidemic PSGN may follow either streptococcal skin disease or pharyngitis.

Etiologic Factors

Only certain strains of streptococci are nephritogenic (such as M-protein type 12, associated with pharyngitis, and type 49, associated with impetigo). The reasons for this strain specificity have not been elucidated but the M-protein itself is probably not the pathogenic entity. Several other streptococcal antigens are being investigated as potential nephritogenic agents.

Pathogenesis

Poststreptococcal glomerulonephritis is thought to be an immune complex–mediated disease on the basis of the finding of glomerular capillary deposits of IgG and C3 on immunofluorescence. It is likely that early formation of subendothelial and mesangial immune complexes is responsible for the acute inflammatory component of the disease as manifest by proliferation and leukocyte recruitment. Although large hump-like subepithelial deposits on electron microscopy are characteristic of PSGN, they are probably not the cause of the inflammation but may contribute to proteinuria. It is also noteworthy that the alternate pathway of complement is activated to a greater extent than the classical pathway, which suggests that streptococcal cell wall components may have a direct role.

Clinical Findings

There is a latent period of about 10 days following streptococcal pharyngitis and 21 days following skin infection before the onset of glomerulonephritis. The classical clinical presentation is the sudden onset of the acute nephritic syndrome with oliguria, gross hematuria (appearing as smoky or dark urine), facial edema, hypertension, and azotemia. Flank or abdominal pain may be present. Pulmonary edema may occur, and some patients may have malignant hypertension accompanied by headache, nausea and vomiting, confusion, and seizures. It is important to note, however, that milder and even subclinical disease is common. The urine sediment reflects the nephritic process, with dysmorphic red blood cells and red blood cell casts. Proteinuria is usually in the subnephrotic range although a small minority of patients develop nephrotic range proteinuria, usually in the recovery phase as the GFR normalizes. Acute renal failure occurs in 1% to 2% of patients and may require temporary dialysis.

Laboratory Findings

Serum creatinine may rise rapidly but usually does not exceed 2 to 3 mg per dL before recovery begins. The diagnosis of PSGN is usually made on the basis of the clinical presentation in conjunction with antistreptococcal antibodies and low C3 with normal C4. Renal biopsy is reserved for cases with an atypical presentation or disease course. Bacteriologic culture is frequently negative at the onset of PSGN, especially in patients already receiving antibiotic therapy. Antibody levels start to rise after about 7 to 10 days and persist for several months. A rise in antistreptolysin O titer (ASO) is helpful in cases following pharyngeal infection, but titers fail to rise in as many as half of individuals with skin infections. Rising titers of antihyaluronidase (AHase), and antideoxyribonuclease B (ADNase B) are a good indicator of both pharyngeal and skin infection. Complement levels suggest preferential activation of the alternate complement pathway with low C3 and normal C1q, C2, and C4 and are helpful in supporting the diagnosis, as the only other glomerular disease commonly associated with this pattern of complement activation is type II membranoproliferative glomerulonephritis (Table 150.2). The C3 levels and total serum hemolytic complement (CH_{50}) levels are low in more than 90% of individuals by the second week of the disease, with normal levels being reestablished by about 8 weeks.

Disease	Complement Profile*	Serology
Poststreptococcal GN	Low (alternate)	Antistreptococcal antibodies
Other postinfectious [†]	Low (classical)	Blood or other cultures
SLE	Low (classical)	ANA, anti-dsDNA, anti-Sm
MPGN: Type I	Low (classical)	Microfilaricemia, secondary anti-Hepatitis C
Type II	Low (alternate)	C3 nephritic factor
Mixed cryoglobulinemia	Low (classical)	IgG, IgM cryoglobulins, HE, anti-Hepatitis C
Anti-GBM nephritis	Normal	Anti-GBM antibodies
Wegener's granulomatosis	Normal	Antineutrophil cytoplasmic antibodies
Microscopic polyangiitis	Normal	Antineutrophil cytoplasmic antibodies
IgA-MPGN	Normal	None
MCD	Normal	None
PGN	Normal	Micoparitic—acute, secondary—HIV
MPG	Normal	Micoparitic—acute, secondary—ANA, HepB

* Pattern of complement activation: classical—low C3, C4, and C5; alternate—low C3, normal C2 and C4.
[†] Includes chronic bacteremia, e.g., infective endocarditis.
 GN, glomerulonephritis; SLE, systemic lupus erythematosus; MPGN, membranoproliferative glomerulonephritis; IgA-MPGN, IgA nephropathy; HE, hepatitis e; ANA, antinuclear antibody; dsDNA, double-stranded deoxyribonucleic acid; anti-dsDNA, antideoxyribonucleic acid; anti-Sm, anti-Smith antibody; HE, hepatitis e; GBM, glomerular basement membrane; PG, postinfectious; MPN, membranoproliferative nephritis.

TABLE 150.2. SERUM COMPLEMENT PROFILE AND SEROLOGY IN GLOMERULAR DISEASES

The histologic feature of PSGN by light microscopy is a diffuse proliferative glomerulonephritis with marked glomerular hypercellularity and a prominent infiltrate of leukocytes (Fig. 150.1A). Extensive crescent formation is rare and is generally limited to those cases that present with acute renal failure. Granular deposits of IgG and C3 are seen on the glomerular capillary walls on immunofluorescence microscopy with variable mesangial deposition (Fig. 150.1B). Different staining patterns may correlate with different patterns of clinical disease. C4 and C1q are absent. On electron microscopy large electron-dense subepithelial “humps” are most characteristic of PSGN (Fig. 150.1C), but subendothelial and mesangial deposits may be seen in early biopsies.

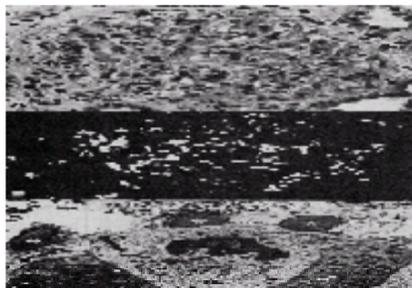

FIGURE 150.1. Acute poststreptococcal glomerulonephritis. **A:** The swollen glomerular tuft shows a prominent polymorphonuclear leukocytic infiltrate (hematoxylin-eosin, $\times 400$). **B:** Granular immunofluorescent deposits of IgG are seen along the glomerular basement membrane and in the mesangial region (antihuman IgG, $\times 400$). **C:** The electron micrograph shows a segment of basement membrane (arrow) with subepithelial “humps” (asterisks). Intracapillary inflammatory cells (IC) fill the capillary lumen ($\times 5,400$).

Optimal Management

Therapy for PSGN is predominantly supportive awaiting spontaneous resolution. Penicillin is usually given to prevent the spread of streptococcal infection to contacts and possibly to limit the severity of PSGN. Treatment is directed at the control of blood pressure and volume overload with diuretics, fluid and sodium restriction, and antihypertensive agents. The overall prognosis is excellent, with most patients recovering completely. A small subset of patients, particularly adults with sporadic disease, may be left with residual proteinuria, hypertension, or mild renal insufficiency, but progression to end-stage renal failure is very rare. In the 1% to 2% of patients who develop severe crescentic glomerulonephritis with acute renal failure, consideration should be given to a course of pulse corticosteroids, although there is no good evidence that this alters the natural history and spontaneous recovery is quite common.

OTHER POSTINFECTIOUS GLOMERULONEPHRITIDES

The acute nephritic syndrome and diffuse or focal proliferative glomerulonephritis can also be seen in association with many other bacterial, viral, fungal, or parasitic infections of which a few deserve emphasis.

Infective endocarditis, both acute and chronic, can present with a focal or diffuse proliferative glomerulonephritis ([Table 150.1](#)). The severity varies from microscopic hematuria to acute renal failure. Nephrotic syndrome is present in 25% of patients. Complement levels are usually low but, in contrast to PSGN, classical complement pathway activation is seen with low C4 as well as low C3 ([Table 150.2](#)). Circulating cryoglobulins and rheumatoid factor are often present, and glomerular deposits of IgG and C3 are found on immunofluorescence. The renal disease generally resolves with treatment of the endocarditis. A similar clinical presentation is seen in "shunt nephritis," a disease that may be seen in children with infection of ventriculoatrial shunts inserted for the treatment of hydrocephalus. Treatment involves appropriate antibiotics and frequently requires removal of the shunt. Recovery of renal function may be slow. Other deep-seated infections, including pulmonary, hepatic, and retroperitoneal abscesses, may be associated with acute proliferative glomerulonephritis. Renal dysfunction may be severe. In contrast to other postinfectious glomerulonephritides, complement levels are often normal and rheumatoid factor is negative although cryoglobulins are often present. Glomerular immune complex deposits may be scanty or absent. The pathogenesis of this disease is not well defined, but treatment involves eradication of the infection.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Definition

Rapidly progressive glomerulonephritis is a syndrome of rapidly declining renal function accompanied by hematuria and red blood cell casts in the urine, and variable degrees of proteinuria and oliguria, with crescentic glomerulonephritis being the predominant pathologic lesion. In the absence of prompt and effective treatment, the disease frequently terminates in end-stage renal failure.

Incidence

Approximately 10% to 15% of patients with acute glomerulo-nephritis have a rapidly progressive course.

Etiologic Factors and Classification

The causes of crescentic glomerulonephritis can be conveniently classified according to the immunofluorescent staining pattern on renal biopsy and associated serologic findings ([Fig. 150.2A](#), [Fig. 150.2B](#), [Fig. 150.2C](#) and [Fig. 150.3](#)). There are three main categories. In anti-GBM nephritis, deposits of IgG decorate the GBM in a linear pattern. About 50% of patients with anti-GBM disease also have pulmonary hemorrhage (so-called Goodpasture's syndrome). Pauci-immune nephritis is characterized by few or no glomerular immune deposits and the presence of circulating antineutrophil cytoplasm antibodies (ANCA). The disease may be limited to the kidneys or associated with small-vessel vasculitis involving other organs (systemic vasculitis). The third group includes various renal limited and systemic diseases with abundant granular immune complex deposits on glomerular capillaries or in the mesangium.

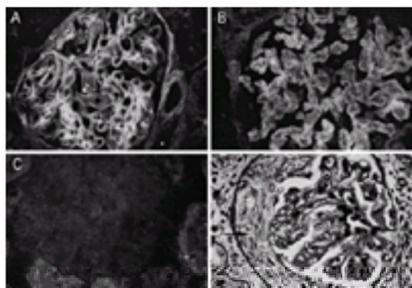

FIGURE 150.2. Rapidly progressive glomerulonephritis. **A:** A continuous (linear) pattern of immunofluorescence staining for IgG is seen along glomerular capillary basement membranes and in Bowman's capsule in a patient with Goodpasture's syndrome (antihuman IgG, $\times 400$). **B:** Granular deposits are seen in the capillary walls in a patient with SLE (antihuman IgG, $\times 400$). **C:** An absence of immunofluorescence staining indicating an absence of immune deposits is seen in the glomerulus of a patient with microscopic polyangiitis (antihuman IgG, $\times 400$). **D:** A cellular crescent (*arrow*) compresses the adjacent glomerular capillary tuft in a patient with Wegener's granulomatosis (periodic acid–Schiff, $\times 400$).

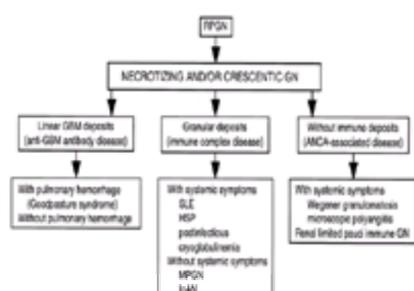

FIGURE 150.3. Immunopathologic classification of necrotizing and crescentic glomerulonephritis. The upper box indicates the typical histologic lesion in rapidly progressive glomerulonephritis; the next level represents the immunohistologic and serologic findings; the lowest level lists the etiologies of each. GBM, glomerular basement membrane; SLE, systemic lupus erythematosus; HSP, Henoch-Schönlein purpura; MPGN, membranoproliferative GN; IgAN, IgA nephropathy; ANCA, antineutrophil cytoplasmic antibody.

Clinical Findings

Rapidly progressive glomerulonephritis generally presents with some or all of the typical features of the nephritic syndrome, including hematuria with red blood cell casts, oliguria, subnephrotic proteinuria, peripheral edema, mild hypertension, and renal impairment, which may progress to end-stage renal failure within weeks. Severe hypertension and nephrotic syndrome are unusual at initial presentation in anti-GBM and pauci-immune nephritis but may be present in the immune complex

diseases causing RPGN. In addition to the renal manifestations, several causes of RPGN are associated with systemic symptoms and signs, including pulmonary hemorrhage (Table 150.3), cutaneous vasculitis (Table 150.3), and various rheumatologic manifestations as in systemic lupus erythematosus (SLE). These are discussed in more detail below (see also Chapter 178 and Chapter 181). Thus, a careful history and physical examination often provides clues to the diagnosis of the cause of RPGN and helps avoid extensive special investigation.

Histopathology

Glomerular crescents are the pathological hallmark of the various diseases that present with RPGN (Fig. 150.2D). The glomerular tuft itself may be the site of a diffuse or focal proliferative and necrotizing glomerulonephritis. Initially, the crescents are composed of macrophages and proliferating glomerular epithelial cells surrounded by a matrix of fibrinogen, fibronectin, and other plasma-derived proteins. Later, there is infiltration of fibroblasts and the crescents become fibrotic. With the formation of large, circumferential crescents in a high proportion of glomeruli, the glomerular tufts are compressed and GFR is impaired. There is frequently an associated periglomerular and interstitial inflammatory infiltrate, which gives rise to interstitial fibrosis and tubular atrophy, the harbingers of chronic renal failure. Immunofluorescence reveals linear staining of the GBM, pauci-immune, or granular deposits. The granular deposits in the immune complex group are characteristic of the specific disease responsible; for example, mesangial IgA in IgA nephropathy and Henoch-Schönlein purpura (HSP), and diffuse IgG and C3 in lupus nephritis (see below). Electron microscopy discloses no immune deposits in anti-GBM and pauci-immune nephritis, whereas immune deposits are seen in the locations characteristic of the various immune complex diseases. GBM disruption may be seen in all groups.

ANTI-GLOMERULAR BASEMENT MEMBRANE ANTIBODY DISEASE

Anti-GBM disease is caused by autoantibodies that recognize and bind to their target antigen in the noncollagenous 1 (NC1) domain of the $\alpha 3$ chain of type IV collagen, a major component of the GBM and alveolar basement membrane. As in other autoimmune diseases, the precise etiologic factors of the immune dysregulation is unknown, but glomerular and alveolar damage is due to the inflammatory response initiated by the binding of anti-GBM autoantibodies to these basement membranes. Anti-GBM disease is uncommon, accounting for approximately 1% to 2% of cases of glomerulonephritis and about 10% to 15% of cases of RPGN. There appears to be a genetic susceptibility to disease, with individuals inheriting the gene for the major histocompatibility complex (MHC) class II molecule HLA-DRw15 being at increased risk. Goodpasture's syndrome tends to be more common in male patients under 40 years of age who may have a history of cigarette smoking, hydrocarbon exposure, or recent respiratory tract infection. Patients with renal-limited anti-GBM nephritis tend to be older and of either sex. Pulmonary involvement may precede nephritis by months or even years in Goodpasture's syndrome and is often accompanied by iron deficiency anemia due to subclinical intra-alveolar hemorrhage. Overt pulmonary hemorrhage ranges from mild to life threatening and is often accompanied by dyspnea, hemoptysis, and cough. Chest x-ray shows diffuse alveolar infiltrates in a "butterfly" pattern.

Diagnosis

The diagnosis is made by finding crescentic glomerulonephritis (Fig. 150.2D) with linear deposits of IgG on renal biopsy (Fig. 150.2A), and by detection of circulating anti-GBM antibodies (Table 150.2). Enzyme-linked immunosorbent assays that utilize a purified source of antigen for the detection of serum autoantibodies to the NC1 domain of type IV collagen $\alpha 3$ chain have a sensitivity and specificity in excess of 90%. Caution should be exercised to ensure that samples are sent to a laboratory that uses these assays and has a rapid turnaround time. Severe iron deficiency anemia is commonly present in patients with Goodpasture's syndrome. Between 10% and 30% of anti-GBM-positive patients are also positive for ANCA. It is not known at present whether these individuals have a different prognosis from those anti-GBM-positive individuals who are ANCA-negative. Complement levels are normal.

Differential Diagnosis

Pulmonary hemorrhage and glomerulonephritis with renal failure (pulmonary-renal syndrome) may also be seen in ANCA-positive pauci-immune vasculitides and less commonly in other systemic autoimmune diseases (including SLE, HSP, and cryoglobulinemia) (Table 150.3). In addition, acute renal failure from any cause may be complicated by superimposed pulmonary edema, infection, or embolism, which may be difficult to distinguish clinically from immune-mediated pulmonary hemorrhage. Serologic tests, if available rapidly, sometimes help with the diagnosis, but measurement of pulmonary capillary wedge pressure, pulmonary carbon monoxide transfer, and lung biopsy are sometimes required to make the distinction.

Disease	Pulmonary Disease	Cutaneous Vasculitis
Goodpasture's syndrome	Present	Absent
Wegener's granulomatosis	Present	Present
Microscopic polyangiitis	Present	Present
Churg-Strauss allergic granulomatosis	Present	Present
Mixed cryoglobulinemia	Rare	Present
Henoch-Schönlein purpura	Rare	Present
Systemic lupus erythematosus	Rare	Unusual

TABLE 150.3. DIFFERENTIAL DIAGNOSIS OF SYSTEMIC DISEASES ASSOCIATED WITH ACUTE GLOMERULONEPHRITIS, PULMONARY DISEASE, AND/OR CUTANEOUS VASCULITIS

Optimal Management

Without treatment nearly all patients with anti-GBM disease either develop end-stage renal failure or die from pulmonary hemorrhage. The early initiation of treatment with plasmapheresis and immunosuppressive drugs is critical if long-term renal function is to be preserved. Progression to end-stage renal failure can usually be prevented if treatment is begun when the plasma creatinine concentration is less than 5 mg per dL and when the patient is not oliguric. On the other hand, if treatment is started when the plasma creatinine concentration is above 5 to 7 mg per dL or the patient is oliguric, progression to end-stage renal failure is almost inevitable. In this situation the risks of aggressive therapy are not warranted for the renal disease. However, if there is pulmonary involvement, treatment should be initiated irrespective of the level of plasma creatinine in order to prevent fatal pulmonary hemorrhage. The treatment of anti-GBM disease involves the removal of circulating anti-GBM autoantibodies with daily plasma exchange until circulating anti-GBM antibodies are no longer detectable, and concomitant immunosuppressive therapy. A typical immunosuppressive regimen includes corticosteroids (three daily doses of intravenous methylprednisolone 15 mg per kg per day followed by oral prednisone 1 mg per kg per day with gradual taper) and oral cyclophosphamide (2 to 3 mg per kg per day) with close monitoring to maintain the leukocyte count above 3,500/mm³. Azathioprine (1 to 2 mg per kg per day) may be used instead if cyclophosphamide is contraindicated or in mild disease. Immunosuppressive therapy is continued for approximately a year. Relapses may occur and careful follow-up is necessary. Renal transplantation is a good therapeutic option for patients who develop end-stage renal failure provided the disease is in remission and circulating autoantibodies have been undetectable for 6 months or more using a reliable assay.

PAUCI-IMMUNE CRESCENTIC GLOMERULONEPHRITIS

Pauci-immune crescentic glomerulonephritis may occur in a renal-limited form or as part of a systemic vasculitis involving small vessels (see also Chapter 181). The clinical manifestations of the individual diseases within the group are determined by the size and location of the affected vessels. Within this subgroup of RPGN there are two diseases in which renal involvement is common and often severe. These are Wegener's granulomatosis and microscopic polyangiitis (including both a systemic and a renal-limited form). In the related Churg-Strauss syndrome, renal involvement is less common and usually mild. The mean age of onset is approximately 50 years of age, with whites being affected sevenfold more commonly than blacks. Disease onset is more common in winter and early spring, and is preceded by a flu-like illness. Constitutional symptoms such as fever, anorexia, malaise, and weight loss frequently accompany the disease. The etiologic factors are unknown. Clinical renal involvement usually manifests as RPGN, but early cases may be detected with hematuria and red blood cell casts. Lower and/or upper airway involvement is almost always present in classical Wegener's granulomatosis, but the respiratory system may also be affected in microscopic polyangiitis. Pulmonary involvement spans the range from trivial infiltrates to life-threatening hemorrhage, and to more chronic conditions such as chronic interstitial pulmonary fibrosis and

bronchiolitis obliterans. Upper respiratory tract involvement includes sinusitis, necrotizing lesions of the nose, eustachian tube blockage, and tracheal stenosis. Involvement of other organs is not unusual and includes the gastrointestinal tract (gastric ulceration, pancreatitis, gastrointestinal bleeding, bowel perforation), nervous system (most commonly mononeuritis multiplex), and eye (iritis, uveitis, sclerokeratitis).

Diagnosis

The diagnosis is made by finding crescentic glomerulonephritis ([Fig. 150.2D](#)) with scant or no immune deposits on renal biopsy ([Fig. 150.2C](#)), and by detection of circulating ANCA ([Table 150.2](#)). Antineutrophil cytoplasm antibodies are positive in about 90% of cases of active pauci-immune crescentic glomerulonephritis. However, ANCA are also found in certain nonvasculitic conditions; therefore, as with any laboratory test, a positive ANCA should be used in conjunction with clinical and pathologic data in making a diagnosis. It is not yet known whether ANCA are involved in disease pathogenesis. In Wegener's granulomatosis the ANCA target antigen is most often proteinase 3, which gives a diffuse cytoplasmic staining reaction on immunofluorescence (cANCA). In microscopic polyangiitis the ANCA antigen is most often myeloperoxidase and gives a perinuclear staining pattern (pANCA), but there is considerable overlap between groups. Serum complement levels are normal. Leukocytosis, thrombocytosis, and a normochromic, normocytic anemia are frequently seen. The erythrocyte sedimentation rate and serum C-reactive protein levels are typically elevated and may serve as imprecise markers of disease activity if ANCA assays are not available. In Wegener's granulomatosis, granulomatous inflammation is present in the upper and lower airways, with or without an accompanying necrotizing vasculitis. It is sometimes necessary to perform a lung biopsy to distinguish between Wegener's granulomatosis and infective causes of granulomas and vasculitis. This granulomatous inflammation is not a feature of microscopic polyangiitis. However, outside of the airways, the necrotizing vasculitis of Wegener's granulomatosis is identical to that of microscopic polyangiitis. Churg–Strauss syndrome is characterized by granulomatous vasculitis rich in eosinophils, peripheral blood eosinophilia, and a history of asthma.

Optimal Management

Corticosteroids combined with cyclophosphamide are the major form of therapy for the ANCA-associated small vessel vasculitides and pauci-immune crescentic glomerulonephritis. Initial immunosuppressive therapy is the same as in anti-GBM nephritis, but cyclophosphamide is continued for 12 to 18 months after clinical remission. Plasma exchange is not used routinely but may be considered in patients who are initially dialysis-dependent, have significant pulmonary hemorrhage, or have concurrent anti-GBM antibody disease. The relapse rate following discontinuation of immunosuppressive therapy is between 20% and 46%. Trimethoprim-sulfamethoxazole may be of use in preventing disease relapse in the upper airway or as sole therapy for mild upper airway disease. Although disease has been reported to recur following renal transplantation, this remains a good therapeutic option for patients who progress to end-stage renal failure.

CLASSIC POLYARTERITIS NODOSA

Polyarteritis nodosa is a necrotizing inflammation of medium-sized or small arteries. Typically, there is no glomerulonephritis or vasculitis of arterioles, capillaries, or venules; however, there may be overlap with microscopic polyangiitis. The renal injury is ischemic (as opposed to inflammatory) and arises as a consequence of necrotizing inflammation of renal arteries. The urine sediment is therefore often relatively normal and proteinuria, if present, is only modest. Renal failure is slowly progressive. Severe hypertension is common and is primarily mediated by ischemia-induced activation of the renin–angiotensin system. Multiorgan involvement, including the liver, gastrointestinal tract, heart, peripheral nerves, and skeletal muscle, is common. Evidence of hepatitis B virus infection may be found, but a causal link is not established. Antineutrophil cytoplasm antibodies are not detected and complement levels are normal. The finding of aneurysms of medium-sized arteries on angiography supports the diagnosis. Blood pressure control, corticosteroids, and cyclophosphamide are the mainstays of treatment. Antiviral therapy and intravenous immunoglobulin are indicated in selected cases.

IMMUNE COMPLEX–MEDIATED CRESCENTIC GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis due to crescentic glomerulonephritis is seen in a fraction of patients with one of the many renal-limited or systemic immune complex diseases shown in [Figure 150.3](#). These are discussed in detail elsewhere in this chapter under the specific diseases. Associated nephrotic syndrome and hypertension are more common on initial presentation in this subgroup. Other clues to the diagnosis are the presence of granular immune deposits on immunofluorescence ([Fig. 150.2B](#)) and characteristic serologic abnormalities ([Table 150.2](#)).

IGA NEPHROPATHY AND HENOCH-SCHÖNLEIN PURPURA NEPHRITIS

Definition and Incidence

Immunoglobulin A nephropathy (IgAN) is a chronic glomerular disease with variable clinical presentation and characterized by mesangial deposits of IgA. It is the commonest form of primary glomerulonephritis, accounting for 8% to 50% of all cases with considerable geographic variability in incidence and severity. There are also ethnic differences, with blacks being relatively rarely affected in comparison to whites and Asians. All age groups may be affected, but it is particularly common in children and young adults. There is a male-to-female predominance of more than 2:1. It is usually a sporadic disease but familial cases have been reported. Certain polymorphisms of the angiotensinogen and angiotensin-converting enzyme (ACE) genes may influence the risk of progression and responsiveness to treatment in white patients with IgAN.

Clinical Findings

The most common clinical presentation is with asymptomatic microscopic hematuria (see [Chapter 134](#)), often found on routine physical examination. Proteinuria in these individuals is usually less than 1 g per day. Alternatively, and characteristically, IgAN can present with recurrent episodes of macroscopic hematuria, often coincident with an upper respiratory tract infection and commonly associated with flank pain. Proteinuria is often modest (1 to 3 g per day) and subsides after the acute episode passes. Nephrotic range proteinuria is not as common and signifies a less favorable prognosis. Red blood cell casts are often seen in the urine sediment but the full nephritic syndrome with hypertension, edema, and renal failure is rare. A third mode of presentation is as part of Henoch-Schönlein purpura (HSP) (see [Chapter 164](#) and [Chapter 181](#)), which is a form of systemic vasculitis more common in children than in adults. The renal involvement in HSP is very similar to that seen in IgAN, and it is likely that they are part of the same disease spectrum. Systemic features of HSP are probably mediated by an IgA immune complex vasculitis and include the following: purpuric skin lesions usually on the extensor surfaces of the legs and forearms and buttocks but sparing the trunk; transient arthralgias of the large joints; and abdominal pain, ileus with vomiting, and bloody diarrhea. An unusual presentation of steroid-responsive nephrotic syndrome, with renal biopsy showing features of both IgAN and minimal change disease, has also been reported.

Differential Diagnosis

Other diseases that present with asymptomatic hematuria in young patients include thin basement membrane disease, Alport's hereditary nephritis (including female carriers), and hypercalciuria and hyperuricosuria (see [Chapter 134](#)). Immunoglobulin A nephropathy should also be distinguished from mesangial (class II) and focal and segmental lupus nephritis (class III), in which prominent IgA deposits may also be seen. In addition, there are several diseases in which mesangial IgA deposits are found in the absence of the typical clinical features of IgAN. They include chronic liver disease, gluten enteropathy, dermatitis herpetiformis, inflammatory bowel disease, cutaneous T-cell lymphomas, bronchial and laryngeal carcinoma, and spondyloarthropathies (including Reiter's syndrome and ankylosing spondylitis). It may not be coincidental that many of these are disorders of immune regulation with a prominent mucosal or skin component.

Diagnosis

Immunoglobulin A nephropathy is diagnosed by finding mesangial or focal proliferative glomerulonephritis with prominent mesangial IgA deposits in a patient with a compatible clinical presentation. Henoch-Schönlein purpura is distinguished from IgAN by its typical extrarenal symptoms. There are no diagnostic serologic markers in either disease ([Table 150.2](#)).

Histopathology

Light microscopy in IgAN and HSP demonstrates mesangial enlargement due to increased mesangial matrix and cellular proliferation ([Fig. 150.4A](#)). In more severe cases presenting with heavy proteinuria or RPGN there may be focal and segmental proliferation and necrosis with crescents. Immunoglobulin A deposits, predominantly of the IgA1 subclass, are seen in the mesangium of all glomeruli on immunofluorescence ([Fig. 150.4B](#)). In addition, IgG or IgM may be seen. C3 is usually present with components of the alternate, but not the classical, complement pathway. Electron microscopy shows mesangial electron-dense deposits,

sometimes extending into a subendothelial location in more severe cases.

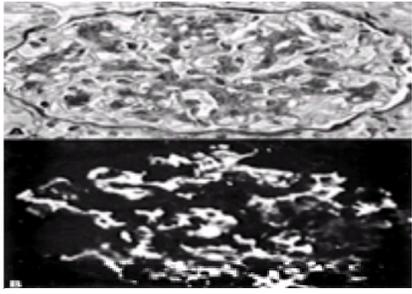

FIGURE 150.4. IgA nephropathy. **A:** Mesangial proliferation associated with normal peripheral capillary basement membranes (periodic acid–Schiff, $\times 400$). **B:** Strong mesangial staining for IgA is present ($\times 400$).

Course and Prognosis

Despite its original designation as “benign recurrent hematuria,” IgAN follows a chronic but not always benign course in the large majority of individuals. Ten-year renal survival ranges from 67% to 94%. About one third of patients follow a benign course with persistent microscopic and episodes of macroscopic hematuria. Renal function remains normal, and proteinuria is generally less than 1 g per day. Spontaneous clinical remission may occur in a small number of patients. About 10% have nephrotic syndrome, and a small number develop RPGN due to crescentic glomerulonephritis. Up to 40% of patients have a progressive course and develop end-stage renal failure within 20 years of presentation. Poor prognostic indicators include hypertension, heavy proteinuria, and reduced GFR at presentation; glomerular sclerosis, crescent formation, interstitial fibrosis, and vascular sclerosis on renal biopsy. The course in HSP nephritis is similar except that recurrent macroscopic hematuria is less common.

Optimal Management

Patients who present with the classical features of IgAN merit close follow-up but require no treatment if they have normal renal function and no hypertension or proteinuria. Pulse steroids, immunosuppressive therapy, and plasmapheresis are used in patients with RPGN due to crescentic glomerulonephritis, but the response is highly variable from patient to patient. In patients with heavy proteinuria, hypertension, and progressive renal insufficiency, blood pressure should be lowered well into the normal range with ACE inhibitors and other antihypertensive agents if necessary in an effort to decrease proteinuria and delay the progression toward end-stage renal failure. Individuals who are homozygous for the D allele of ACE may derive particular benefit. The ACE inhibitors may be of value even in normotensive patients with heavy proteinuria. Two out of four controlled studies showed that some patients with progressive IgAN have stabilization of renal function when treated with fish oils containing a high concentration of omega-3 fatty acids [eicosapentaenoic acid (EPA) 1.8 g per day and docosahexaenoic acid (DHA) 1.2 g per day]. Extended courses of alternate-day prednisone have also been found to stabilize renal function and modestly reduce proteinuria in some patients with progressive IgAN. Transplantation is a good therapeutic option for patients with end-stage IgAN; however, recurrence occurs in about one third of cases, with equal frequency in cadaveric and living related transplants. Such cases follow a slowly progressive course of allograft dysfunction, similar to that of the primary disease.

GLOMERULOPATHIES PRESENTING WITH THE NEPHROTIC SYNDROME OR ISOLATED PROTEINURIA

An approach to the patient with nephrotic syndrome, including differential diagnosis, metabolic complications, indications for renal biopsy, and general management, is given in [Chapter 135](#). The following is a discussion of the specific immune-mediated diseases that cause nephrotic syndrome and isolated proteinuria ([Table 150.1](#)).

MINIMAL CHANGE DISEASE

Definition and Incidence

Minimal change disease causes severe nephrotic syndrome with essentially normal glomeruli on light and immunofluorescence microscopy ([Fig. 150.5A](#)). It accounts for about 90% of cases of nephrotic syndrome in children less than 10 years of age and for approximately 50% of cases in older children. In adults, about 20% of cases of nephrotic syndrome are due to minimal change disease. Boys are affected twice as frequently as girls, but the sex ratio is equal in adults.

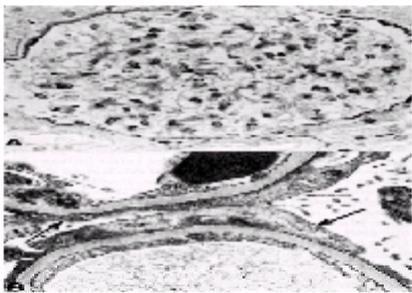

FIGURE 150.5. Minimal change disease. **A:** The glomerular capillary loops demonstrate no appreciable abnormalities (periodic acid–Schiff, $\times 400$). **B:** The electron micrograph shows effacement of the visceral epithelial cell foot processes (*arrows*; $\times 11,000$).

Etiologic Factors and Pathogenesis

Minimal change disease is nearly always idiopathic (primary), especially in children. An identical glomerular lesion with nephrotic syndrome may be seen rarely in association with Hodgkin's lymphoma and allergic reactions, especially to drugs. When caused by an idiosyncratic reaction to nonsteroidal anti-inflammatory drugs, minimal change nephrotic syndrome is accompanied by interstitial nephritis and acute renal failure. Association with T-cell lymphoma and responsiveness to steroids and immunosuppressive agents that interfere with T-lymphocyte function provide indirect evidence that immune-mediated mechanisms might be involved in the pathogenesis of idiopathic minimal change disease. Whatever the initiating pathogenic factors may be, the end result is damage to the visceral epithelial cells with consequent proteinuria.

Clinical Findings

The clinical presentation is dominated by the rapid onset of severe nephrotic syndrome with anasarca and associated hyperlipidemia. Severe hypertension and renal insufficiency are unusual, although creatinine clearance is mildly reduced. Urinalysis reveals lipiduria. Microscopic hematuria may be present in 20% of patients, but red blood cell casts are absent. Acute renal failure occurs occasionally, especially in adults after treatment with diuretics.

Histopathology

Glomerular morphology is normal on light microscopy ([Fig. 150.5A](#)) except for mild mesangial expansion in some cases. Immune deposits are absent on immunofluorescence microscopy. The characteristic and consistent feature on electron microscopy is diffuse effacement of the foot processes of visceral epithelial cells ([Fig. 150.5B](#)).

Diagnosis

There are no diagnostic laboratory tests ([Table 150.2](#)), and a definitive diagnosis can be made only on renal biopsy. However, because most children with nephrotic syndrome have minimal change disease, renal biopsy is reserved for those with an unusual clinical presentation or an inadequate response to treatment. In adults, the diagnosis is usually made on renal biopsy. When interpreting the finding of normal glomeruli on light microscopy in a patient with nephrotic syndrome, it is important to remember that early lesions of focal and segmental glomerulosclerosis may be missed due to sampling error in the biopsy. Similarly, early membranous nephropathy may appear normal on light microscopy, but the diagnosis is evident from the presence of granular glomerular deposits of IgG on immunofluorescence.

Optimal Management

In addition to general measures to control edema with diuretics and reduce proteinuria with ACE inhibitors, corticosteroids are particularly effective in the management of minimal change disease. They produce complete remission in about 90% of children within 8 weeks of starting treatment. Adults may take longer to remit. A typical dosing regimen in adults is to give prednisone at 1 mg per kg as a single daily dose for up to 12 weeks. A progressive shift to alternate day dosing, beginning at 1 mg per kg, is started 1 week after proteinuria remits and then tapered off over 2 to 3 months. If remission of proteinuria has not been achieved by 12 weeks, the disease is considered steroid-resistant. About 50% of adults relapse at least once after steroid therapy is discontinued, which requires retreatment with prednisone followed by a slower taper. Patients who relapse during steroid taper or shortly thereafter are said to be steroid-dependent. Those who relapse more than three times a year are termed frequent relapsers. Cytotoxic therapy with either cyclophosphamide (2 mg per kg per day for 8 to 12 weeks with a total cumulative dose of less than 200 mg per kg) or chlorambucil (0.1 to 0.2 mg per kg per day with a total cumulative dose of less than 10 mg per kg) is useful in the treatment of steroid-dependent, frequently relapsing, and some steroid-resistant individuals, and often induces long-lasting remissions. Cytotoxic therapy is usually started just after completing a course of steroids. Risk-benefit considerations are important in deciding whether to initiate cytotoxic therapy in an individual patient. Cyclosporin A (4 to 5 mg per kg per day for a year) is also effective in treating individuals who do not achieve lasting remission with steroids alone; however, relapse is common after cyclosporin A is discontinued and nephrotoxicity is a potential concern.

Course and Prognosis

Despite its relapsing course, the overall prognosis in minimal change disease is excellent. Complications are related to the nephrotic syndrome (see [Chapter 135](#)) in treatment-resistant individuals and to side effects of the medications.

FOCAL AND SEGMENTAL GLOMERULOSCLEROSIS

Definition

Focal and segmental glomerular sclerosis (FSGS) is a clinical-pathologic syndrome dominated by proteinuria, a high incidence of progressive renal failure, and focal and segmental sclerotic glomerular lesions.

Incidence, Etiologic Factors, and Pathogenesis

Focal and segmental glomerulosclerosis may be primary (idiopathic) or secondary to various causes. Primary FSGS is responsible for about 10% to 15% of cases of nephrotic syndrome in children and as many as 35% of cases in adults. It is the predominant cause of idiopathic nephrotic syndrome in African-Americans. The etiologic factors contributing to primary FSGS are unknown, although they appear to involve widespread injury to all visceral epithelial cells. It is speculated that clinical and histologic similarities between FSGS and minimal change nephropathy point to a common cause and pathogenesis, with FSGS representing the more severe side of the disease spectrum. As in minimal change nephropathy, responsiveness of FSGS to immunosuppressive therapy, including cyclosporin A, suggests that immune mechanisms might be involved in the pathogenesis.

Secondary FSGS differs from primary FSGS in that visceral epithelial cell injury is limited to the sclerotic areas. Several factors are likely responsible for this, but glomerular hypertension plays an important role in many of the recognized causes. These include diseases causing substantial, longstanding nephron loss, such as unilateral renal agenesis and nephrectomy in childhood, and chronic renal diseases associated with areas of interstitial scarring and tubular atrophy. Examples of the latter include reflux nephropathy, analgesic nephropathy, chronic lithium toxicity, heroin abuse, and sickle cell disease. Glomerular hypertension may be directly responsible for FSGS associated with morbid obesity and sleep apnea. A severe variant of FSGS, termed collapsing glomerulopathy, is seen most commonly in HIV-associated nephropathy but may also occur in the absence of HIV infection. It is characterized clinically by massive proteinuria and a rapid decline in renal function, and histologically by segmental collapse and sclerosis of the glomeruli. Focal and segmental glomerular sclerosis can also be a relatively nonspecific consequence of previous focal and segmental proliferative glomerulonephritis.

Clinical and Laboratory Features

It is important to differentiate primary FSGS from secondary FSGS because the treatments differ. Primary FSGS usually presents with the acute onset of nephrotic syndrome, often accompanied by hypertension and microscopic hematuria. Reduced GFR is not unusual on presentation. A minority of patients are detected because of asymptomatic proteinuria. There is no history of antecedent renal, urologic, or other medical disorders, and serologic tests are normal ([Table 150.2](#)). Renal ultrasound shows symmetric, hyperechoic kidneys of normal or slightly reduced size. In secondary FSGS proteinuria is often in the subnephrotic range, and even when it is in the nephrotic range hypoalbuminemia and edema are not common. Symptoms and signs of one of the underlying causes can often be elicited, and renal imaging studies may show evidence of renal scarring, caliectasis, papillary necrosis, unilateral agenesis, or other clues to a previous urinary tract abnormality.

Histopathology

The diagnosis of FSGS is made on renal biopsy. Light microscopy reveals segmental sclerosis of a variable number of glomeruli with interstitial fibrosis and tubular atrophy in neighboring areas ([Fig. 150.6](#)). Acellular hyaline subendothelial deposits and adhesions to Bowman's capsule are common, and there may be associated capillary collapse. Deep cortical glomeruli are affected first, with subsequent progression to the outer cortex. Immunofluorescence microscopy shows focal deposits of IgM and C3 in sclerotic areas, which probably represent nonspecific entrapment. In primary FSGS, electron microscopy reveals diffuse effacement of visceral epithelial cell foot processes, whereas foot process effacement is limited mainly to the sclerotic areas in secondary FSGS. Collapsing glomerulopathy is characterized by visceral epithelial hyperplasia, marked capillary collapse, and, in HIV nephropathy, tubuloreticular structures in the endothelial cells.

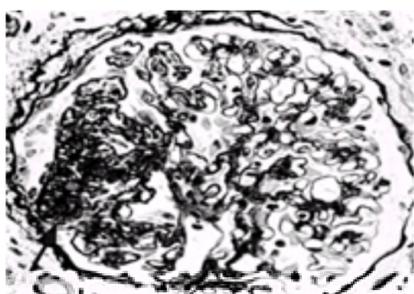

FIGURE 150.6. Focal segmental glomerulosclerosis. A segmental area of sclerosis (*arrow*) adheres to Bowman's capsule (periodic acid–Schiff, $\times 400$).

Course, Prognosis, and Treatment

Most patients with untreated primary FSGS and nephrotic syndrome eventually progress to end-stage renal failure. The prognosis is worst in individuals with renal dysfunction at baseline or persistent heavy proteinuria, whereas the course is generally favorable in those with subnephrotic proteinuria and those who have partial or complete remission on treatment. Substantially longer courses of treatment with prednisone are required to induce remission in primary FSGS than in minimal change disease; even then, only about 40% of patients respond. Cytotoxic agents may be successful in steroid-resistant cases. Cyclosporin A effectively reduces proteinuria in primary FSGS, but relapse generally occurs when the drug is discontinued. Moreover, the incidence and severity of cyclosporin A nephrotoxicity is greater than in minimal change disease and is related to the extent of sclerosis and interstitial fibrosis. Primary FSGS may recur after renal transplantation. This occurs most often in children with severe and rapidly progressive FSGS and appears to be due to a circulating factor that can be removed by plasmapheresis.

Secondary FSGS is best treated by removing the cause, if possible, and by lowering intraglomerular pressure with ACE inhibitors. The addition of a low dose of diuretic appears to have a synergistic effect in reducing proteinuria, even in the absence of edema. Because of the protracted course in both forms of FSGS, general measures to limit the complications of nephrotic syndrome, control hypertension well into the normal range, and reduce proteinuria should be instituted early and pursued aggressively (see [Chapter 135](#)).

MEMBRANOUS NEPHROPATHY

Definition

Membranous nephropathy is a proteinuric disease characterized by subepithelial immune deposits and expansion of the GBM.

Incidence, Etiologic Factors, and Pathogenesis

Membranous nephropathy is responsible for approximately 25% to 35% of cases of idiopathic nephrotic syndrome in adults but less than 5% in children. Most cases occur between the ages of 30 and 60 years with a male-to-female predominance of 2:1. It is usually idiopathic (primary), but a secondary cause may be identified in up to 30% of cases. Notable secondary causes include membranous lupus nephritis, antirheumatic drugs (gold, penicillamine, nonsteroidal anti-inflammatory agents), and solid tumors of breast, colon, and other organs. It might also be associated with infections (hepatitis B, hepatitis C, schistosomiasis, congenital and secondary syphilis, leprosy, malaria, hydatid disease, filariasis), thyroiditis and other autoimmune diseases, sarcoidosis, and other miscellaneous disorders. Idiopathic membranous nephropathy itself is thought to be an autoimmune disease, probably caused by antibodies to antigenic determinants on the glomerular visceral epithelial cell with subsequent formation of the C5b-9 membrane attack complex of complement being responsible for cell damage.

Clinical Findings

Eighty percent of patients with idiopathic membranous nephropathy present with nephrotic syndrome. The remainder come to medical attention because of proteinuria. Microscopic hematuria is seen in up to 50% of adults and most children, but macroscopic hematuria and red blood cell casts are rare. Hypertension and impaired renal function are uncommon at initial presentation but become more common with disease progression. Complications of the nephrotic syndrome such as anasarca, hyperlipidemia, and growth retardation in children are common and might be severe. Hypercoagulability leading to deep vein and renal vein thrombosis and pulmonary embolism is a potential life-threatening complication. Rarely, anti-GBM-mediated RPGN may supervene.

Diagnosis

Membranous nephropathy is diagnosed by renal biopsy, as there are no clinical or laboratory features that distinguish it from other causes of the nephrotic syndrome. Serologic studies, including complement levels, are normal in idiopathic membranous nephropathy ([Table 150.2](#)). Once membranous nephropathy is diagnosed, secondary causes should be excluded where possible by careful history and selected laboratory tests, including antinuclear antibodies and screening for hepatitis B and C. Limited screening for occult malignancy with physical examination, chest X-ray, mammography, and stool tests for occult blood is warranted, particularly in patients over the age of 60 years, for whom the prevalence of malignancy in membranous nephropathy may be as high as 20%.

Histopathology

The histology of membranous nephropathy reflects the response of the glomerular basement membrane and visceral epithelial cell to the subepithelial immune complexes. Typically, light microscopy reveals diffuse thickening of the GBM with normal glomerular cellularity and absence of inflammation ([Fig. 150.7A](#)). Silver staining demonstrates characteristic spikes of newly synthesized basement membrane projecting between the subepithelial immune deposits ([Fig. 150.7B](#)). In early cases, the glomeruli may appear normal on light microscopy, but membranous nephropathy can be distinguished from minimal change disease by immunofluorescence, which reveals bright granular deposits of IgG and C3 along the capillary walls ([Fig. 150.7C](#)). As the disease progresses, the immune complexes may become totally enclosed by the newly synthesized basement membrane producing the typically expanded GBM. Electron microscopy reveals electron-dense immune deposits on the subepithelial surface of the GBM and effacement of adjacent visceral epithelial cell foot processes ([Fig. 150.7D](#)). Newly synthesized GBM is seen to extend between and around the deposits.

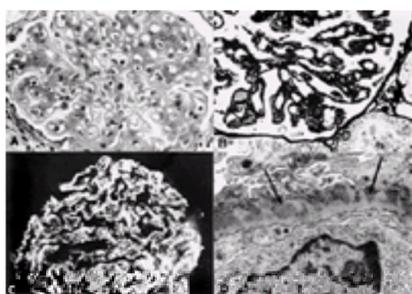

FIGURE 150.7. Membranous nephropathy. **A:** Thickened capillary basement membranes are seen throughout the glomerular tuft (periodic acid–Schiff, $\times 400$). **B:** A silver methenamine stain shows prominent subepithelial spikes (*arrows*, $\times 625$). **C:** Granular deposits of IgG are present along the glomerular capillary loops (antihuman IgG, $\times 400$). **D:** The electron micrograph shows subepithelial deposits (*arrows*) between projections of glomerular basement membrane material ($\times 12,000$).

Course and Prognosis

The natural history of untreated idiopathic membranous nephropathy is uncertain in individual cases, and this complicates decisions about therapy. More than 50% of children and about 25% of adults will have a spontaneous complete remission within 5 years. An additional 25% of adults will have spontaneous partial remission with continuing subnephrotic proteinuria and stable renal function. The remaining 50% will have persistent nephrotic syndrome, and of these about 25% to 40% will develop end-stage renal failure or die within 5 years. Factors at presentation that are associated with a high risk for disease progression include male sex, older age,

hypertension, impaired renal function, and nephrotic range proteinuria (particularly if greater than 10 g per day).

Optimal Management

An important part of treatment is general medical management to decrease complications of the nephrotic syndrome together with nonspecific measures to decrease the degree of proteinuria (see [Chapter 135](#)). These include the use of ACE inhibitors, control of hyperlipidemia with lipid-lowering agents, and control of edema with sodium restriction and diuretics. The treatment of idiopathic membranous nephropathy with immunosuppressive medication is controversial. Corticosteroid monotherapy has not been convincingly demonstrated to decrease proteinuria or to improve the long-term renal outcome. Addition of cyclophosphamide or chlorambucil appears to retard progression and diminish proteinuria in some patients. Cyclosporin A induces partial or complete remission of proteinuria in about 40% of patients, who then relapse when it is stopped. Given the uncertain natural history and the risks of long-term cytotoxic agents, a reasonable approach at this time is to reserve them, in combination with corticosteroids, for patients in a high-risk category with progressive renal dysfunction or severely debilitating nephrotic syndrome not responsive to conservative therapies. The cornerstone of treatment of secondary membranous nephropathy is treatment of the associated disease where possible or discontinuation of the offending drug. This usually, but not always, leads to resolution of the nephrotic syndrome over time. Membranous nephropathy may recur after renal transplantation, and it is a common cause of de novo nephrotic syndrome in kidneys transplanted into patients with renal failure from other diseases

GLOMERULOPATHIES PRESENTING WITH BOTH NEPHRITIC AND NEPHROTIC FEATURES

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

The membranoproliferative glomerulonephritides (MPGNs) are a heterogeneous group of glomerular diseases that present with nephritic and nephrotic features and have a similar histopathologic appearance at the light microscopic level. There are two main types of MPGN (I and II). Type I is further divided into idiopathic (primary) and secondary forms, the latter being far more common. In addition, some authorities recognize idiopathic MPGN type III as an overlap group having features of MPGN type I and membranous nephropathy. As with other types of glomerular diseases, it is essential to carefully exclude secondary causes using all available clinical, laboratory, and histopathologic data before making a diagnosis of idiopathic MPGN. Secondary causes of MPGN type I include chronic hepatitis C virus infection (discussed in greater detail below), other chronic infections (hepatitis B, HIV, infective endocarditis), systemic autoimmune diseases (SLE, Sjögren's syndrome), malignancy (chronic lymphocytic leukemia, non-Hodgkin's lymphoma), chronic liver disease, and hereditary deficiencies of complement (C1q, C2, C4, C3).

Idiopathic MPGN is a relatively uncommon disease, with an overall incidence of roughly 1% to 2% of renal biopsies. It usually occurs in children and young adults between the ages of 6 and 30 years. It is observed more frequently in whites than in other racial groups, but males and females are affected equally. MPGN type I most often presents with nephrotic range proteinuria or the nephrotic syndrome, accompanied by microscopic hematuria and red blood cell casts, and hypertension. The GFR is normal or only slightly decreased at first, and full-blown nephritic syndrome is unusual. C3 serum levels are low in up to two thirds of individuals together with low C4 ([Table 150.2](#)), which indicates classical pathway activation. MPGN type II can also present with nephrotic syndrome but, in addition, the acute nephritic syndrome and oliguric acute renal failure are quite common. The C3 serum levels are nearly always low and remain so for the duration of the illness, whereas classical pathway components (C4 and C2) are normal. This is due to a circulating IgG autoantibody called C3 nephritic factor (C3NeF) that binds to the alternative pathway C3 convertase, protecting it from inactivation by factor H and thereby causing continuous breakdown of C3. Partial lipodystrophy, the loss of fat in the upper half of the body including the face, is frequently present in patients with MPGN type II.

Histopathology

There are a number of characteristic features of MPGN on light microscopy. There is mesangial expansion due to an increase in both mesangial matrix and mesangial cellularity, which may cause a lobulated appearance of the glomerular tuft ([Fig. 150.8A](#)). The glomerular capillary wall appears thickened, and there may be reduplication of the GBM giving rise to the classical “double-contour” or “tram-track” appearance. In idiopathic MPGN type I, subendothelial and mesangial deposits are seen on electron microscopy ([Fig. 150.8B](#)). These can be shown by immunofluorescence microscopy to be immune complexes containing IgG and C3, sometimes accompanied by IgM and IgA. In MPGN type II (also known as “dense deposit disease”) electron microscopy reveals distinctive ribbon-like, strongly electron-dense deposits in the GBM ([Fig. 150.8C](#)). These dense deposits stain for C3 at their margins, but immunoglobulins are absent and there is no evidence that the deposits are immune complexes.

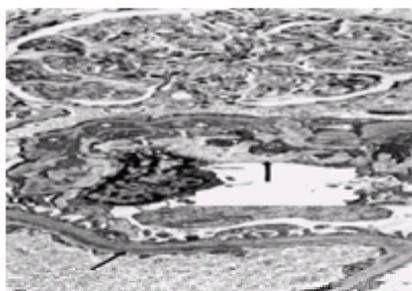

FIGURE 150.8. Membranoproliferative glomerulonephritis. **A:** Mesangial proliferation and basement membrane abnormalities result in an accentuated lobular architecture (periodic acid–Schiff, $\times 400$). **B:** Subendothelial deposits (*asterisks*) and mesangial interposition (*arrows*) are seen in an electron micrograph of type I disease ($\times 7,000$). **C:** Electron micrograph of an intramembranous dense deposit (*arrow*) is diagnostic of type II disease ($\times 9,800$).

Both the idiopathic and many secondary forms of MPGN type I have many features of immune complex–mediated diseases, including hypocomplementemia, circulating autoantibodies, and cryoglobulinemia. However, a similar morphology is seen in other diseases, such as chronic thrombotic microangiopathy, antiphospholipid antibody syndrome, and light chain deposition disease, in which endothelial injury or deposition of abnormal immunoglobulins is an etiologic factor rather than immune complex formation.

Optimal Management

Secondary causes of MPGN type I should be diligently sought and treated if possible. Idiopathic MPGN type I and MPGN type II in children and young adults is treated with a prolonged course of alternate-day prednisone if there is nephrotic syndrome or renal insufficiency. This sometimes causes severe hypertension, which should be treated to normalize the blood pressure. There is less information on the efficacy of such treatment of MPGN in adults. Diuretics are often required for control of edema, and an ACE inhibitor may help to diminish proteinuria. Initial promise with dipyridamole was not borne out in follow-up studies, and the role of newer platelet inhibitors, immunosuppressive agents, or anticoagulants in the treatment of MPGN is unclear. The MPGN types I and II frequently recur in renal allografts and may lead to graft failure.

HEPATITIS C-ASSOCIATED MPGN AND MIXED CRYOGLOBULINEMIA

Hepatitis C virus (HCV) infection has emerged as a common cause of adult MPGN type I and may be associated with mixed cryoglobulinemia. In the absence of cryoglobulinemia, HCV-associated MPGN presents as a renal-limited disease. Those with mixed cryoglobulinemia have a syndrome that includes weakness, cutaneous vasculitis causing purpura and leg ulcers, large joint arthralgias, and neuropathy. However, not all patients with HCV-related cryoglobulinemia actually develop renal disease. The clinical and laboratory features of MPGN secondary to HCV infection are very similar to those of idiopathic MPGN type I (see above), with the important additional findings of rheumatoid factor and/or mixed cryoglobulins (usually monoclonal IgMk anti-IgG and polyclonal IgG). Clinical evidence of liver disease may or may not be present. Renal pathology is likewise very similar except that in cryoglobulinemic MPGN electron microscopy may reveal fibrillary “thumb-print” structures indicative of cryoglobulin deposition. The diagnosis of HCV infection is established by the finding of anti-HCV IgG or HCV RNA in the serum or cryoprecipitates. If the renal failure is rapidly progressive or if the extrarenal disease is severe treatment with corticosteroids, cyclophosphamide and interferon- α is generally employed. In milder and more chronic disease, monotherapy with interferon- α is usually used. Adjunctive therapy with ribavirin is under investigation. Less

commonly, cryoglobulinemic MPGN may be associated with lymphoma, myeloma, infective endocarditis, systemic autoimmune diseases, or hepatitis B infection.

SYSTEMIC LUPUS ERYTHEMATOSUS NEPHRITIS

Glomerulonephritis is one of the two most serious complications of SLE, the other being cerebritis (see [Chapter 178](#)). Approximately 40% to 80% of unselected patients with SLE have renal involvement as assessed by urinalysis or impairment of renal function, but often the disease is mild. Clinical assessment likely underestimates the actual frequency as histologic evidence of renal disease may be present even when urinalysis is essentially normal. The spectrum of lupus nephritis is wide, encompassing the acute nephritic syndrome, nephrotic syndrome, acute or chronic renal failure, and isolated abnormalities of the urinary sediment. However, proteinuria is the most constant feature, being present in almost every patient with clinical lupus nephritis. Although microscopic hematuria is common, it rarely occurs in isolation. The type of renal involvement may vary over time in an individual patient.

Histopathology and Clinical–Pathologic Correlation

Renal biopsy is an important component of the renal assessment of patients with SLE and is indicated in all cases involving abnormalities of the urine sediment or impaired renal function. There are two main reasons for this. First, it is not possible in an individual patient to predict the renal histology with any accuracy from the clinical presentation, although, in general, more severe histology tends to correlate with more severe clinical disease. Second, in untreated patients the renal histology, as classified by the World Health Organization (WHO), is a powerful predictor of eventual outcome.

Immune complexes are nearly always seen in diseased glomeruli. Although the basis for loss of self-tolerance and the precise composition and mechanism of glomerular immune deposit formation are still under intense investigation, it is likely that these complexes initiate the inflammatory pathways that lead to glomerular injury. It is important to emphasize that tubulointerstitial nephritis and involvement of the intrarenal vasculature (by immune complex deposition, vasculitis, or arteriolar thrombi) may coexist with the glomerular lesions and may be important contributors to renal failure.

The WHO classification recognizes six histologic classes. Although rarely performed, a class I biopsy is normal by light microscopy, sometimes associated with minimal mesangial deposits on immunofluorescence microscopy. Renal function and urinalysis are normal except for mild proteinuria in some cases. Class II (10% to 20% of cases) describes mesangial lupus nephritis in which immune complexes containing IgG, IgM, and C3 are seen only in the mesangium on immunofluorescence and electron microscopy. In Class IIA light microscopy is normal whereas in class IIB mesangial proliferation is seen. Moderate proteinuria is present with or without hematuria. Renal function is usually normal and the long-term prognosis is excellent unless there is transformation to a higher WHO class. Class III (30% to 40% of cases) describes a focal and segmental proliferative lesion on light microscopy, often with areas of necrosis ([Fig. 150.9A](#)). On immunofluorescence and electron microscopy there are diffuse mesangial and focal subendothelial immune deposits ([Fig. 150.9B](#)). IgG is usually predominant, but IgA and IgM can also be seen and C3, C4, and C1q are usually present. Focal tubulointerstitial nephritis may be present. Proteinuria is common and nephrotic syndrome occurs in about 30% of patients. Class IV (40% to 60% of cases) is diffuse proliferative lupus nephritis, the most aggressive lupus renal lesion. The nephrotic syndrome and impaired renal function are common. The histologic findings are similar to those of class III, except that nearly all of the glomeruli are involved and the lesions themselves are more severe ([Fig. 150.10A](#) and [Fig. 150.10B](#)). Crescents may also be present, but inflammation and necrosis of the glomerular tuft is predominant. Tubulointerstitial nephritis is present in up to 75% of cases. Class V represents membranous lupus nephropathy (10% to 15% of cases), so named because of its close similarity both clinically and histologically to idiopathic membranous nephropathy. Glomerular pathology is identical to idiopathic membranous nephropathy, except that the presence of abundant mesangial immune deposits and multiple immunoglobulin isotypes (IgG, IgA, and IgM) on immunohistology favors a diagnosis of lupus nephritis. Tubuloreticular structures in the glomerular endothelial cells may be seen in all classes of lupus nephritis and, if present, strongly suggest the diagnosis of lupus nephritis. The other disease in which such structures are frequently seen is HIV-associated nephropathy. The usual presentation and course of lupus membranous nephropathy is similar to idiopathic membranous nephropathy (see above). Class VI describes a biopsy with diffuse glomerulosclerosis and tubulointerstitial disease. In addition to the above classification, each biopsy is usually assigned a semiquantitative score of activity and chronicity (scarring) based on certain defined histologic criteria. Some studies, but not all, have shown that these scores have predictive value in terms of renal outcome. It is not unusual for transformation to occur over time from one class to another either spontaneously or following treatment. Thus, a renal biopsy performed during an initial evaluation might not reflect the actual histologic lesion at a later time, and repeat biopsies may be required to guide therapy if the clinical presentation changes.

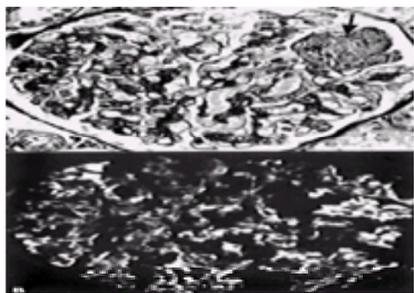

FIGURE 150.9. Focal proliferative glomerulonephritis in systemic lupus erythematosus. **A:** Segmental proliferation (*arrow*) is associated with mild mesangial expansion in a patient with class III glomerulonephritis (periodic acid–Schiff, $\times 400$). **B:** Staining with antihuman IgG shows mesangial and peripheral capillary basement membrane deposits ($\times 400$).

FIGURE 150.10. Diffuse proliferative glomerulonephritis in systemic lupus erythematosus. **A:** Extensive cellular proliferation and thickened glomerular basement membranes are present (*arrows*) giving a “wire loop” appearance (periodic acid–Schiff, $\times 400$). **B:** The electron micrograph reveals large subendothelial (*asterisk*) and intramembranous (*short arrows*) deposits with mesangial interposition (*long arrow*, $\times 5,200$). A fingerprint pattern within the deposits (*inset*) is seen in some patients with lupus glomerulonephritis ($\times 32,500$).

Diagnosis

The diagnosis of SLE as defined by criteria of the American Rheumatism Association is discussed in detail in [Chapter 178](#). The large majority of patients with renal lupus will have SLE by these criteria at the time of diagnosis. An exception to this is membranous lupus nephropathy, which may predate by months the development of extrarenal and serologic features of lupus. Thus, one should exercise a high index of suspicion that a young woman with nephrotic syndrome and apparently idiopathic membranous nephropathy might have lupus nephritis. Separate and apart from the actual diagnosis of SLE is the question of whether there are laboratory tests (other than renal biopsy) that are helpful in determining renal lupus disease activity and predicting renal flares. Although no test is completely sensitive or specific in this regard, high titers of antibodies against double-stranded DNA appear to correlate best with active lupus nephritis. The development of

hypocomplementemia with low levels of C3 and C4 might also indicate activity, but some patients have intermittently or chronically low levels without overt clinical activity.

Optimal Management

The optimal treatment of lupus nephritis remains controversial, in large part because controlled clinical trials have not been done comparing many of the treatment options. It is useful to consider treatment in two phases: acute and chronic. In the acute phase, the emphasis is on rapid reduction of disease activity. In the chronic phase, the emphasis is on maintaining suppression of low-grade disease activity and avoiding disease relapses while minimizing the potentially serious side effects associated with the long-term use of different immunosuppressive medications. Because the renal histology is the most powerful predictor of eventual outcome, treatment decisions are based largely on the renal biopsy result. Class II (mesangial) lupus nephritis is often treated with a course of corticosteroid monotherapy in the belief that prognosis might be improved, although no trial has been done to directly compare corticosteroid treatment with no treatment in this group. The optimal treatment of membranous lupus nephritis (class V) is not well defined in large part because of the unpredictable natural history of the disease. Nevertheless, oral corticosteroid therapy, often together with an ACE inhibitor, is frequently used both for symptomatic control of the nephrotic syndrome and for a potential but unproved benefit in delaying the progression of some patients to end-stage renal failure. Cyclophosphamide and cyclosporin A may also be of use in certain individuals. Untreated class III and IV lupus nephritis progress commonly to end-stage renal failure, and it is in these groups that immunosuppressive treatment is clearly indicated. The acute phase is initially treated with high-dose prednisone, sometimes administered intravenously as "pulse" methylprednisolone. This is then tapered to the lowest possible dose consistent with control of renal and systemic disease activity. Most patients with class III or IV lupus nephritis also receive cytotoxic therapy, generally given as monthly doses of intravenous cyclophosphamide for 6 months and then one dose every 3 months for 12 to 18 months. The purpose is to prevent lupus flares and preserve renal function in the long term. Such therapy requires intensive monitoring of the leukocyte count and dose adjustment to avoid excessive leukopenia. Azathioprine is sometimes substituted for cyclophosphamide if the latter is contraindicated or if the patient is unwilling to accept the risks associated with cyclophosphamide therapy, the most important of which are infertility, hemorrhagic cystitis, late neoplasia, and infection. There is no good evidence to support the use of other immunosuppressive agents or plasma exchange in class III and IV lupus nephritis. An important point to keep in mind is that the long-term survival of patients who develop end-stage renal failure secondary to lupus and who are treated with dialysis or transplantation is quite good and does not differ from the long-term survival of patients with lupus nephritis who do not develop end-stage lupus nephritis. Therefore, continued intensification of immunosuppression to improve renal function is not acceptable if it is accompanied by serious actual or potential treatment related side effects, or if there is evidence of advanced chronic renal disease. There is no single test to assess response to therapy; however, anti-double-stranded DNA levels, complement levels, urine sediment, proteinuria, and creatinine clearance are all of use. Despite optimal current therapy, approximately 10% to 20% of patients with proliferative lupus nephritis (class III or IV) will progress to end-stage renal failure. For reasons that are not clear the systemic activity of SLE decreases as patients develop end-stage renal failure, and both the systemic features of SLE and lupus nephritis are uncommon in patients after renal transplantation. Some patients with SLE have circulating antiphospholipid antibodies that can cause thrombotic microangiopathy and can further aggravate lupus nephritis or cause renal damage independently. This condition does not respond to immunosuppression and is best treated by long-term anticoagulation.

nephritogenic antigens and provide a basis for understanding their typically self-limiting nature. The failure to downregulate underlies many forms of experimental interstitial nephritis, which are progressive instead of self-limited. This failure of immune regulation in some instances also determines susceptibility to tubulointerstitial disease.

The effector phase, the final portion of the nephritogenic immune response, encompasses the processes that lead directly to renal injury. These processes are mediated by antibody, immune deposits, complement, and various cell-mediated subpopulations. The presence of a cellular infiltrate is required in the pathologic definition of interstitial nephritis, and mononuclear cells, particularly T lymphocytes, are thought to play a preeminent role in the immunopathogenesis of interstitial damage. The particular combination of cytokines and cytotoxic mediator proteins expressed by infiltrating T cells is important in determining the severity and phenotypic pattern of the resultant interstitial injury.

Although immune deposit-mediated interstitial nephritis was historically thought to be an important feature of parenchymal renal injury, it has been difficult to document this claim consistently by immunofluorescent analysis. Primary interstitial nephritis following the formation of tubulointerstitial immune deposits is unusual. Circulating immune complexes probably do not precipitate to cause immune deposit disease in primary interstitial nephritis because they would probably have precipitated first in glomeruli. Interstitial immune deposits are most consistently seen in “spillover” reactions stemming from immune deposit-mediated glomerulonephritis associated with progressive interstitial injury. Anti-TBM disease producing antibodies and cell-mediated infiltrates is one example of antibody- and cell-mediated processes that are codominantly expressed to produce injury. Complement components have been routinely observed along the TBM in anti-TBM disease. Anti-TBM antibodies can also act as an informational bridge between antigen and the cellular immune response through antibody-dependent, cell-mediated cytotoxicity reactions. Macrophage chemotactic factors are released by the deposition of anti-TBM antibodies. T cells and macrophages are subsequently found in these interstitial lesions. These cells probably damage tubular architecture via degradation of the basement membrane matrix by proteolysis or oxygen radical formation. Cytokines from tubular antigen-reactive T cells can also stimulate fibroblast proliferation and collagen synthesis. Therefore, progressive fibrogenesis may be directly linked to cell-mediated immunity in the overall pathogenesis of interstitial disease.

Most forms of interstitial nephritis, however, involve only the cell-mediated immune response, and T cells in particular probably play a major role. These T cells may alter the tubulointerstitial architecture by release of cytokines or through direct cytotoxic mechanisms of injury. In certain allergic drug reactions, eosinophils may predominate. Eosinophils can be chemotactically attracted to the kidney by T-cell cytokines or by soluble mediators released by mast cells.

CLINICAL FINDINGS

The presentation of AIN is typically that of a sudden decrease in renal function in an otherwise asymptomatic patient who has experienced an intervening illness or has been taking a new medication. Acute interstitial nephritis secondary to medications can occur in patients who have previously tolerated those medications. The clinical distinction among acute tubular necrosis, subtle glomerulonephritis, or AIN may be impossible without a renal biopsy. Several clinical features may help distinguish AIN from these other diagnoses. Factors in the patient's history, such as systemic infection or drug reaction, might suggest interstitial nephritis. The patient with drug-induced AIN commonly has systemic manifestations of an allergic process, including a maculopapular skin rash, fever, or eosinophilia. A prior allergic history is rarely obtained. Skin rash is present in less than 50% of patients, fever occurs in about 75%, and eosinophilia is found in 50% to 75%. The entire triad is present in less than 33% of drug-induced cases, and is distinctly uncommon in patients with AIN secondary to NSAID use. The onset of disease ranges from days (antibiotics) to months (NSAIDs) after initiation of therapy, and in most cases it appears to parallel the kinetics of a primary immune response. In patients previously sensitized to the offending drug, an anamnestic response may occur within several days. The reactivity usually peaks at about 2 weeks. Renal failure generally evolves over several days to several weeks. Bilateral or occasionally unilateral lumbar pain can occur and is probably due to distention of the renal capsule from swelling of the kidney.

LABORATORY FINDINGS

Urinalysis reveals nonnephrotic-range proteinuria, commonly with microscopic hematuria. Gross hematuria has been reported, although the sediment in about 75% of patients shows only moderate amounts of red and white blood cells. White cell casts can be observed (in the absence of infection), but red cell casts are so uncommon that their presence should suggest an alternative diagnosis of glomerulonephritis. The finding of eosinophils in the urine supports the diagnosis of allergic interstitial nephritis but is neither sensitive nor specific for this diagnosis. The absence of eosinophiluria should never preclude the diagnosis of AIN. The magnitude of proteinuria in AIN varies. Nephrotic-range proteinuria occasionally is seen when interstitial lesions are associated with minimal change lesions in the setting of NSAID use. Patients with AIN may be oliguric or nonoliguric and typically have a fractional excretion of sodium greater than 1%.

Although various specific renal tubular disorders, electrolyte abnormalities, and acid-base disturbances tend to occur in chronic interstitial nephritis, the metabolic complications of AIN are, in essence, the general complications associated with acute renal failure. Radiographic imaging procedures such as ultrasound can be performed if clinically indicated to rule out other causes of acute renal failure. There are no noninvasive imaging procedures that strongly indicate the presence of AIN. Gallium scanning, for example, has very limited predictive value.

Because many features of the history, presentation, urinalysis, and laboratory evaluation may lead to indefinite conclusions, a renal biopsy may be indicated in patients with acute renal failure presenting with signs or symptoms suggestive of an interstitial process, or in patients who lack a typical clinical picture for acute tubular necrosis and in whom obstructive nephropathy and prerenal azotemia have been ruled out. The decision to perform a renal biopsy must take into account whether the biopsy interpretation will influence clinical management (see below). Renal biopsy by experienced operators is generally safe, can provide valuable prognostic information, and can serve as a guide to therapy in defined clinical settings.

The most obvious histologic feature of AIN is the absence of glomerular injury and the presence of inflammatory cells in the cortical interstitium. These inflammatory cells are usually a mixture of T lymphocytes, macrophages, and an occasional plasma cell. Eosinophils, neutrophils, basophils, and natural killer cells may be present, and rarely eosinophils predominate. When infection is responsible for AIN, neutrophils are typically present in large numbers. Cellular infiltrates in AIN are profuse throughout the cortical interstitium in association with interstitial edema, disruption of the TBMs, and, in severe cases, the dissolution of normal interstitial architecture. Immune deposits in the interstitium are unusual in primary interstitial nephritis, although some forms of drug-associated AIN are associated with deposition of antibodies to the TBM. Immunofluorescent analysis is not used in the classification of interstitial disease as it is with forms of glomerulonephritis, as the presence of these reactants is uncommon and their pattern of deposition, when present, is not informative with regard to cause, clinical course, or therapy. Pathologic evaluation of the interstitium may reveal an active interstitial nephritis superimposed on preexisting renal injury. In such instances, it can be difficult to determine which is the primary process.

OPTIMAL MANAGEMENT

Most cases of AIN due to drugs or infection resolve after prompt discontinuation of the offending agent or treatment of the infection. The likelihood of full functional recovery, however, depends on the duration of renal failure. Serum creatinine levels at resolution average about 1.0 mg per dL in patients with acute renal failure of less than 2 weeks duration and 3.0 mg per dL in those diagnosed and treated after 3 weeks of acute renal failure. Prolonged, unrecognized interstitial injury usually leads to irreversible chronic interstitial fibrosis. The presence of scattered, patchy infiltrates in AIN is associated with a return of normal renal function, whereas diffuse involvement portends persistent functional impairment. Unless the offending agent can be identified and removed, progression to end-stage disease is likely.

The primary therapeutic principle in the treatment of AIN is to remove or treat any inciting factor. A limited course of high-dose prednisone is generally prudent for biopsy-proven AIN in which renal failure has persisted for more than a week after removal of any inciting factors. A general time frame exists for the use of steroids in AIN, usually after 1 week of rising serum creatinine levels but before several weeks of persistent renal failure. Steroids should be discontinued if no meaningful response is achieved after 3 to 4 weeks of therapy. Cytotoxic drugs may have a role in some treatment regimens, such as in patients with progressive renal failure who are not responding to corticosteroids. Plasmapheresis may be an effective adjuvant therapy in patients with anti-TBM antibodies. There is no reported clinical experience with drug desensitization regimens.

CHRONIC INTERSTITIAL NEPHRITIS

DEFINITION

Chronic interstitial nephritis (CIN) is pathologically defined as an abnormal process involving the interstitial compartment of the kidney characterized by increased interstitial fibrosis, abnormal tubulointerstitial architecture, and, at times, an infiltrate of chronic inflammatory cells. The glomeruli can additionally become sclerotic

most often associated with renal involvement caused by multiple myeloma and light-chain nephropathy. Other, less common etiologic factors include anti-TBM disease, heavy-metal nephropathy, paroxysmal nocturnal hemoglobinuria, and immune complex glomerulonephritis.

The distal tubule is responsible for urinary acidification, aldosterone responsiveness, and fine homeostatic adjustments in sodium and potassium balance. When dysfunction occurs at this level of the nephron, various clinical problems can appear. These include distal renal tubular acidosis, an aldosterone-resistant state with hyperkalemia and hyperchloremic metabolic acidosis, and apparent salt wasting. Any of these can be seen in obstructive nephropathy, either during or after relief of obstruction. Aldosterone resistance has also been reported in amyloidosis and sickle cell disease. Relative salt wasting is typically seen during postobstructive diuresis and medullary cystic disease. Isolated defects in concentrating ability, indicating disruption of the medullary gradient or dysfunction of the collecting tubule, have also been associated with certain tubulointerstitial nephropathies. These include analgesic abuse, sickle-cell disease, and cystic disease of the kidney.

The hyperchloremic metabolic acidosis associated with CIN is probably related to the progressive loss of interstitial mass and the associated impairment of renal ammonia production. If the GFR is not too low, the first morning urine in patients with a defect in ammonia production has a pH level below 6.0. Although there is poor ammonium excretion with a 24-hour acid load, these patients have normal fractional excretion of bicarbonate, excluding a proximal tubular defect. Eventually, progressive nephron loss results in an anion gap acidosis, and the hyperchloremia disappears. Hyperkalemia is typically present in these patients as well. The hyperkalemia is often out of proportion to the degree of renal failure and is probably related to a generalized impairment of distal tubular function.

In addition to regulating the transport properties of the renal tubules, the interstitium also plays a role in hormone metabolism. With progressive interstitial fibrosis, erythropoietin and renin secretion, as well as 1-hydroxylation of 25-hydroxyvitamin D, are impaired. There is a general impression that the anemia associated with CIN is more marked than that seen with primary progressive glomerular disease. Osteodystrophy may also be more severe in patients with chronic interstitial nephropathy.

OPTIMAL MANAGEMENT

By definition, CIN is an indolent, very slowly progressing form of interstitial nephritis that can evolve to end-stage renal disease after many years of follow-up. The treatment of the underlying disease or the elimination of inciting factors can contribute to the attenuation of progressive disease. Generally, there are no anti-inflammatory drugs or immunosuppressive agents that are appropriate to administer in this setting. Chronic fibrogenesis is probably irreversible, and the risk/benefit ratio of aggressive chemotherapy does not warrant its use. Good control of blood pressure may alter the rate of progression in hypertensive patients with CIN.

CHAPTER 152: VASCULAR DISEASES OF THE KIDNEY

WILLIAM L. HENRICH

[Embolization of the Renal Arteries](#)
[Renal Vein Thrombosis](#)
[Hemolytic-Uremic Syndrome](#)
[Scleroderma](#)
[Arterial Nephrosclerosis](#)
[Sickle Cell Nephropathy](#)

EMBOLIZATION OF THE RENAL ARTERIES

The term *renal artery obstruction* refers to a heterogeneous group of diseases that cause obstruction to the main renal artery or its branches by embolic or atherothrombotic phenomena. Embolic diseases of the renal artery can cause silent and insidious loss of renal function or fulminant acute renal failure with oligoanuria, fever, flank pain, and hematuria.

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES

Emboli to the main renal artery or its branches most often occur in the setting of cardiac disease (myocardial infarction, valvular heart disease, or atrial fibrillation). The presence of a dilated left ventricle or a left ventricular aneurysm predisposes the patient to the formation of a mural thrombus, which may embolize. Rheumatic valvular disease also is associated with peripheral embolization, as is atrial fibrillation. Septic embolization from bacterial endocarditis used to be the most common cause of renal artery embolism. Chest, abdominal, flank, and back pain are present in most patients with emboli of cardiac origin, and nausea, vomiting, and fever occur in half the patients. Laboratory abnormalities may include leukocytosis, hematuria, proteinuria, azotemia, and increased levels of lactic acid dehydrogenase, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase.

Atheroembolism of the kidneys involves the embolization of small cholesterol crystals or microemboli from the surface of existing ulcerated plaques, or the detachment of atheromatous plaques from the intimal surface of the aorta. These emboli travel peripherally and cause occlusion of the microcirculation; the arcuate, interlobular, and terminal renal arteries, and even the glomeruli, may be affected. These cholesterol atheroemboli are seen in patients with extensive aortic atherosclerosis and may occur spontaneously or, more commonly, after aortic, carotid, or coronary angiography, especially if the femoral route for arterial puncture has been used. This disease also may be seen after aortic reconstructive surgery. The antemortem diagnosis is difficult to make, and autopsy studies suggest that the disease is more common than previously thought. Recent studies have suggested that some patients with extensive aortic and renal atherosclerosis have small showers of atheroemboli intermittently. This may contribute to a gradual loss of renal function in such patients.

The disease may present as an acute or catastrophic form with abdominal and back pain, acute hypertension, agitation, diarrhea (often bloody), foot and leg pain, extremity numbness or paralysis, skin discoloration (livedo reticularis, or "purple toes"), acute renal failure, and even hypotension and death. The chronic or noncatastrophic form also is called the *multiple cholesterol emboli syndrome* (MCES). This syndrome occurs most commonly after aortic surgery and is marked by slowly progressive renal failure. There may be episodic or malignant hypertension, acute pancreatitis, myopathy, peritonitis and ischemic colitis, livedo reticularis, and gangrene of the toes and feet (in as many as 30% of patients). Laboratory abnormalities may include leukocytosis, particularly eosinophilia (reported in as many as 70% of patients), an elevated erythrocyte sedimentation rate, decreased platelets (disseminated intravascular coagulation may be seen), and azotemia.

Multiple cholesterol emboli syndrome may be confused with polyarteritis nodosa, allergic vasculitis, subacute bacterial endocarditis, and left atrial myxoma. The cause of the eosinophilic response to MCES is not fully understood, but may be analogous to a foreign bodylike reaction in tissue. Atheroembolic disease should be suspected when the typical findings are seen after aortic surgery or angiography, especially if the patient has known atherosclerotic disease or widespread arterial bruits. Tissue demonstration of cholesterol crystals confirms the diagnosis, but these cannot always be obtained. The diagnosis may be suggested strongly by the finding of cholesterol crystals in the retinal arteries (Hollenhorst plaques).

Definitive diagnosis of renal embolic disease is made by renal angiography, but the less invasive dynamic ^{99m}Tc pertechnetate renal flow scan occasionally may prove diagnostic by demonstrating decreased flow to all or part of the kidney. Computed tomography of the kidneys with contrast medium enhancement may show focal or generalized decreased attenuation of the renal tomogram, or even a rim of cortical enhancement around the area of embolization. Magnetic resonance imaging with the use of paramagnetic contrast agents may be useful in defining the extent of tissue ischemia and disruption of blood flow. The degree of renal damage depends on the size of the embolus, the presence of collateral circulation, and the interval between diagnosis and therapy.

TREATMENT AND COURSE

The most efficacious treatment of embolization of the large renal arteries has not been established. No clear difference exists between medical therapy with anticoagulants and surgical embolectomy, with the exception that surgical mortality rates range from 11% to 25%. Fibrinolytic agents have been used successfully, as has percutaneous transluminal angioplasty in a few cases. Although the algorithm requires confirmation, one group has suggested that unilateral embolization with a functioning contralateral kidney is approached best by fibrinolytic therapy and the use of transluminal angioplasty, followed by anticoagulation. For patients with embolization to a single functioning kidney or those with bilateral embolization, initial therapy with fibrinolytic therapy and transluminal angioplasty is recommended; if there is no response, surgical embolectomy should be considered. Further study of this approach is needed.

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) is defined as thrombosis of the main renal vein or one of its tributaries.

ETIOLOGY, PATHOGENESIS, AND FREQUENCY

Renal vein thrombosis occurs most commonly as a complication of the nephrotic syndrome and usually is associated with membranous nephropathy, although it also may be seen with membranoproliferative glomerulonephritis, amyloidosis, renal allograft rejection, and minimal change disease. Cases also have been reported from the surgical literature in patients with no evidence of renal disease. The syndrome may be present as an acute or chronic problem; the chronic presentation predominates. The exact incidence cannot be established with certainty and ranges from 2% to 33% of cases of nephrotic syndrome. The duration of the nephrotic syndrome, amount of albuminuria, use of corticosteroid and diuretic therapy, and type of venography used to diagnose RVT all contribute to this wide range in incidence.

CLINICAL FEATURES

The nephrotic syndrome is associated with alterations in the coagulation system. These alterations lead to an increased incidence of thromboembolism, ranging from RVT to pulmonary thrombosis, deep venous thrombosis of the lower extremity, peripheral thrombophlebitis, and arterial occlusion. Elevated levels of factors V, VII, VIII, IX, and X and of fibrinogen may contribute to the hypercoagulable state seen in the nephrotic syndrome. In addition, thrombocytosis and enhanced platelet aggregation may be seen. Thromboplastin levels may be increased and antithrombin III levels may be low in some patients. Volume depletion caused by diuretics and an increase in the hypercoagulable state caused by corticosteroid therapy also may predispose to the development of RVT. In addition, RVT may occur after blunt abdominal trauma, dehydration in infants, and the use of oral contraceptive agents.

Renal vein thrombosis is most often a silent syndrome. Chronic RVT usually is not associated with loss of renal function and in the absence of pulmonary involvement gives little clue to its presence. Preservation of renal function depends on the degree of collateral blood flow to the kidney and the amount of recanalization of the renal vein. The presence of RVT should be suspected when pulmonary embolism, unexplained loss of renal function, or a large increase in proteinuria occurs.

DIAGNOSIS

Renal venography should be performed when there is a strong clinical suspicion of the diagnosis based on the foregoing findings. Renal venography remains the best test available to make the diagnosis. It is difficult to interpret, however, because of the large volume of blood that perfuses the kidney, making adequate renal vein contrast imaging difficult. Renal ultrasonic scanning and Doppler ultrasonography may prove to be useful and reliable diagnostic tests but require further study. Computed tomography with contrast media also is a promising diagnostic tool, but prospective studies are needed to evaluate its sensitivity and specificity.

TREATMENT AND COURSE

Anticoagulant therapy with heparin for 5 to 7 days followed by therapy with sodium warfarin is indicated in patients with RVT, particularly if pulmonary embolism has occurred. Long-term therapy is advocated by many for as long as the nephrotic syndrome is present because recurrent RVT and pulmonary emboli are seen shortly after discontinuation of anticoagulant therapy. Renal function in the setting of acute RVT typically improves with treatment, although this may require 6 months. There is no indication for surgical thrombectomy. The role of fibrinolytic therapy is intriguing but relatively unstudied. Similarly, the use of antiplatelet therapy in nephrotic patients with RVT probably is safe but its efficacy has not been tested rigorously.

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome (HUS) is a disease that is closely related to thrombotic thrombocytopenic purpura. It is characterized by renal failure, thrombocytopenia, and a microangiopathic hemolytic anemia. The kidney is the target organ of vascular endothelial damage in HUS; in thrombotic thrombocytopenic purpura, however, there is widespread vascular endothelial damage with extensive brain involvement. Hemolytic-uremic syndrome was first described in children but it also occurs in adults. The overall prognosis of HUS is better in children than in adults, and is better than that of thrombotic thrombocytopenic purpura.

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES

Childhood Hemolytic-Uremic Syndrome

The usual presentation of HUS in childhood typically follows an episode of acute nonfebrile gastroenteritis. Clinically, the disorder presents abruptly with bleeding (melena, hematemesis, or hematuria) and oliguria, with anuria seen in 30% of patients. This is the most common cause of acute renal failure in children, and is more common in whites than blacks. Petechiae, scleral icterus, hyperbilirubinemia, hepatosplenomegaly, congestive heart failure, and hypertension also are common. The peripheral blood smear shows evidence of a microangiopathic hemolytic anemia. Hemolytic-uremic syndrome usually occurs in summer and fall, and may occur as single cases or as small clusters of cases. Although the exact pathogenesis of HUS is unknown, it is strongly believed that vascular endothelial cell damage is the primary pathologic event. However, thrombocytopenia, enhanced platelet aggregation, and the presence of an abnormal factor VIII level also contribute. A strong association has been established between HUS and verocytotoxin-producing *Escherichia coli* (VTEC). Verocytotoxins are potent protein exotoxins that can produce an irreversible cytopathic effect in certain cells, particularly endothelial cells. Hemolytic-uremic syndrome developed in 7% of a pediatric population with VTEC infection and in 24% of an elderly nursing home population with VTEC infection, most of whom died. The reservoir for VTEC is primarily animal intestinal tracts, and foods of animal origin probably are responsible for human infection. The toxin appears to bind to specific glycoprotein receptors on renovascular endothelial cells and then inactivates ribosomes, killing them.

Adult Hemolytic-Uremic Syndrome

Adult HUS has a more varied presentation and the diagnosis may not be obvious initially. The renal function may decline subacutely, there may be minimal evidence of hemolysis, and thrombocytopenia may be minimal. There also may be an acute presentation with a severe hemolytic anemia, profound thrombocytopenia, and rapid loss of renal function. Hemolytic-uremic syndrome may be seen after infection with VTEC or other bacterial agents, such as *Shigella*, *Salmonella typhi*, *Campylobacter*, *Yersinia*, *Streptococcus pneumoniae*, or *Legionella*, and after rickettsial, viral, or fungal infection. A strong association exists between HUS and the use of mitomycin C as anticancer therapy. Thirty-five percent of patients with HUS occurring after the use of mitomycin C are cancer-free at the time of diagnosis, and the development of HUS often coincides closely with the transfusion of blood products. Noncardiogenic pulmonary edema occurs in 65% of these patients. Hemolytic-uremic syndrome also is seen in patients using oral contraceptives and in women in the postpartum period. The presentation usually is acute, and the patient's condition deteriorates rapidly. Hemolytic-uremic syndrome has also followed cisplatin therapy and the disorder is recognized to occur during therapy with cyclosporin as an antirejection medicine. In this regard, recent reports point out that HUS has developed following liver, kidney, and heart transplantation. A hereditary form of HUS may appear in children and adults, occasionally causing recurrent episodes of disease in children, and typically follows an autosomal recessive inheritance pattern. An immunologic form of HUS also occurs that is associated with a low C3 complement concentration. Finally, HUS also has been seen in patients with scleroderma, systemic lupus erythematosus, and malignant hypertension, and in those who have received renal irradiation or immunosuppressive therapy with cyclosporin A.

LABORATORY AND PATHOLOGIC FINDINGS

Azotemia is present and the microangiopathic anemia usually is severe. There are obvious signs of hemolysis with anemia, fragmented helmet and burr cells, reticulocytosis, elevated lactic acid dehydrogenase and bilirubin levels, and a low haptoglobin value. Renal damage always is present and acute renal failure occurs in more than 90% of patients. Thrombocytopenia is a constant finding. The term *thrombotic microangiopathy* is used to describe the renal pathologic process, especially in children. There is widespread renal capillary wall thickening and capillary thrombi. In adults and older children, arteriolar necrosis and interlobular arterial thrombosis are seen. Pure glomerular disease, arterial disease, or a combination of the two may be seen.

TREATMENT AND COURSE

The most important part of the therapy for HUS is supportive, with vigorous control of blood pressure, fluid and electrolytes, hemorrhage, and azotemia, using dialysis as needed. There are no large prospective trials of therapy for HUS. Exchange transfusion, plasmapheresis, and corticosteroids have been associated with remission of the disease, with normalization of the hematologic abnormalities often occurring. Vitamin E therapy has been successful in children. The use of anticoagulant therapy with heparin has been proposed for the postpartum form of HUS but may worsen the hemorrhagic complications of the disease. Aggressive therapy with heparin, antiplatelet drugs, converting enzyme inhibitors, and plasmapheresis seems most justified in postpartum renal failure and HUS occurring after the use of oral contraceptives.

SCLERODERMA

Scleroderma is a collagen vascular disease in which the predominant pathologic event is progressive sclerosis of connective tissue and the vascular system (see [Chapter 179](#)). Patients with renal scleroderma usually have either an insidious or a rapidly progressive course. The insidious course is characterized by mild azotemia, hypertension, or nonnephrotic-range proteinuria. The rapidly progressive course is marked by severe hypertension and steady renal deterioration over weeks to months, finally progressing to end-stage renal disease. The hypertension may be accompanied by retinopathy, neurologic abnormalities (e.g., seizures, coma), or heart failure. These patients probably represent less than 10% of all patients with scleroderma. Rare reports have surfaced of a rapid decline in renal function without an elevation of blood pressure. In addition, a recent study has pointed out that black women appear more vulnerable to developing systemic complications than white women. The less severe or progressive form of renal involvement is seen in 15% to 37% of patients. The renin-angiotensin system appears to play a key role in the pathogenesis of renal failure and hypertension in renal scleroderma. The kidney seems particularly vulnerable to the vasoconstrictive effects of angiotensin, which the vascular lesion is likely to stimulate. Once this cycle of angiotensin stimulation begins, more renal ischemia (and a decline in renal function) and more hypertension are likely to ensue.

In view of the accelerated decline in renal function produced by the renin-angiotensin system, it is not surprising that successful treatment of sclerodermatous renal crisis has involved angiotensin-converting enzyme inhibition (see [Chapter 179](#)). Blood pressure control constitutes the primary therapy in this disorder. Corticosteroid therapy has not proven helpful. Dialysis is useful in prolonging survival in those who progress to chronic renal failure. These patients have major difficulties with vascular access and continued severe hypertension. Bilateral nephrectomy has been used to control poorly responsive hypertension. Patients may undergo successful renal transplantation, but hypertension may be difficult to control. Recurrence of the disease in the allograft has been reported, but this is not a

contraindication to transplantation.

ARTERIAL NEPHROSCLEROSIS

The term *arterial nephrosclerosis* refers to the progressive obliteration of the renovascular bed that occurs in systemic hypertension. As a cause of end-stage renal disease, hypertension and nephrosclerosis account for between 15% and 30% of new patients entering dialysis units. Hypertension accelerates the cessation of renal function in all primary renal diseases; hence, hypertension worsens the prognosis in primary and secondary nephropathies and in interstitial renal diseases. Hypertension occurs in up to 80% of patients with chronic renal insufficiency and may hasten the progression of renal disease in these patients. Nephrosclerosis is important both as a primary disease and as a disease that complicates other primary illnesses. Hypertension undoubtedly is the most important and treatable cause of renal insufficiency.

PATHOGENESIS

The kidneys of hypertensive patients usually are reduced in size and may weigh as little as 120 g. The cortex is thin and scars often are visible over the renal surface. Involved glomeruli may be completely hyalinized or wrinkled and shrunken in appearance. Larger blood vessels show fibroelastic thickening of the internal elastic lamina. A hyalinized thickening of the entire wall may occur in patches along the vessel. All this is accompanied by a fine fibrosis with or without chronic inflammatory cells. In malignant hypertension, the glomeruli show fibrinoid necrosis in the capillary tuft in continuity with a necrotic afferent arteriole. Epithelial crescents also may be present, depending on the duration of the disease. Fibrinoid necrosis of arterioles is the hallmark of malignant hypertension. In interlobular arteries, concentric thickening is seen. Recent studies suggest that hyalinization of renal arterioles may be a marker for development of atherosclerosis in other locations, particularly the coronary arteries.

TREATMENT AND COURSE

Antihypertensive therapy is beneficial in decreasing hypertension-related morbidity and mortality in patients with already existing end-organ damage or risk factors (black race, diabetes mellitus, hyperlipoproteinemia, cigarette smoking) and in patients with moderate to severe hypertension. The benefits of therapy in patients with mild hypertension and no risk factors are less clear. Although many physicians still use the stepped-care approach to therapy for hypertension, there is increasing emphasis on using drugs that have a favorable side effect profile (no alteration in lipid status, improvement in left ventricular compliance) and especially in monotherapy with calcium channel blockers, vasodilators, and angiotensin-converting enzyme inhibitors.

SICKLE CELL NEPHROPATHY

ETIOLOGY AND INCIDENCE

The term *sickle cell nephropathy* refers to changes in the kidneys of patients who are heterozygous or homozygous for the hemoglobin S gene. These changes may cause acute or chronic symptoms and signs. About 8% of African-Americans are heterozygotes and 0.2% are homozygotes. American whites and persons of Italian, Greek, or Middle Eastern descent may carry the hemoglobin S gene.

PATHOGENESIS AND CLINICAL FEATURES

Hemoglobin S polymerizes during deoxygenation, internal red blood cell viscosity increases, and an irregular sickle-shaped red blood cell shape occurs. Hypertonicity accentuates this process. These conditions of deoxygenation and hypertonicity exist in the renal medulla; hence, sickling of red blood cells is prominent in this location. Renal function related to an intact medulla, such as renal concentration and acidification, is impaired in this disorder. Even worse, scarring may result from ischemia to the region; therefore, interstitial fibrosis and papillary necrosis are features of the disease. Medullary changes also include local edema, tubular atrophy, and round cell infiltrates. Several clinical consequences of sickle cell disease are listed in [Table 152.1](#).

Medullar and Tubular Disorders

Polyuria: Decreased maximum urinary concentration ability.
Renal tubular acidosis type IV, incomplete; type IV and type I also described

Papillary necrosis: May be exacerbated by use of nonsteroidal anti-inflammatory drugs

Hematuria
Small infarcts

Cortical and Glomerular Disorders

Nephrotic syndrome: Due to glomerular sclerosis (? from hyperfiltration); membranous, membranoproliferative, and nil lesions also described (immune complex lesions)

Chronic renal failure: Unusual, progressive sclerosis

Acute renal failure: Clinical course similar to that of rhabdomyolysis; nonsteroidal anti-inflammatory drugs may provoke this

Hematuria: Possibly due to hyperfiltration

TABLE 152.1. RENAL INVOLVEMENT IN SICKLE CELL DISEASE

One interesting feature of the pathology of sickle cell nephropathy is the association of the disease with glomerular lesions. Proteinuria (including the nephrotic syndrome), hypertension, and hematuria are present in many patients, particularly children. One study observed that about 25% of patients with sickle cell disease have proteinuria. Glomerular enlargement and perihilar focal sclerosis were common lesions. Membranoproliferative glomerulonephritis with granular capillary deposits has been reported. Cryoprecipitable deposits of renal tubular epithelial antigen–antibody complexes have been detected in the circulation of some patients. An immune complex, normocomplementemic glomerulonephritis, may occur that is related to the deposition of renal tubular antigen–antibody complexes. The hypothesis that initial damage to the tubular structures of the medulla incites this reaction has been entertained. Other typical lesions described in patients with sickle cell nephropathy who have proteinuria or the nephrotic syndrome are focal sclerosis and mesangial proliferation.

Glomerular filtration and renal blood flow in patients with sickle cell nephropathy are highly dependent on the presence of vasodilator prostaglandins. As a result, these patients may be vulnerable to the effects of nonsteroidal anti-inflammatory agents, even when renal function is normal. Type I, type IV, and incomplete type IV renal tubular acidosis also have been described. Continued intramedullary sickling eventually leads to a loss of concentrating ability. This complication may be seen in school-aged children but is more prominent in older persons. As long as the glomerular filtration rate is preserved, renal sodium wasting is rare and free water clearance remains normal. The loss in concentrating ability is believed to be related to the washout of medullary solute secondary to damage of the vasa recta, decreased water permeability in the distal tubule, or both. Exogenous vasopressin administration has no effect on improving the concentrating ability.

Other clinical features of sickle cell nephropathy include hematuria in homozygotes (11%), in heterozygotes (62%), and in patients with hemoglobin SC disease (27%). Hematuria most commonly occurs from the left kidney and is not necessarily bilateral. The presence of asymptomatic bacteriuria is increased in pregnant women with sickle cell disease, but the incidence of pyelonephritis is not increased. Oligoanuric acute renal failure may occur during the course of a crisis; this may be secondary to pigment damage. Complete renal artery occlusion during a sickle cell crisis also has been reported. Asymptomatic papillary necrosis may occur in as many as 40% of patients with SS disease. Only 30% of patients with SS disease have a normal excretory urogram. Deterioration of renal function leading to dialysis does occur, and its incidence probably is underestimated. Finally, an association has been made between sickle cell trait and renal medullary carcinoma. The origin of this tumor is believed to be calyceal epithelium; the lesion is highly malignant and the prognosis is poor.

TREATMENT AND COURSE

Hematuria has been managed most effectively by L-aminocaproic acid. The nephrotic syndrome is unresponsive to corticosteroids and immunosuppressive agents, although corticosteroids may be useful if a biopsy lesion of minimal change disease is found. The use of angiotensin-converting enzyme inhibitors has been tested in patients with mild to moderate proteinuria. In these studies, a 57% decrease in protein excretion was observed after treatment with an angiotensin-converting enzyme

inhibitor. Nonsteroidal anti-inflammatory agents should be avoided. Bicarbonate therapy occasionally may be required for the treatment of a renal tubular acidosis. Dialysis can be performed safely in these patients, and extracorporeal hemodialysis and peritoneal dialysis with hypertonic dextrose solutions do not lead to increased sickle cell crises. Renal transplantation is successful in these patients, although the experience is limited.

CHAPTER 153: DIABETES AND THE KIDNEY

FRANK C. BROSIUS III AND CHARLES W. HEILIG

[Definition](#)
[Incidence And Epidemiology](#)
[Etiology And Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

Diabetic nephropathy is characterized by the development of proteinuria followed by a progressive decline in renal function in patients with either type 1 or type 2 diabetes, who usually have some degree of diabetic retinopathy. Although the natural history of diabetic nephropathy is that of an inexorable reduction in renal function until end-stage renal disease (ESRD) is reached, there is increasing evidence that such progression can be indefinitely forestalled in many patients by aggressive medical intervention.

INCIDENCE AND EPIDEMIOLOGY

Diabetic nephropathy occurs in only a minority of both type 1 and type 2 diabetic patients. Approximately 30% of patients with type 1 diabetes ultimately develop nephropathy. Although it was originally felt that nephropathy was less common in type 2 patients, more recent data suggest that the prevalence in type 2 patients is similar to that of type 1 patients. However, there is heterogeneity among type 2 patients with some ethnic groups being at much higher risk of developing nephropathy (see below). Diabetic kidney disease is by far the most common cause of ESRD in the United States, accounting for over 39% of all patients reaching ESRD in the 1990s. Of these, approximately two thirds have type 2 diabetes, given the higher prevalence of type 2 disease. Unfortunately, the prognosis for diabetic patients with end-stage renal disease on dialysis is significantly worse than for other ESRD patients.

ETIOLOGY AND PATHOGENESIS

The specific cause or causes of diabetic nephropathy remain unidentified. However, a number of factors are clearly important for the development of diabetic nephropathy. Many of these factors can be best understood in the context of the pathologic features of the disease. Early pathologic features that are predictive of progressive diabetic nephropathy can occur within the first few years of diabetes, well before there is any clinical manifestation of the process. A prominent finding early during the course of either type 1 or type 2 diabetes is enhanced renal growth. The glomeruli and other structures increase in size, and total renal size (often gauged by the longitudinal diameter) is frequently significantly greater than normal. The increase in renal size occurs in most patients with diabetes, whether or not they ultimately develop nephropathy.

Within 5 years after onset of diabetes, pathologic changes can be found that do correlate with progressive diabetic kidney disease. These changes are mostly, though not exclusively, confined to the glomerulus. The initial pathologic changes that best correlate with progressive disease are widening of the glomerular basement membrane and expansion of the extracellular portion of the mesangial space by extracellular matrix proteins. Gradually, over years, these lesions evolve into those of advanced diabetic nephropathy: nodular glomerulosclerosis (the Kimmelstiel–Wilson lesion), diffuse intercapillary glomerulosclerosis, and arteriolar hyalinization. It appears that accumulation of extracellular matrix in the mesangium best predicts development of clinical nephropathy. Thus, many of the studies on the pathogenesis of diabetic nephropathy have concentrated on abnormalities that can promote such accumulation.

Although the causes of the glomerular changes are still a matter of intense investigation, recent basic and clinical research findings have identified, at least in broad strokes, many of the factors that are important in the pathogenesis of the disease. [Figure 153.1](#) shows a pathway of progression of diabetic nephropathy that outlines, albeit simplistically, those factors that appear to ultimately result in the pathological lesions of diabetic nephropathy. This formulation implies that interruption of any of the abnormalities in the pathway could retard or potentially prevent progression of diabetic kidney disease.

FIGURE 153.1. Proposed scheme for the pathogenesis of diabetic nephropathy. Present therapies are aimed at interruption of hemodynamic (*left*) and metabolic (*middle*) factors. The genetic factors (*right*) that predispose to nephropathy have yet to be defined precisely, but they appear to play a significant role in determining outcomes.

Clinical studies and recent genetic analyses have strongly suggested that there is a genetic predisposition to nephropathy among certain type 1 and type 2 patients. There are significant familial-associated risks of developing nephropathy in type 1 patients and similar genetic influences exist in the type 2 population, as the risk of developing nephropathy is several fold greater in African-American, American Indian, and Hispanic patients with type 2 diabetes than it is in other type 2 populations. Many recent studies have examined potential candidate genes to determine whether differences in these genes could predispose diabetic patients to develop nephropathy. One area of focus has been on genes that encode components of the renin–angiotensin–aldosterone system. At this point, none of the genes in this system, or any other genes, have been unequivocally linked to development of nephropathy in patients with diabetes. Although there are no genetic alterations that have been unequivocally shown to lead to an increased risk of developing diabetic nephropathy, various genetic loci have been identified that may contain such genes. It seems likely that specific genes that increase (or decrease) the risk of developing nephropathy will be identified in the near future for at least some populations with diabetes. It has been suggested that these genetic alterations are likely to alter renal hemodynamics in a way that potentiates the abnormalities found in most diabetic patients (see below), or may predispose to enhanced scarring responses to glomerular injury by increasing extracellular matrix protein deposition and enhancing recruitment of fibroblasts into the glomerulus.

Another factor that appears to be a critical component of the pathogenetic progression to diabetic glomerulosclerosis is glomerular hyperfiltration. During the first few years of diabetes, the glomerular filtration rate is usually increased above normal in both type 1 and type 2 diabetic patients ([Fig. 153.2](#)). This hyperfiltration is most pronounced in the postprandial period but can persist for hours after eating. In animal models, this hyperfiltration is due to enhanced glomerular pressure resulting from abnormal vasodilatation of the glomerular afferent arteriole. Although the specific causes of these abnormalities have not been clearly identified, it is certain that poor glycemic control predisposes to this phenomenon. In patients who have good glycemic control for several weeks, hyperfiltration disappears. Hyperfiltration and glomerular hypertension by themselves do not lead to the pathologic features of diabetic nephropathy, but they appear to facilitate its development. In experimental situations in which hyperfiltration is abolished, diabetic nephropathy does not occur. Similarly, several case reports of diabetic patients with unilateral renal artery stenosis (and hence reduced glomerular pressure and filtration) found that diabetic nephropathy did not occur in the kidney behind the stenosis, whereas it progressed unabated in the contralateral kidney, presumably because the kidney with the stenosis was protected from the increase in glomerular pressure and

hyperfiltration.

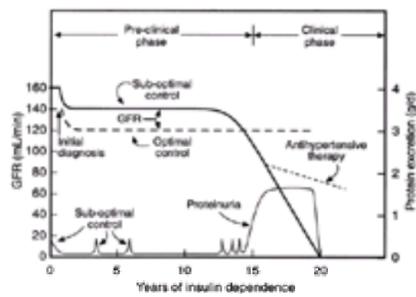

FIGURE 153.2. The natural history of diabetic nephropathy in type 1 patients. Type 2 patients appear to follow a similar course, although the time scale may be somewhat more compressed in type 2 patients with nephropathy. (From Hostetter TH. Diabetic nephropathy. In: Brenner BM, Rector F, eds. *The kidney*, third edition. Philadelphia: WB Saunders, 1986, with permission.)

Systemic hypertension significantly aggravates glomerular hypertension. Normal kidneys respond to elevated systemic blood pressure by vasoconstriction of the renal afferent arterioles thereby preventing transmission of elevated blood pressure to the glomerulus. However, in diabetes, the renal afferent arteriole is abnormally dilated (in animals and presumably in humans) and does not constrict in response to an increase in systemic blood pressure. Therefore, glomerular pressures increase substantially in the presence of systemic hypertension. This phenomenon may partly explain why systemic hypertension is such an important risk factor for progression of diabetic nephropathy.

A final set of factors that are critical for the evolution of diabetic nephropathy are responsible for enhanced accumulation of extracellular matrix proteins in the glomerular tuft. Experimental studies have suggested that the enhanced matrix expansion is due to both increased secretion of extracellular matrix proteins (such as fibronectin and collagen IV) by glomerular mesangial cells as well as reduced degradation of secreted extracellular matrix proteins. It appears that mesangial cells exposed to abnormally high glucose levels take up more glucose, perhaps due to an increase in the number of glucose transport proteins on the cell surface. This in turn leads to a number of abnormalities including enhanced transforming growth factor- β secretion from the mesangial cells, which in an autocrine manner stimulates enhanced elaboration of matrix proteins.

Another factor that appears to be important in the accumulation of matrix proteins is the increased production of advanced glycosylation end-products (AGEs). Nonezymatically driven reactions between glucose and free amino groups in proteins lead to covalent modification of these proteins which, through a number of intermediate steps, leads to formation of AGEs. The AGEs are extremely stable and accumulate at a rate proportional to the extracellular glucose level; therefore, they accumulate to higher levels in patients with diabetes, especially those with poor glycemic control. AGEs can cross-link extracellular matrix proteins, prevent their proteolysis, and hence enhance their accumulation. Moreover, AGEs can stimulate mesangial cells to augment fibronectin production and can attract fibroblasts into the glomerular tuft. All of these effects can lead directly to worsening of typical diabetic glomerular pathology. Both AGE levels and glucose effects on mesangial cells are enhanced by hyperglycemia and are reduced by normalization of blood sugar, again implicating glycemic control as a critical determinant of the development of diabetic nephropathy.

CLINICAL FINDINGS

Most diabetic patients have some degree of glomerular hyperfiltration early in the course of their diabetes ([Fig. 153.2](#)). This hyperfiltration may persist for years. Thus, measurements of renal function during this time may show elevated function. As described in the previous section, early glomerular pathologic changes precede any clinical manifestation of nephropathy, but these glomerular abnormalities ultimately lead to increased loss of larger circulating proteins that are normally retained by an intact glomerular filtration barrier. Since albumin is the most abundant circulating protein, the first clinical indication of these glomerular changes is microalbuminuria, the presence of small but abnormal amounts of albumin in the urine (discussed more fully under "Laboratory Findings," below). This abnormality is usually not detectable in type 1 patients until 5 or more years after the onset of diabetes. In type 2 patients, microalbuminuria can occur sooner after diagnosis because the onset of diabetes may go undetected for some time and because the progression of disease may be faster in type 2 than in type 1 patients. It has been clearly demonstrated that the great majority of type 1 diabetic patients who develop microalbuminuria, and therefore have so-called incipient nephropathy, will progress to overt diabetic nephropathy ([Fig. 153.2](#)). For type 2 patients, the situation is more complex because older patients can develop microalbuminuria independently of diabetes. However, the finding of microalbuminuria in a patient with type 2 disease is associated with a significantly increased likelihood of developing overt nephropathy, and most experts suggest that screening and intervention should be tailored similarly in both type 1 and type 2 patients. Approximately 90% of type 1 patients have some degree of diabetic retinopathy by the time they develop nephropathy. Although the prevalence of retinopathy is lower in type 2 patients with nephropathy, most type 2 patients will have evidence of retinopathy at the time of diagnosis of nephropathy. Therefore, the presence of clinically detectable renal disease in the absence of retinal abnormalities (especially in type 1 patients) raises the possibility that the kidney disease is due to some cause other than diabetes.

After onset of microalbuminuria, most patients will have a 5- to 10-year period of relative stability with few other clinical manifestations of nephropathy ([Fig. 153.2](#)). This period can be extended in many patients, perhaps indefinitely, if they receive aggressive intervention at this point. However, in the absence of aggressive treatment and in some patients who are aggressively managed, the degree of albuminuria tends to gradually increase until it is detectable on routine urinary dipstick evaluation. At this point, overt diabetic nephropathy is present. Peripheral edema is likely to occur and may be the first symptom of nephropathy noted by many patients. Moreover, by this stage, hypertension is likely to be present in both type 1 and type 2 patients. Hypertension is almost universal in type 2 patients with overt nephropathy. Thereafter, the glomerular filtration rate, previously elevated above normal, begins to fall. Uncontrolled hypertension accelerates the deterioration of renal function in patients with overt nephropathy. With the onset of overt nephropathy, patients who do not receive aggressive treatment will progress inexorably to ESRD over a 5- to 15-year period.

The presence of overt nephropathy also correlates with a much higher risk of cardiovascular disease. The relative morbidity and mortality in diabetic patients with overt nephropathy are increased many fold when compared to age-matched diabetic patients without albuminuria. This finding is true for both type 1 and type 2 patients, but the relative increase in mortality conferred by nephropathy may be up to 40-fold in type 1 patients, whereas it is less than 10-fold in type 2 patients. Most of this increase in mortality is attributable to accelerated cardiovascular disease. Because other risk factors for cardiovascular disease, such as hypertension and hyperlipidemia, are prevalent among these groups, aggressive management of all risk factors is required to ameliorate the profound increase in cardiovascular risk. It is noteworthy that microalbuminuria itself, even in the absence of diabetes, is associated with an increased risk of progressive vascular disease. Thus, any patient with microalbuminuria, with or without diabetes, should be managed aggressively.

LABORATORY FINDINGS

As noted above, the first laboratory indication of diabetic kidney involvement is microalbuminuria. The diagnostic algorithm for the approach to screening for microalbuminuria is shown in [Figure 153.3](#). Microalbuminuria is defined as the urinary excretion of more than 30 mg, but less than 300 mg, of albumin in a 24-hour period (more than 300 mg per day is detectable by conventional dipsticks and is defined as overt nephropathy). Over the past decade, a number of sensitive assays for urinary albumin have been developed and have been validated as good screening tests. Microalbuminuria can be most easily tested on spot urine samples by determining the albumin-to-creatinine ratio. This is usually expressed as a ratio of milligrams of albumin to grams of creatinine. A ratio of between 30 and 300 usually signifies microalbuminuria for most laboratories (since approximately 1 g—or 1,000 mg—of creatinine is excreted daily, a ratio of 30 would correspond to a daily excretion of 30 mg of albumin). In order to make the diagnosis of persistent microalbuminuria and hence of incipient diabetic nephropathy, other causes of a transient increase in urinary albumin excretion, such as severe hyperglycemia, severe hypertension, urinary tract infection, fever, recent exercise, and congestive heart failure, should be excluded. The test should be performed at least three times over a 3- to 6-month period and must be abnormal on at least two of those occasions to indicate persistent microalbuminuria. Otherwise, screening should continue yearly ([Fig. 153.3](#)). Once the diagnosis is made, it might be helpful to continue monitoring the albumin-to-creatinine ratio to help determine responses to treatment (see below). Screening for microalbuminuria should begin 5 years after onset of diabetes in

type 1 patients and at the time of diagnosis for type 2 patients.

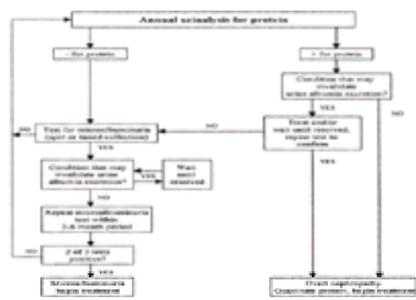

FIGURE 153.3. Algorithm for screening for microalbuminuria in both type 1 and type 2 patients. (From American Diabetes Association. Diabetic nephropathy. *Diabetes Care* 1999;22[Suppl 1];S66, with permission.)

Because diabetes is associated with renal growth, especially during the first several years of diabetes, radiographic studies will often show enlarged kidneys. The presence of bilateral small kidneys in a type 2 patient might suggest the presence of significant renovascular disease associated with so-called ischemic nephropathy. The presence of one small kidney and one normal-sized or enlarged kidney in a type 2 patient with severe hypertension could suggest unilateral renal artery stenosis.

There are usually no other significant laboratory abnormalities directly related to diabetic nephropathy until overt nephropathy occurs. Patients will then tend to have a gradual decline in renal function, detectable by decreased creatinine clearances or increases in serum creatinine. Hypercholesterolemia may become manifest if not previously present, and hypoalbuminemia can develop as proteinuria worsens. As renal function worsens, patients with diabetic nephropathy will experience the plethora of metabolic and laboratory abnormalities that occur with progressive chronic renal insufficiency of any cause. Hyperkalemia tends to occur earlier, however, in diabetic patients due to hyporeninemic hypoaldosteronism (type IV renal tubular acidosis), insulin resistance, hypoinsulinemia, and/or hyperglycemia. This may limit intervention with angiotensin-converting enzyme (ACE) inhibitors (see below).

OPTIMAL MANAGEMENT

The Diabetes Complication and Control Trial (DCCT), published in 1993, demonstrated unequivocally that glycemic control was critical for preventing diabetic complications, including nephropathy. In that study, patients who received intensive insulin treatment achieved tight glycemic control (with a mean hemoglobin A_{1C} of approximately 7%) and had an approximately 50% decrease in the risk of developing nephropathy during the 9-year study period. A number of recent studies, some using a design very similar to that of the DCCT, have shown that tight glycemic control in type 2 diabetic patients is associated with a similar reduction in the number of patients progressing to nephropathy over a several year period. For both type 1 and type 2 patients, there is a continuous positive relationship between glucose levels and the risk of developing nephropathy; the risk of nephropathy increases as glycemic control worsens. Thus, both type 1 and type 2 patients without nephropathy (i.e., no abnormal microalbuminuria) should be treated with insulin or other hypoglycemic agents to achieve a hemoglobin A_{1C} of 7% or lower whenever possible. It must be appreciated that intensive insulin treatment is associated with an increased risk of severe hypoglycemic episodes, and its use in patients with hypoglycemia unawareness requires special caution. It is also likely that tight control helps prevent or delay progression from microalbuminuria to overt nephropathy, but there are no confirmatory data at present. Once overt nephropathy is reached, the risks of tight glycemic control may outweigh the benefits.

After microalbuminuria is confirmed, treatment with ACE inhibitors should be initiated, even in patients who are normotensive. Several studies, including the Collaborative Group report in 1993, have shown that treatment of patients with ACE inhibitors can reduce progressive decline in renal function in patients with diabetic nephropathy, independent of the level of blood pressure control. These agents reduce hyperfiltration and glomerular hypertension by (relatively) selectively dilating the efferent arteriole. They may also have a salutary effect on renal cell growth by inhibiting the intrarenal renin-angiotensin system and may reduce matrix protein accumulation by blocking angiotensin II effects on mesangial cells. In normotensive patients, treatment should begin at the lowest dose and then gradually be increased to levels that approximate those of the various published studies (e.g., enalapril or lisinopril of 20 mg per day). Major side effects include cough, orthostatic hypotension, angioedema, and hyperkalemia. Acute renal failure can occur in patients with bilateral renal artery stenosis who begin ACE inhibitor treatment, since these patients are dependent on efferent arteriolar constriction to achieve an intraglomerular pressure compatible with filtration. Therefore, all patients should have serum potassium and creatinine checked within the first few days of initiating therapy. A relatively small percentage rise (less than 40%) in serum creatinine does not signify bilateral renal artery stenosis and should not prevent continuation of therapy. Many patients develop a dry cough due to accumulation of bradykinin (which is metabolized by ACE). The cough is not dangerous, but can be irritating and prevent continuous therapy. In those patients, it is recommended that angiotensin II receptor blockers be utilized, though there are no clinical data available to demonstrate renal protection similar to that achieved with ACE inhibitors. Finally, it is imperative that ACE inhibitors not be used during pregnancy due to severe toxic effects on the fetus. These effects are manifested in the second and third trimesters. Therefore, ACE inhibitors should be used cautiously in women of child-bearing age.

Any time that hypertension occurs it should be aggressively treated. The recommendations of the American Diabetes Association for treatment of hypertension are contained in the "Standards of Medical Care for Patients with Diabetes Mellitus." The goal for blood pressure control should be less than 130/85 mm Hg for almost all patients. The only exceptions should be for type 2 patients with severe vascular disease in whom perfusion of vital organs is dependent on a higher blood pressure, and in type 1 or 2 patients with severe orthostatic hypotension due to autonomic neuropathy. Isolated systolic hypertension should be initially reduced to 160 mm Hg for those with systolic blood pressures greater than 180 mm Hg, reduced by 20 mm Hg for those with initial systolic blood pressures lower than 180 but higher than 160 mm Hg. Subsequent reduction of systolic blood pressures to 140 mm Hg or lower can be achieved as tolerated. Aggressive blood pressure control may be the single most critical treatment in forestalling progressive diabetic nephropathy.

Restriction of dietary protein may also be helpful in preventing or ameliorating the progression of diabetic nephropathy. The mechanism of this action is uncertain, but protein restriction may work by reversing hyperfiltration and glomerular hypertension. Adult type 1 and type 2 patients can usually be safely restricted to 0.8 g per kg per day (plus any urinary protein losses), without significant risk of protein malnutrition. Further restriction is difficult to achieve and may be accompanied by nutritional deficiency. Such restricted diets require monitoring by a registered dietitian.

Other treatment modalities to retard progression of nephropathy are less well defined, but there are increasing data which suggest that hyperlipidemia promotes progression whereas reduction of low-density lipoprotein cholesterol with the use of b-hydroxy-b-methylglutaryl coenzyme A reductase inhibitors can delay or prevent progression of nephropathy. Other suggested treatments include use of spironolactone to block the effects of aldosterone and cessation of smoking, which has a salutary effect on all microvascular disease.

Patients with diabetic nephropathy with elevated creatinines are at especially high risk of developing acute renal failure when exposed to radiocontrast media. If radiologic evaluation with radiocontrast materials is necessary, one should consider use of nonionic contrast agents in this group.

Finally, in patients who progress toward end-stage renal disease, despite all efforts, early transplant evaluation is indicated. For diabetic patients who are acceptable candidates for transplant, this is clearly the preferred modality of renal replacement therapy. Patient survival, at least over the first several years, for diabetic patients receiving either cadaveric or living donor transplants is now virtually identical to that of nondiabetic patients. The U.S. Renal Data System has reported that 1-year survival for diabetic patients receiving cadaveric allografts was 91.3% in 1995, compared with 92.6% for the nondiabetic population. Survival is even better for recipients of living donor allografts (95.4% for diabetic patients and 96.3% for nondiabetic patients). Renal allograft survival has also improved for diabetic patients and is now identical to that of the nondiabetic population. Excellent glycemic control, the use of ACE inhibitors, and aggressive blood pressure management all help to prevent recurrence of diabetic kidney disease in the transplanted kidney. Over the past few years, the use of combined kidney-pancreas transplants has increased. This procedure, when successful, has cured a growing number of type 1 patients. Short-term morbidity and mortality is greater for kidney-pancreas recipients than for type 1 diabetic patients receiving kidney allografts alone. However, it appears that long-term patient and kidney allograft survival is comparable to those type 1 patients receiving kidneys alone. Better long-term evaluation of combined kidney-pancreas will be forthcoming in the next several years.

RENAL LESIONS ASSOCIATED WITH MONOCLONAL IMMUNOGLOBULIN LIGHT-CHAIN DEPOSITION

Renal lesions related to deposition of monoclonal immunoglobulin or fragments of immunoglobulin represent about 2.7% of all morphologic abnormalities identified by kidney biopsy. They have in common abnormal accumulation in the kidney of monoclonal immunoglobulin fragments: light chains alone or, more rarely, a combination of light and heavy chains or heavy chains alone. Deposition of light chains in the various compartments of the kidney produces several clinicopathologic syndromes (Table 154.1). The presence of monoclonal light chains in the kidney confirms a plasma cell dyscrasia. The most common underlying diseases are multiple myeloma and primary amyloidosis (Table 154.2).

Glomerulopathies
 Amyloidosis, type AL
 Light-chain–related glomerulopathy of systemic light-chain deposition disease
 Tubulointerstitial lesions
 Fanconi's syndrome
 Isolated hyperphosphaturia
 Proximal tubule necrosis (acute tubular necrosis, or "tubulopathy")
 Cast nephropathy ("myeloma kidney")
 Tubulointerstitial nephritis
 Vascular lesions
 Asymptomatic (Bence Jones proteinuria)

TABLE 154.1. RENAL LESIONS RELATED TO MONOCLONAL LIGHT-CHAIN DEPOSITION

Disease	Neoplastic Infiltration	Type of Renal Involvement		
		Glomerular	Tubulointerstitial	Vascular
Multiple myeloma	No	Light-chain–related glomerulopathy; AL type amyloid; AL type amyloid	Cast nephropathy; Acute tubulopathy; proximal nephrosis; Acute tubulopathy	Infiltration of arterioles/arteries
Primary amyloidosis	No	AL type amyloid	Acute tubulopathy	Infiltration of arterioles/arteries; Infiltration of arterioles
Systemic light-chain deposition disease	No	Light-chain–related glomerulopathy; IgA-related glomerulopathy	Acute tubulopathy	Infiltration of arterioles/arteries; Infiltration of arterioles
Waldenström's macroglobulinemia	Common	IgM-related glomerulopathy	Cast nephropathy; None	No
Heavy-chain disease	Uncommon	AL type amyloid; AL type amyloid (AL ₂); AL type amyloid (AL ₃); AL type amyloid (AL ₄)	None	No
Chronic lymphocytic leukemia	Uncommon	AL type amyloid	Cast nephropathy; None	No
Multiple myeloma	No	No	Cast nephropathy; None	No

*AL type amyloid; AL₂ type amyloid; AL₃ type amyloid; AL₄ type amyloid.

TABLE 154.2. CAUSES OF MONOCLONAL LIGHT-CHAIN PROTEINURIA AND ASSOCIATED RENAL MORPHOLOGIC LESIONS

PATHOGENESIS

Light chains of immunoglobulins are 22-kD proteins that have two independent globular domains derived from a multigene family. The constant region is a homogeneous 105- to 107-polypeptide chain that is the product of genes located on chromosome 2 for the kappa light chain and on chromosome 22 for the lambda light chain. The variable region makes up the remaining 110 to 120 amino acids of the light chain and forms part of the antigen binding site. Multiple gene segments are rearranged to produce the variable polypeptide region. Thus, despite similar chemical properties, no two light chains are identical. Once synthesized and released into the plasma, light chains are cleared from the circulation by glomerular filtration. The glomerular filter serves as a minimal restrictive barrier for these low molecular weight proteins. After appearance in the tubule fluid, light chains are reabsorbed by the proximal tubule. When this process is saturated, light chains appear in distal tubule fluid and urine as Bence Jones proteins. Bence Jones protein is the original term for monoclonal light chain in the urine in amounts sufficient to demonstrate the unique thermal solubility properties of light chains (precipitation on heating to 45°C to 60°C, followed by solubilization after continued heating to 100°C). Thus, during transit through the kidney, light chains may interact with the glomeruli, proximal tubules, and distal nephron. In doing so, different renal lesions may develop, depending on the intrinsic physicochemical properties of the light chain.

In the glomerulus, some light chains bind to mesangial cells and stimulate these cells to produce transforming growth factor-β, a fibrogenic growth factor that in turn stimulates matrix production by these resident glomerular cells. The result is light-chain-induced glomerulosclerosis (light-chain-related glomerulopathy of systemic light-chain deposition disease). Other light chains can deposit in glomeruli and under proper environmental conditions can polymerize to form AL-amyloid (A for amyloid, L for light chains), in contrast to AA-amyloid, named after amyloid A protein, which occurs secondary to an underlying inflammatory or chronic infectious process. The amyloid replaces the normal architecture of the glomeruli and results in glomerular damage. After filtration through the glomerulus and subsequent reabsorption into the proximal tubule epithelium, light chains ordinarily are hydrolyzed and the amino acid components are returned to the circulation by the basolateral circulation. However, some light chains appear to be poorly hydrolyzed. They congest and disrupt the endolysosomal system of these cells, producing proximal tubule cell toxicity. Other light chains escape absorption into the proximal tubule and appear in the lumen of the distal nephron where they bind to a specific site on Tamm–Horsfall glycoprotein, which is synthesized by the thick ascending limb of the loop of Henle. With binding, these proteins aggregate to form dense casts in the distal nephron. A subsequent inflammatory response with giant cell formation around the cast is typical. Cast nephropathy or "myeloma kidney" appears to be the direct result of the interaction between these proteins.

Finally, some of these proteins transit the kidney without consequences and produce no evident clinical manifestations. The physicochemical properties of the light chain that confer toxicity remain poorly defined, but changes as subtle as alteration of one amino acid can cause toxicity.

CLINICAL FINDINGS

The diagnosis of renal disease related to deposition of monoclonal light chain has traditionally been confirmed by the setting in which it developed. For example, over half of patients who present with clinical features of multiple myeloma have concomitant renal failure related to light-chain overproduction. However, renal failure can be the presenting feature of a plasma cell dyscrasia. Demonstration of monoclonal light-chain deposition in the kidney can thus uncover a hematologic disorder. The clinical manifestations of these renal lesions vary, depending on which compartment of the kidney is involved. Usually a progressive chronic loss of renal function is observed, but acute renal failure might be seen. A clinical syndrome reminiscent of rapidly progressive glomerulonephritis might also occur, particularly in the glomerulopathy associated with systemic light-chain deposition disease. Clinical findings of a glomerular lesion include hematuria with or without red blood cell casts, nephrotic syndrome, and nephrotic-range proteinuria. In the absence of an overt nephrotic syndrome, it is important to quantify the albumin component of proteinuria. Ordinarily, heavy proteinuria suggests a glomerular lesion, but because filtration of light chains is not restricted significantly by the normal glomerulus, large amounts of protein may be present in the urine of these patients, and yet no glomerular pathology is present. Associated albuminuria suggests AL-type amyloidosis or

light-chain-related glomerulopathy of systemic light-chain deposition disease. The AL type of amyloidosis develops in about 10% of patients with multiple myeloma, less frequently with Waldenström's macroglobulinemia. The clinical presentation and type and degree of organ infiltration are similar between primary and myeloma-associated amyloidosis.

LABORATORY FINDINGS

Several electrolyte abnormalities may result from the presence of abnormal g-globulins in serum. By displacing water in the volume of serum used to quantify sodium by flame photometry, large quantities of circulating protein produce pseudohyponatremia, a laboratory phenomenon. Correction for the portion of serum displaced by protein usually reveals that the serum sodium concentration is not altered. Plasma osmolality and serum sodium measured by ion-selective electrodes are normal in these circumstances. Hypercalcemia is the most common electrolyte disturbance in myeloma. Myeloma proteins may bind phosphate and produce spurious hyperphosphatemia. Rarely, abnormal protein binding of copper causes hypercupremia and Kayser–Fleischer–like rings. Multiple myeloma may be associated with a low anion gap because the immunoglobulin, particularly IgG, may have a net positive electrostatic charge, thereby reducing the normal anion gap by increasing the amount of counterbalancing anions in the serum. The result may be an anion gap of less than 5 mEq per L (normal, 12 mEq per L). Isolated damage to the proximal tubule can produce renal tubular acidosis, along with derangement of other sodium-coupled transport processes. The result is Fanconi's syndrome, which is characterized by hyperchloremic metabolic acidosis, glycosuria, and aminoaciduria. Fanconi's syndrome may be the presenting manifestation of multiple myeloma. Isolated hyperphosphaturia with attendant hypophosphatemia can occur in myeloma and can improve with successful treatment.

Diagnosis and classification of a plasma cell dyscrasia generally depend on the identification and quantification of the abnormal immunoglobulin molecule. Often, this is accomplished by electrophoretic analysis of proteins in the serum and urine. In over two thirds of patients, a monoclonal gammopathy is detected in the serum. Quantitative assay of the abnormal immunoglobulin ("M" component) is one of the best indexes used to follow the progression of the disease and the response to treatment. Examination of the urine further supports the diagnosis. Polyclonal light chains may appear normally in the urine, but in very small amounts (less than 2.5 µg per mL). The urinary light-chain concentration generally ranges from 0.02 to 0.5 mg per mL in patients with monoclonal gammopathies of undetermined significance, but the concentration is usually much higher (0.02 to 11.8 mg per mL) in patients with multiple myeloma or Waldenström's macroglobulinemia. Routine protein electrophoresis is too insensitive as a screening test and has been replaced by antibody detection assays, which confirm the presence and monoclonal nature of the immunoglobulin and light chain. Immunofixation electrophoresis, which is very sensitive, detects monoclonal light chains even in very low concentrations. However, occasionally the amount of monoclonal light chain is very small and can be masked by coexistent tubulointerstitial disease, which produces significant proximal tubule damage and therefore results in increased excretion of low molecular weight proteins, including polyclonal light chains.

Despite problems with detection, a diagnostic hallmark of plasma cell dyscrasias has been Bence Jones proteinuria. The causes of monoclonal light-chain proteinuria are listed in [Table 154.2](#). Rifampin can rarely induce Bence Jones proteinuria and renal failure from cast nephropathy. Light-chain overproduction resolves by stopping this antibiotic. Because of difficulties with currently available detection techniques, renal monoclonal light-chain deposition may be diagnosed by kidney biopsy despite the absence of detectable paraprotein in serum or urine. Thirty to fifty percent of patients with documented systemic light-chain deposition disease have normal serum and urine immunoelectrophoretic profiles.

Bone marrow biopsy may reveal that plasma cells make up more than 20% of the total nonerythroid cells. When these cells appear vacuolated, bizarre, and multinucleated, a diagnosis of multiple myeloma is strongly supported. Immunophenotyping to document a monoclonal population of plasma cells may be useful when other findings are ambiguous. Nevertheless, a "negative" bone marrow biopsy does not exclude the existence of abnormal light-chain-producing plasma cells as a cause of renal failure. Patients with renal failure from documented systemic light-chain deposition disease but without diagnostic criteria for myeloma may develop overt multiple myeloma over time. Patients with monoclonal gammopathy of undetermined significance and normal renal function on presentation should also be closely followed because as many as one fourth will develop overt myeloma, amyloidosis, macroglobulinemia, or malignant lymphoproliferative disorder.

OPTIMAL MANAGEMENT

The mainstay of therapy is to abolish production of immunoglobulin light chains, the pathogenic feature of all of these renal lesions. As a group, these lesions belong to an unusual class of potentially reversible renal failure. The standard chemotherapeutic regimen, including melphalan and prednisone, ameliorates renal failure in over half of patients presenting with renal failure and multiple myeloma.

TREATMENT OF GLOMERULAR DISEASES

Although successful chemotherapy decreases the bone marrow biosynthesis of abnormal monoclonal light chains in systemic light-chain deposition disease, light-chain-related glomerulopathies are particularly resistant to chemotherapy. Uncontrolled trials of chemotherapy in systemic light-chain deposition disease have suggested benefit in some patients by preventing progression and occasionally improving renal function. Although most studies examining the role of chemotherapy in the management of glomerular lesions of systemic light-chain deposition disease are uncontrolled, given the inexorable progression of these glomerular lesions when untreated and the proven pathogenic role of monoclonal light chains in these glomerulopathies, a trial of chemotherapy should be considered, especially if the serum creatinine concentration at the time of diagnosis is less than 2 mg per dL. To identify these early lesions, however, a careful and comprehensive evaluation must be performed early in the course of the disease. The cumulative dose of melphalan and clinical response should be monitored during treatment.

Alkylating agents and prednisone decrease proteinuria, ameliorate nephrotic syndrome, and improve renal dysfunction in some patients with AL-type amyloidosis. Chemotherapy appears to prolong survival, although the overall response rate to chemotherapy approaches only 20% in amyloidosis. Generally, however, progressive systemic amyloid deposition continues, and deterioration of renal function is the rule. Unlike amyloidosis in familial Mediterranean fever, treatment of AL-type amyloidosis with colchicine alone has been disappointing.

TREATMENT OF CAST NEPHROPATHY ("MYELOMA KIDNEY")

Reducing the plasma concentration of monoclonal light chain generally improves renal function in cast nephropathy. Plasmapheresis to clear circulating light chains rapidly may be used initially in acute renal failure. However, despite chemotherapy, progressive loss of renal function subsequently occurs in many patients with cast nephropathy. Thus, other potential treatments designed to disrupt coprecipitation of Tamm–Horsfall glycoprotein with cast-forming light chains should be implemented. Factors known to aggravate nephrotoxicity of light chains by facilitating coprecipitation with Tamm–Horsfall glycoprotein in the distal nephron include hypercalcemia, an acidic urine, furosemide, radiocontrast material, low tubule fluid flow rates, and a high sodium chloride concentration in tubule fluid. Correction of hypercalcemia usually improves renal function. Alkalinization of the urine prevents renal failure from Bence Jones proteins in rats. In one inadequately controlled trial in humans, however, alkalinization of the urine by itself was not readily beneficial. Thus, alkalinization should be used only in conjunction with other measures, especially those aimed at enhancing hydration and keeping the urine flow rate high and the sodium chloride concentration in the distal nephron low. It is prudent to recommend a daily intake of 2 to 3 L of dilute fluids, as long as no significant defect in plasma osmoregulation coexists with renal failure. The detrimental effect of radiocontrast agents on renal function has been shown in several studies, so that radiocontrast agents should be avoided in patients with multiple myeloma. Nonsteroidal anti-inflammatory agents produce a significant incidence of renal failure in myeloma and should be avoided. Because furosemide aggravated cast formation in an experimental animal model and facilitates coprecipitation of Tamm–Horsfall glycoprotein and light chains in vitro, this loop diuretic should be used with caution, particularly when extracellular fluid depletion is present.

CLINICAL COURSE

The clinical course of patients who have a monoclonal light-chain-related renal disease varies depending on the type of renal lesion. If untreated, however, virtually all of the renal lesions cause progressive loss of renal function and contribute to mortality because renal insufficiency predisposes to infection, the major cause of death in myeloma. For all patients with myeloma, median survival approaches 25 months. When significant renal failure coexists (creatinine concentration at least 180 µmol per L, or 2 mg per dL), median survival decreases to 4.3 months. In general, systemic light-chain deposition disease that shows a nodular glomerulopathic morphologic pattern has a poor renal prognosis, with most patients progressing rapidly to end-stage renal failure. Along with the glomerulopathy, proximal tubule injury (acute tubulopathy) contributes to progressive loss of renal function in systemic light-chain deposition disease. Adequate control of light-chain proteinuria promotes resolution of the proximal tubule injury. Overall, patients with myeloma and amyloidosis also have a poor prognosis, with median survival of less than 12 months. However, in patients with remissions induced by chemotherapy, survival can be prolonged and amyloid deposits might regress.

Renal replacement therapy in the form of hemodialysis or peritoneal dialysis is generally recommended in patients with renal failure from monoclonal light-chain-related renal diseases, especially if the renal failure is of recent onset. Recovery of renal function sufficient to survive without dialysis occurs in as many as

5% of patients with multiple myeloma but requires months in some patients. In addition, although multisystem involvement and advanced age at the time of diagnosis of myeloma shorten the life span (death often occurs early in the course of treatment), some patients, particularly those with disease limited mostly to the kidney, achieve functional rehabilitation and survive for more than 2 years.

Renal transplantation may also be considered for patients with myeloma, AL-type amyloidosis, or systemic light-chain deposition disease after the extrarenal manifestations of the disease have been absent for more than a year. Renal transplantation in these patients may be particularly beneficial if the disease has remained limited to the kidney. Transplant experience is limited, but glomerular light-chain deposition may also recur in the allograft and cause renal failure. Despite careful screening, myeloma may also recur after transplantation.

WALDENSTRÖM'S MACROGLOBULINEMIA

About 12% of patients with monoclonal gammopathy have Waldenström's macroglobulinemia, a B-cell line neoplastic transformation distinct from multiple myeloma. This condition behaves more like a lymphoma, and clinical manifestations are related primarily to organ infiltration, anemia, and hyperviscosity of blood. Osteolytic lesions are typically absent. The neoplastic cell, a large plasmacytoid lymphocyte, secretes monoclonal IgM (macroglobulin). Some of these immunoglobulins can bind autologous IgG (rheumatoid factor) and behave as cryoglobulins, producing cryopathic signs and symptoms. Direct neoplastic infiltration of the kidneys is more common in macroglobulinemia than in multiple myeloma. Plasmacytoid cells have been recovered from the urine sediment in patients with massive renal infiltration, and IgM in the urine supports the diagnosis of renal involvement. A peculiar glomerular lesion that is relatively common in macroglobulinemia is associated with massive subendothelial deposits of IgM. The glomerular capillary loops occasionally are filled with occlusive thrombi that contain IgM. These deposits must be differentiated from amyloid by Congo red staining and immunofluorescence and electron microscopy. Other immunoglobulins and complement are usually absent. The AL type of amyloid deposition occurs in about 5% of these patients. Although Bence Jones proteinuria is often detected, cast formation and "myeloma kidney" are rare.

The most dramatic, and usually initial, manifestation of macroglobulinemia is hyperviscosity syndrome related to the presence of large amounts of the abnormal macroglobulin in the circulation. Symptoms and signs attributable to hyperviscosity and hypervolemia are present in most patients with macroglobulinemia at some time during the illness. Characteristics of hyperviscosity syndrome include fatigue, weakness, bleeding diathesis, confusion, headache, visual disturbances, and circulatory congestion. In addition, renal dysfunction is usually present and manifested by impaired urine concentration, azotemia, and, occasionally, hematuria. The acute renal failure that may occur is typically reversible with treatment. The diagnosis of hyperviscosity syndrome rests on demonstration of the typical "M" spike in the serum, venous congestion (best observed by marked dilatation of retinal veins), and an elevated "relative" serum viscosity, although this latter parameter does not correlate linearly with the serum concentration of abnormal immunoglobulins. A relative serum viscosity of more than 4 and a serum concentration of abnormal immunoglobulin of more than 5 g per dL are usually encountered when symptoms of hyperviscosity are present. In contrast to macroglobulinemia, less than 5% of patients with IgG- and light-chain-secreting multiple myeloma show symptoms attributable to increased serum viscosity. This difference is probably related to the high molecular weight and structure of multimeric IgM, which permits slow removal from the circulation and accumulation in the intravascular compartment.

In patients with macroglobulinemia and hyperviscosity, emergent plasmapheresis is the treatment of choice, and it should be continued until symptoms have resolved. Chemotherapy in the form of alkylating agents and prednisone helps to maintain a stable serum viscosity. Many patients with macroglobulinemia have an indolent course; the overall median survival (5 years) is much higher than in multiple myeloma.

CRYOGLOBULINEMIA

Cryoglobulins are circulating proteins that precipitate on cooling. They are usually immunoglobulins or their fragments (light chains) but also may contain other components, including complement (C1q, C3, C4), fibronectin (cold-insoluble globulin), and endogenous (DNA) or exogenous (hepatitis B virus, hepatitis C virus, bacteria, or fungi) antigens. Cryoglobulinemic states are traditionally divided into three types. In type I cryoglobulinemia, the cryoprotein is a monoclonal immunoglobulin or light chain. Such patients typically have an associated plasma cell or lymphocytoid neoplasia, such as multiple myeloma or Waldenström's macroglobulinemia. Renal disease may result from precipitation of the cryoprotein in the glomerular capillaries. The cryoprotein in type II (mixed IgM and IgG) cryoglobulinemia consists of two or more distinct immunoglobulin classes, one of which is a monoclonal paraprotein, usually IgM. The IgM component has rheumatoid factor activity and binds to the Fc portion of polyclonal IgG. This type is associated with a plasma cell or lymphocytoid neoplasia, certain infections (especially hepatitis B and C), or autoimmune disease, or occurs as a primary (essential) disorder. The incidence of essential mixed cryoglobulinemia declined when hepatitis C infection was shown to account for the cryoglobulinemia in many of these patients. Presenting features can include purpura, fever, arthralgias, splenomegaly, and liver disease. Serum C4 levels are often decreased more than C3 levels. Renal disease may be severe and progressive, and is usually due to glomerulonephritis in which glomerular capillary deposits of the cryoprotein and complement components are accompanied by an intense monocytic infiltrate. Vasculitis and crescents may also occur. Renal failure and nephrotic syndrome are common. In type III cryoglobulinemia, the cryoprotein consists of two or more immunoglobulin classes, both polyclonal. The cryoglobulins are believed to be immune complexes that are insoluble at low temperatures. Type III cryoglobulinemia occurs in autoimmune and inflammatory disorders, including poststreptococcal glomerulonephritis, systemic lupus erythematosus, chronic infections, and neoplasias. An unidentifiable (essential) etiology is found in about 40% of patients with type III cryoglobulinemia.

Treatment of cryoglobulinemia depends on the underlying etiology. General measures should include avoidance of exposure to cold temperatures, particularly when peripheral necrotizing and purpuric skin lesions are present. In essential cryoglobulinemia, intensive plasma exchange or cryopheresis, glucocorticoids, and cytotoxic agents may be beneficial, especially when the plasma level of cryoglobulins is very high. Recent evidence suggests that interferon- α therapy can improve hepatitis C-induced cryoglobulinemia and associated renal injury and hypertension in some patients.

DISTAL RENAL TUBULAR ACIDOSIS

Distal renal tubular acidosis (RTA) is characterized by hyperchloremic (normal anion gap) metabolic acidosis in association with a urine that is less than maximally acidic ([Table 155.1](#)). Acid is produced in the body (at a rate of 1.0 to 1.5 mEq/kg body wt/day) by acids in the diet, cellular metabolism and alkali losses in the stool. In steady state conditions, H⁺ excretion by the kidney as free ions and buffered acid (with ammonia and anions such as phosphate) equals H⁺ production from the processes mentioned above. Normal distal tubules can generate a H⁺ concentration gradient (>100:1) between urine and blood, and the urine pH will fall to less than 5.4 during the excretion of an acid load. This lower pH increases the amount of H⁺ excreted as free ions and as buffered acid. In distal RTA, the H⁺ gradient is not achieved because of an impairment of the H⁺ secretory mechanism or an increased back-diffusion of H⁺ from urine to blood. This distal tubular defect reduces the absolute rate of acid excretion (both free and buffered H⁺). The kidney fails to replace completely the bicarbonate that has neutralized ingested acid, and the serum bicarbonate level falls. In some cases, associated defects in distal tubule function may increase potassium excretion, leading to hypokalemia. Proximal tubules respond to distal RTA with increased reabsorption of sodium chloride producing hyperchloremia. Chronic metabolic acidosis stimulates skeletal buffering mechanisms and increases calcium mobilization from bone. Patients develop hypercalciuria, nephrocalcinosis and bone disease.

	Distal	Proximal	Type IV
Basic defect	No H ⁺ gradient in distal tubule	Reduced bicarbonate reabsorption	Decreased K ⁺ secretion by distal tubule
Urine pH after acid load	>5.4	<5.4	Usually <5.4
Diagnostic test	NH ₄ ⁺ load	Maximum capacity for HCO ₃ ⁻	Urinary K ⁺ excretion, renal, aldosterone
Serum K ⁺ before treatment	Low	Low	High
Serum K ⁺ after bicarbonate	Normal	Lower	Toward normal
Long-term complications	Renal stones, renal insufficiency	Osteopenia, growth retardation	None
Associated disease	Autoimmune	Fanconi syndrome	Diabetes mellitus, essential nephritis

TABLE 155.1. FEATURES OF RENAL TUBULAR ACIDOSIS

Distal RTA is rare. In children it may occur as a familial trait with several modes of inheritance. In some families, idiopathic hypercalciuria appears to be the inherited trait and the distal RTA develops later. In adults, distal RTA usually occurs as a secondary event in association with autoimmune disorders (systemic lupus erythematosus, Sjogren's syndrome), hypercalciuria (hypervitaminosis D, hyperparathyroidism), drugs (amphotericin B, ifosfamide) and tubulo-interstitial disease (pyelonephritis, obstructive uropathy). In these cases it goes away with resolution of the primary disorder. Children with distal RTA present with failure to thrive and grow; adults present with symptoms of nephrocalcinosis, nephrolithiasis, or hypokalemia. Hypokalemic symptoms include muscle weakness, cardiac arrhythmias, and inability to form a concentrated urine. Laboratory values include a urine pH of greater than 5.4 when the patient is acidemic. Serum bicarbonate is reduced (may be less than 10 mg/dl), the serum chloride level is increased, and often there is hypokalemia. Patients with chronic distal RTA have hypercalciuria with nephrocalcinosis or nephrolithiasis at some point in the disease. Bone pain and pathological fractures may occur. This disorder is characterized by slowly progressive renal insufficiency. Effective treatment includes neutralizing the daily acid load with oral preparations of sodium bicarbonate or sodium citrate (1 to 2 mEq/kg/d). Potassium citrate may be used if hypokalemia is present.

PROXIMAL RENAL TUBULAR ACIDOSIS

Proximal RTA is caused by a decrease in the maximum capacity (T_m) of the proximal tubule to reabsorb bicarbonate; it presents as a hyperchloremic, hypokalemic metabolic acidosis. The urine pH may be less than 5.4. The serum bicarbonate level is usually between 12 and 20 mEq/L. The proximal tubule reclaims about 85 to 90% of filtered bicarbonate by a process that involves the exchange of cellular H⁺ for urine sodium, the activity of the enzyme carbonic anhydrase in the brush border and the cell, and the activity of the sodium, potassium ATPase in the basolateral membrane of the tubular cell. The defect in proximal RTA is unknown, but may related to an abnormality in one of the above parameters. With this defect, bicarbonate is lost into the urine (reduced T_m) until the filtered load of bicarbonate (serum concentration times filtration rate) is less than the reabsorptive capacities of proximal and distal tubules. Because distal acidification is normal, the urine pH may be appropriately low (less than 5.4) when all the bicarbonate has been reabsorbed. Reduced reabsorption of sodium bicarbonate by proximal tubules results in volume contraction, increased activity of the renin-angiotensin-aldosterone system, increased reabsorption of sodium chloride (hyperchloremia) and increased secretion of potassium by distal tubules (hypokalemia).

Proximal RTA is rare. It may be an inherited disorder, either as an isolated defect or as a part of a more generalized defect in proximal tubular function (i.e. a Fanconi syndrome). Acquired forms of proximal RTA are associated with the Fanconi syndrome and the conditions listed under that heading. Familial cases present with growth retardation. Patients may have symptoms of hypokalemia and reduced extracellular fluid (ECF) volume. They do not have problems with nephrolithiasis or bone disease (unless the disorder is part of a Fanconi syndrome). Urine pH may be maximally acid when plasma levels of bicarbonate are significantly reduced. Hypokalemia is usually present and worsens with sodium bicarbonate therapy. In some inherited forms, the child outgrows the disorder.

In secondary proximal RTA, treatment of the primary disorder may improve proximal tubular function; otherwise, the disorder is difficult to treat. Huge doses of sodium bicarbonate result in large urinary losses of bicarbonate and increased urinary losses of potassium. Replacement therapy should include a mixture of sodium and potassium salts (bicarbonate or citrate) at about 1 to 2 mEq/kg/day. Modest volume depletion enhances proximal reabsorption, minimizes potassium losses from distal tubule and may reduce symptoms.

TYPE IV RENAL TUBULAR ACIDOSIS

Type IV RTA is characterized by hyperkalemia and a hyperchloremic metabolic acidosis. It results from an aldosterone deficiency or an unresponsiveness of the renal tubule to aldosterone. Aldosterone stimulates the reabsorption of sodium and the secretion of potassium and H⁺ by the distal nephron. Patients with type IV RTA have either a defect in renin and aldosterone release or an alteration in the structure or function of distal tubules rendering them unresponsive to normal levels of aldosterone. A functional decrease in aldosterone activity reduces distal tubular reabsorption of sodium and reduces secretion of potassium and H⁺. Acidosis occurs because hyperkalemia inhibits ammonium production by the renal tubules and thereby reduces the buffer capacity for H⁺ in the urine.

Type IV RTA, the most common type of RTA, is often seen in patients with diabetes mellitus and mild to moderate renal insufficiency; in some patients taking nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, cyclosporine, or potassium-sparing diuretics; and in some patients with interstitial renal diseases such as systemic lupus erythematosus, obstructive uropathy, and sickle cell disease or HIV nephropathy. Patients are usually asymptomatic and the abnormality is discovered during routine laboratory studies. Laboratory findings include mild renal insufficiency and hyperkalemia. Hyperchloremic acidosis occurs in

about half of the patients. The urine pH is usually normal.

Type IV RTA usually requires no therapy if contraction of ECF volume is avoided. Volume contraction with reduced delivery of sodium and fluid to the distal tubule reduces the renal excretion of potassium and exacerbates the hyperkalemia. Some patients require discontinuation of the offending drug or addition of a potassium-wasting diuretic, such as furosemide. A few patients need mineralocorticoid replacement therapy to correct the hyperkalemia and often require supraphysiologic doses.

FANCONI SYNDROME

The Fanconi syndrome results from a generalized defect in proximal tubular function that may reduce transport rates for glucose, phosphate, amino acids, bicarbonate, uric acid and sodium. The transport of glucose, phosphate, amino acids and urate across brush-border membranes of proximal tubules is coupled to sodium transport. The Fanconi syndrome can be produced by factors which reduce the favorable sodium gradient, such as a reduction in the availability of ATP, inhibition of Na^+ , K^+ -ATPase activity, or an alteration in membrane permeability. Decreased proximal tubular reabsorption of filtered solute usually results in low serum levels and high urinary excretion rates. The magnitude of the defect varies because transport mechanisms may be incompletely inhibited, more than one transport mechanism may exist for a solute, and increased rate of distal tubular reabsorption may reduce the impact of a proximal transport defect.

Fanconi syndrome rarely occurs as a primary disorder (Table 155.2) more often it is associated with other disorders of renal tubule structure and metabolism. These include genetic diseases (cystinosis, galactosemia, fructose intolerance and some glycogen storage diseases), dysproteinemic states (multiple myeloma, amyloidosis), drugs and toxins (heavy metals, outdated tetracycline) and tubulo-interstitial diseases (Sjogren's syndrome, medullary cystic disease, Balkan nephropathy). Children with Fanconi syndrome present with growth failure, osteomalacia or rickets, and symptoms related to hypokalemia. Adults present with abnormal laboratory values. Serum levels of potassium, bicarbonate, phosphorus and uric acid are reduced and urinary excretion rates of these same solutes are increased. Bones may show evidence of osteomalacia. Plasma creatinine levels are elevated, usually as a result of renal damage from the underlying disease.

	Tubule Site	Involved Solute	Clinical Expression
Fanconi syndrome	Proximal	Phosphate, glucose, amino acid, bicarbonate	Hypophosphatemia, metabolic acidosis, bone disease
Nephrogenic diabetes insipidus	Distal	Water	Polyuria, hypernatremia
Vitamin D-resistant rickets	Proximal	Phosphate	Poor growth, bone disease
Hemiparesis	Proximal	Tryptophan, histidine	Intel, mental retardation
Bartter's syndrome	Loop of Henle	Sodium chloride	Metabolic alkalosis, hypokalemia
Renal glycosuria	Proximal	Glucose	Glycosuria without hyperglycemia

TABLE 155.2. INHERITED DEFECTS IN TUBULAR TRANSPORT

Chronic hypophosphatemia causes growth retardation and progressive bone disease, osteomalacia and pathological fractures. The associated diseases may cause tubular necrosis, interstitial inflammation and scarring, and progressive decline in all renal functions. Therapy is directed toward the underlying disease and includes providing supplements of phosphate, bicarbonate, and potassium to replace excess urinary losses. Vitamin D therapy with calcitriol may be needed to treat osteomalacia.

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus is characterized by an unresponsiveness of renal tubules to antidiuretic hormone (ADH). The action of ADH on the collecting ducts of the kidney involves binding to specific V2 receptors on the basolateral membrane, activation of adenylate cyclase and generation of intracellular cAMP, cAMP-dependent phosphorylation of membrane proteins in the cell and the insertion of the aquaporin-2 water channel into the urinary membrane. These events increase the membrane permeability to water, sodium and urea and are modified by calcium and prostaglandin E2. In the presence of ADH and an osmotic gradient, water and solutes are reabsorbed and the urine becomes more concentrated. In the absence of an ADH response, the urine leaves the kidney as dilute as it was when it entered the collecting tubule. Nephrogenic diabetes insipidus is associated with defects in the V2 receptor or with the insertion of aquaporin-2 into the membrane. Thus, patients with nephrogenic diabetes insipidus have increased volumes of urine and increased losses of water and sodium. Water losses are proportionally greater than sodium losses (as compared to plasma).

Nephrogenic diabetes insipidus has familial and acquired forms. The familial form is rare. One type of defect in the V2 receptor is carried on the X chromosome and this inherited trait is X-linked recessive. Affected males present in infancy, and incomplete forms of the disease occur in female carriers of the gene. An autosomal recessive form of nephrogenic diabetes insipidus occurs when there is a defect in the function of the aquaporin-2 water channel. Acquired forms of the disorder occur in adults or children and are most commonly associated with the therapeutic use of lithium (for manic-depressive diseases) or with hypercalcemia or hypokalemia. The acquired forms are more prevalent, but often have an incomplete expression of the defect; they are recognized only during episodes of water deprivation. The presenting symptoms are polydipsia, polyuria, and a marked impairment in the ability to form a concentrated urine. In the familial form, affected males present shortly after birth with polyuria, dehydration if fluids are withheld, unexplained fever, failure to gain weight and constipation. In the females of affected families, the disorder has a variable expression and the polydipsia and polyuria may not be sufficient to bring them to medical attention. People with acquired forms of this disorder are usually asymptomatic. The disorder presents clinically when they are stressed with a solute diuresis or can not regulate their water intake.

Laboratory findings are hypernatremia, hypertonicity and normal or elevated values of serum ADH. Glomerular filtration rates may be reduced with dehydration, but all laboratory abnormalities should return to normal with administration of adequate fluid. The X-ray examination in severely affected patients may show dilated ureters and bladder, presumably from chronic polyuria. Nephrogenic diabetes insipidus is distinguished from central diabetes insipidus and primary polydipsia with a water deprivation test. This test measures the response of the kidney (in urine osmolality) to an increase in serum osmolality and to an injection of exogenous ADH after the urine osmolality has reached a plateau. In nephrogenic diabetes insipidus, the maximum urine osmolality is reduced (>800 mOsm/mg) and the response to ADH is blunted (an increase of <50 mOsm/kg).

Therapy should be aimed at correcting any underlying disorder such as dehydration, lithium use, or an electrolyte disorder. A second approach for patients with chronic dysfunction is to induce a mild degree of volume depletion with amiloride and a thiazide diuretic. This maneuver limits the water delivery to the ADH-sensitive segments of the nephron and minimizes potassium losses. A low sodium diet may also reduce the daily urine excretion. In patients with recurring episodes of severe dehydration, renal injury and reductions in glomerular filtration rate occur over time.

HYPOPHOSPHATEMIC VITAMIN D-RESISTANT RICKETS

Hypophosphatemic vitamin D-resistant rickets results from a defect in renal phosphate transport and is characterized by hypophosphatemia and osteomalacia that are unresponsive to standard doses of vitamin D. In this disorder the maximum rate of phosphate transport by the renal proximal tubules is decreased, phosphate is lost into the urine and hypophosphatemia develops. Additionally, there is a defect in vitamin D metabolism by these same proximal tubules. Serum levels and production rates of 1,25-dihydroxy-vitamin D3 by the renal tubules are abnormally low for the degree of hypophosphatemia. The genetic basis of this abnormality is being characterized. The gastrointestinal tract has reduced rates of calcium and phosphorus absorption, but these defects respond to vitamin D treatment. The bone disease (rickets or osteomalacia) occurs because of chronic hypophosphatemia and a blunted response to metabolites of vitamin D. Parathyroid hormone excess appears to enhance the clinical manifestations of the disorder (the phosphaturia) but does not have a primary role in the pathogenesis of the disease.

Several subtypes exist. The most common type is familial, with an X-linked dominant pattern of inheritance and a frequency of about 1 in 25,000 live births. Another type, which is not familial, is associated with the presence of specific tumors, such as giant cell tumors of bone, sarcomas, hemangiomas, breast carcinoma and prostate carcinoma. Children present with rickets and short stature in the first year of life. Later skeletal changes include lateral curvature of femora and tibia. There is

no muscle weakness, tetany or convulsions which accompany vitamin D-responsive rickets. Adults have inactive rachitic deformities such as bowed legs or short stature. A few have active osteomalacia with pseudofractures, coarsened trabeculation and rarified areas of bone. Affected females have a lower incidence of bone disease than males. Hypophosphatemia is the biochemical marker of this disease. Affected individuals have increased urinary phosphate excretion. The serum calcium level is normal, but urinary calcium level is low due to poor intestinal absorption. Serum alkaline phosphatase activity is elevated and correlates roughly with the activity of bone disease. Serum levels of 1,25-dihydroxy-vitamin D₃ are in the normal range, but should be higher in the presence of hypophosphatemia. Serum parathyroid hormone levels are normal or slightly elevated.

In patients with hypophosphatemia, bone disease is present in 95% of affected males and 53% of affected females. Bone disease and growth retardation are the major concerns of patients and their families. Treatment with pharmacologic doses of vitamin D fails to correct the disease process and may produce vitamin D intoxication. Better results have been achieved with a combination of oral phosphate (1-4 g/d in divided doses) and 1,25-dihydroxy-vitamin D₃ (0.5 to 2.0 µg/d). This treatment improves hypophosphatemia, bone histomorphology and growth. This therapy may be associated with hypercalciuria, hypercalcemia and reduced renal function, so patients should be followed closely for these complications.

SELECTIVE DISORDERS OF AMINO ACID TRANSPORT

Disorders involving defects in the renal transport mechanisms for specific amino acids or groups of amino acids are inherited, usually as autosomal recessive traits. Plasma levels of the affected amino acids may be low as a consequence of decreased absorption from the intestinal tract and increased losses into the urine. Usually an adequate diet can maintain plasma levels of these amino acids near normal despite the specific transport defects, because amino acids can be absorbed by the intestine by other transport mechanisms. These disorders are rare and often have no specific clinical features. Symptoms may occur if the diet is poor or deficient in the critical amino acids. Examples of these inherited defects in amino acid transport are Hartnup disease (neutral amino acids, such as tryptophan, histidine, and methionine), iminoglycinuria (proline, hydroxyproline, and glycine), dicarboxylic amino-aciduria (aspartic and glutamic acids), and cystinuria (see [Chapter 414](#)).

BARTTER'S SYNDROME

Bartter's syndrome is a rare disorder characterized by hypokalemia, metabolic alkalosis, and hyperplasia of the juxtaglomerular apparatus (the source of renin) with hyperaldosteronism. The genetic defects appear to involve the sodium, potassium, chloride transporter in the tubules of the thick ascending limb of the loop of Henle. Hypokalemia and metabolic alkalosis are explained by increased urinary sodium losses leading to mild volume depletion, increased renin-angiotensin-aldosterone system activity, increased secretion of potassium and hydrogen ions by the distal nephron and increased reabsorption of sodium bicarbonate by the proximal nephron. Hypertension is not present. Increased release of prostaglandins (PGE₂ and prostacyclin) may oppose the hypertensive action of other hormones. Patients usually have an impaired ability to dilute urine, consistent with a defect in the thick ascending limb of the loop of Henle. There appears to be several genetic variants of Bartter's syndrome. One of these variants is now called Gitelman's syndrome. The genetic defect in Gitelman's syndrome is in the sodium chloride transporter in the distal nephron (the site of action of thiazide diuretics). This syndrome differs from the classic Bartter's syndrome in that magnesium wasting in the urine and hypomagnesemia are present, and the concentrating ability of the kidney is maintained (normal loop of Henle function).

Most cases are sporadic, but the syndromes can have a familial pattern which is transmitted usually as an autosomal recessive trait. Patients usually present in childhood with symptoms of hypokalemia such as muscle cramps, weakness, ileus, nocturia and polyuria. There is no hypertension or edema. They often have delayed growth and may have mental retardation. Presentation of the syndrome in adults is less common and may be mimicked by diuretic abuse or surreptitious vomiting. The prominent biochemical findings are described above. Additional biochemical abnormalities may include hypomagnesemia (Gitelman's syndrome), hyperuricemia and increased urinary excretion of PGE₂ (Bartter's syndrome). Renal biopsy reveals hyperplasia of the juxtaglomerular apparatus.

This syndrome must be distinguished from surreptitious vomiting or unreported diuretic abuse. The urine chloride is low (<20 mEq/L) with vomiting. Diuretic use may be detected by assays for the drug in urine. Therapy is aimed at minimizing the effects increased prostaglandin and aldosterone production. The combination of a nonsteroidal antiinflammatory drug and a potassium-sparing diuretic (e.g., spironolactone or amiloride) can raise serum potassium levels and reverse the metabolic alkalosis. The use of angiotensin-converting enzyme inhibitors can also improve the electrolyte abnormalities but produces a lower blood pressure. Most patients require oral potassium and magnesium supplements in addition to drug therapy.

RENAL GLYCOSURIA

Renal glycosuria is an isolated abnormality of glucose transport by renal tubules, in which glucose appears in the urine when plasma concentrations are normal. The clinical expression and pattern of inheritance of renal glycosuria are variable; thus, the syndrome may result from more than one defect in renal glucose transport. The disorder is asymptomatic and is detected on a routine urinalysis. The Joslin Clinic found only 94 cases of renal glycosuria in 50,000 cases evaluated for diabetes mellitus. Patients have a negative evaluation for diabetes mellitus, (i.e. normal storage and use of glucose), excrete 800 mg to several grams of glucose a day (normal people excrete <300 mg/d) in their urine, and have no other abnormality in renal function. Intestinal transport of glucose is usually normal. These patients have the disorder for many years without developing other signs of renal or metabolic disease.

CHAPTER 156: RENAL CYSTS AND CYSTIC DISEASES

WILLIAM D. KAEHNY

[Simple Renal Cysts](#)
[Autosomal Dominant Polycystic Kidney Disease](#)
[Medullary Sponge Kidney](#)
[Medullary Cystic Disease](#)
[Acquired Renal Cystic Disease](#)
[Other Renal Cystic Diseases](#)

The advent of sensitive and minimally invasive imaging techniques presented clinicians with the problem of managing largely asymptomatic renal cysts. More recently, molecular biology has provided the potential for presymptomatic diagnosis of autosomal dominant polycystic kidney disease (ADPKD), the most common inherited disease in the United States. Thus, the well-prepared internist will be familiar with the more common causes and effects of these fluid-filled sacs lined by epithelium and located within renal parenchyma. All cysts probably arise as dilatations or diverticuli of renal tubules. Some are connected, such as early (small) cysts in ADPKD and the ectatic tubular cysts of medullary sponge kidneys. Most become disconnected as they enlarge, as do simple cysts and larger ADPKD cysts.

SIMPLE RENAL CYSTS

Simple renal cysts develop with aging and can be detected in one-third of persons aged 60 years and older. The incidence is low in persons younger than 40 years of age, although simple cysts do occur rarely in infants and children. Simple cysts may be single or multiple, and enlarge with time. Most simple cysts are asymptomatic and are detected fortuitously. Occasionally, the cysts may cause abdominal masses, abdominal or back pain from bleeding, sepsis from infection (uncommon), and (even more uncommonly) erythrocytosis or hypertension (case reports).

More commonly, the clinician must decide whether single or multiple cysts are simple or are due to renal cell carcinoma, ADPKD, or other disorders. This problem is statistically small but highly important for the individual patient. Single cysts with smooth walls by ultrasonography require no further evaluation. Simple cysts are present in up to 3% of kidneys containing renal cell carcinoma, but renal cell carcinoma occurs rarely (less than 0.1%) in the walls of simple cysts. Perhaps 15% of renal cell carcinomas are cystic. Thick and irregular cyst walls and cyst fluid abnormalities allow diagnosis in almost all instances. Multiple simple cysts cannot be distinguished from the cysts of ADPKD by appearance and location. The presence of multiple but not many (about five) cysts in a 70-year-old asymptomatic patient with a family history of ADPKD is not likely to be ADPKD, whereas this presentation is highly likely to be ADPKD in a 20-year-old. Time is the best diagnostic tool in most cases.

Treatment is rarely needed. Infection of a cyst, pain, or hypertension may be alleviated by cyst puncture, drainage, and instillation of antibiotics or sclerosing agents. If the unlikely prospect of renal cell carcinoma is suspected, surgical exploration is required.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Autosomal dominant polycystic kidney disease is a hereditary disease that occurs in 1 in 200 to 1,000 of the world's population. The more common type (ADPKD1) appears to be caused by an abnormal gene on the short arm of chromosome 16. A second type (ADPKD2; 10%) is related to a gene on the long arm of chromosome 4. A third genotype is proposed. ADPKD may be found in fetuses, infants, children, and adults. ADPKD causes advanced renal failure in about 50% of affected persons, thus accounting for about 10% of cases of end-stage renal failure.
