In the case of *S. minus*, the major route of transmission is through rat bites. In contrast to *S. moniliformis*, oral ingestion has never been shown to transmit *S. minus* infection. In endemic areas of Asia, approximately 25% of tested rats are positive for *S. minus* in nasopharyngeal and conjunctival secretions, pulmonary lesions, and blood.

ETIOLOGY

S. moniliformis is a pleomorphic, nonmotile, nonsporulating, nonencapsulated gram-negative bacillus. Filaments and beadlike chains may contain fusiform swellings. The organism is microaerophilic, requiring a partial pressure of CO₂ between 8% and 10%. On blood agar small cottonlike colonies appear after approximately 3 days of incubation at 37° C. In broth media, flocculent puffs are seen at the bottom of the broth after 2 to 10 days. Fatty acid analysis by gas liquid chromatography is useful for rapid identification of *S. moniliformis*.

In contrast, the other agent of rat-bite fever, *S. minus*, is a short, thick, gram-negative, tightly coiled spiral rod. Terminal flagella confer darting motility, visible on darkfield examination. The organism cannot be cultured on artificial media, but can be recovered through xenodiagnosis (see [Laboratory Findings](#)).

PATHOGENESIS AND PATHOLOGY

Streptobacillary rat-bite fever is probably the consequence of failed local cutaneous defenses followed by bacterial dissemination. Autopsy reports describe focal mononuclear infiltrates. For the ingestion-induced form of the infection, Haverhill fever, organisms probably gain access to peripheral blood by penetrating gastrointestinal mucosa.

Relapsing spirillary rat-bite fever is postulated to be due to seeding of blood and distant foci during periodic reactivation of the primary bite lesion. Autopsy specimens show granulomatous inflammation at the original site of inoculation, accompanied by epithelial necrosis and mononuclear infiltration of the dermis. Regional lymph nodes are hyperplastic. Distant skin rash lesions contain dilated blood vessels and round cell infiltrates, whereas liver and kidney show hemorrhage and necrosis.

CLINICAL FINDINGS

The two forms of rat-bite fever share certain common clinical features but also possess their own distinctive signatures ([Table 293.1](#)). In streptobacillary infection, a brief incubation period follows the bite of the rat (usually less than 10 days; range 1 to 22 days). Abrupt onset of fever, chills, headache, vomiting, and migratory arthralgias and myalgias marks the onset of clinical disease. By that time, the wound itself has typically already healed. Indeed, the diagnosis is often initially missed because the patient may be unaware of a bite that occurred during sleep. Regional lymphadenopathy is minimal or absent. Within 2 to 4 days after the onset of fever, a nonpruritic maculopapular, morbilliform, petechial, or pustular rash erupts over the palms, soles, and extremities. Approximately 50% of patients develop asymmetric large-joint polyarthritis or true septic arthritis simultaneously with the rash or within a few days thereafter.

Haverhill fever differs from percutaneously acquired disease in the high incidence of pharyngitis and heightened severity of vomiting. The peripheral white blood cell count may range as high as 30,000/mm³ with left shift. Fever typically subsides spontaneously after 3 to 5 days without specific antibiotic therapy, and the remaining symptoms gradually resolve within 2 weeks. However, fever may occasionally relapse in an irregular pattern for weeks or months, producing a picture of fever of undetermined origin. Arthritis may persist for as long as 2 years.

Complications of *S. moniliformis* infection include endocarditis, myocarditis, pericarditis, meningitis, pneumonia, and amnionitis. Mortality of untreated cases ranges as high as 13%, and endocarditis in the preantibiotic era was uniformly fatal. Most of those intravascular infections occurred on valves with underlying lesions such as rheumatic valvulitis or calcification.

In *S. minus* infection, the initial bite wound promptly heals but then becomes painful, swollen, and purple approximately 1 to 4 weeks later. In contrast to streptobacillary disease, the bite wound is associated with prominent regional lymphangitis and lymphadenitis. The local inflammatory response heralds a systemic

illness characterized by fever, chills, headache, and malaise. In contrast to streptobacillary rat-bite fever, arthritis and myalgias are rare in *S. minus* infection.

Next, the bite wound of *S. minus* infection commonly progresses to chancre-like ulceration and induration with eschar formation. During the first week of fever, a diffuse violaceous or reddish-brown macular rash erupts. Leukocytosis is common, with peripheral white blood cell counts of 10,000 to 20,000/mm³. Without specific antimicrobial therapy, fever lasts 3 to 4 days and recurs at regular intervals between afebrile periods of 3 to 9 days. Spontaneous resolution usually occurs within 1 to 2 months, but rarely leads to relapsing fever for years. Complications are similar to those of streptobacillary rat-bite fever, and mortality of untreated *S. minus* infection in the preantibiotic era was 6% to 10%.

LABORATORY FINDINGS

For *S. moniliformis* infection, direct visualization of pleomorphic bacillary organisms in Giemsa-, Wayson-, or gram-stained smears of blood, joint fluid, or pus may provide an early clue to diagnosis. However, laboratory diagnosis ultimately is based on culturing *S. moniliformis* using enriched media. The slide agglutination test is no longer available, but an enzyme-linked immunosorbent assay (ELISA) has recently been developed for detection of specific antibody against *S. moniliformis*.

S. minus cannot be grown on synthetic media, so initial diagnosis relies on direct visualization of spirochetes in blood, exudate, or lymph node tissue using Giemsa or Wright's stain or darkfield microscopy. Organisms can also be recovered from mice or guinea pigs 1 to 3 weeks after intraperitoneal inoculation, with the precaution that the animals must be prescreened to exclude preexisting spirochete infection. No specific serologic test is available for *S. minus* infection. Given the similarities between rat-bite fever and secondary syphilis, the clinician needs to be mindful of false-positive serologies for syphilis among those with rat-bite fever (25% to 50%).

OPTIMAL MANAGEMENT

Both agents of rat-bite fever are susceptible to penicillin. In the past, procaine penicillin G was given as 600,000 units intramuscularly every 12 hours for 10 to 14 days. Currently, intravenous penicillin G appears more appropriate. The Jarisch–Herxheimer reaction may complicate initial therapy of *S. minus* infection. Oral tetracycline, 500 mg every 6 hours, is preferred for penicillin-allergic patients.

Most patients respond promptly to therapy. For persons who appear well after 5 to 7 days of intravenous penicillin, therapy can be completed with an additional week of oral penicillin V or ampicillin, 500 mg every 6 hours. Patients with mild disease can probably be treated orally for the entire course. Endocarditis is so rare that optimal therapy is uncertain, but 4 weeks of intravenous penicillin, with or without streptomycin, is probably adequate.

After a rodent bite, the wound should be thoroughly cleaned, and tetanus prophylaxis should be administered if warranted by the patient's immunization history. A 3-day course of oral penicillin, 2 g per day, seems reasonable. However, the prophylactic efficacy of penicillin in this setting is unknown, and the patient should be advised to report any subsequent symptoms. Measures to limit the incidence of rat-bite fever include eradication of rats, avoidance of nonpasteurized milk and potentially contaminated water, and the use of gloves by laboratory workers when handling rodents.

DEFINITION

Tuberculosis (TB) has been recognized in its various forms for thousands of years. Descriptions of TB date back to the first millennium B.C. in medical texts from Greece to India. The Greeks named the malady *phthisis*, which means “to waste.” In the English-speaking world, *consumption* was the common name given the disease. It was during the Middle Ages, when TB became common in Europe, that it became known as the *white plague*. Other manifestations were described, including the rapid lung destruction of galloping consumption and the skin manifestations of lupus vulgaris. Percival Pott's description of TB of the spine resulted in the application of his name to this form of TB. With its varied manifestations, TB was considered to represent many different diseases. It was not until 1804 that Rene Laennec proposed his theory of a unified view of the various manifestations of this disease. In 1839, Schönlein proposed that the pathologic entity known as the *tubercle* was the fundamental basis of the disease and suggested that the word *tuberculosis* be used as a generic name for all its varied manifestations. In 1882, Robert Koch discovered that the causative agents of TB were the organisms of the *Mycobacterium tuberculosis* complex.

INCIDENCE AND EPIDEMIOLOGY

Two billion people (one-third of the world population) are infected with *M. tuberculosis*. In 1997, nearly 6 million cases of active TB worldwide were reported to the World Health Organization. Twenty-two countries in Asia and Africa account for more than 70% of these reported cases of TB. The number of reported cases of TB probably is an underestimate of the true number of cases in the world because many developing countries lack resources for TB control and public health programs. One of the highest estimated case rates (467 per 100,000 population) worldwide occurs in Africa, where TB is the most common opportunistic infection among persons with HIV infection.

In the United States, TB case rates steadily declined from the beginning of national TB surveillance in 1953 until 1985. During this time, national case rates decreased from 53.0 to 9.3 per 100,000 population. From 1985 to 1992, a resurgence of TB occurred, resulting in a 20% increase in cases nationwide ([Fig. 294.1](#)). This increase was attributable to the following factors: (a) the emergence of both drug resistance and the HIV epidemic, (b) increased immigration of persons from countries with a high prevalence of TB, (c) increased transmission in congregate settings, and (d) decreases in resources available to TB control programs. The development of complacency about TB during the previous period of decline in national case rates in conjunction with a lack of clinical expertise in management of the disease resulted in a deterioration in TB control programs and diagnostic suspicion of the disease.

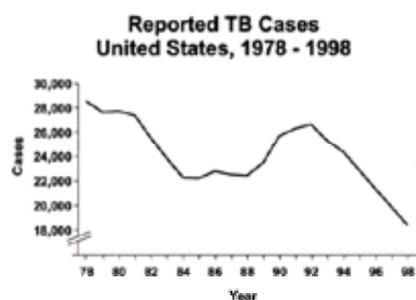

FIGURE 294.1. Reported cases of tuberculosis in the United States, 1978–1998.

In 1993 the number of cases of TB in the United States began to decline and has continued to decrease approximately 7% per year. This decline was attributable to three major changes, as follows: (a) decreased transmission in hospitals and correctional facilities, (b) implementation of directly observed therapy (DOT) nationwide, and (c) improvement in TB control efforts such as case finding, contact investigation, and administration of preventive therapy. In 1998 there were 18,361 cases (case rate 6.8 per 100,000) which represented a decrease of 1,480 (7%) cases compared from the previous year.

Six states of the United States share a disproportionate burden of cases of TB. More than 56% of cases are reported from California, Florida, Illinois, New Jersey, New York, and Texas. National surveillance of TB morbidity has consistently demonstrated that the burden of TB in the United States exists disproportionately among members of racial and ethnic minorities and tends to cluster in urban areas. Since 1985, case rates for persons of Asian and Pacific Island descent, blacks, and Hispanics have been as high as 15, 7, and 6 times higher, respectively, than case rates among whites born in the United States ([Table 294.1](#)). Although case rates for these racial and ethnic groups have declined simultaneously with national case rates, this trend of disproportionately higher case rates has remained undisturbed. TB among persons born outside the United States accounted for 42% of U.S. reported cases in 1998. Overall, the steady and appreciable decreases in TB case rates in other ethnic groups since 1993 are not paralleled among persons born outside the United States. Case rates for this group have remained two to three times higher than those for all persons born in the United States.

Race, Ethnicity	Rate ^a			Percentage Change	
	1985	1992	1997	1985 vs 1992	1992 vs 1997
Non-Hispanic white	45	40	25	-11.1	-37.5
Non-Hispanic black	250	217	205	+30.0	-36.3
Hispanic ^b	21.4	22.4	18.4	+4.7	-25.7
Asian, Pacific Islander	41.6	46.6	46.6	+12.0	-12.0

TABLE 294.1. REPORTED RATES OF TUBERCULOSIS BY RACE AND ETHNICITY—UNITED STATES, 1985, 1992, 1997

The HIV epidemic had considerable bearing on the resurgence of TB. Reporting of HIV status for persons with TB has been sporadic and incomplete since 1993, when TB was first included as an AIDS-defining illness. Attempts to cross-match TB and HIV registries have shown that less than 15% of persons with reported cases of TB also have HIV infection. The incomplete reporting of HIV test results limits the evaluation of temporal trends in HIV-related TB, and current data likely represent

a gross underestimation of the number of persons with both TB and HIV disease. It is clear that the timing of the increase in cases of TB in the United States (1983–1992) coincided with the onset of the AIDS epidemic. Epidemiologic similarities between the two epidemics suggest that the number of coinfecting persons is much higher. For instance, the largest increase in cases of TB between 1985 and 1992 occurred among persons 25 to 44 years of age, the same group who had the largest number of AIDS cases in the same years. Overlapping demographic data suggest a link among the two diseases. The geographic distributions of the two epidemics were similar; most cases of both diseases were reported from large urban areas in New York, California, Florida, and Texas.

The resurgence of TB in the United States was accompanied by an increase in the number of cases of multidrug-resistant tuberculosis (MDRTB). Primary drug-resistant TB is disease caused by infection with a drug-resistant strain of *M. tuberculosis*. Secondary, or acquired, drug resistance results from the development of resistance during therapy for disease. MDRTB has no standard definition. Some clinicians define multidrug resistance as resistance to any two or more of the five first-line antibiotics used for TB treatment (isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide). Others have defined it as resistance to at least isoniazid and rifampin because these two antibiotics have been shown to be the most potent anti-TB agents. Resistance to these two drugs greatly complicates the treatment of patients with TB and their contacts.

The increase in cases of MDRTB in the United States was caused in part by inappropriate, incomplete, or erratic management of active disease and several outbreaks of MDRTB related to poor infection control measures in health care settings and transmission in congregate settings, such as shelters for the homeless and prisons. In 1998, however, only 1.1% of all reported culture-positive cases of TB were resistant to isoniazid and rifampin. Approximately 50% of these cases were reported in California and New York.

ETIOLOGY

The *M. tuberculosis* complex belongs to the family Mycobacteriaceae and includes the subspecies *M. tuberculosis*, *M. africanum*, *M. bovis*, *M. canettii*, and *M. microti*. These bacilli are genetically similar but can be differentiated through biochemical analysis. *M. bovis* is primarily a pathogen of ruminants and may cause disease among humans that is clinically indistinguishable from TB. *M. africanum* is most commonly found in Africa, *M. microti* is a pathogen of rodents, and *M. canettii* is a newly described variant of *M. tuberculosis* that has been isolated from several patients who acquired infection in Africa.

The diagnosis of TB begins with stains performed on clinical specimens to find acid-fast bacilli (AFB). Detection of AFB requires approximately 10^4 colony-forming units (CFU) per milliliter of specimen with both the classic carbolfuchsin stains (Kinyoun and Ziehl–Neelsen) and the fluorochrome stains (auramine or auramine–rhodamine). AFB staining is not particularly sensitive or species specific, but it is rapid and inexpensive. Fluorochrome stains are more sensitive because they are easier to read. In many parts of the world the laboratory diagnosis of TB relies solely on AFB microscopic examination.

M. tuberculosis may be grown on specialized solid or liquid media. Solid media components include an egg base, such as Löwenstein–Jensen or agar base, such as Middlebrook 7H10 or 7H11. Use of liquid media systems has been shown to decrease the time to the detection of growth. It is recommended that liquid media systems be used for routine mycobacterial cultures. Compared with other bacteria, mycobacteria grow slowly; it usually takes 2 to 8 weeks to detect them.

DNA probes can be used to detect four species of mycobacteria (*M. tuberculosis* complex, *M. avium* complex, *M. kansasii*, and *M. gordonae*). When these DNA probes are used, subspecies may be identified in isolates within hours through the detection of species-specific messenger RNA. Nucleic acid amplification tests can be used to identify *M. tuberculosis* organisms directly from smear-positive sputum specimens. Because of the high cost and lack of sensitivity of smear-negative specimens, the practical applications of nucleic acid amplification tests are unclear. High-performance liquid chromatography (HPLC) also can be used for rapid identification. An advantage of this method over DNA probes and nucleic acid amplification tests is that many subspecies of mycobacteria can be identified with HPLC, whereas molecular diagnostics are limited to the small number of species for which DNA probes and primers have been identified and included in commercial kits.

Susceptibility testing against the primary anti-TB drugs is recommended for the initial isolate from all culture-positive cases of TB in the United States. Susceptibility testing should be repeated when clinical response to treatment is delayed or if patients have a relapse. Drug resistance is tested in the United States with the liquid medium BACTEC and the modified agar proportion method. In the modified agar proportion method, suspensions of *M. tuberculosis* bacilli are inoculated onto drug-containing solid media plates and a drug-free control plate. The number of colonies is counted for all plates, and the proportion of resistant bacilli are calculated by means of comparing the growth on the drug-containing media with the growth on the drug-free control media. Susceptibility testing takes 1 to 4 weeks.

Despite laboratory advances, complete testing, including detection, isolation, identification, and drug susceptibility, for *M. tuberculosis* is long process, requiring weeks and sometimes months. In any of these tests, new or old, contamination from environmental mycobacteria or direct contamination from other specimens in the laboratory may lead to false-positive results. The diagnosis of TB must be made carefully with both clinical and laboratory information.

PATHOGENESIS

TRANSMISSION

M. tuberculosis is transmitted through the air in the form of very small (1 to 3 μ m) infectious particles, called *droplet nuclei*, which are expelled in the cough of a person with pulmonary or laryngeal TB. Two reported exceptions are prospector's wart caused by skin inoculation from contaminated sharp instruments and person-to-person transmission through contaminated bronchoscopes. The risk of transmission from an infected source person to a susceptible host is associated with the potential concentration of viable bacilli in an airspace. The risk of transmission from an infected source patient is low outdoors, where there is much exchange and essentially infinite dilution, or in spaces fitted and maintained with specialized ultraviolet light fixtures. The risk of transmission is greater in spaces lacking air volume, fresh air, and natural or ultraviolet light.

INFECTION AND DISEASE

Droplet nuclei are small enough to remain suspended in air currents and are able to bypass the natural filtering of larger particles in the upper respiratory tract. Once inhaled, the droplet nuclei may lodge in the alveoli of the lung to establish infection. Among approximately 5% of persons infected, bacilli may multiply locally over weeks to months to cause hilar or peritracheal lymph node enlargement or lobar pneumonia (usually in the middle or lower lobes) or incite a serosal reaction and pleural effusion. These events constitute primary TB. Most patients show no signs of infection other than development of delayed-type hypersensitivity to tuberculin proteins. The infection includes invasion of alveolar macrophages within which *M. tuberculosis* can survive and disseminate throughout the body. In response, macrophages containing bacilli may combine to form swirls of multinucleated giant cells in a stroma of fibrous inflammatory tissue, the hallmark of a tuberculous granuloma, or tubercle. Over a period of years, granulomas may become relatively large and calcified and become manifest on chest radiographs as small densities in the upper lung fields, apical pleura, and hilar lymph nodes.

If disease does not develop soon after infection, a relative equilibrium is established between host and pathogen. With the exception of immunocompromised persons, those who have been infected with *M. tuberculosis* are thought to be protected from reinfection. However, infection may progress to active disease over time. Factors that influence progression from infection to disease usually are host related and include extremes of age and immunocompromising medical conditions such as HIV infection ([Table 294.2](#)). Among immunocompetent persons, the risk of development of active disease after infection with *M. tuberculosis* is thought to be 10% over a lifetime. In contrast, three prospective studies in the United States showed that the rate of development of active disease among persons with HIV infection and *M. tuberculosis* infection ranged from 1.7% to 7.9% per year.

HIV infection
 Diabetes mellitus
 Prolonged corticosteroid use
 Chronic renal failure
 Bone marrow transplantation, organ transplantation
 Malnutrition
 Hematologic disorders (leukemia, lymphoma)
 Silicosis
 Gastrectomy
 Jejunioileal bypass
 Old, healed tuberculosis lesions on chest radiograph without history of appropriate therapy
 Some forms of cancer chemotherapy

TABLE 294.2. HIGH-RISK CATEGORIES FOR TUBERCULOSIS

For a small portion of patients with latent infection, the infection reactivates after any number of years. Because lymphohematogenous dissemination takes place around the time of initial infection, reactivation can take place in almost any tissue. Certain locations are much more prone to reactivation, primarily the lung parenchyma (Fig. 294.2). Reactivation occurs in a granulomatous focus in the lung, often in the apical regions, in which caseation and local spread produce pneumonia. Large caseous foci may produce visible cavities in the lung parenchyma. Over several years, these foci may destroy lung tissue to such an extent as to induce pulmonary failure. Reactivation disease manifests much more commonly than primary disease.

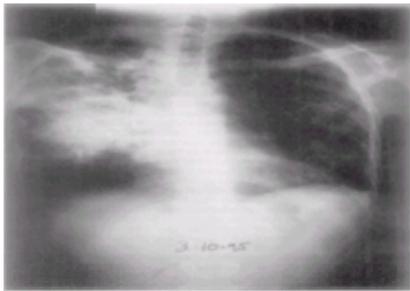

FIGURE 294.2. Radiograph of the chest shows signs of reactivation tuberculosis.

INFECTIOUSNESS OF TUBERCULOSIS

Latent *M. tuberculosis* infection is not contagious. Pulmonary and laryngeal TB are the only active forms of TB considered contagious. The best predictors of infectiousness are the number of bacilli in the pulmonary secretions and the presence and frequency of coughing. The extent of pulmonary disease is based on the presence on a chest radiograph of signs of tuberculous infiltrates and cavities in the lung parenchyma. The number of bacilli in the pulmonary secretions is most easily determined by means of microscopic examination of sputum for AFB. Most clinical laboratories quantify the AFB in sputum specimens in three or four categories, such as rare, few, or many. This system may be used to ascertain whether a patient with pulmonary TB has contagious disease. At least 10^4 AFB per milliliter of sputum must be present for detection of AFB by means of microscopic examination. However, patients with fewer bacilli in their sputum may still have contagious disease even though they have negative smear results.

Current clinical dogma is that 2 weeks of appropriate anti-TB therapy renders patients noncontagious. However, the time needed to eliminate AFB from sputum, as determined with microscopic examination, varies greatly. For patients with extensive cavitory disease and a heavy burden of bacilli in the sputum or for patients with drug-resistant disease, conversion of sputum from AFB-positive to AFB-negative may take several months. For a patient with extensive cavitory disease and a florid positive smear result, it is possible that subsequent positive smears may contain nonviable organisms. Whether a patient undergoing therapy for TB has contagious disease has to be individually assessed on the basis of symptoms, especially coughing, AFB microscopic findings, and culture results.

CLINICAL FINDINGS

Tuberculosis can become manifest as pulmonary or extrapulmonary disease. Pulmonary TB constitutes 80% to 85% of active cases; the other 15% to 20% of cases are extrapulmonary. Concomitant pulmonary and extrapulmonary disease occurs in approximately 7% of cases, and miliary TB accounts for about 0.2% of cases. The diagnosis of TB can be elusive because TB can masquerade as many pulmonary illnesses, including bacterial or viral pneumonia, interstitial lung disease, and neoplasia. A thorough medical history and physical examination are essential to obtain pertinent information regarding the likelihood of infection and disease. Other important elements of an evaluation for TB include a Mantoux tuberculin skin test (TST), the result of which is positive among 85% to 90% of immunocompetent patients with pulmonary TB, chest radiography, and AFB smears and cultures. It is important to obtain accurate information about past medical illnesses and about immunocompromising medications, which may place persons in high risk categories (Table 294.2). Information about exposure to persons with active cases of TB or past treatment of infection and disease assists in determining risk of active TB.

PULMONARY DISEASE

Patients with pulmonary TB exhibit a wide range of signs and symptoms, including cough with or without sputum production, fever, night sweats, and weight loss. Other symptoms include pleuritic chest pain, dyspnea, hemoptysis, fatigue, and anorexia. Ten percent to 20% of persons with active TB, particularly persons with early cases and elderly persons, may have no symptoms. TB often is an indolent illness, and symptoms may take several weeks to appear; therefore it is not uncommon for patients to come to medical attention with advanced disease.

Cough is the most prominent symptom of TB, particularly for the immunocompetent patients, although it may go unrecognized by patients with a history of chronic lung disease such as bronchitis or chronic obstructive pulmonary disease. Fever and night sweats occur among as many as 50% of patients. Considerable weight loss accompanies chronic illness and is a late manifestation of disease. Hemoptysis also is a prominent feature of pulmonary disease and usually accompanies advanced disease. Rasmussen's aneurysm is an uncommon source of massive hemoptysis and is caused by erosion of the pulmonary artery by intrusion of an expanding tuberculous cavity.

Physical examination findings are nonspecific and vary with stage of disease. In early disease the physical examination findings may be normal. Later notable symptoms include rales, rhonchi, or signs of consolidation, such as tubular breath sounds or vocal and tactile fremitus. In considerably advanced disease, wasting may be present.

EXTRAPULMONARY DISEASE

Extrapulmonary TB generally is a consequence of lymphohematogenous dissemination of *M. tuberculosis* during primary infection. Persons with immunosuppressive illnesses are more likely to have extrapulmonary TB. The most common forms of extrapulmonary TB are lymphatic (41%), pleural (21%), bone and joint (11%), genitourinary (7%), meningeal (5%), and peritoneal (4%). Other sites account for 11% of cases. Manifestations in extrapulmonary disease vary according to the presence of local (lymphatic) versus systemic (miliary) disease. Symptoms of local disease generally are limited to the affected site. Symptoms of systemic disease are nonspecific and often are only constitutional symptoms such as fever, anorexia, and weight loss.

Lymphadenitis associated with TB (scrofula) is the most common form of extrapulmonary disease. Any node may be involved, but cervical and supraclavicular chains are most frequently affected. Patients come to medical attention with painless adenopathy, which often drains spontaneously. In early disease, nodes may be firm and discrete. In late disease, nodes may become soft and fluctuant. With the exception of fever, there usually are no systemic symptoms unless disease is present elsewhere. Diagnosis is by means of fine-needle aspiration or incisional biopsy of the affected node. AFB smears and cultures of nodal tissue usually show AFB and *M. tuberculosis* organisms.

Pleural disease usually becomes manifest with mild to severe pleuritic chest pain, which may be accompanied by dyspnea. Other constitutional symptoms include fever, night sweats, and weight loss. Disease may be acute or chronic and often causes a subtle effusion. Effusions generally are unilateral and accompany active parenchymal disease in 70% of patients. Pleural TB may develop at any stage of disease but frequently occurs as a primary disease manifestation and may occur as long as 6 months after infection with *M. tuberculosis*.

Vertebral TB (Pott's disease) accounts for 50% to 70% of skeletal TB. It is characterized by kyphosis and spinal-cord compression, so patients may have neurologic or motor symptoms. The lower thoracic and upper lumbar vertebrae are the most common sites of disease. Patients typically have a history of 2 weeks to 3 months of back pain, fever, and weight loss. Paravertebral abscesses occur among 50% of patients. Patients with Pott's disease usually have radiographic evidence of spinal involvement, and 50% of patients have radiographic evidence of either active or old pulmonary TB. Diagnosis requires biopsy and culture of infected bone. Tuberculous arthritis characteristically manifests as an indolent monoarticular arthritis of weight-bearing joints (knees, hips, ankles). Pain is the most common symptom, and swelling with decreased range of motion in the involved joint may be present. Infection is preceded by trauma in 25% of cases. Biopsy of synovial tissue may contain granuloma, and culture results are positive for *M. tuberculosis* 60% to 75% of the time.

Genitourinary TB is indolent. It can produce signs and symptoms of local infection with few systemic manifestations, or disease may be completely asymptomatic. Urinary tract involvement typically causes dysuria, urinary frequency, and gross hematuria with or without flank pain. Disease among women may cause pelvic pain, menstrual irregularities, and infertility. Men may have a painless scrotal mass. One-fifth of patients with pyuria may have no symptoms. Disease is suspected when urinalysis shows white blood cells and hematuria without bacteria. The diagnosis is confirmed with a urine culture. Urine culture results are negative for the usual bacteria (sterile pyuria) and positive for *M. tuberculosis*. The diagnostic yield is greatest from early morning specimens. Three specimens should be submitted for culture. Findings at intravenous pyelography usually are nonspecific and often are unhelpful. Given the paucity of symptoms and its indolence, renal TB often is advanced at the time of diagnosis. Two-thirds of patients with genitourinary TB have abnormal chest radiographs that show signs of active or old pulmonary disease.

Tuberculous meningitis is caused by hematogenous spread of mycobacterial organisms into the meningeal space. This process may occur weeks to years after infection, and the presentation of central nervous system (CNS) TB may be acute or subacute. Disease may manifest clinically as bacterial meningitis. Acute symptoms may include headache, fever, or change in mental status. Other symptoms may last for weeks to months; these include fever, weight loss, anorexia, night sweats, malaise, and cranial nerve palsies. Sixth-nerve nerve palsy is the hallmark of CNS TB, but cranial nerves II, III, IV, and VII also may be affected. Examination may reveal meningism and papilledema. CNS TB may progress in three distinct stages. Stage 1 is characterized by nonspecific symptoms with few or no clinical signs of meningitis. Stage 2 denotes the development of signs of meningitis such as meningism, lethargy, and cranial nerve palsies. Stage 3 portends coma and neurologic sequelae such as paralysis. The diagnosis often is made on clinical grounds and is based on the presence of risk factors of TB, TST results, and chest radiography. Patients with CNS TB often have a gratifying response to TB treatment if therapy is initiated expeditiously (before stage 3). This alone may be adequate for diagnosis when clinical suspicion is high and results of laboratory studies are not enough to provide a diagnosis.

Miliary TB, an insidious and clinically elusive form of disease, develops after hematogenous dissemination of tubercle bacilli. This dissemination produces a miliary pattern (so named because it resembles millet seeds 2 mm in diameter) on chest radiographs or in biopsy specimens from the bone marrow, liver, or spleen. Miliary disease usually occurs among high-risk groups, including persons with HIV infection or other immunosuppressive illnesses, connective tissue disease, or hematologic neoplasms, persons who abuse alcohol, and those taking immunosuppressive medications, including high doses of steroids. Patients may have a mild illness for several weeks or months before seeking medical attention. Fever is the most prominent symptom of miliary disease, but many patients report nonspecific symptoms such as weakness, anorexia, weight loss, and night sweats. The physical examination is nonfocal. The diagnosis of miliary TB is made on the basis of clinical history, presence of a miliary pattern on a chest radiograph, and a positive culture results for *M. tuberculosis* from blood or a biopsy site such as the liver or bone marrow. The TST is an insensitive indicator of prior *M. tuberculosis* infection among persons with miliary disease; results have been reported to be positive in 25% to 75% of cases. In cases in which a laboratory diagnosis is difficult, monitoring the clinical response to anti-TB therapy may be helpful. Fever abates among 30% of patients within 2 weeks and among 60% to 70% of patients within 4 weeks.

Peritoneal TB is uncommon and often presents a diagnostic dilemma. The pathogenesis is not clearly understood, but the disease is thought to develop after hematogenous seeding, as in other forms of extrapulmonary disease. Symptoms vary from patient to patient but most commonly include abdominal pain and distention, fever, weight loss, and malaise. Symptoms may become chronic, and disease may progress to ascites or abdominal masses, which are probably amassed omentum, mesentery, and bowel, which are responsible for the classic doughy abdomen found at physical examination. As many as 30% of patients may have pleural effusions.

Pericardial TB is an uncommon form of disease and carries considerable morbidity and mortality. The diagnosis may be extremely difficult because patients may have no evidence of disease at other sites. Localization of disease is caused by erosion of a mediastinal lymph node, which spreads directly into the pericardial sac. Symptoms include chest pain, cough, weight loss, dyspnea, orthopnea, ankle edema, and night sweats. Patients often seek medical attention because of symptoms of pericarditis such as relief of pain when they lean forward. Signs of disease include fever, cardiomegaly, hepatomegaly, jugular venous distention, and muffled heart tones. Electrocardiographic findings may be those of pericardial effusion or early tamponade (tachycardia, ST depression, low voltage). Management generally consists of anti-TB therapy with or without drainage in conjunction with parenteral administration of steroids, which may decrease the risk of long-term sequelae such as constrictive pericarditis.

LABORATORY FINDINGS

A posterior-anterior radiograph of the chest is imperative for evaluation of pulmonary TB. TB may have various manifestations on a chest radiograph, but the hallmark of pulmonary disease is an infiltrate with cavitation, mainly in the apical region ([Fig. 294.2](#)). Cavitation has been reported to occur in 19% to 50% of cases of reactivation of TB. Other findings include lymphadenopathy, lobar infiltrates, and interstitial infiltrates. The diagnosis of TB should not be eliminated on the basis of the radiographic location or appearance of infiltrates, because patients, especially those with HIV infection, may have atypical infiltrates or minimal radiographic findings. Computed tomography may be used to evaluate the extent of disease, but in general, unless occult disease is suspected, it is not helpful in the initial evaluation for TB. Chest radiography also is useful for identifying effusions in pleural disease. In pericardial disease, chest radiography usually shows cardiomegaly with or without a left-sided pleural effusion.

Laboratory abnormalities in pulmonary disease may include leukocytosis or leukopenia (either lymphocytic or neutrophilic), normochromic, normocytic anemia (usually with disseminated infection or long-term disease), or in rare instances hyponatremia due to extensive lung disease or concomitant CNS involvement. These laboratory abnormalities may be present in extrapulmonary disease but are much less common than in pulmonary disease.

Fluid chemical analysis is useful for some extrapulmonary sites such as the peritoneum, pleura, and pericardium. Effusions from these sites may be bloody or nonbloody lymphocytic exudates. Fluid glucose level usually is decreased but may be normal, and the protein is elevated. Smears, cultures, and biopsy specimens from peritoneal, pleural, and pericardial sites are necessary for diagnosis. The diagnostic yield of collective AFB smear, culture, and biopsy for these sites is 65%, 75% and 85%, respectively.

In CNS disease, laboratory findings in subacute and acute disease may reveal neutrophilic or lymphocytic predominance in the CSF with normal or low glucose and elevated protein. The diagnostic yield from CSF smear and culture is disappointingly low (15% and 50%, respectively). Polymerase chain reaction may be useful for detecting *M. tuberculosis* in the cerebrospinal fluid; however, this technique is expensive and is not standardized. Although imaging studies may reveal areas of enhancement, infarction, or hydrocephalus in CNS TB, these findings are not specific for TB and offer little diagnostic utility.

In miliary disease, blood cultures obtained with lysis centrifugation techniques often have been the initial means of diagnosis among persons with HIV infection. Such cultures also may be helpful in the diagnosis of miliary disease among immunocompetent persons. Yield from sputum specimens is less gratifying than in pulmonary TB; the results may be positive in only 50% to 60% of cases. Given this, biopsy specimens from alternative sites such as bone marrow, liver, lymph nodes, or lung should be examined for evidence of granuloma formation. Liver biopsy has been the most successful procedure in yielding a diagnosis. Classic chest radiographic

findings may lag 2 to 3 weeks behind early clinical presentation.

STRATEGIES FOR OPTIMAL CARE

TREATMENT OF A PATIENT BELIEVED TO HAVE TUBERCULOSIS

Some cases of TB are identified when a patient comes to medical attention with symptoms of TB. Other cases are found through screening after a TST result is read as positive (Table 294.3). It is important to determine the persons's degree of infectiousness when making decisions regarding disposition and restrictions in activity. Patients believed to have TB may be hospitalized or treated as outpatients depending on the severity of illness and the living situation (Fig. 294.3). In many cases, patients with TB have previously exposed household members, and there is minimal risk of continued transmission of infection in the home. If, however, the household includes children younger than 5 years or persons who are immunocompromised, it is prudent to minimize continued exposure from the persons with suspected TB. If patients are hospitalized, prompt isolation in a negative- pressure room is critical for interrupting transmission and preventing transmission in the health care setting. For all patients believed to have TB, sputum specimens should be obtained on three consecutive mornings and subjected to AFB smear and culture. Anti-TB therapy should be initiated as soon as the presence of TB is suspected. If three smears do not contain AFB, the patient is considered not contagious and should have no restrictions placed on activity.

$\geq 5\text{ mm}$	$\geq 10\text{ mm}$	$\geq 15\text{ mm}$
Persons with HIV infection Injection drug users of unknown HIV status	Persons from high-prevalence countries	Persons with no risk factors
Persons with recent exposure to TB	Low-income populations	
Persons with chest radiographs that suggest TB	HIV-negative injection drug users Residents of nursing homes or correctional facilities Health care workers	
	Persons with certain medical conditions: diabetes, corticosteroid therapy, gastroctomy, silicosis, chronic malabsorption	

TABLE 294.3. CRITERIA FOR TUBERCULIN POSITIVITY BY RISK GROUP^a

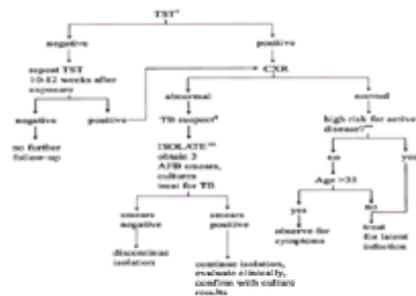

FIGURE 294.3. Initial treatment of patients exposed to tuberculosis. * TST, tuberculin skin test; CXR, chest radiograph. **See Table 294.2. †Report to local health department. ‡Isolation necessary only if hospitalized. Outpatients may have to restrict activity. Discharge conducted with local health department.

Patients in the hospital who have positive smear results should remain in isolation. Persons being treated as outpatients should remain at home until they have three consecutive negative smear results for AFB and have demonstrated a clinical response to anti-TB therapy (decrease in frequency of cough, defervescence, or decreasing bacterial burden on smear). Patients who do not have clinical improvement with therapy should undergo thorough reassessment of both the clinical and laboratory diagnoses. If clinical suspicion for TB remains high, additional specimens should be obtained for culture and susceptibility testing. Lack of response to what appears to be an appropriate anti-TB regimen suggests drug resistance. All patients believed to have TB must be reported to the local health department. When TB is confirmed, discharge planning should be coordinated with the local health department.

MANAGEMENT OF TUBERCULOSIS

Since the introduction of streptomycin in the 1940s, TB has become a preventable and curable disease. There are three guiding principles for effective treatment of TB, as follows: (a) regimens must contain at least three drugs to which the organisms are susceptible, (b) the drugs must be taken regularly, and (c) drug therapy must continue for a sufficient period of time. The treatment regimen ideally should provide the safest, most effective therapy in the shortest period of time. Several drug regimens have been identified that cure TB among 95% of susceptible cases. For patients believed to have drug-susceptible disease, the regimens are based on the use of combinations of five first-line anti-TB drugs—isoniazid, rifampin, ethambutol, pyrazinamide, and streptomycin. Options for regimens are shown in Table 294.4.

Regimen	Time (Weeks of Treatment)											
	0	1	2	3	4	5	6	7	8	9	10	11
1	INH, RIF, and PZA taken daily (weeks 0-6)						INH, RIF taken daily or 2-3 times/week (weeks 7-12)					
2	INH, RIF, PZA, and EMB or SM taken daily (weeks 0-6)						INH and RIF taken 1 time/week (weeks 7-12) with EMB or SM until susceptibility known					
3	INH, RIF, PZA, and EMB or SM taken 3 times/week (weeks 0-12)											
4	INH, RIF, PZA, and EMB or SM taken daily or in tablets 1, 2, or 3 (weeks 0-6)						INH, RIF, PZA, and EMB or SM taken daily or 2-3 times/week (weeks 7-12)					
5	When PZA is contraindicated, INH and RIF taken daily (weeks 0-6)						INH and RIF taken 1 time/week (weeks 7-12)					

TABLE 294.4. TIME LINE: REGIMEN OPTIONS

The course of therapy is divided into two main components, the initial intensive phase and the continuation phase. The intensive phase (which generally is 2 weeks to 2 months in duration depending on the chosen regimen) is designed to accomplish rapid killing of most of the bacilli causing disease. The continuation phase is 4 months or longer and is aimed at killing the few bacilli harbored in intracellular compartments that make disease eradication difficult.

For any patient, especially those with HIV coinfection, treatment should be extended beyond 6 months if the clinical or bacteriologic response is slow or otherwise suboptimal. Therapy for extrapulmonary TB follows the same principles as for pulmonary TB; the drug regimens and durations are the same. The exceptions are miliary TB, TB of bones and joints, and TB meningitis. Patients with these conditions should receive 12 months of therapy. For patients with TB pericarditis or meningitis, adjunctive therapy with corticosteroids has been shown to help prevent constrictive pericarditis and neurologic sequelae, respectively, especially when

administered early in the course of disease.

There is a dearth of information concerning regimens for the management of MDRTB. The number of potential resistant patterns make randomized prospective trials almost impossible, and the drug regimens use for treatment are individualized on the basis of results of drug susceptibility testing and other factors. Regimens for drug-resistant TB always should be prescribed by an experienced health care provider.

Drug-resistant TB may be suspected when the source of infection is known to have had drug-resistant disease or when a patient does not respond to an adequate therapy. Drug resistance may be identified with drug susceptibility testing of isolates. When a patient is believed to have disease that is resistant to at least isoniazid and rifampin, the initial treatment regimen should contain at least three drugs to which susceptibility is considered likely and to which the patient is naive. First- and second-line agents should be combined to achieve the optimal regimen. Second-line anti-TB drugs include quinolones, capreomycin, cycloserine, kanamycin, ethionamide, and para-aminosalicylic acid. Drug therapy ultimately should be guided by a complete panel of in vitro susceptibility results, and the medications should be administered under directly observed therapy. In the event of treatment failure, a single drug should never be added to a failing regimen. The correct procedure is to add to the regimen at least two new drugs not previously taken by the patient. Therapy for MDRTB should extend for at least 12 months after culture-negative status is achieved.

MANAGEMENT OF ACTIVE TUBERCULOSIS AMONG PERSONS WITH HIV INFECTION

It is estimated that more than 5 million people worldwide are coinfecting with HIV and TB. TB is now an AIDS-defining illness. Given this, it is imperative to consider the diagnosis of TB when a person with HIV infection reports pulmonary symptoms. The reduction of cellular immunity is the greatest known risk factor for progression from *M. tuberculosis* infection to active disease.

Early diagnosis and management of TB among persons with HIV infection is critical for interrupting TB transmission, prompt initiation of therapy, and cure. In early HIV infection (CD4 count >300), TB becomes manifest in the same way it does among persons without HIV infection. In late HIV infection, symptoms generally are subtle, and chest radiographic findings may be atypical for TB. Lymphadenopathy or small lobar infiltrate may be the only radiographic manifestation, or the chest radiograph may be entirely normal. Immunosuppressed persons often are incapable of mounting an immune response sufficient for cavity formation or formation of dense lobar infiltrates. Disease then may present as fever, wasting, nonproductive cough, or night sweats.

Although persons with HIV infection are at increased risk of reactivation TB, cases of exogenous reinfection with a different strain of *M. tuberculosis* have been reported. Extrapulmonary disease, particularly miliary disease, is more common among persons with HIV infection than among those without HIV infection. All persons with HIV infection should undergo tuberculin skin testing at initial evaluation of the HIV infection to determine the need for preventive therapy. For persons with HIV infection, greater than or equal to 5 mm is considered a positive reaction ([Table 294.3](#)). Persons with advanced immunosuppression who are believed to be anergic should undergo periodic, thorough TB symptom reviews. Persons with known exposure to a person with an active case of TB (regardless of TST status) or who have a positive skin test result but no signs and symptoms of active disease should undergo treatment of latent infection as soon as possible regardless of age.

In cases of active TB, some clinicians choose to interrupt antiretroviral therapy during therapy for active TB. Others continue both medication regimens simultaneously. It is now recommended that rifampin be avoided by patients taking protease inhibitors as part of the antiretroviral regimen. In these cases, rifabutin should be substituted for rifampin because this drug is a less potent inducer of the cytochrome P450 system and has less interaction with protease inhibitors. When protease inhibitors and rifabutin are used concomitantly, it may be necessary to increase the dosages of the protease inhibitor, especially for patients taking nelfinavir and indinavir. Ritonavir should not be used with either form of rifamycin. Therapy for active TB among persons with HIV infection should be undertaken only by care providers who are very familiar with both the side effects and pharmacologic interactions of anti-TB and antiretroviral medications.

SCREENING

Tuberculin skin test screening is performed to identify persons at high risk of infection with *M. tuberculosis* would benefit from preventive therapy ([Table 294.5](#)). Although cases of clinical disease often are identified with screening, this method should not be used to find new cases of active TB.

Persons with HIV infection
Close contacts of persons with infectious tuberculosis
Persons with immunocompromising medical conditions^a
Injection drug users
Persons from areas where tuberculosis is common
Homeless persons
Medically underserved, low-income population, including high-risk racial and ethnic groups (Asians, Pacific Islanders, blacks, Hispanics, Native Americans)
Residents or workers in congregate settings (e.g., correctional institutions, nursing homes, mental institutions, long-term care facilities, shelters)

^a See [Table 294.2](#).

TABLE 294.5. GROUPS AT RISK OF *M. TUBERCULOSIS* INFECTION AND FOR WHOM SKIN TESTING IS INDICATED

The Mantoux TST performed with 5 tuberculin units of purified protein derivative (PPD) is the standard method for detecting of *M. tuberculosis* infection. The PPD is placed subcutaneously into the volar surface of the forearm. Induration (palpable swelling) at the site of antigen placement is the hallmark of TB infection. Tests to detect induration are read 48 to 72 hours after PPD placement. Erythema often occurs, but this alone does not constitute a positive skin test reaction and should not be measured. A positive reaction is determined by the width of the induration in millimeters, which varies according to risk category ([Table 294.3](#)).

Persons with a positive TST reaction should undergo chest radiography and clinical evaluation to rule out active disease ([Fig. 294.3](#)). Contacts of a person with an active case of TB should undergo skin testing as soon as possible after exposure. If the results of initial testing are negative, the TST should be repeated 10 to 12 weeks after the last time of exposure to the person with the infectious case, because delayed-type hypersensitivity (DTH) may take several weeks to become manifest. A false-negative reaction does not exclude the possibility of infection or disease. False-negative skin test reactions may occur among 15% to 20% of persons tested. False-positive reactions also may occur with administration of the TST. False-positive reactions are most often caused by the presence of antigens in tuberculin that are shared with nontuberculous mycobacteria such as *Mycobacterium avium* complex. Nontuberculous mycobacteria are ubiquitous in the environment; exposure to these may produce hypersensitivity responses to PPD.

Some persons may have incurred *M. tuberculosis* infection many years in the past. In these cases delayed-type hypersensitivity may wane over time, and the initial TST result may be negative. If waning sensitivity is suspected, two-step skin testing may be used to elicit the booster phenomenon. The booster phenomenon represents restimulation of the delayed-type hypersensitivity response among persons whose immunologic reaction to *M. tuberculosis* has waned. In two-step testing, the initial skin test is read 72 hours after placement of PPD. If the reaction is negative, the skin test should be repeated in 1 to 3 weeks. A positive result at repeat testing generally reflects a boosted reaction. A negative result of the repeated test is likely a true-negative reaction. Two-step testing is used to establish a baseline TST result for persons who undergo skin testing periodically and for persons who are at risk of exposure to *M. tuberculosis*, such as health care workers. Two-step testing in the health care setting also reduces the likelihood of misclassifying persons with boosted reactions as recent converters.

For persons born outside the United States who have a remote history of vaccination with bacille Calmette–Guerin, a positive TST reaction should be interpreted as infection with *M. tuberculosis*. Repeated intradermal injections of PPD do not sensitize uninfected persons to tuberculin.

MANAGEMENT OF LATENT TUBERCULOSIS INFECTION

Therapy for latent TB infection is recommended for certain groups of persons who have a positive TST reaction, many of whom are felt to be at increased risk of active disease ([Table 294.6](#)). The decision to treat a patient for latent infection should also be based on tuberculin positivity for risk groups ([Table 294.5](#)). For

example, a close contact of a person with an active case of TB who has a TST reaction that shows 5 mm induration should undergo treatment of latent infection. However, a person younger than 35 years with no identifiable risk factors for progression to disease should undergo therapy for latent infection if the tuberculin induration is 15 mm or more. Children and adolescents with negative TST reactions (<5 mm induration) who have been close contacts of contagious persons within the 3 months before tuberculin testing are candidates for therapy for latent TB infection until a second test is performed 10 to 12 weeks after last exposure. If the second test reaction is positive, therapy is continued to completion; if it is negative, therapy may be discontinued unless there is continuing exposure to the contagious person.

Treat Regardless of Age

Persons known to have or likely to have HIV infection
Close contacts of a person with infectious tuberculosis
Persons who have a chest radiograph that suggests previous tuberculosis and who have received inadequate treatment
Persons who inject drugs
Persons with certain medical conditions*
Recent converters*
Children younger than 5 years

Treat Persons Who Are Younger Than 35 Years

Persons from areas where tuberculosis is common
Medically underserved, low-income populations, including high-risk racial and ethnic groups and residents of long-term care facilities
Locally identified high-prevalence groups (e.g., homeless, migrant farm workers)

* See Table 294.2.
* Persons whose tuberculin skin test reaction converted from negative to positive within the past 2 years (= 10 mm increase if younger than 35 years; = 15 mm increase if 35 years or older).

TABLE 294.6. HIGH-PRIORITY GROUPS FOR THERAPY FOR TUBERCULOSIS THERAPY FOR TUBERCULOSIS INFECTION.

A 6-month course of isoniazid once was the recommended and standard therapy for latent infection. Revised recommendations emphasize the greater efficacy of longer durations of therapy for latent infection. A 9-month course of daily isoniazid is now thought to be the most effective regimen. Other options for management of latent TB infection include intermittent isoniazid therapy given twice a week for 6 or 9 months or the previous standard of isoniazid given daily for 6 months. For persons with conditions in which neuropathy is common, such as diabetes, uremia, alcoholism, HIV infection, pyridoxine should be coadministered with isoniazid. Regimens with rifampin alone or rifampin plus pyrazinamide are being studied in clinical trials and are promising. Rifampin and pyrazinamide given for 2 months to persons with dual infection (HIV and *M. tuberculosis*) was as effective as 12 months of isoniazid therapy in a prospective, randomized trial. This regimen is thought to be equally efficacious in the care of persons without HIV infection. Although the cost is higher than that of regimens with isoniazid alone, a 2-month regimen may increase the acceptability of therapy for latent TB infection.

COST-EFFECTIVENESS

Regardless of patients' need for treatment of active TB disease or treatment of latent infection, TB control programs in most nations offer drugs and care at no charge. Many health departments offer directly observed therapy programs to help patients complete the full course of therapy. In a directly observed therapy program a health care provider watches patients swallow all doses of anti-TB drugs. The programs often provide food, transportation, and even housing if needed. This and many other strategies are necessary to achieve the national health goal of TB elimination by the year 2010. A multipronged approach that includes early recognition and timely therapy for active disease, effective contact investigations to find infected persons, and administration of therapy for latent infection are pivotal for successful elimination.

those without HIV infection are presented in [Table 295.2](#).

- A. If three sputum or bronchial wash results are available from the previous 12 months
1. Three positive culture results with negative acid-fast bacillus (AFB) smear results
 - or
 2. Two positive culture results and one positive AFB smear
- B. If only one bronchial wash is available:
1. Positive culture with a 2+, 3+, or 4+ AFB smear or 2+, 3+, or 4+ growth on solid medium
- C. If sputum or bronchial wash evaluations do not provide enough information for diagnosis or another disease cannot be excluded:
1. Transbronchial or lung biopsy yielding nontuberculous mycobacteria (NTM)
 - or
 2. Biopsy showing mycobacterial histopathologic features (granulomatous inflammation, AFB, or both) and one or more sputum or bronchial washings positive for NTM even in low numbers

TABLE 295.2. DIAGNOSTIC CRITERIA OF NONTUBERCULOUS MYCOBACTERIAL LUNG DISEASE AMONG HIV-SEROPOSITIVE AND -SERONEGATIVE HOSTS

Some radiographic findings suggest nontuberculous mycobacterial disease, especially the presence of large, thin-walled cavities ([Fig. 295.1](#)). No radiographic finding, however, provides enough information to confirm a diagnosis or can be used reliably to differentiate tuberculosis from nontuberculous mycobacterial disease. Cavitory nontuberculous mycobacterial disease frequently accompanies chronic pulmonary disease related to pneumoconiosis, previous tuberculosis, smoking-related chronic obstructive lung disease, bronchiectasis, cystic fibrosis, and chronic aspiration.

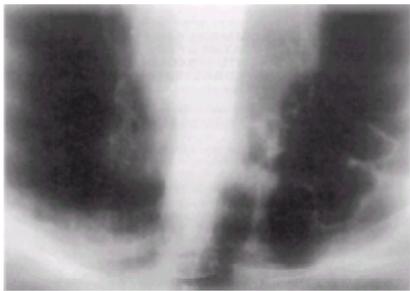

FIGURE 295.1. Multiple, large, thin-walled cavities in a young woman with infection with *Mycobacterium kansasii*. Although not enough information for diagnosis, cavities of this type with minimal surrounding infiltrate often are seen with infection by organisms of this species.

MYCOBACTERIUM AVIUM COMPLEX

M. avium and *M. intracellulare* are separate species that resemble each other so closely they are indistinguishable with routine microbiologic methods and for practical purposes are referred to as the *M. avium* complex (MAC). MAC can be isolated from water and soil throughout the United States but is present in greatest concentration in the Southeast, especially in coastal waters and estuaries. In a study involving 275,000 Navy recruits who had never lived outside the counties in which they were born, reaction to MAC skin test antigen (PPD-B) was found among more than 70% of those who had resided in the coastal states from Virginia to Texas. Although the pathogenesis of chronic lung disease due to MAC infection is unknown, evidence strongly supports aerosol spread to humans from infected water sources as the principal mode of infection. There is no evidence of animal-to-human or human-to-human transmission. Whether this infection is contained and then reactivates, as does tuberculosis, is unknown but seems likely among patients with upper lobe predominance of MAC lung disease.

Patients with the first form of pulmonary MAC disease typically are middle-aged or older men from the rural southeastern United States who smoke and have preexisting chronic obstructive lung disease. Symptoms include coughing, sputum production, weight loss, and hemoptysis. Fever is infrequent, but if it does occur, it is less severe than with tuberculosis. A chest radiograph typically shows upper lobe cavitory infiltrates ([Fig. 295.2](#)).

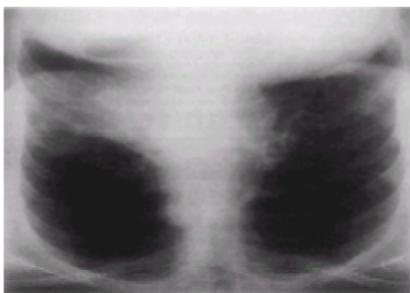

FIGURE 295.2. Upper lobe cavitory disease caused by *Mycobacterium avium* complex in a middle-aged male smoker.

A second form of MAC lung disease, often called *nodular bronchiectasis*, has been recognized since the late 1980s. Most of the patients are older women who do not smoke but who have coexistent bronchiectasis. The radiographic abnormalities are best defined with computed tomography. They include evidence of cylindrical bronchiectasis and fibronodular and interstitial infiltrates predominant in the middle and lower portions of the lung ([Fig. 295.3](#)). Initial symptoms usually are only cough and progressive fatigue but with progression may mimic those of classically described MAC lung disease. These patients once were considered “colonized” with MAC; however, it is clear that this form of MAC lung disease is not benign and can progress to respiratory failure.

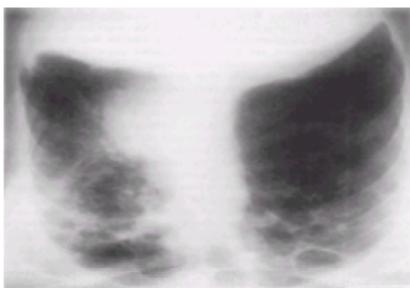

FIGURE 295.3. Nodular and interstitial infiltrates caused by *Mycobacterium avium* complex in an elderly female nonsmoker.

The outcome of successful therapy for MAC pulmonary disease is conversion of positive sputum culture results to negative results. The best sputum culture conversion rates before the introduction of macrolide antibiotics ranged from 60% to 80%. Conversion was achieved with a regimen of isoniazid, rifampin, and ethambutol for 18 to 24 months and intramuscularly administered streptomycin for the first 3 to 6 months of therapy. This regimen was recommended by the American Thoracic Society in 1990. A problem in the management of MAC lung disease has been the lack of correlation between the results of in vitro drug susceptibility tests of the standard antituberculous drugs for *M. tuberculosis* infection and clinical or bacteriologic outcome. Relapse with antituberculous drug regimens has been common; long-term negative culture results have occurred in only 50% of cases.

An important development in therapy for MAC lung disease was the direct result of efforts to manage disseminated MAC disease among patients with AIDS. The AIDS epidemic stimulated the development and use of three new therapeutic agents: clarithromycin, azithromycin, and rifabutin. The macrolide antibiotics (clarithromycin and azithromycin), perhaps because of high tissue and macrophage concentrations, have rapidly evolved into the cornerstone of therapy for MAC lung disease. Studies involving patients with MAC lung disease have demonstrated the superiority of macrolide-based regimens for MAC lung disease over previously used antituberculous regimens. The principal limitation of these new treatment regimens is side effects, especially of rifabutin. Studies are being conducted to determine the optimal drug combination for successful management of MAC lung disease ([Table 295.3](#)).

Species	Drugs
<i>M. avium</i> complex	Clarithromycin (Azithromycin), ethambutol, rifabutin (rifampin), with or without streptomycin (amikacin)
<i>M. kansasii</i>	Isoniazid, rifampin, ethambutol
<i>M. fortuitum</i> group	Amikacin, cefoxitin, imipenem, clarithromycin (80%), newer quinolones, sulfonamides, doxycycline or minocycline (50%)
<i>M. abscessus</i>	Amikacin, cefoxitin, imipenem, clarithromycin
<i>M. chelonae</i>	Tobramycin, imipenem, clarithromycin, doxycycline or minocycline (25%), ciprofloxacin (20%)
<i>M. marinum</i>	Trimethoprim—sulfamethoxazole, doxycycline or minocycline, clarithromycin, rifampin, rifampin plus ethambutol

TABLE 295.3. COMMONLY USED DRUGS FOR TREATMENT OF NONTUBERCULOUS MYCOBACTERIAL INFECTIONS

The regimen recommended by the American Thoracic Society in 1997 is clarithromycin 1,000 mg per day (or azithromycin 250 mg per day), rifabutin 150 to 300 mg per day, and ethambutol 25 mg per kilogram daily for the first 2 months then 15 mg per kilogram per day. Streptomycin 500 to 1,000 mg twice a week should be added in the first 3 months for patients with extensive disease. Intermittent treatment (three times a week with macrolide-containing regimens) has proved to be effective against MAC lung disease. For this regimen the drug doses remain the same, except that the dose of ethambutol is 25 mg per kilogram for the duration of treatment. Monthly sputum cultures must be obtained if possible, and patients are treated until they have negative culture results with therapy for 12 months. An initial study showed sputum conversion rates of 80% to 90% among patients able to tolerate all three drugs in the regimen. The success was more than 90% among patients not previously treated but was much lower among patients who had undergone an unsuccessful course of therapy.

Combined medical and surgical therapy has had excellent results for selected patients with localized cavitary disease and adequate pulmonary reserve. It generally has been restricted to patients with upper lobe fibrocavitary disease who do not have improvement after a minimum of 6 months of drug therapy or whose MAC isolate becomes macrolide resistant. Surgical resection is not an option for most patients who have extensive or bilateral disease. Other drugs such as clofazimine and the newer fluorinated quinolones have added little if anything to these treatment regimens.

MAC lung disease is a diagnostic and therapeutic challenge. Before the introduction of improved antibiotic therapy against MAC, nihilism about an aggressive approach to the care of these patients was understandable. With the availability of improved medical approaches, however, care must be taken in determining the importance of a MAC isolate in a sputum specimen. Some patients with indolent disease may need follow-up care for an indefinite period to determine whether a respiratory isolate of MAC is clinically significant and whether therapy against MAC is indicated.

MYCOBACTERIUM KANSASII INFECTION

The presence of *M. kansasii* organisms in the piped water systems of cities that have pulmonary disease caused by this species has led to the concept that infected aerosols from local tap water are the source of *M. kansasii* lung disease. Pulmonary *M. kansasii* disease is clinically and radiographically indistinguishable from tuberculosis. The typical patient is a middle-aged man from the Southwest or Midwest who is likely to have chronic obstructive pulmonary disease and resides in a major metropolitan area. The course of disease usually is slow progression over a number of years that may lead to extensive lung destruction, although more rapid disease progression can occur.

Untreated isolates of *M. kansasii* are susceptible to achievable serum concentrations of isoniazid (5 µg per milliliter), rifampin (1 µg per milliliter), and ethambutol (5 µg per milliliter), and sputum conversion rates with rifampin-containing regimens approach 100%. This differs from the standard regimen used to treat patients with tuberculosis. The tuberculosis regimen includes pyrazinamide, a drug that has no activity against *M. kansasii*. The American Thoracic Society recommends isoniazid 300 mg per day, rifampin 600 mg per day, and ethambutol 15 mg per kilogram per day for 18 months for disease management. Patients with HIV infection who take protease inhibitors should receive rifabutin at 150 mg daily in place of rifampin. Shorter regimens such as a 12-month regimen with these three drugs plus intramuscular streptomycin twice a week for the first 3 months also have proved successful. However, long-term results with short-course regimens are not known to be as good as those obtained with the American Thoracic Society recommended regimen.

Localized lung disease among patients with AIDS usually responds well to therapy. Lung disease associated with disseminated infection carries a less favorable prognosis. The key to successful therapy for *M. kansasii* infection is in vitro sensitivity to rifampin, because susceptibility to other drugs with tuberculosis test concentrations (0.2 or 1 µg per milliliter isoniazid) does not influence the outcome. Extensive disease and coexistence of other diseases also does not influence outcome of therapy. In rare instances rifampin resistance may emerge during drug therapy. Multidrug treatment regimens that contain clarithromycin may be beneficial in the treatment of these patients. With the availability of rifampin there is no proven role for surgical resection.

MYCOBACTERIUM ABSCESSUS INFECTION

M. abscessus is a rapidly growing species of mycobacteria and is ubiquitous. It is responsible for approximately 85% of cases of lung disease due to rapidly growing mycobacteria. Most *M. abscessus* lung disease occurs among women older than 60 years who do not smoke and have no underlying lung disease. Approximately 15% of patients have coinfection with MAC. Achalasia, previous granulomatous disease, bronchiectasis, cystic fibrosis, and chronic vomiting, but not HIV disease, are risk factors evident among a small percentage of patients, primarily those younger than 50 years. The disease is slowly progressive, and the symptoms usually are mild.

Radiographic examination shows that *M. abscessus* lung disease is primarily interstitial (reticulonodular) and that cavitation is infrequent. Medical therapy for this disease has had generally disappointing results. Antituberculous drugs are uniformly ineffective. Antibiotics such as amikacin, cefoxitin, and the newer macrolides provide temporary clinical improvement. Cure usually is effected only when surgical resection is possible. Clustered outbreaks of pseudoinfection have been caused by sampling with a bronchoscope contaminated in an automated washer.

INFECTION WITH OTHER MYCOBACTERIUM SPECIES

In rare instances, other nontuberculous mycobacteria can cause pulmonary disease. *M. xenopi* grows best at 45°C and is found in hot-water generators and storage tanks. It has been responsible for false outbreaks related to contamination of hot water systems in hospitals and for sporadic true outbreaks of disease. *M. xenopi* is especially common in England and Canada and appears to be increasing in frequency in the United States. The infection can be managed with the macrolide-containing regimen for MAC infection, but relapses appear to be common during periods when the patient is not taking the drugs. Other rare organisms that cause nontuberculous mycobacterial lung disease are *M. szulgai*, *M. fortuitum*, *M. smegmatis* group, *M. celatum*, and *M. simiae*.

LYMPHADENITIS

Lymphadenitis caused by nontuberculous mycobacteria is more common today than tuberculous lymphadenitis. Since the mid 1980s, MAC has become the most commonly recovered pathogen and is responsible for almost 80% of cases of nontuberculous mycobacterial lymphadenitis. Before that time *M. scrofulaceum* was the most common pathogen. More than 95% of cases of disease involve only the cervical lymph nodes, are unilateral, and become manifest as a mass of matted, enlarged nodes, often with associated skin changes. The patients have no evidence of mycobacterial disease elsewhere, and their chest radiographs are normal. Children 1 to 5 years of age are most commonly affected and usually have no constitutional symptoms. The involved nodes may regress spontaneously or progress to softening, rupture, sinus formation, and drainage.

The diagnosis usually is established with the surgical finding of caseating granulomatous disease with or without acid-fast bacilli and (in only 50% of cases) a positive node culture result. The presence of disease is suspected on the basis of signs and symptoms, especially if a child with no tuberculosis contacts has a PPD test result that is weakly or strongly positive. Because of the threat of a chronically draining sinus, incision and drainage are contraindicated, and the treatment is excision of the major involved nodes. Antituberculous drugs usually are not helpful. Clarithromycin with rifabutin or ethambutol may be useful to patients with a poor response to surgical excision or patients who cannot undergo complete surgical excision of involved lymph nodes. No clinical trial has been conducted of this regimen in this setting.

SKIN AND SOFT-TISSUE INFECTION

RAPIDLY GROWING MYCOBACTERIA

The three major pathogenic species of rapidly growing mycobacteria, *M. abscessus*, *M. chelonae*, and *M. fortuitum*, produce a wide spectrum of diseases but are primarily responsible for skin and soft-tissue infections. Most infections occur among otherwise healthy hosts and follow surgery or accidental environmental wound contamination. Most are caused by *M. fortuitum*. The most common nosocomial infections include wound infection after median sternotomy or augmentation mammoplasty, abscesses at injection sites, and infection caused by long-term use of catheters. Outbreaks of pseudoinfection have occurred from contamination of automated bronchoscope washers in which tap water is used for rinsing. Disseminated cutaneous disease due to *M. chelonae* and occasionally *M. abscessus* infection occurs almost exclusively among patients undergoing long-term corticosteroid therapy who have multiple, nodular, draining skin lesions usually on the extensor surfaces of the lower legs with minimal systemic symptoms. HIV disease appears to be associated with no special risk of infection with these organisms.

The pathogenic, rapidly growing mycobacteria are highly resistant to antituberculous drugs but are susceptible to a number of traditional antibacterial agents. Because drug susceptibility is variable, susceptibility testing should be performed. The *M. fortuitum* group (*M. fortuitum*, *M. peregrinum*, *M. fortuitum* third biovariant complex) is uniformly susceptible to ciprofloxacin and ofloxacin, amikacin, imipenem, cefoxitin, and sulfonamides. About 80% of organisms are susceptible to clarithromycin and cefoxitin and about 40% to doxycycline. In *M. chelonae* disease, clarithromycin is effective against all untreated strains, but there is an approximately 10% risk with monotherapy of development of mutational resistance with therapy for disseminated disease. The best additional agents are tobramycin, which is better than amikacin against organisms of this species, and imipenem. For *M. abscessus* infection, amikacin, imipenem, cefoxitin, and clarithromycin are the most active agents (Table 295.3). In general, serious or invasive disease due to infection with *M. fortuitum* group or *M. abscessus* is managed with amikacin plus cefoxitin for 4 to 8 weeks followed by the best available oral agent to complete 6 months of therapy. Drugs used to manage infection caused by gram-positive bacteria, including evernimocins and linezolid, are under investigation as therapy for infection with mycobacteria.

MYCOBACTERIUM MARINUM INFECTION

M. marinum is responsible for fish-tank granuloma. Fanciers of tropical fish and persons with saltwater injuries are the main populations at risk of disease. *M. marinum* skin lesions first appear as small papular or nodular lesions with central ulcerations at the site of inoculation (usually the hands or arms). The lesions characteristically appear weeks to months after exposure. The disease usually is self-limited, but in the absence of therapy may persist for 1 to 3 years. Some patients have proximal secondary lesions similar to those of sporotrichosis. Disseminated skin disease is rare but can occur among immunosuppressed patients, including patients with AIDS.

The key to diagnosis is a careful history interview. The diagnostic procedure of choice is skin biopsy for culture. Organisms of this species can be readily grown, but initial or primary isolation requires incubation at lower temperatures (28°C to 32°C) than the standard 35°C. Histopathologic study of biopsy specimens shows granulomatous inflammation, but only 5% to 10% specimens have demonstrable acid-fast bacilli. The PPD skin test result often is positive. There is no one drug treatment of choice, and trimethoprim-sulfamethoxazole, doxycycline, clarithromycin, and rifampin with or without ethambutol all have proved effective when given for a minimum of 3 months (Table 295.3). Surgery may be needed to manage extensive or rapidly progressive disease, especially when it involves the hand.

INFECTION WITH MISCELLANEOUS SPECIES

A number of other nontuberculous mycobacterial species may occasionally cause primary skin and soft-tissue disease, usually after trauma to an otherwise healthy host. This group includes MAC, *M. kansasii*, *M. smegmatis*, *M. goodii*, *M. wolinskyi* (the latter two closely related to *M. smegmatis*), and *M. terrae* complex (almost always infection of the hand). *M. ulcerans* infection is a relatively common cause of large necrotizing ulcers of the extremities in localized areas of Australia (Bairnsdale ulcer) and Africa (Buruli ulcer) but is not endemic in the United States.

DISSEMINATED DISEASE AND DISEASE ASSOCIATED WITH AIDS

INFECTION WITH MYCOBACTERIUM AVIUM COMPLEX

Disseminated disease caused by nontuberculous mycobacteria was rare before the 1980s. It occurred among immunocompromised patients, particularly those who had undergone renal transplantation. Disease was usually manifested by multiple subcutaneous nodules. *M. chelonae* and *M. kansasii* were the most commonly recovered agents.

With the advent of AIDS, however, disseminated nontuberculous mycobacterial disease, usually disseminated MAC disease, became relatively common. At one time, as many as 50% of persons with AIDS had evidence of disseminated *M. avium* disease at autopsy. The risk is closely related to CD4 count, risk by year reaching as high as 40% among patients with CD4 counts less than 10 cells per cubic millimeter. More than 95% of isolates are *M. avium* rather than *M. intracellulare*, and most belong to serotypes 4, 6, and 8.

The initial symptoms are nonspecific and include fever. With early disease the fever often is the only finding. With advanced disease, hepatosplenomegaly often is present, as are anemia and elevated levels of alkaline phosphatase. The organism can be isolated from numerous sites, including blood, bone marrow, liver, spleen, lymph nodes, and the gastrointestinal tract. Persistent bacteremia is present and provides the easiest and most accurate method of diagnosis (blood cultures). The lungs often are culture positive at autopsy, but histopathologic changes are rare. Chest radiographic abnormalities and respiratory symptoms usually are not a prominent feature. At bone marrow biopsy, well-formed granulomas are absent, so the histologic appearance of advanced disease is similar to that of lepromatous leprosy with large clumps of acid-fast bacilli. Isolation of the organism from the lower respiratory tracts of persons with AIDS does not necessarily confirm the presence of disease but can be a harbinger of dissemination.

Both clarithromycin (500 mg twice a day) and azithromycin (500 mg per day) have been shown to be effective therapy for disseminated *M. avium* disease. One of

these agents should be used in a multidrug regimen that includes ethambutol. Clarithromycin appears to be more effective in sterilizing the bloodstream but has more drug interactions than does azithromycin. Results of one study showed that rifabutin did not increase bacteriologic clearing of the bloodstream but significantly reduced the risk of clarithromycin resistance, compared with a placebo, when included with ethambutol and clarithromycin. Other agents used are rifabutin and occasionally amikacin. Monotherapy for disseminated *M. avium* infection with clarithromycin or azithromycin results in emergence of a macrolide-resistant *M. avium* strain. Treatment is presumably lifelong. Disseminated *M. avium* disease clearly hastens death, and treatment seems to enhance short-term survival. In randomized prophylaxis treatment trials, clarithromycin (500 mg twice a day), azithromycin (1,200 mg once a week), and rifabutin (300 mg per day) reduced the incidence of disseminated *M. avium* infection. All three are approved for prophylaxis.

The most recent recommendations suggest that adults and adolescents with HIV infection who have a CD4 T-lymphocyte count of fewer than 50 cells per microgram per milliliter should undergo chemoprophylaxis against MAC. Most physicians appear to prefer the azithromycin regimen, because it requires fewer drug doses and has fewer drug interactions. Relapse isolates also are less likely to be macrolide resistant than with clarithromycin therapy. In the era of highly active anti-retroviral therapy, CD4 cell counts in many patients may increase above the threshold for instituting MAC prophylaxis. This recovery in CD4 cell counts appears to reduce but not abolish the risk of disseminated *M. avium* disease. Pending results of further studies, patients continue with MAC prophylaxis regimens even if their CD4 count exceeds 50 cells per milliliter. With improved AIDS treatment and with effective prophylaxis regimens, the threat of disseminated *M. avium* disease among patients with AIDS has dramatically abated.

Other nontuberculous mycobacteria, including *M. kansasii*, *M. genavense*, *M. haemophilum*, and *M. goodnae*, may cause localized or disseminated disease among patients with AIDS, although much less frequently than does *M. avium*. The isolation of any nontuberculous mycobacterium from a patient with AIDS necessitates careful evaluation. The profound immunosuppression associated with AIDS has allowed some mycobacterial species that are rarely encountered as pathogens, such as *M. haemophilum*, *M. genavense*, and *M. goodnae*, to emerge as pathogens.

CHAPTER 296: LEPROSY

ROBERT R. JACOBSON

[Definition](#)
[Incidence And Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies For Optimal Care](#)
[Prognosis](#)

DEFINITION

Leprosy is a chronic infectious disease primarily involving skin and peripheral nerves. The more advanced types also may affect the eyes and mucous membranes of the upper respiratory tract.

INCIDENCE AND EPIDEMIOLOGY

Intensified control efforts worldwide have reduced the registered case load of leprosy to fewer than 900,000. About 150 new cases occur yearly in the United States, 20% of them among native-born citizens. The spread of the infection is believed to be mainly respiratory with a 3- to 5-year incubation period. Household contacts are at greatest risk.

ETIOLOGY

Leprosy is caused by *Mycobacterium leprae*, a slow-growing, obligate, intracellular parasite. It has never been grown in artificial media and divides only every 12.5 days in animal models.

PATHOGENESIS

Leprosy is believed to occur as a result of a relatively specific defect in the patient's cell-mediated immune response to *M. leprae*. More than 95% of a given population are apparently not susceptible to infection. The earliest manifestation may be indeterminate leprosy, which may self-heal or progress to another type. Persons with the most intact immune response keep the infection localized as tuberculoid leprosy, and few bacilli are evident. At the other extreme, among persons with a poor response the infection becomes generalized as lepromatous leprosy with large numbers of bacilli. Between these two extremes is the broad borderline group, which is usually subdivided into those with borderline-tuberculoid, mid-borderline, and borderline-lepromatous leprosy. The bacilli have a predilection for nerves, and the nerves involved may be damaged or destroyed.

CLINICAL FINDINGS

Leprosy should always be suspected when any patient has skin lesions and sensory loss. Physical examination includes inspection of the skin with documentation of the extent and types of lesions; sensory and motor testing; palpation of peripheral nerves for enlargement or tenderness; and examination of the eyes. The skin manifestations are protean and may include macules, plaques, papules, and nodules. Indeterminate disease commonly appears as a single, hypopigmented, occasionally erythematous macule, which may be hypoesthetic.

Tuberculoid disease typically becomes manifest with a single, large, scaly, anesthetic, hypopigmented macule that has a raised, well-defined margin. The sensory loss is confined to the lesion, but peripheral nerves in the vicinity of the lesion may be involved, leading to distal loss or to motor loss.

Lepromatous leprosy usually is generalized at diagnosis. It may appear as diffuse disease with no distinct lesions, as faint erythematous macules, or, most commonly, as papules and nodules. Early in the course of disease, there may be little or no sensory loss, but later the loss may be extensive, particularly over the distal extremities. Multiple peripheral nerves may be involved, but motor loss occurs late. Partial or complete loss of eyebrows and eyelashes, upper respiratory tract involvement, and eye involvement may occur. The lesions in borderline disease ([Fig. 296.1](#)) range from tuberculoid-like to lepromatous in character.

FIGURE 296.1. Borderline lepromatous leprosy. The multiple papules and nodules are typical of lepromatous disease, but the larger lesions, some of which are tuberculoid-like, indicate a borderline component.

The borderline portion of the leprosy spectrum is characterized by immunologic instability and may shift toward lepromatous disease before treatment and toward tuberculoid disease with treatment. The latter may produce reactive episodes called *type 1* or *reversal reactions*. Nerve involvement often is extensive in borderline cases, and sensory and motor loss frequently occurs.

Reactive episodes vary markedly in severity and are more common after treatment is initiated. Type 1 reactions are characterized by the sudden onset of neuritis and edema and erythema of preexisting lesions and other skin areas that rarely may progress to ulceration. The neuritis may produce extensive loss of motor and sensory function if the patient is not properly treated. Erythema nodosum leprosum (type 2; ENL) reactions cause fever and erythematous, frequently painful nodules. Erythema multiforme-like, pustular, and ulcerating forms also may be found. Neuritis, arthralgia, leukocytosis, lymphadenitis, iridocyclitis, orchitis, and nephritis may accompany ENL. Patients with lepromatous disease may have ENL, patients with borderline lepromatous disease may have either, and patients with other classifications may have only type 1 reactions. Neuritis, orchitis, and occasionally other components of reactive episodes may occur independently. The ulnar and median nerves are the most commonly involved.

LABORATORY FINDINGS

Diagnosis is based on the physical findings, the results of examination of skin scrapings, and biopsy findings. Some biopsy sections are stained for histopathologic study, and classification is based on the type of cellular infiltrate and the involvement of dermal nerves. Other biopsy sections and skin scrapings are stained for acid-fast bacilli. Bacilli are counted by means of a semilogarithmic scale to obtain the bacterial index (BI). This index ranges from 0 (no bacilli in 100 oil-immersion

fields) to 6+ (more than 1,000 bacilli per oil-immersion field).

STRATEGIES FOR OPTIMAL CARE

Every patient should be given multidrug therapy to avoid drug resistance. Patients with paucibacillary disease (indeterminate, tuberculoid, and borderline tuberculoid with a BI of 0 at all sites on skin scrapings) are given dapsone 100 mg per day plus rifampin either 600 mg per day (U.S. recommendation) or once a month (World Health Organization [WHO] recommendation) for 12 months (U.S.) or 6 months (WHO). Therapy is then discontinued. Patients with multibacillary disease (mid-borderline, borderline lepromatous, and lepromatous or any patient with a BI of 1+ or greater at any site) are treated with dapsone 100 mg per day plus clofazimine 50 mg per day plus rifampin either 600 mg per day (U.S.) or per month (WHO). Therapy is given for 2 years (U.S.) or 1 year (WHO) and then discontinued, although patients in the United States often have been continued with dapsone indefinitely to prevent relapse.

Relapses apparently are uncommon even when therapy is stopped after 2 years. However, a relapse can occur 5 or more years after the original illness, so patients should undergo follow-up examinations at least once a year for 10 years. The *M. leprae* organisms in these patients usually remain fully sensitive to the drugs used, so treatment involves repeating the same regimen. Most skin lesions clear within 6 to 12 months, and the BI usually falls at a rate of 0.5 to 1 unit per year. Ofloxacin (400 mg per day), clarithromycin (500 mg per day), and minocycline (100 mg per day) are highly bactericidal for *M. leprae*, although less so than rifampin, and a number of regimens with one or more of them together with rifampin are under study to determine whether therapy can be further shortened.

Complications during therapy are most commonly reactions and neuritis. These respond to prednisone in a daily dose of 60 mg or more. This is the only approach that may reverse or prevent nerve damage. The time during which prednisone is needed varies from several weeks to years. Clofazimine in high doses is useful for the management of ENL. Thalidomide usually can control ENL, but it is teratogenic and must be used with caution. Assistance in the management of all cases can be obtained at any time from the Gillis W. Long Hansen's Disease Center in Louisiana.

PROGNOSIS

Treatment rapidly renders leprosy noninfectious, and the overall results are excellent. When they come to medical attention, however, some patients have disabilities caused by the disease. These disabilities are not reversed with treatment.

CHAPTER 297: SYPHILIS

NAIEL N. NASSAR AND JUSTIN DAVID RADOLF

[Definition](#)
[Incidence And Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies For Optimal Care](#)
[Syphilis And Human Immunodeficiency Virus Infection](#)
[Prevention And Control](#)

DEFINITION

Syphilis is a chronic, systemic, sexually transmitted disease caused by the spirochete *Treponema pallidum* subspecies *pallidum*. After a variable incubation period (mean 21 days), classic untreated syphilis progresses through stages with highly variable clinical manifestations. Syphilis is capable of causing a wide spectrum of clinical disease that can affect almost all organ systems. The disease can cause manifestations over a tremendous length of time, varying from a genital ulcer weeks after the initial infection to a form of dementia 15 to 20 years later.

INCIDENCE AND EPIDEMIOLOGY

Humans are the only known natural hosts of *T. pallidum*. Most cases of newly acquired syphilis are caused by direct contact during sexual intercourse with the mucocutaneous lesions that occur during the primary or secondary stages of syphilis. Late syphilis is considered noninfectious. Other forms of sexual activity such as kissing, oral-genital, and oral-anal contact also may cause infection. An untreated pregnant woman can transmit syphilis to the fetus regardless of the stage of disease. Syphilis is rarely transmitted through nonsexual contact, accidental inoculation, or blood transfusion from a donor with syphilis.

By some estimates, the prevalence of syphilis in the late 1800s was as high as 10% of the population. Over the past 50 years, the incidence of syphilis in the United States has shown great variation. Reported cases of primary and secondary syphilis, which had been increasing steadily during the 1940s, peaked in 1947. From 1947 to 1957 a rapid diminution in reported cases appeared to be related to both the end of World War II and the introduction of penicillin as therapy for syphilis. Between 1955 and 1960, however, the number of new cases of syphilis rebounded substantially, and there were nearly steady annual increases through 1982. At the same time, a striking increase in the incidence of infectious syphilis among homosexual white men paralleled the newly recognized HIV epidemic.

Between 1986 and 1990, there was a surge in reported cases of syphilis in the United States. The highest rates of primary and secondary syphilis were in the southern states, where the rate was two to five times higher than in other regions of the United States. Higher levels of poverty and less access to health care services are postulated to be responsible for this regional variation. Throughout the 1990s, the rates of primary and secondary syphilis have declined 84% in the United States in all regions. Syphilis rates also have declined for all racial and ethnic groups; the largest decline occurred among Hispanics (90%) followed by blacks (85%) and non-Hispanic whites (81%). Rates of primary and secondary syphilis, however, remain high among blacks and among women of all races. Although syphilis remains an endemic disease in parts of the South, rates in this region have declined 80% since 1990. Factors that may have contributed to the decline in syphilis include increased state and federal resources allocated to syphilis control programs, implementation of HIV prevention activities, a decline in use of crack cocaine, and the presence of acquired immunity in the population at risk after the epidemic.

ETIOLOGY

The genus *Treponema*, which belongs to the family Spirochaetaceae, contains two species pathogenic for humans, *T. pallidum* and *T. carateum*, and a number of genetically unrelated nonpathogenic species. The causative organism of venereal syphilis is *T. pallidum* subspecies *pallidum*. Yaws and endemic syphilis are caused by *T. pallidum* subspecies *pertenue* and *T. pallidum* subspecies *endemicum*, respectively, whereas *T. carateum* is the agent of pinta. Although limited replication has been achieved in tissue culture systems, the pathogenic treponemes cannot be cultivated continuously in vitro. Experimental strains of *T. pallidum* subspecies *pallidum* are most commonly maintained by means of repeated intratesticular inoculation of rabbits. All four treponemes are morphologically and antigenically indistinguishable. Speciation traditionally has depended on differences in host range, mode of transmission, geographic distribution, and the clinical features of the respective diseases. More recently, however, investigators have identified genetic differences that should prove useful for differentiating these organisms.

T. pallidum subspecies *pallidum* is a fragile, helical bacterium 5 to 20 μm long and 0.1 to 0.2 μm wide. It divides by means of longitudinal binary fission with a dividing time of 30 to 33 hours. Although *T. pallidum* frequently is referred to as gram-negative, this is a misnomer inasmuch as the organism poorly takes up aniline dyes and contains no lipopolysaccharide. Electron micrographs demonstrate that the organism possesses both outer and cytoplasmic membranes separated by a periplasmic space. Ultrastructural studies reveal that *T. pallidum* organisms have an outer membrane that is unique among prokaryotes in that the membrane contains an extraordinarily low content of integral membrane proteins. The organelles of motility, the endoflagella, are located within the periplasmic space. Three endoflagella insert near each end of the organism. As in other spirochetes, peptidoglycan is thought to be associated with the cytoplasmic membrane. The approximately one megabase circular chromosome of the bacterium has been completely sequenced. This information confirms that *T. pallidum* lacks much of the metabolic and biosynthetic machinery typically found in cultivated bacterial pathogens.

PATHOGENESIS

The specific mechanisms and determinants of treponemal virulence are still being elucidated. The genomic sequence surprisingly revealed that *T. pallidum* appears to lack virulence factors previously characterized among other bacterial pathogens. Pathogenic, but not nonpathogenic, treponemes readily attach to and penetrate a variety of cultured cell monolayers. Attachment may be mediated by treponemal receptors for components of the extracellular matrix. Motility is thought to play an important role in cell penetration and host dissemination. Although evasion of host cellular and humoral immune responses is presumably prerequisite to establishment of latent infection, the mechanisms responsible for this phenomenon are poorly understood. It is known, however, that the surface of the organism reacts poorly with specific antibodies. The paucity of surface-exposed proteins is believed to explain this phenomenon. The tissue damage caused by syphilitic infection appears to be more a result of the host immune response rather than a direct toxic effect of *T. pallidum*.

Much of our knowledge of the course of untreated syphilis derives from three clinical studies. From 1910 onward, Boeck and successors at the University of Oslo followed the cases of approximately 2,000 patients with untreated early syphilis for almost 40 years (the Oslo Study). In 1932, the United States Public Health Service began a 30-year study of untreated syphilis among 431 black men with latent syphilis (the Tuskegee study) that provided insights into the incidence and nature of cardiovascular syphilis among black men. A study by Magnuson et al. in the 1950s with human volunteers in the Sing Sing Correctional Facility helped to clarify the time course of incubation of human syphilis and documented the development of immunity to reinfection among persons with untreated late latent syphilis.

Endogenous resistance to treponemal infection has been inferred from epidemiologic studies showing that syphilis develops among only one-third of persons exposed. Nevertheless, experiments with both human subjects and rabbits in which standardized inocula were used indicated that fewer than 10 organisms are capable of producing infection. In natural infection, organisms rapidly penetrate intact mucous membranes and microscopically abraded skin and disseminate hematogenously soon thereafter. Blood from a patient with incubating syphilis is infectious long before the appearance of a chancre. Transfusion of blood from such patients has transmitted the infection. Although neurologic symptoms may not become apparent until years after infection, treponemal invasion of the central nervous system occurs early. A high proportion of patients with early syphilis (syphilis of less than 1 year's duration) have cerebrospinal fluid (CSF) abnormalities despite a lack of neurologic symptoms. Treponemes often can be recovered by means of inoculation of rabbits with normal or abnormal spinal fluid during this period. Conversely, normal findings at spinal fluid examination 2 or more years after infection indicate low risk of subsequent development of neurosyphilis.

Syphilitic lesions at all stages of disease have two histopathologic characteristics. The first is obliterative endarteritis in which hyperplasia and swelling of endothelial cells cause narrowing and complete occlusion of blood vessels. The second is a loose perivascular infiltrate consisting of lymphocytes, macrophages, and, most characteristically, plasma cells. Granuloma formation in both secondary and, particularly, tertiary syphilitic lesions also is common. Circulating immune complexes

containing treponemal antigens are regularly present in secondary syphilis and may contribute to clinical manifestations.

CLINICAL FINDINGS

Classic syphilis is divided into stages. It is important to emphasize at the outset, however, that staging of syphilis is imprecise because of the considerable temporal, clinical, and histopathologic overlap among stages.

A chancre, the primary lesion of syphilis, appears after an incubation period of 10 to 90 days (average 3 weeks) at the site of inoculation. It begins as an erythematous papule that ulcerates before healing within 2 to 4 weeks ([Fig. 297.1](#)), even without treatment, and leaves a thin, atrophic scar. The typical chancre is painless, solitary, rounded, and has a raised, discrete border with a rubbery or cartilaginous consistency. The individual lesions vary in size from a few millimeters to 1 to 2 cm. Among heterosexual men, chancres are most commonly found on the glans, the coronal sulcus, and the foreskin. Among women clinically evident lesions usually are found on the external genitalia, particularly the labia majora and minora, the fourchette, and the perineum. Perianal, anal, and rectal lesions are common among homosexual men. Most chancres outside the anogenital region occur in or about the mouth, particularly the lips, where they tend to be somewhat painful, although any area of the body may become infected. Approximately 50% of patients with primary syphilis have painless, nonsuppurative, bilateral regional adenopathy.

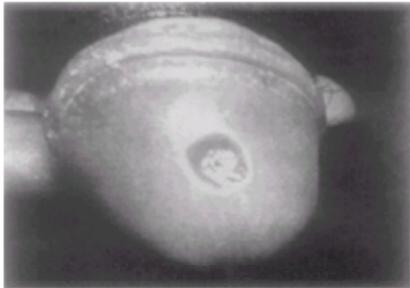

FIGURE 297.1. Typical syphilitic chancre.

Because many chancres are atypical in appearance, it is important to suspect that any genital lesion may be syphilitic. Papular lesions may occur among patients who seek treatment before the onset of ulceration. Multiple lesions occur among as many as 30% of patients. Tender, even exquisitely painful, primary lesions sometimes occur. Among homosexual men, chancres may be mistaken for trauma-induced anal fissures. Primary syphilis must be differentiated from the multiple other causes of genital ulceration, including venereal infection (e.g., chancroid, herpes genitalis, lymphogranuloma venereum, granuloma inguinale), nonvenereal infection (e.g., cat-scratch fever, rat-bite fever, sporotrichosis), and noninfectious lesions (e.g., traumatic wounds, malignant tumors).

Approximately 6 to 24 weeks after infection, usually when the chancre is either healing or has disappeared entirely, the secondary, or disseminated, stage of syphilis begins. Although characterized by widespread, sometimes florid, mucocutaneous lesions, secondary syphilis is a systemic infection that can affect almost every organ system. The ability of secondary syphilis to mimic many other clinical conditions is largely responsible for its reputation as the “great imitator.”

The cutaneous lesions of secondary syphilis (syphilids) usually are described as macular, maculopapular, papular, papulosquamous, and pustular. More than 95% of the skin lesions are of the first four varieties, macular and maculopapular lesions predominating in most series. The lesions usually are symmetrical and widespread, varying from several millimeters to several centimeters in diameter ([Fig. 297.2](#)). Pruritic eruptions can occur. Successive eruptions may evolve from macular to papular or papulosquamous; the different forms may be present simultaneously. Among some patients, lesions are characteristically confined to the distal extremities, especially the palms and soles. Syphilids with a squamous component may resemble psoriasis, lichen planus, or pityriasis rosea. A rare, unusually severe type of secondary syphilis formerly called *lues maligna* sometimes occurs. It appears as nodular-pustular lesions on the torso, the extremities, and sometimes the oral mucosa that evolve over the course of months into large, necrotic ulcerations. In the AIDS era, *lues maligna* has been linked with HIV infection; however, it is important to know that this rare but severe form of secondary syphilis was well recognized in the preantibiotic era. Other common mucocutaneous manifestations of secondary syphilis include patchy (“moth-eaten”) alopecia and thinning of the eyebrows and beard; diffuse redness of the tonsils and pharynx; superficial ulcers of the oral and genital mucosa (mucous patches); and moist, papular excrescences in the intertriginous areas (condyloma lata) that teem with treponemes and are highly infectious.

FIGURE 297.2. Typical rash of secondary syphilis.

Generalized lymphadenopathy often is present, and splenomegaly often is evident in florid presentations. Other organ systems that may be involved in secondary syphilis include the gastrointestinal tract, the central nervous system, the eyes, the kidneys, and the bones. A markedly elevated alkaline phosphatase level, with or without other liver function abnormalities, usually indicates granulomatous hepatitis and occur in about 10% of patients with early syphilis. Renal involvement caused by immune complex deposition in secondary syphilis is rare. It usually manifests with isolated proteinuria, nephrotic syndrome, or acute glomerulonephritis. Symptomatic central nervous system involvement, usually headache and meningism (syphilitic meningitis), occurs among a small percentage of patients. In rare instances patients may have more severe neurologic disorders, such as a basilar meningitis with cranial nerve abnormalities (most commonly involving the third, sixth, seventh, and eighth cranial nerves), acute syphilitic hydrocephalus, optic neuritis, or cerebrovascular syndromes.

Anterior uveitis is relatively common in secondary syphilis and should be ruled out for all young adults with iritis. Less common is posterior uveitis, which can cause blindness through vitritis or destruction of the macula, and optic neuritis. There is a general impression that posterior syphilitic uveitis has become more prevalent, particularly among homosexual men, and it should be included among the causes of chorioretinitis in examinations of patients with HIV coinfection. Clinically significant osteitis and arthritis are rare; in contrast, mild forms of osteitis associated with bone pain are frequent.

After the manifestations of secondary syphilis subside, untreated patients enter the asymptomatic stage, called *latency*. An important finding of the Oslo Study was that approximately 25% of patients have one or more infectious relapses during the first 4 years of latency, primarily in the first year, and that infectious relapses thereafter are rare. This is the basis for the traditional distinction between early and late latency, whereas the period of greatest infectiousness is designated *early syphilis*. Relapses may be indistinguishable from the patient’s previous secondary episode. Cutaneous lesions tend to be less florid than those in secondary disease, whereas mucosal lesions, such as mucous patches and condyloma lata, may predominate. Isolated visceral relapses, such as hepatitis, osteitis, and uveitis, also

occur. Pregnant women with early latent syphilis are at great risk of infecting the fetus in utero.

According to the Oslo Study, approximately 30% of untreated patients with late latent disease have one or more forms of tertiary syphilis years, even decades, after infection. Tertiary syphilis is traditionally divided into the following three categories: benign tertiary (gummatous) syphilis, cardiovascular syphilis, and neurosyphilis. At present in the United States, all categories of tertiary syphilis are rare.

Gummatous syphilis is characterized by the development of one or more granulomatous lesions (gummas) 7 to 10 years after initial infection. Although most common on mucocutaneous surfaces and in bone, the lesions can occur in almost any location. Gummas begin as one or more small nodules that slowly enlarge through inflammatory changes, and central necrosis develops. They may vary from large, ulcerative skin lesions to space-occupying lesions within the central nervous system. Gummas of the facial structures and upper respiratory tract can produce marked disfigurement. Bone gummas can produce bone pain and give rise to pathologic fractures.

Cardiovascular syphilis is more common among men than among women and is a major cause of death among all patients with late syphilis. It is caused by obliterative endarteritis of the vasa vasorum of the large arteries, particularly the proximal ascending thoracic aorta. Medial necrosis develops and leads to progressive fusiform or saccular aneurysmal dilatation. In addition to extensive adventitial fibrosis, degeneration of the intima results in atherosclerotic plaque formation with calcification, evident as "tree barking" on chest radiographs. Syphilitic thoracic aortic aneurysms frequently remain asymptomatic until they rupture or encroach on neighboring mediastinal structures. Aortic root dilatation may give rise to aortic regurgitation and congestive heart failure. Some patients have symptoms of ischemic heart disease due to coronary artery ostial stenosis.

Syphilis of the central nervous system (neurosyphilis) constitutes a group of neurologic syndromes that occur mainly but not exclusively as a late manifestation of infection. Four categories of neurosyphilis usually occur in late syphilis: asymptomatic, meningovascular, parenchymatous, and gummatous. Asymptomatic neurosyphilis is the presence of one or more CSF abnormalities in a patient with late syphilis, usually defined as 1 or more years after infection. Meningovascular syphilis, manifesting as stroke, usually occurs 5 to 10 years after infection and can involve all parts of the central nervous system. The parenchymatous neurosyphilitic syndromes are tabes dorsalis and generalized paresis. Tabes dorsalis is caused by demyelination of the posterior columns of the spinal cord, dorsal roots, and dorsal root ganglia. Patients have lancinating pain, pupillary abnormalities (most characteristically Argyll Robertson pupils), impotence, bladder incontinence, truncal ataxia, lower extremity areflexia, and a profound loss of position and vibratory sensation in the legs that gives rise to chronic traumatic arthritis (Charcot joints). Generalized paresis is an insidious dementia that may include seizures, dramatic and bizarre changes in personality, and intellectual deterioration. Gummas of the central nervous system are rare and manifest as mass lesions with or without CSF abnormalities consistent with chronic inflammation.

Congenital syphilis, a consequence of intrauterine infection, usually at 18 weeks or later during gestation, is divided into early and late stages. Early infection occurs within the first 2 years of life and is analogous to the secondary stage of acquired syphilis among adults. It can be fulminant, causing stillbirth and neonatal death. Other disorders include rhinitis (snuffles); highly infectious mucocutaneous lesions, such as bullae, maculopapules, mucous patches, and condyloma lata; and periostitis, hepatosplenomegaly, thrombocytopenia, leukopenia, anemia, and nephrosis. After a period of latency, manifestations of late congenital syphilis develop that include interstitial keratitis, dental anomalies (mulberry molars and Hutchinson's teeth), eighth nerve deafness, osteitis, gummas, facial deformities (saddle nose), and neurosyphilis. For unclear reasons, cardiovascular syphilis is a rare complication of congenital infection.

LABORATORY FINDINGS

Because *T. pallidum* cannot be cultivated in vitro, diagnosis relies on either identification of the treponeme in clinical specimens or reactive serologic tests. Misdiagnosis or failure to diagnose the disease expeditiously is more frequently a consequence of the physician's unfamiliarity with the diverse manifestations of syphilitic infection than a lack of precision of diagnostic tests. Nevertheless, the limitations of syphilis diagnostics are such that a final diagnosis must at times be based on empiricism and mature clinical judgment.

The most rapid and direct means of identification of treponemes in clinical material is dark-field microscopic examination ([Fig. 297.3](#)). Exudates from chancres and moist secondary lesions such as condyloma lata are most amenable to this procedure. A slide should be examined for a minimum of 10 minutes before it is considered to be normal. Because visualization of treponemes with a dark-field microscope requires between 10⁴ and 10⁵ organisms per milliliter of fluid, normal findings do not eliminate the diagnosis of syphilis. Dark-field examination of material from mucosal surfaces is not recommended because these surfaces are colonized with nonpathogenic treponemes that may be confused with *T. pallidum*. Characteristic histopathologic findings may raise the suspicion of syphilis. Demonstration of treponemes in tissue may be accomplished by means of silver stain or the more sensitive and specific immunologic techniques in which anti-*T. pallidum* antibodies are used.

FIGURE 297.3. Photograph from dark-field microscopic examination depicts *Treponema pallidum* organisms.

Serologic tests for syphilis are the mainstay of diagnosis. The fact that the assays can be used to measure two distinctly different kinds of antibodies, nontreponemal and treponemal, is a perpetual source of confusion to practicing physicians. *Nontreponemal tests*, such as the Venereal Disease Research Laboratory test (VDRL) and the rapid plasma reagin test (RPR), are used to measure flocculating antibodies to a mixture of cardiolipin, cholesterol, and lecithin. These antibodies are presumed to arise from the interaction of virulent treponemes with host tissue. Titers of nontreponemal antibodies tend to be highest in secondary disease and decline gradually thereafter. Approximately 30% of patients with primary, late latent, and tertiary disease have nonreactive results of nontreponemal tests. Some patients with extremely elevated levels of nontreponemal antibodies, as in secondary syphilis, have nonreactive nontreponemal results when the tests are performed at low serum dilutions but have reactive test results after the sera are diluted (prozone phenomenon). This phenomenon can be detected by means of performing nontreponemal tests on diluted and undiluted sera.

The *treponemal tests*, which are used to measure antibodies specific for the pathogenic treponemes, are needed to confirm that reactive nontreponemal serologic results are caused by treponemal infection. The most commonly used treponemal tests are the fluorescent treponemal antibody absorption test and the microhemagglutination assay–*T. pallidum*. In the fluorescent treponemal antibody absorption test indirect immunofluorescence is used to detect serum antibody bound to treponemes dried on microscope slides. The microhemagglutination assay is used to measure the ability of serum antibodies to agglutinate red blood cells coated with *T. pallidum* antigens. The specificity of both assays is enhanced by the absorption of sera with material derived from a nonpathogenic commensal treponeme to remove cross-reacting antibodies. Inability completely to remove such antibodies is the most frequent cause of the falsely reactive treponemal tests that occur among as much as 2% of the general population.

A third treponemal test, called the *T. pallidum immobilization test*, is used to measure the ability of *T. pallidum*-specific antibody to immobilize virulent treponemes in the presence of complement. This highly specific test is not generally available. The sensitivities of the nontreponemal and treponemal tests for the different stages of syphilis are presented in [Table 297.1](#). Newer tests such as the Captia Syph G and Capita Syph M, which are used to detect *T. pallidum*-specific IgG and IgM, appear to be helpful in the diagnosis of early primary and congenital syphilis and in differentiating biologic false-positive reactions and true syphilis. Although not commercially available, immunoblot assays facilitate differentiation of false- and true-positive treponemal tests. Polymerase chain reaction amplification of *T. pallidum* DNA appears to be of limited value because treponemes often are not present in the clinical specimens, such as serum, most easily obtained from persons with

syphilis.

Stage	RPR	FTA-ABS	MHATP	TPI Test
Primary	75	85	80	40
Secondary and early latent	>99	100	100	98
Late latent and tertiary	70*	>99	98	95

Note: Values represent approximate means based on data from several clinical studies.
 RPR, rapid plasma reagin; FTA-ABS, fluorescent treponemal antibody absorption test; MHATP, microhemagglutination assay–*Treponema pallidum*; TPI, treponemal immobilization.
 * Reactivity of nontreponemal tests in tertiary syphilis varies greatly according to the specific syndrome.

TABLE 297.1. SENSITIVITY (%) OF SEROLOGIC TESTS IN DIFFERENT STAGES OF SYPHILIS

Many diseases may give rise to either acute or chronic falsely reactive nontreponemal tests (“biologic” false positives). Some causes of the former include *Mycoplasma pneumoniae* infection, various viral illnesses (especially Epstein–Barr virus infections), and malaria. Chronic falsely reactive nontreponemal tests are produced most often by autoimmune disorders, such as systemic lupus erythematosus but also occur in conditions such as narcotic addiction, leprosy, and pregnancy and as an accompaniment of aging. A nonreactive treponemal test excludes syphilis for a patient with a reactive nontreponemal test.

For the diagnosis of neurosyphilis, CSF examination should be performed on any patient with reactive syphilis serologic findings and neurologic abnormalities. In the absence of a traumatic lumbar puncture, a reactive CSF-VDRL result is almost always specific for neurosyphilis. However, the CSF-VDRL may be reactive among only 50% to 70% of patients with neurosyphilis, ranging from nearly 100% in meningovascular syphilis to as little as 50% among patients with tabes dorsalis. Active neurosyphilis usually is accompanied by CSF pleocytosis, usually lymphocytic, and often by an elevated protein level. A decrease in CSF glucose level also can occur. Cases of neurosyphilis have been reported among patients with normal spinal fluid. A presumptive diagnosis of neurosyphilis can be made when a patient is believed to have neurosyphilis and has a nonreactive CSF-VDRL. Empiric therapy usually is indicated in this situation, and response to therapy may help confirm the diagnosis.

All patients with late syphilis ideally should undergo lumbar puncture to identify asymptomatic neurosyphilis. The Centers for Disease Control and Prevention (CDC), however, recommends that these efforts concentrate on patients with clinical signs or symptoms of neurologic or ophthalmic syphilis; serum nontreponemal antibody titers greater than 1:32 (unless duration of infection is less than 1 year); treatment failure (see later); other evidence of tertiary syphilis (aortitis, gummas, iritis); and penicillin allergy for whom nonpenicillin therapy for late latent syphilis is planned.

Physicians frequently encounter patients whose nontreponemal serologic results, usually obtained as screening tests, are unexpectedly reactive. A treponemal test should be obtained because a nonreactive treponemal test excludes the diagnosis of syphilis. A reactive treponemal test requires the physician to perform a complete evaluation, including consideration of lumbar puncture, and to treat the patient accordingly. In appropriate circumstances, the physician should ask about residence in areas endemic for nonvenereal treponematoses that is serologically indistinguishable from venereal syphilis.

For infants with relatively high treponemal burdens, the presence of congenital infection can be confirmed with detection of spirochetes in suspicious lesions, body fluids, or tissues by means of dark-field microscopic examination, silver staining or immunofluorescence, or polymerase chain reaction for *T. pallidum* DNA. Otherwise, serologic tests are the mainstay of diagnosis, as in acquired infection. A triad of enlarged hypercellular villi, proliferative fetal vascular changes, and acute or chronic villitis can be evident at microscopic examination of the placenta and can be helpful in establishing a diagnosis of congenital syphilis. Prenatal diagnosis of fetal syphilis is possible with ultrasonography, which can help identify hydrops fetalis, hepatosplenomegaly, and placentomegaly in the presence of maternal syphilis. Any infant born to a seropositive mother should undergo a complete examination to rule out evidence of congenital syphilis. In addition to the serologic testing, a lumbar puncture is necessary to evaluate the CSF for cell count, protein, and VDRL result. Immunoblot studies have demonstrated the feasibility of using *T. pallidum*-specific IgM antibodies in neonatal sera as unequivocal evidence of intrapartum infection.

STRATEGIES FOR OPTIMAL CARE

Penicillin is the drug of choice for therapy for all stages of syphilis. *T. pallidum* is exquisitely sensitive to this agent, and results with the drug have been excellent. Although regimens with benzathine penicillin G have come under considerable scrutiny, these agents are the preferred formulations for uncomplicated forms of syphilis because they provide prolonged treponemicidal levels. Despite reports of treatment failures with penicillin, there is no evidence that the sensitivity of *T. pallidum* to penicillin has diminished since the introduction of this antibiotic. Alternative antibiotics, such as tetracycline, erythromycin, and chloramphenicol, are believed to be less efficacious. There is much less clinical experience with these agents than there is with penicillin, particularly in therapy of complicated forms of disease such as neurosyphilis. The 1998 therapeutic recommendations of the CDC are shown in [Table 297.2](#).

Primary and secondary syphilis.
 Benzathine penicillin G 2.4 million units IM in a single dose.
 Penicillin allergy: Tetracycline 500 mg orally twice a day for 2 weeks or erythromycin 500 mg orally four times a day for 2 weeks.
Early latent syphilis.
 Benzathine penicillin G 2.4 million units IM in a single dose.
 Tetracycline 500 mg orally twice a day for 2 weeks or erythromycin 500 mg orally four times a day for 2 weeks.
Secondary and early latent syphilis.
 Benzathine penicillin G 2.4 million units IM every 3 weeks for 3 doses.
 Penicillin allergy: Tetracycline 500 mg orally twice a day for 2 weeks or erythromycin 500 mg orally four times a day for 2 weeks.
Tertiary syphilis.
 Benzathine penicillin G 2.4 million units IM every 3 weeks for 3 doses.
 Penicillin allergy: Tetracycline 500 mg orally twice a day for 2 weeks or erythromycin 500 mg orally four times a day for 2 weeks.
Neurosyphilis.
 Aqueous crystalline penicillin G 18–24 million units/day, administered as 3–4 million units IV every 4 hours for 10–14 days.
 If compliance with therapy can be assured, patients may be treated with benzathine penicillin G 2.4 million units IM every 3 weeks for 3 doses or erythromycin 500 mg orally four times a day for 10–14 days.
Syphilis in pregnancy.
 Benzathine penicillin G 2.4 million units IM every 3 weeks for 3 doses.
 Penicillin allergy: Erythromycin 500 mg orally four times a day for 10–14 days.
Concomitant syphilis.
 Benzathine penicillin G 2.4 million units IM every 3 weeks for 3 doses.
 Penicillin allergy: Tetracycline 500 mg orally twice a day for 2 weeks or erythromycin 500 mg orally four times a day for 2 weeks.
 Patients with a history of penicillin allergy or those who are allergic to penicillin should be treated with penicillin if possible. If necessary, and treated with penicillin.

TABLE 297.2. THERAPY FOR THE DIFFERENT STAGES OF SYPHILIS

More than 95% of HIV-negative patients with syphilis of less than 1 year's duration are cured with intramuscular administration of 2.4 million units of benzathine penicillin G. Patients with complicated forms of early syphilis, such as posterior uveitis or meningeal infection with cranial nerve involvement, should receive high doses of intravenous penicillin, as for neurosyphilis. Nonpregnant patients with early syphilis who are allergic to penicillin can be treated effectively with tetracycline. Pregnant patients who are allergic to penicillin should undergo skin tests to confirm penicillin hypersensitivity. If skin tests are reactive, desensitization should be performed. Erythromycin should not be used to treat pregnant patients with penicillin allergies because of an unacceptable frequency of treatment failures among neonates.

Patients who seek treatment of gonorrhea are often presumed to be coinfecting with syphilis. All treatment regimens for gonorrhea in which b-lactam antimicrobial agents are used probably are effective in the management of early, incubating syphilis. Quinolones, such as ciprofloxacin, levofloxacin, and grepafloxacin, and spectinomycin are not effective against incubating syphilis. Persons who have had sexual contact within 90 days with an untreated patient with early syphilis are also presumed to be infected and need the treatment given for early syphilis.

Patients who are not allergic to penicillin who have late latent, cardiovascular, and benign tertiary syphilis are treated with benzathine penicillin G. Symptomatic cardiovascular lesions may not improve with therapy, but progression of asymptomatic lesions usually is arrested. Tetracycline is recommended to treat patients who

are -allergic to penicillin who have late latent syphilis. Intravenous penicillin G is recommended therapy for both asymptomatic and symptomatic neurosyphilis. Because of numerous reports of treatment failures, the CDC has eliminated regimens in which only benzathine penicillin G is used to manage neurosyphilis. It is highly desirable that patients with neurosyphilis who are allergic to penicillin undergo skin tests to confirm penicillin hypersensitivity and that desensitization be attempted if skin test results are reactive. If desensitization fails or is not attempted, the patient should be treated in consultation with an expert in syphilis treatment.

Ceftriaxone, a third-generation cephalosporin with a relatively long half-life, has been used experimentally in the management of primary and secondary syphilis. Treatment is multiple once-daily intramuscular injections. Although initial reports appear promising, further studies need to be conducted before ceftriaxone therapy can be recommended. One small retrospective study evaluated ceftriaxone in the treatment of HIV-positive patients with late latent and asymptomatic neurosyphilis. There was a disappointing 23% failure rate with 10- to 14-day treatment with ceftriaxone. The failure rate was very similar for another group treated with the standard therapy of injection of benzathine penicillin G once a week for 3 weeks.

The azalide antibiotic, azithromycin has many properties that suggest it might be useful as therapy for early syphilis. It is active against *T. pallidum* in vitro and has been effective in experimental models of syphilis. Although plasma concentration of azithromycin may be nearly immeasurable, high levels can be achieved in tissue. The half-life of azithromycin is 68 hours, which makes it ideal for therapy against *T. pallidum*, an organism with a prolonged doubling time. Ongoing studies suggest that azithromycin may be useful for early syphilis and may be efficacious in a single-dose to prevent incubating syphilis among patients treated for gonococcal and chlamydial urethritis.

Patients who have initially reactive nontreponemal serologic results should be examined at regular intervals, ideally beginning 3 months after therapy, to determine that a cure has been achieved. Patients should be reexamined clinically and serologically 6 and 12 months after treatment ends. More frequent evaluation may be prudent if the likelihood of follow-up care is uncertain. It once was believed that 95% of patients with primary syphilis will have nonreactive nontreponemal test results within 1 year of therapy and that at least 75% of patients with secondary and early latent syphilis will have nonreactive nontreponemal test results within 2 years of therapy. However, a carefully performed retrospective study conducted in Canada demonstrated that the rate of serologic decline after successful therapy for early syphilis was slower than previously thought. The investigators found fourfold and eightfold decreases in rapid plasma reagin titers 6 and 12 months, respectively, after treatment among patients with primary and secondary syphilis and fourfold decreases 12 months later among patients with early latent syphilis. Serologic test titers may decline more slowly for patients who previously had syphilis.

Seroreversion is definitive evidence of cure. Patients with early syphilis whose nontreponemal test results remain reactive at a low, stable titer also may be considered cured. If a patient has signs or symptoms that persist or recur or has a sustained fourfold rise in nontreponemal test titer, treatment probably has failed or the patient has been reinfected. These patients should be treated after reevaluation for HIV infection. Unless reinfection with *T. pallidum* is certain, lumbar puncture also should be performed. Failure of nontreponemal test titers to decline fourfold within 6 months after therapy for primary or secondary syphilis indicates that a patient is at risk of treatment failure. Such patients should undergo reevaluation for HIV infection. Optimal treatment of such patients is unclear. At a minimum, they should undergo additional clinical and serologic follow-up studies. Patients with HIV infection should be examined more frequently (every 3 months rather than every 6 months). If additional follow-up care cannot be ensured, repetition of treatment is recommended. Some experts recommend CSF examination in such situations. When patients undergo repetition of treatment, most experts recommend intramuscular injection of 2.4 million units benzathine penicillin G once a week for 3 weeks unless CSF examination indicates that neurosyphilis is present.

Patients with late latent syphilis should have nontreponemal serologic tests repeated 6, 12, and 24 months after treatment. Serologic response to therapy for late latent syphilis is difficult to judge because there are limited data. Titers should decrease fourfold (two dilutions) if pretreatment titers are high (1:32 or more). Patients with late syphilis frequently have low (1:8 or more) nontreponemal titers that do not decline appreciably after therapy. Such results are considered "serofast," and treatment has not necessarily failed. Patients who have a fourfold rise titer or whose titers do not decline fourfold within 12 to 24 months and those who have symptoms and signs of syphilis should undergo reevaluation for neurosyphilis and be treated accordingly.

Patients with neurosyphilis should undergo spinal fluid examinations at 6-month intervals for a minimum of 3 years or until the cell count is normal. Pleocytosis should improve considerably within 6 months of therapy. Failure to normalize within 2 years suggests a need for repetition of treatment. Protein and CSF-VDRL values decline slowly after therapy and may take years to normalize. A serofast CSF-VDRL result is common and is not by itself an indication for repetition of treatment. Meningeal and meningovascular forms of neurosyphilis usually show good clinical response to therapy. Improvement in the presence of a parenchymatous syndromes is highly variable; the conditions of some patients may continue to deteriorate even after appropriate therapy.

Several hours after receiving therapy some patients experience sudden onset of symptoms that include chills, fever, tachycardia, headache, flushing, and mild headache. Patients with neurosyphilis may have exacerbations of their neurologic symptoms, and further transient visual deterioration may occur among patients with ophthalmologic involvement. This response, called the Jarisch–Herxheimer reaction, is especially common among patients with secondary syphilis, although it has been described in all stages of syphilis and with therapies other than penicillin. Symptoms of the reaction usually abate within 24 hours and can be managed with aspirin. Severe localized forms of the reaction may necessitate short courses of glucocorticoids. The mechanism of this reaction has not been identified.

SYPHILIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Epidemiologic data have suggested that genital ulcers, including those caused by syphilis, are cofactors for HIV infection. Syphilitic lesions disrupt the normal epithelial and mucosal barriers and provide portals of entry for HIV. Moreover, the bases of chancres also contain large numbers of activated HIV target cells (activated lymphocytes and macrophages).

Because the cellular arm of the immune system is thought to be important in the containment of syphilitic infection, there is widespread concern that current recommendations regarding the diagnosis and management of syphilis may be inadequate in the care of patients with immunosuppression due to HIV infection. Numerous case reports document unusual presentations of syphilis, treatment failures, and accelerated development of neurosyphilis among patients with HIV infection. There also is concern that serologic tests for syphilis may not be reliable among patients with HIV infection. There have been three case reports in which both treponemal and nontreponemal test results were negative in the presence of biopsy-proven secondary syphilis.

Results of four controlled studies examining whether syphilis infection behaves differently among patients with HIV infection have been published. In a prospective study, neither neurologic manifestations nor central nervous system invasion by *T. pallidum* (detected by means of intratesticular inoculation of rabbits with CSF) were more common among patients with HIV infection. Another study compared results among users of injected drugs, 31 of whom had HIV infection and 19 of whom did not. No differences in stage of disease, serologic manifestations, or response to treatment were found in a median follow-up period of 11 months.

A case-control study involved 309 patients with early syphilis, of whom 70 (23%) had HIV infection. The clinical signs and symptoms of syphilis were different among the group with HIV infection in that they were more likely to come to medical attention with secondary syphilis and to have coexistent chancres with the secondary syphilis. However, no unusual dermatologic manifestations, no increased incidence of neurologic complications, and no increased rate of treatment failure with conventional regimens were found among the patients with HIV infection.

A recent CDC-sponsored, multicenter study compared use of the standard benzathine penicillin G regimen with use of the same regimen plus 2 g amoxicillin and 500 mg probenecid (orally three times a day for 10 days) for 553 HIV-seropositive and HIV-seronegative patients with primary, secondary, or early latent syphilis. There was only one reported clinical failure, which involved an HIV-seropositive patient who received standard therapy. Approximately 15% of patients who received treatment with either regimen did not meet the standard criterion for serologic success (a two-dilution decrease in nontreponemal serological titer) as late as 12 months after treatment. This occurrence was statistically more likely among HIV-seropositive participants than among their HIV-seronegative counterparts, although the clinical importance for both patient groups was uncertain. In the relatively short follow-up period of that study, none of the HIV-seropositive patients experienced the type of dramatic treatment failure that has been reported anecdotally over the past 10 years.

Despite the reports of unusual serologic responses among patients with HIV infection, the 1998 recommendations of the CDC state that treponemal and nontreponemal tests for syphilis are accurate for most persons with HIV coinfection. If there is suspicion of syphilis in the face of negative serologic results, other tests, such as dark-field microscopic examination, biopsy, and direct fluorescent staining of lesion material, should be performed.

Expert opinion based on available data is that patients with HIV coinfection may be at increased risk of treatment failure and neurologic complications, but the amount of increased risk appears to be small. In its 1998 treatment guidelines, the CDC recommended that patients with HIV infection and early syphilis receive the same treatment as patients without HIV infection and that they undergo follow-up evaluation 3, 6, 9, and 12 months after therapy to establish the adequacy of treatment.

Patients with HIV infection who have particularly florid secondary syphilis may benefit from large intravenous doses of penicillin. Although the practice is of unproven benefit, some experts advocate examining the CSF of all HIV-positive patients who have early syphilis. Routine lumbar puncture is not endorsed by the CDC.

PREVENTION AND CONTROL

Major strides in the prevention and control of syphilis were made with the institution of routine premarital and prenatal screening by means of nontreponemal tests. In view of the far lower incidence of syphilis in the postantibiotic era, it has been argued that routine screening is no longer cost-effective. However, increases in the incidence of syphilis among lower socioeconomic groups has demonstrated the importance of continued targeted surveillance. Aggressive epidemiologic tracing and treatment of contacts remains the most effective means available to public health workers for curtailment of syphilis transmission by patients with active infection.

The marked decline in the incidence of syphilis during the past several years has encouraged the CDC to make complete eradication of syphilis within the United States a public health objective. The emerging strategy to reach this lofty but potentially achievable objective involves a series of epidemiologic, public health, and behavioral initiatives. The development of a syphilis vaccine, a long-standing goal of researchers into treponemal disease, should be viewed as a complementary approach. Efforts at identifying specific treponemal molecules that might function as vaccinogens have been hampered by the inability to cultivate pathogenic treponemes in vitro and a poor understanding of *T. pallidum* proteins capable of inducing a protective immune response. Although prospects for a syphilis vaccine have improved with the advent of recombinant DNA methods and the availability of the *T. pallidum* genomic sequence, it is unclear whether a vaccine will be available in the near future.

[Diagnosis And Laboratory Findings](#)
[Strategies For Optimal Care](#)
[Control And Prevention](#)

DEFINITION

The nonvenereal or endemic forms of treponematoses—yaws, pinta, and endemic syphilis—constitute a group of chronic, granulomatous diseases in tropical and subtropical countries. They are caused by treponemes morphologically and serologically indistinguishable from *Treponema pallidum* subspecies *pallidum*, the agent of venereal syphilis. These diseases are transmitted by means of nonvenereal inoculation of mucocutaneous surfaces. They progress, as does venereal syphilis, through more or less defined clinical stages.

INCIDENCE AND EPIDEMIOLOGY

At the beginning of the twentieth century endemic treponematoses was rampant in almost all areas of the tropical belt but also occurred in some communities in the temperate zones. Endemic treponematoses typically is confined to remote, rural areas with poor sanitation and overcrowding. Economically disadvantaged peoples with frequent skin trauma, scanty clothing, and little or no access to health care are particularly at risk. Infection with the organisms that cause yaws and endemic syphilis occurs primarily during childhood, whereas infection with the pinta organism occurs during late childhood or adolescence.

YAWS

Yaws is known by a number of other names, including *frambesia*, *piar* (French), *parangi* (Malay), *paru* (Malay), and *bubas*. It is prevalent in rural, warm, tropical regions and initially affects children and adolescents, with a peak incidence between 6 and 10 years of age. Almost all new cases are diagnosed among children younger than 15 years. It is estimated that in the preantibiotic era 50 to 100 million active cases of yaws affected the 400 million people living in Africa, Asia, Latin America, and the Caribbean region. Yaws eradication programs launched in endemic areas by the World Health Organization in the 1950s brought about dramatic decreases in the prevalence of yaws in endemic areas. Unfortunately, there has been a mild resurgence of yaws because of inadequate facilities for treatment and inadequate surveillance methods. The main reservoirs of yaws are West and Central Africa, Southeast Asia, the Pacific islands, and Central and South America.

PINTA

Pinta is also known as *mal de pinto* (Mexico), *carate* (Colombia and Venezuela, and *azu* (Chile and Peru). Countries with high prevalence are Brazil, Venezuela, Colombia, Peru, Ecuador, Central America, and Mexico. In Brazil, some parts of the Amazonas state are an endemic focus of pinta. A few cases also have been reported from Southeast Asia, Central Africa, and the Pacific regions. However, the presence of pinta outside the Americas is the subject of controversy. Most patients acquire the disease in childhood or young adulthood. Like yaws and endemic syphilis, the primary foci of pinta are in remote rural regions. Precise data about the prevalence of pinta are scanty. A serosurvey taken in 1982 and 1983 in Panama revealed a 20% seropositivity rate. In this same survey, 2% to 3% of the population, primarily children younger than 5 years, were found to have active pinta.

ENDEMIC SYPHILIS

Also known as *bejei* (Bedouin Arabs in Syria and Iraq), *firjai* or *loath* (elsewhere in the Middle East), and *njovera* or *dichuchwa* (Zimbabwe), endemic syphilis continues to be a serious problem, particularly in dry, hot climates. Disease transmission occurs by means of direct contact with infectious lesions and by sharing drinking and eating utensils. Children between the ages of 2 and 15 years who live in isolated, closed communities with unhygienic and crowded conditions are the primary reservoir. Once highly prevalent among the nomadic and seminomadic rural populations of North Africa and the Middle East, endemic syphilis today is confined primarily to the Arabian peninsula and the Sahel, the southern border of the Sahara. The most recent data reveal that 15% to 40% of children in the Sahel have serologic evidence of treponemal infection and 2% to 20% have evidence of active infection. A prevalence of 27% has been documented among the Bedouin tribes of the Middle East.

ETIOLOGY

The agents of venereal syphilis, yaws, and endemic syphilis are *T. pallidum* subspecies *pallidum*, *pertenue*, and *endemicum*, respectively. *T. carateum* is the agent of pinta. The pathogenic treponemes are delicate, actively motile, helical bacteria 5 to 20 μm long and 0.1 to 0.2 μm wide. They stain poorly with aniline dyes, cannot be cultivated on artificial media, and can be seen only with a dark-field microscope or by means of histopathologic study. Differentiating these four treponemes is difficult. Speciation depends primarily on differences in host range in experimental animals, modes of transmission, geographic distribution, and clinical features of the respective diseases (Table 298.1). Differences identified at the genetic level may help in this regard. All four pathogenic treponemes stimulate the production of antibodies that are reactive in both nontreponemal and treponemal serodiagnostic tests.

Disease	Organism	Endemic Area	Primary Lesion	Secondary Lesion	Tertiary Lesion
Yaws	<i>T. pallidum</i> subspecies <i>pertenue</i>	Rural areas of Africa, Central and South America, the Caribbean, equatorial islands of Southeast Asia, and remote parts of India and Thailand	Typical papule Papilloma Ulcer	Diffuse papules, papillomas, or ulcers Osseous Splenitis	Destructive gummas of skin and bone
Pinta	<i>T. carateum</i>	Underdeveloped rural areas of Mexico and northern South America	Syphilitic papule	Subly papules Area of altered skin pigmentation	Area of altered skin pigmentation, hyperkeratosis
Bejei	<i>T. pallidum</i> subspecies <i>endemicum</i>	West Africa, small foci in Southeast Asia, Arabian peninsula, and remote Australia	Oral mucosal ulcer	Oral and pharyngeal ulcers Mucous patches Condylomata lata Pilonitis	Gummas of skin, bone, and joints

TABLE 298.1. NONVENEREAL TREPONEMAL INFECTIONS

PATHOGENESIS

All three nonvenereal forms of treponematoses are transmitted by close, person-to-person, nonsexual contact that allows inoculation of skin and mucosal surfaces with virulent organisms from infectious lesions. Pinta is the least contagious of the three diseases and *T. carateum* the least virulent of the pathogenic treponemes. Soon after inoculation, treponemes invade local lymphatic vessels and the bloodstream to disseminate systemically. With the exception of endemic syphilis, in which primary lesions rarely are seen, a primary lesion develops at the site of inoculation after an incubation period of 3 to 4 weeks. Weeks to months later, highly infectious secondary lesions appear on skin or mucosal surfaces. In both untreated yaws and pinta, recurrences of secondary lesions may occur for months to years. With all three infections, after the secondary manifestations fade, the infection enters a highly variable latency period that is followed by late or tertiary disease. Patients with

tertiary yaws and endemic syphilis have highly destructive, necrotizing granulomas of skin, mucous membranes, cartilage, and bone that histologically and clinically resemble the gummas of tertiary venereal syphilis. Lesions of late pinta, however, are nonnecrotizing cutaneous granulomas characterized by hyperkeratosis and depigmentation. Unlike venereal syphilis, endemic syphilis rarely involves the cardiovascular or central nervous system.

CLINICAL FINDINGS

YAWS

Primary yaws (frambesia) is characterized by a raised papule at the site of inoculation that enlarges to form a hyperkeratotic papilloma (mother yaw) before eventually forming a shallow ulcer that can persist for a few months to several years ([Fig. 298.1](#)). It often is accompanied by regional lymphadenopathy. The lesions of yaws tend not to be painful, except in cases of secondary bacterial infection. Yellow crust on the surface of a papilloma and a raised lesion are the best clues that a lesion is that of yaws. Crops of highly infectious, papular, lobulated, and verrucous secondary lesions appear weeks to months after infection and frequently are accompanied by painful periostitis. Goundou is a rare form of hypertrophic osteitis of the nasal process of the maxilla that may occur in early yaws and produces a characteristic facies. After multiple infectious relapses, the disease enters an asymptomatic latent period.

FIGURE 298.1. Shallow ulcers of yaws.

Approximately 10% of untreated patients eventually have tertiary disease, which generally consists of solitary destructive lesions of bone or mucocutaneous surfaces. Chronic osteitis of the tibia may lead to curvature, producing saber shins. Rhinopharyngitis mutilans (gangosa), highly destructive ulceration of facial structures, is a particularly severe form of tertiary yaws. Although yaws was classically described as sparing the nervous and cardiovascular systems (unlike venereal syphilis), some reports suggest the possibility of late ophthalmologic and neurologic involvement in yaws. The difficulty in definitively differentiating previous yaws infections from venereal syphilis makes conclusions in this regard difficult.

It is rare to see lesions of late yaws now. Patients usually have papilloma, lesions of early yaws. The classic yaws appearance of a person covered in papillomas is rare. There is some consensus that an attenuated form of yaws with less florid skin manifestations may have developed as a result of mass treatment campaigns in the 1950s.

PINTA

Pinta is unique among the spirochetal diseases in having only skin manifestations. The initial lesion of primary pinta appears after an incubation period of 1 week to 4 months. The initial lesions are small squamous papules, which may be single or multiple, never ulcerate, and cause no lymphadenopathy. The papular lesion frequently is localized on exposed areas of the lower limbs, face, arms, and torso. The primary papule can resemble a lichenoid, eczematoid, or psoriasiform lesion. It may resolve spontaneously or continue its evolution, becoming indistinguishable from a secondary lesion. Secondary lesions (pintids) usually appear 2 to 6 months after the initial lesion. They are usually few. Pintids are usually smaller, nonpruritic, dyschromic, and more morphologically consistent than the primary lesions. They can become hyper- or hypopigmented and keratotic, particularly over bony prominences. The pintids do not show symmetry. Lichenoid, eczematoid, or psoriasiform lesions may develop simultaneously in the same patient.

Tertiary pinta (late pinta) takes 2 to 5 years to occur and has a tendency toward generalization and symmetry. Atrophy of the epidermis and epidermal appendages occurs mainly close to joints. Mucous membrane involvement (pigmentation) may occur but is not frequent. Tertiary lesions are characterized by well-defined patches of hyperchromic, hypochromic, achromic, or dyschromic areas. Hyperchromic spots occur preferentially in skin areas that are exposed to the sun; hypochromic spots appear in unexposed areas. Achromic lesions appear mainly over bony prominences; preferred areas are the hands, feet, face, and extensor aspects of the extremities.

ENDEMIC SYPHILIS

Endemic syphilis usually begins as a generalized infection in the absence of an obvious primary lesion. It is characterized by ulcerative lesions of the oropharyngeal mucosa (mucous patches), hoarseness, angular stomatitis and split papules at the corners of the mouth, intertriginous condylomata (similar to those of venereal syphilis), and painful periostitis. Skin lesions, such as disseminated papules, may occur but are rarer than secondary venereal syphilis. Tertiary gummas develop among most untreated patients after a latency period of several years. These occur most commonly on the skin, in the nasopharynx, and in bone and may cause severe destruction and disfigurement.

DIAGNOSIS AND LABORATORY FINDINGS

Presumptive diagnosis of all three types of nonvenereal treponematoses can be based largely on the clinical presentation of the disease and its occurrence in an endemic area. Both the ulcerated primary lesion and the tertiary gummas of yaws have to be differentiated from other causes of skin ulceration common in tropical countries, including Buruli ulcer, sporotrichosis, pyoderma, leishmaniasis, and mycetoma. The skin lesions in all three stages of pinta may resemble conditions such as leprosy, psoriasis, and lichen planus.

Early lesions of all three infections contain large numbers of treponemes. A definitive diagnosis can be reached with dark-field microscopic or histopathologic analysis. As with venereal syphilis, treponemes usually are difficult to find in tertiary lesions. Reactivity in both nontreponemal (Venereal Disease Research Laboratory and rapid plasma reagin) and treponemal (fluorescent treponemal antibody absorption and microhemagglutination assay—*T. pallidum*) tests occurs with both nonvenereal treponematoses and syphilis and cannot, by itself, be used to differentiate these infections. In pinta, serologic tests may not become reactive until several months after infection, whereas nearly all patients with endemic syphilis have reactive serologic results when they come to medical attention.

STRATEGIES FOR OPTIMAL CARE

Intramuscular benzathine penicillin G is the therapy of choice for all three types of nonvenereal treponematoses. Adults and children older than 10 years with disease in the incubatory stage, with symptomatic disease, or with latent disease or those who are close contacts of infectious patients should receive 1.2 million units. Younger children should be given 600,000 units. Patients allergic to penicillin may be given 500 mg tetracycline by mouth four times a day for 15 days (total of 30 g). Children between 8 and 15 years of age should be given one-half the adult dose. Although erythromycin frequently is used as an alternative drug to treat young children, results of studies to determine its effectiveness have not been reported for any of the forms of nonvenereal treponematoses.

The lesions of patients with yaws become noninfectious within several days of therapy. The rate of decline of antibody titers is inversely proportional to the length of time the patient had been infected. Patients with endemic syphilis also become noninfectious within several days of therapy. If these patients are treated early, nontreponemal test results revert to nonreactivity. Pinta responds slowly to therapy. Early lesions take months to heal and frequently leave discolored residua. The

serologic response to therapy for pinta likewise is absent or slow.

Therapy for all three diseases in the tertiary stages may arrest disease progression but does not always bring about healing of the destroyed tissues. As is true of venereal syphilis, serologic reactivity of treponemal tests usually lasts for life, regardless of therapy. Failure of penicillin therapy for yaws has been reported in Papua, New Guinea. The implications of this observation, if confirmed, for mass treatment programs in remaining yaws-endemic areas are very serious.

CONTROL AND PREVENTION

Earlier global eradication programs have demonstrated that mass treatment in conjunction with improved living standards can dramatically reduce the prevalence of nonvenereal treponematoses in endemic areas. Failure to continue surveillance and treatment programs in many endemic areas has led to resurgence of these diseases, particularly yaws. Improving overall health care access and integrating surveillance and treatment into the existing health care system in endemic areas may be the best method to control and eradicate nonvenereal treponematoses.

CHAPTER 299: LEPTOSPIROSIS

GEORGE J. ALANGADEN

[Definition](#)
[Incidence And Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies For Optimal Care](#)

DEFINITION

Leptospirosis is zoonosis of worldwide distribution caused by the pathogenic spirochetal species *Leptospira interrogans*. Human infection occurs through exposure to water or soil contaminated with infected animal urine. The clinical spectrum of illness can range from subclinical infection to life-threatening multisystem illness.

INCIDENCE AND EPIDEMIOLOGY

Leptospirosis affects most species of wild and domestic mammals. Humans are affected through exposure to infected animal urine. In the United States leptospirosis is currently not a reportable disease except in a few states. Thus the exact incidence and prevalence are not known. Until 1993 about 40 to 100 cases were identified each year, about one-half being reported from Hawaii. In the United States leptospirosis generally occurs sporadically; however, outbreaks have been reported in occupational or recreational settings. Persons at risk of leptospirosis are those likely to have contact with infected animals or contaminated water, such as farmers, veterinarians, abattoir workers, sewer workers, and military personnel. Sporadic cases of leptospirosis in urban settings have been reported.

The incidence of leptospirosis due to exposure during recreational activities such as swimming, canoeing, and hunting has been increasing. In 1996 an outbreak was identified among five persons who had returned from a whitewater rafting expedition on flooded rivers in Costa Rica. River water contaminated with leptospires was implicated as the probable cause of the disease. Leptospirosis also was the likely cause of an acute febrile illness among about 24 athletes who participated in a triathlon in Illinois and Wisconsin in 1998. The participants probably were exposed to the organism while swimming in a contaminated lake.

Although leptospirosis is uncommon in the United States, it is one of the most widespread zoonotic diseases in the world, especially in temperate or tropical climates. It is being increasingly recognized in some Latin American, Caribbean, and Asian countries, and temporal associations between heavy rainfall and flooding and leptospirosis among humans have been observed.

The pathogenic species is *L. interrogans*. Specific serotypes have been associated with infection among at least 160 different mammalian species. Human disease can be caused by different serovars (serologic variants) the prevalence of which varies worldwide. Human disease is generally caused by serotypes Canicola (found in dogs), Pomona, Hardjo and Hebdomadis (all found in livestock), Icterohaemorrhagiae (rodents), and Autumnalis and Grippityphosa (found in wildlife).

ETIOLOGY

Leptospires are aerobic, mobile, thin (0.1 mm in diameter), heliocoid, bacteria about 6 to 20 mm long with semicircular hooked ends. The genus *Leptospira* consists of two species *L. interrogans* (pathogenic) and *L. biflexa* (saprophytic). On the basis of agglutinogenic characteristics these species have been classified into 300 serovars, which have been grouped into about 23 serogroups. Seven species of pathogenic leptospires have been identified on the basis of DNA homology. They can be grown on artificial media (10% rabbit serum or 1% bovine broth and long-chain fatty acids) at pH of 6.8 to 7.4 and incubation at 30°C for 1 to 4 weeks. They can be seen with a dark-field or phase-contrast microscope.

PATHOGENESIS

Infection of humans occurs when the leptospires gain access to the bloodstream through abraded skin, mucosa, or conjunctiva. They then rapidly disseminate throughout the body including the central nervous system. The clinical manifestations are thought to result from generalized vasculitis. Leptospiral products such as sphingomyelinase C and possibly other leptospiral cytotoxins may be responsible for the vasculitis. In severe cases of leptospirosis hemorrhagic diathesis and hepatic and renal dysfunction can be caused by endothelial damage from the vasculitis. Hepatic dysfunction is associated with minimal hepatocellular necrosis. Renal ischemia and hypoxia causing tubular damage without appreciable interstitial inflammation is thought to be the primary cause of renal insufficiency. Complete resolution of the hepatic and renal dysfunction occurs with clinical recovery. Myalgia is common and is associated with transient nonspecific inflammatory changes within the myofibrils. Central nervous system involvement occurs during the leptospiremic phase, but signs of meningeal inflammation occur during the second week of illness. The vasculitis can lead to hemorrhagic pneumonitis or myocarditis. In severe cases multisystem involvement can cause shock. Recovery occurs when an immune response develops in the production of specific antibodies and elimination of leptospiremia although leptospiruria can persist for weeks.

CLINICAL FINDINGS

The incubation period of leptospirosis is about 5 to 14 days. Leptospirosis is typically a biphasic illness. The first phase is a septicemic phase characterized by leptospires in the blood and cerebrospinal fluid (CSF). The second phase is an immune period in which IgM antibodies develop and leptospires are present in the urine. The clinical manifestations are highly variable. This is an acute, systemic febrile illness without any specific features. In general two clinical syndromes have been described—anicteric leptospirosis, which accounts for as many as 90% of cases, and icteric leptospirosis (Weil's syndrome). Subclinical infections are rare.

Anicteric leptospirosis is a generally an acute, self-limited illness with abrupt onset of fever, chills, headache, myalgia (calf and back), anorexia, nausea, vomiting, and an occasional rash. Fevers (38°C to 39°C), conjunctival suffusion (without discharge), and muscle tenderness often are found at examination. Transient rashes, lymphadenopathy, and hepatosplenomegaly are found less commonly. The acute symptoms subside after a week when the leptospires clear from the blood and CSF and specific IgM antibodies develop. Aseptic meningitis with mild pleocytosis or low-grade fever can occur during the second week (immune phase). Leptospiruria develops and can persist for as long as 3 weeks. Anicteric leptospirosis can become manifest with pulmonary hemorrhage, respiratory failure, and death, as occurred in Nicaragua.

Icteric disease is more severe than anicteric disease. The patient has varying degrees of hepatic, renal, hematologic, and other systemic dysfunction. The mortality is 5% to 10%. Jaundice and azotemia occur during the first week. Hyperbilirubinemia occurs but without appreciable hepatocellular dysfunction, as evidenced by relatively mild elevations in liver transaminase levels. Acute tubular necrosis manifested by oliguria, anuria, proteinuria, and hematuria can occur during the second week of the disease. Hemorrhagic manifestations such as epistaxis, gastrointestinal bleeding, hemorrhagic pneumonitis, hypotension, and myocarditis occur less commonly. It can take several weeks for patients with severe disease to recover completely.

LABORATORY FINDINGS

Mild leukocytosis with neutrophilia generally is present. Fivefold elevations in creatine kinase level occur in about one-half of cases. In the icteric form of leptospirosis bilirubin levels (predominantly conjugated) are generally less than 20 mg per deciliter and are associated with only mild elevations in liver transaminase levels (100 to 200 U per liter). Elevation in blood urea nitrogen level seldom exceeds 100 mg per deciliter and in creatinine level seldom exceeds 8 mg per deciliter. For an acutely ill and jaundiced patient the combination of marked increases in creatine kinase level with modest elevation in liver transaminase levels differentiates leptospirosis from viral hepatitis.

Most patients have CSF pleocytosis with cell counts generally less than 500 per cubic millimeter, normal glucose level, and mild elevations in protein level. About half of these patients may have meningeal signs. Nonspecific infiltrates from small nodular densities, or a diffuse ground-glass pattern, to areas of consolidation may be

found on a chest radiograph. An electrocardiogram may show nonspecific transient changes.

The definitive diagnosis of leptospirosis requires demonstration or isolation of leptospire in clinical specimens, seroconversion, or a fourfold or greater rise in antibody titer. Leptospire can be isolated from blood and CSF during the first 10 days of illness and from the urine for as long as 4 weeks. Direct examination for leptospire in urine or CSF by means of dark-field microscopy often shows no abnormalities. Leptospire may be demonstrated in a clinical specimen by means of immunofluorescence. Isolation of the organisms requires inoculation of clinical specimens onto semisolid media, such as Fletcher medium or Ellinghausen–McCullough–Johnson–Harris and incubation at 28°C to 30°C for up to 6 weeks. Selective agent 5-fluorouracil may be added to the medium when it is believed the specimen might have been contaminated. A dark-field microscope is used to examine the cultures periodically for leptospire.

The microscopic agglutination test with live or formalin-fixed antigens is the standard confirmatory serologic procedure. Antigens representing the serovars in a geographic area must be used because of the serovar specificity of this test. A fourfold or greater increase in *Leptospira* agglutination between acute- and convalescent-phase serum obtained at least 2 weeks apart is needed. This test is labor intensive and usually is performed at leptospirosis reference centers. Thus a variety of easier screening tests to detect leptospiral IgM antibodies with enzyme-linked immunosorbent assay (ELISA) or dot-ELISA have been developed. Polymerase chain reaction (PCR) assays have been used to detect leptospiral DNA in blood, serum, CSF, urine, and aqueous humor. Rapid DNA-based typing of serovars using PCR assays, DNA probes, and pulse-field-gel electrophoresis techniques have been reported.

STRATEGIES FOR OPTIMAL CARE

Patients with severe disease are given supportive therapy to correct dehydration, hypotension, hemorrhagic diathesis, and hepatic and renal dysfunction. Although antimicrobial therapy is efficacious when initiated during the first 4 days, it can still be effective later in the course of the illness. Antimicrobial therapy can shorten the duration of the fevers, ameliorate the disease, prevent leptospiuria, and decrease hospital stay. Patients with moderate to severe disease need high doses of intravenously administered penicillin G (80,000 to 100,000 U per kilogram) or intravenous ampicillin (0.5 to 1.0 g every 6 hours). Patients with milder disease can be treated with oral amoxicillin or ampicillin (500 mg every 6 hours) or doxycycline (100 mg twice a day). A Jarisch–Herxheimer reaction may occur after treatment with penicillin. Most cases of leptospirosis are anicteric and self-limited with an uneventful recovery. The prognosis generally correlates with severity of the illness and the condition of the patient. Death is caused by hemorrhagic complications or renal failure.

Effective control and prevention are difficult because of the ubiquitous nature of the organism and the persistence of infection among animals. Control measures for leptospirosis include vaccination of domestic animals, rodent control, use of protective clothing, and avoidance of swimming in contaminated water. Doxycycline (200 mg a week) has been used as effective short-term chemoprophylaxis among military personnel. Vaccination of humans has been used in Europe and Asia.

CHAPTER 300: RELAPSING FEVER

THOMAS BUTLER

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies for Optimal Care](#)

DEFINITION

Relapsing fever is an acute febrile illness caused by blood spirochetes belonging to the *Borrelia* species. The two kinds are tick-borne relapsing fever, for which rodents are the reservoirs and ticks are the vectors, and louse-borne relapsing fever, for which humans are the reservoir and body lice are the vectors. The natural course consists of one or more phases of fever and spirochetemia, which last several days and are separated by afebrile intervals of several days without spirochetemia.

INCIDENCE AND EPIDEMIOLOGY

Tick-borne relapsing fever occurs in endemic foci in the western United States, southern British Columbia, Mexico, Central and South America, Africa, and the Middle East. Louse-borne relapsing fever occurs in parts of South America, Europe, Africa, and Asia. The disease often goes unrecognized because patients with febrile illnesses do not routinely have blood smears examined for spirochetes. Ethiopia appears to be the country with the highest incidence, estimated to be 10,000 or more cases per year.

The major reservoirs of the tick-borne relapsing fevers are wild rodents, including squirrels, deer mice, rats, and chipmunks. The vectors of these organisms are soft-bodied argasid ticks of the genus *Ornithodoros*. The infection is passed between the reservoir animals through tick bites. Humans become accidental hosts when they are bitten by infected ticks. Tick bites are painless and usually occur at night. Ticks are able to survive as long as 15 years between blood meals and to harbor viable spirochetes for years. Female ticks can pass *Borrelia* spirochetes through the ovaries to their offspring, allowing ticks to be infective without having bitten an infected host. Persons at greatest risk of infection are campers who sleep in log cabins. In tropical countries, people who live in dwellings that are not rodent proof are prone to infection.

For louse-borne relapsing fever, the human body louse *Pediculus humanus* is the vector, and the only known reservoir is humans. Lice acquire the infection by feeding on a person who has spirochetemia, and they remain infected for their entire life span, which is 10 to 61 days under laboratory conditions. Persons at risk are those living in crowded, unhygienic conditions that favor infestation with lice. Migrant workers and soldiers at war are particularly prone to this infection. Men are at much greater risk than women. In endemic areas of Ethiopia, the incidence increases during the cool winter season, when people wear heavier clothing that becomes infested with lice.

ETIOLOGY

The species of *Borrelia* that cause tick-borne relapsing fever are numerous and include *B. duttonii* in East Africa, *B. hispanica* in Spain, *B. persica* in Asia, and *B. hermsii* and *B. turicatae* in North America. *B. recurrentis* is the only species that causes louse-borne relapsing fever. *Borrelia* spirochetes are spiral organisms that measure 5 to 20 μm in length and about 0.5 μm in diameter. They are too thin to be seen in wet preparations with a light microscope, but they can be seen with a dark-field or phase-contrast microscope. The spirochetes have corkscrew-like motility. They can be stained with aniline dyes, such as Wright's and Giemsa stains, and can be seen well in tissue with application of silver stains, such as Dieterle's or Warthin–Starry stain.

Borrelia bacteria are microaerophilic and fermentative in their growth characteristics. They can be cultivated in a complex broth, Barbour–Stoenner–Kelly medium. The relapsing feature of *Borrelia* infection has been attributed to antigenic variation in the infecting population of spirochetes. In experimental infection of rats with *B. hermsii*, separate serotypes emerged sequentially during relapses, and specific antibody appeared in response to each of the antigenic variants. Each of 25 serotypes of *B. hermsii* expresses different variable major proteins that are encoded by genes located on linear plasmids of the spirochete. A specific antigen G1pQ is not present in the Lyme disease spirochete *B. burgdorferi* and promises improved serologic testing of patients.

PATHOGENESIS

After a person is exposed to an infected tick or louse, spirochetes enter the body through the skin and divide in the blood plasma during an incubation period, estimated to last from 4 to 18 days. When the spirochetes have built up to a concentration of 10^4 to 10^9 per milliliter of blood, symptoms begin suddenly. A small proportion of the spirochetes are within circulating polymorphonuclear phagocytes, and some spirochetes have been phagocytosed by fixed macrophages of the reticuloendothelial system of the spleen, liver, and bone marrow. Although occasionally present in other tissues, such as brain, hepatic cells, kidneys, and subcutaneous tissues, spirochetes do not proliferate or elicit inflammatory reactions in these extravascular sites.

Borrelia spirochetes possess a heat-stable, nonendotoxic pyrogen that stimulates mononuclear phagocytic cells to elaborate the inflammatory cytokines tumor necrosis factor and interleukins 1, 6, and 8. Thrombocytopenia is caused by sequestration of platelets and disseminated intravascular coagulation and causes petechiae and sometimes other hemorrhagic phenomena. Levels of serum complement, Hageman factor, and prekallikrein are decreased, suggesting that activation of certain plasma proteins contributes to the pathogenesis. Before and during the Jarisch–Herxheimer reaction (a rigor elicited by antibiotic treatment), blood levels of the inflammatory cytokines rise. The reaction has been prevented in experiments by means of administration of antibodies against tumor necrosis factor. Patients develop antiborrelial antibodies. The antibodies kill and opsonize spirochetes and render patients immune to future infection with the same serotype of *Borrelia*. Patients who die of the disease have enlarged spleens with microabscesses, enlarged livers with necrosis and hemorrhage, hearts with myocarditis, and cerebral edema sometimes with cerebral hemorrhage.

CLINICAL FINDINGS

Relapsing fever begins abruptly with shaking chills, fever, headache, and fatigue. Most patients have these symptoms almost continuously throughout the day, whereas some patients report the intermittent appearance of symptoms several times a day. Patients frequently report myalgia, arthralgia, anorexia, dry coughing, and abdominal pain. Epistaxis occurs occasionally, and children may have seizures. These symptoms usually are mild on the first day of illness and increase in intensity over a few days, leading to prostration and a visit to a physician. The nonspecific nature of these symptoms leads patients or their physicians to believe they have a flulike illness. Patients may have seen ticks on their bodies, but the bites rarely leave a mark.

For pregnant women, severe disease is common and can induce labor, leading to abortion or preterm delivery with and high infant mortality. Neonates may acquire congenital infection from maternal blood, the illness being detected 4 to 12 days after delivery.

Temperature rises to 38.5°C to 40°C, and heart rate increases to about 115 beats per minute. Blood pressure decreases to about 105/70 mm Hg. Patients appear lethargic. Physical signs that are common but not regularly present are conjunctival injection, petechial skin rash that is more apparent on the torso than on the extremities, and palpable liver and spleen. Jaundice sometimes is present. Generalized muscle weakness is common. Some patients display mental confusion, delirium, or coma, and some have nuchal rigidity.

LABORATORY FINDINGS

Relapsing fever is readily diagnosed through microscopic examination of a thin film of peripheral blood obtained by means of fingerstick or venipuncture. *Borrelia* spirochetes are stained blue in a routine blood smear treated with Wright's or Giemsa stain. The spirochetes are 5 to 20 μm long and lie in the plasma spaces between blood cells or overlie the blood cells (Fig. 300.1). Patients with relapsing fever who have an active fever typically have several spirochetes per high-power field. Patients who are in an afebrile interval between relapses have normal smear findings and undergo reexamination when the fever reoccurs. Serologic tests for relapsing fever are not generally available, and serologic tests for Lyme disease show false positive results caused by the presence of cross-reactive antigens.

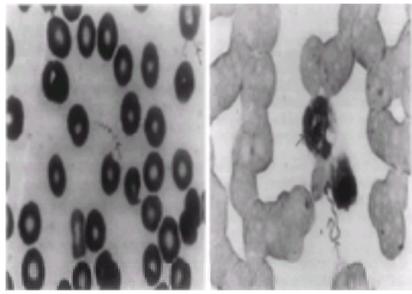

FIGURE 300.1. Blood smears of patients with relapsing fever show spirochetes (arrows) in plasma (left, Wright's stain) and within a polymorphonuclear leukocyte and in plasma (right, Warthin–Starry stain).

The white blood cell count of patients with relapsing fever usually is normal, or there are with increased band forms and decreased eosinophils. Platelet counts often are less than 50,000 per cubic millimeter, and there may be prolongations of prothrombin time and partial thromboplastin time and increased titers of fibrinogen-fibrin degradation products. Results of liver function tests frequently are abnormal, and there are elevations in serum levels of alanine aminotransferase and bilirubin. Renal function tests often show mild abnormalities in the serum urea nitrogen and creatinine values, and patients may have proteinuria and microscopic hematuria.

STRATEGIES FOR OPTIMAL CARE

The relapsing fevers are effectively managed with tetracycline, erythromycin, or penicillin. Tetracycline is the treatment of choice except among children younger than 7 years and among pregnant women. A single 500-mg oral dose of tetracycline is as effective in clearing spirochetemia and preventing relapse as a longer course of treatment. Erythromycin, 500 mg by mouth in a single dose, is equally effective and is a satisfactory alternative to tetracycline. For patients unable to take oral medication, intravenous injection of 250 mg tetracycline or erythromycin is curative. Penicillin G has been used as therapy for relapsing fever, but it has been associated with slow clearance of spirochetes and relapses after treatment. Good results have been reported from Africa with 400,000 or 600,000 units of procaine penicillin G given intramuscularly once or with the same dose repeated 12 hours later.

For most patients, antibiotic treatment provokes a distressing Jarisch–Herxheimer reaction. About 2 to 3 hours after antibiotic treatment is started, patients notice a chill that progresses to rigor. Temperature subsequently rises sharply, and blood pressure declines while spirochetes are cleared from the blood. Patients are extremely uncomfortable for several hours with shivering, intense body aches, and sometimes expressing a fear of impending death. Patients may need intravenous infusion of 0.9% saline solution to maintain adequate blood pressure on the day of treatment. Attempts to ameliorate the reaction by giving antipyretic or anti-inflammatory drugs have not been useful.

Complete recovery is expected among 95% or more of treated patients. Unfavorable prognostic signs are jaundice, coma, high spirochete counts in the blood, and hypotension. Death is caused by shock, liver failure, hemorrhage, or arrhythmia. Most neonates with relapsing fever die. During epidemics of louse-borne relapsing fever, untreated patients have mortality rates as high as 40%. Untreated patients also have relapses. In tick-borne relapsing fever, the first attack lasts about 3 days and is followed by an interval of about 7 days, after which an average of three relapses occur, each lasting about 2 days. In louse-borne relapsing fever, the first attack lasts about 6 days and is followed by an afebrile period of about 9 days. There usually is one relapse, which lasts only about 2 days.

Approaches to the control of relapsing fever include detection of disease among humans and treatment of the patients, vector control, rodent control, and public health education. Campers and hikers going into endemic areas should be advised to avoid staying in cabins that are inhabited by rodents and their ticks and to apply topical tick repellent (35% diethyltoluamide [DEET]) to their skin.

CHAPTER 301: ACTINOMYCETES: NOCARDIOSIS, ACTINOMYCETOMA, ACTINOMYCOSIS

RICHARD J. WALLACE

[Nocardiosis](#)
[Strategies for Optimal Care](#)
[Actinomycetoma](#)
[Actinomycosis](#)

NOCARDIOSIS

DEFINITION

Nocardiosis is the clinical disease produced by one of multiple species of the genus *Nocardia*. The spectrum of disease is extremely wide. It includes posttraumatic skin infections, brain abscess, pneumonia, and disseminated infection.

INCIDENCE AND EPIDEMIOLOGY

There does not appear to be a geographic predominance of nocardial infection in the United States. There is a male predominance of 3:1; 85% of disease is pulmonary infection, disseminated disease, or brain abscess. Published data (although from work done in the early 1970s) suggest that between 500 and 1,000 new cases of disease due to *Nocardia* infection occur in the United States each year. The effect of HIV infection on this number is unknown, but in several series, only 10% to 15% of patients with nocardiosis had AIDS.

Among patients with primary (posttraumatic) cutaneous disease, about 80% have no underlying disease. Among patients who have the more serious and invasive types of disease, about 80% have serious underlying disease. The most common single predisposing factor is use of high-dose corticosteroids to manage an underlying malignant disease, connective tissue disorder, or effects of organ transplantation. Other risk factors include advanced HIV disease, pulmonary alveolar proteinosis, and occasionally alcoholism. Among persons with HIV infection, nocardiosis occurs late. The mean CD4 lymphocyte count was 100 in one series of 30 patients.

ETIOLOGY

The causative agents of nocardiosis are aerobic members of the family Actinomycetaceae, genus *Nocardia*. *N. asteroides* complex is by far the most common clinical taxon and is responsible for 90% of cases of pulmonary disease, disseminated disease, or brain abscess. *N. asteroides* complex has long been recognized as containing multiple taxonomic groups. In the early 1990s two new species, *N. nova* and *N. farcinica*, were recognized as representing 20% each of isolates identified by means of routine methods as *N. asteroides* complex. The clinical disease appears comparable with that described in the past for *N. asteroides*, although *N. farcinica* appears to be the more virulent. The term *N. asteroides* complex has been introduced to describe the *N. asteroides* group in recognition of its taxonomic heterogeneity. *N. brasiliensis* is responsible for 60% to 80% of primary skin infections. Most pulmonary and extracutaneous disease caused by organisms that biochemically look like *N. brasiliensis* are caused by another new species, *N. pseudobrasiliensis*. Other species such as *N. transvalensis* and *N. otitidis-caviarum* are rare causes of any of these syndromes ([Table 301.1](#)).

Common	Rare
<i>Nocardia nova</i>	<i>Nocardia transvalensis</i>
<i>Nocardia farcinica</i>	<i>Nocardia otitidis-caviarum</i>
<i>Nocardia asteroides</i> complex	<i>Nocardia pseudobrasiliensis</i>
<i>Nocardia brasiliensis</i>	

TABLE 301.1. CLINICALLY IMPORTANT PATHOGENIC SPECIES OF *NOCARDIA*

PATHOGENESIS

Nocardia are environmental organisms but are rarely recovered from humans in the absence of disease. In primary cutaneous disease, a history of trauma at the site of infection is almost always present. Most of these injuries occur outdoors and are associated with obvious potential soil contamination, such as a motorcycle accident or gardening accident. The point of entrance for other types of clinical disease (lung disease, disseminated disease, brain abscess) is assumed to be the lower respiratory tract, although the place and source where this inhalation occurs is rarely identified.

The nature of the immune response to *Nocardia* organisms is still under investigation. The basic tissue inflammatory response involves polymorphonuclear leukocytes. Microabscess and macroabscess formation is present with purulent drainage. Despite the polymorphonuclear leukocyte response, cell-mediated immunity and macrophage functions are considered to be extremely important in the pathogenesis of disease. Antibodies are measurable in most infections in an immunocompetent host, but they probably play no role in protection from disease.

CLINICAL FINDINGS

[Table 301.2](#) lists the clinical diseases associated with *Nocardia* infection. Patients with primary cutaneous nocardiosis usually have a low-grade fever or no fever and have few or no systemic symptoms. Clinical disease is manifested as localized pyoderma with a central, ulcerated, draining lesion or an obvious abscess. These lesions are almost always on an extremity, but they frequently occur around the faces or necks of young children. Proximal lymphangitic spread with multiple subcutaneous nodules (abscesses) can exactly mimic sporotrichosis. This form of the disease is known as *sporotrichoid nocardiosis* and is almost always caused by *N. brasiliensis*.

Pneumonia	Brain abscess
Lung abscess	Bacteremia
Localized cutaneous infection	Disseminated disease
Sporotrichoid cutaneous infection	Meningitis
Osteomyelitis	Catheter sepsis
Septic arthritis	

TABLE 301.2. CLINICAL DISEASES ASSOCIATED WITH *NOCARDIA* INFECTION

Patients with pulmonary disease have the usual symptoms of pneumonia. Cough, usually productive of thick purulent sputum, is present. Chest pain of a pleuritic type occurs among some patients. Almost all patients have a fever, including those taking corticosteroids. The temperature may be as high as 39°C (103°F). In some instances the disease is detected at chest radiography before the onset of clinical symptoms.

Dissemination from a pulmonary focus (primarily to skin or brain) occurs among about 20% of patients. Symptoms of brain abscess may develop before or after the pulmonary symptoms or may occur without any apparent respiratory disease. The condition ranges from an asymptomatic state to the presence of fever, headache, lethargy, confusion, focal or grand mal seizures, or sudden development of a neurologic deficit.

LABORATORY FINDINGS

Nocardia organisms are not fastidious, but they grow more slowly than most bacterial species, taking 3 to 5 days to produce good growth. They grow well aerobically on blood and chocolate agar as well as on Löwenstein–Jensen medium. The presence of other mixed flora, especially in sputum, may obscure or even inhibit the growth of *Nocardia* organisms and is a major reason for failure to recover the organism. Despite the common misconception that these are fungi, nocardiae often grow poorly on Sabouraud's or antibiotic-containing media.

On Gram stain, the organism appears as beautiful, somewhat delicate, beaded, branched gram-positive filaments in tangled masses surrounded by acute inflammatory cells (Fig. 301.1). Only the anaerobic *Actinomyces* or *Propionibacterium* (formerly *Arachnia*) species such as *Actinomyces israeli*, have the same morphologic appearance. *Nocardia* organisms grow in blood cultures, usually from patients who are severely immunosuppressed, have overwhelming clinical disease, or have catheter-related sepsis.

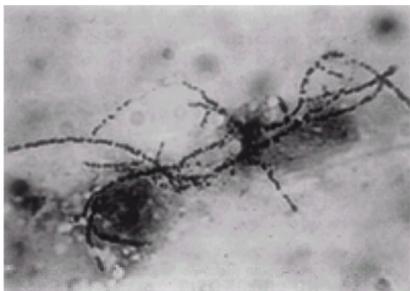

FIGURE 301.1. Gram stain of *Nocardia* organisms from the sputum of a patient with pulmonary nocardiosis. The organisms appear as a beaded, gram-positive, branching tangle adjacent to three necrotic white cells (original magnification $\times 1,000$.)

The diagnosis of nocardial infection by means of Gram stain and culture is not difficult if the disease is considered and good laboratory assessment is available. Because purulent sputum is available from most patients with pulmonary disease and the organisms are easily identified with Gram stain, there should be little need for invasive procedures. Unfortunately, this often is not the case, and bronchoscopy, percutaneous needle aspiration, or in rare instances open lung biopsy is needed to make a definitive diagnosis.

Identification to species has traditionally involved hydrolysis of casein, tyrosine, and xanthine. This technique does not separate *N. nova* and *N. farcinica* from *N. asteroides* complex and *N. pseudobrasiliensis* from *N. brasiliensis*. The use of polymerase chain reaction restriction analysis of a heat-shock protein gene sequence, and antimicrobial susceptibility patterns have been suggested to allow more accurate species identification.

Radiographic studies of patients with pneumonia often show a dense, rounded infiltrate that goes on to cavitation with an air-fluid level (Fig. 301.2). Such a finding in an immunocompromised patient is almost enough evidence to confirm the diagnosis of nocardial infection. Unfortunately, nocardial infection has many other manifestations in the lung. They range from a nonspecific bronchopneumonic infiltrate to diffuse reticulonodular disease.

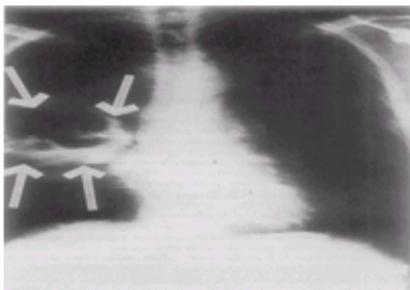

FIGURE 301.2. Chest radiograph of a patient with nocardial pneumonia (arrows) shows a large, rounded infiltrate that has undergone cavitation and has an air-fluid level.

Because of the pyogenic nature of the nocardial disease, radionuclide scans or computed tomography of the abdomen should be considered in the evaluation of patients with pulmonary disease to find unsuspected sites of clinical involvement. Computed tomography or magnetic resonance imaging of the brain should be performed for all patients with pulmonary or presumed disseminated disease to exclude the presence of a brain abscess, which profoundly alters the patient's treatment and prognosis.

No serologic tests (antigen or antibody) are available. Leukocytosis of 15,000 to 25,000 cells per milliliter is present in most patients with serious disease.

COURSE AND PROGNOSIS

A number of factors have been associated with the poor prognosis of pulmonary nocardiosis, including the need for continued use of immunosuppressive drugs, disseminated disease, and central nervous system involvement. As recently as the early 1970s, these factors were said to be associated with a mortality of 80% or greater. Although exact numbers are not available, the current mortality of uncomplicated pneumonia is probably only about 10%. The presence of overwhelming disease, including diffuse pulmonary disease with respiratory failure, clearly carries a high mortality. Brain abscess is difficult to treat. It necessitates surgical drainage in most cases, and the mortality when only sulfonamides are used is 50%. The mortality appears to be much lower with the use of initial combination drug therapy (often sulfa, ceftriaxone, and amikacin). Patients with AIDS as the risk factor seem to respond as well to therapy as do patients at risk because of use of

corticosteroids.

The course of primary cutaneous disease is not known but is probably self-limited. Cure with surgical debridement alone occurs in at least one-third of cases. Nevertheless, drug therapy is recommended for all patients.

STRATEGIES FOR OPTIMAL CARE

The therapy of choice for all forms of nocardiosis is a sulfonamide. The usual adult doses are sulfamethoxazole, 1 g three times a day, or sulfisoxazole, 2 g four times a day. Sulfadiazine is less desirable because of its high degree of insolubility in the urine. The optimal serum levels needed for clinical response have not been determined. An advantage of one sulfonamide preparation over another is not clinically evident.

Drugs in combinations with a sulfonamide are being used increasingly to manage nocardiosis. Trimethoprim has little in vitro activity against nocardiae, and a clinical advantage to using this drug in combination over using a sulfonamide alone has never been shown. Despite this, the combination of trimethoprim and sulfamethoxazole is commonly used to manage nocardiosis. Some practitioners consider it the treatment of choice.

In uncomplicated pulmonary or cutaneous nocardiosis, the response to sulfonamide therapy alone is so good that additional therapy is not routinely recommended, regardless of the risk factor. The need for additional agents comes with poor clinical response, overwhelming disease, disseminated disease, and brain abscess, for the mortality with sulfonamides alone is as high as 50%. Low-dose amikacin (peak serum levels approximately 20 µg per milliliter) and high-dose ceftriaxone (2 g twice a day for adults) are the usual choices to add to the sulfonamide until clinical improvement has occurred, which can take as long as 4 to 8 weeks. Amikacin is omitted first because of its greater toxicity. Other alternative agents include imipenem and cefotaxime.

The susceptibility of *N. asteroides* complex to antimicrobial agents other than the sulfonamides, is variable, so susceptibility testing should be performed if these agents are being considered. In vitro studies have shown that amikacin (95% susceptible to 2 µg per milliliter), imipenem (90% susceptible to 8 µg per milliliter), and cefotaxime or ceftriaxone (75% susceptible to 8 µg per milliliter) are the best alternative parenteral agents against *N. asteroides* complex. Minocycline (90% susceptible to 4 µg per milliliter) and amoxicillin-clavulanate (about 40% susceptible to 8/2 µg per milliliter) are the best oral agents. Specific drug susceptibility patterns are associated with other species or taxons of *Nocardia*. Isolates of *N. nova*, for example, are uniformly susceptible to erythromycin, clarithromycin, amikacin, and imipenem, whereas isolates of *N. farcinica* are resistant to all aminoglycosides except amikacin and the third-generation cephalosporins, including cefotaxime and ceftriaxone. Isolates of *N. brasiliensis* usually are susceptible to cefotaxime or ceftriaxone (less than 8 µg per milliliter), amoxicillin-clavulanate (less than 4/2 µg per milliliter), and amikacin (less than 2 µg per milliliter) but are resistant to imipenem (more than 8 µg per milliliter). Published experience with these agents is limited. Acquired drug resistance with therapy is rare but has occurred with amoxicillin-clavulanate and clarithromycin.

Because of the pyogenic and suppurative nature of nocardiosis, abscess formation is common. Drainage of these abscesses, especially in the brain and pleural space, is important.

The duration of therapy for nocardiosis varies with the type and extent of disease. The treatment period usually is 3 months for primary cutaneous disease, 6 months for pulmonary disease, and 8 to 12 months for a brain abscess. Relapses, if they occur, usually do so within 4 to 6 weeks of discontinuation of therapy.

ACTINOMYCETOMA

Actinomycetoma (Madura foot) is characterized by a large, swollen extremity with multiple draining sinuses and multifocal osteomyelitis. *Actinomyadura madurae*, an aerobic, slow-growing species of actinomycetes, is the most common pathogen, but *Nocardia* species and true fungi also can produce this disease, which usually occurs among people from developing nations. Because of the extensive nature of this disease, the long-term prognosis is poor. *Actinomyadura* organisms grow aerobically on routine and fungal media and appear as a large clump of beaded gram-positive filaments. Some but not all isolates of *Actinomyadura* produce b-lactamase. Penicillin or ampicillin is the therapy of choice for b-lactamase-negative strains, whereas erythromycin, sulfonamides, trimethoprim-sulfamethoxazole, and tetracycline are active against most but not all b-lactamase-producing isolates. Therapy for 12 to 24 months usually is needed. Surgery, including amputation, may be needed to control or cure the disease.

ACTINOMYCOSIS

Actinomycosis is the name for the group of diseases produced by six of the 14 currently recognized species of the genus *Actinomyces* and one species of the genus *Propionibacterium* (formerly *Arachnia*). Approximately 80% of cases of this disease are caused by the species *A. israeli*. These organisms are anaerobic bacteria. The usual reservoir is the gingival and tonsillar crypts, the gastrointestinal tract, and the female genital tract. *Actinomyces* are microaerophilic or obligate anaerobes and grow slowly. In disease they are almost always recovered with other anaerobic organisms.

Clinical disease is most commonly produced when oral anaerobic flora can be pathogenic. Facial or cervical actinomycosis, so-called lumpy jaw (named for the hard, woody induration of the skin produced by the disease), usually is associated with periodontal disease. An intense fibrotic reaction, sinus track formation, and tendency to produce metastatic infections in other sites, especially the skin, are unique features of actinomycosis wherever it occurs and are not seen with infection by other anaerobes.

Pulmonary disease is rare and can be difficult to diagnose because the organisms rarely are seen on Gram stains of the sputum. It has the radiographic features of anaerobic lung disease, sometimes including cavitation. The actinomycotic nature of the disease usually is demonstrated when a draining chest wall abscess is found or when biopsy of a lesion shows typical sulfur granules (Fig. 301.3). Not uncommonly, the infiltrate can mimic carcinoma of the lung and ends up being resected, so-called pseudotumor. Because of difficulty in growing the organism, microbiologic diagnosis of more than 50% of cases is based on histopathologic findings. In rare instances actinomycosis can occur in sites other than the face or lung. Such conditions include perforation of the gastrointestinal tract, endometritis associated with the presence of an intrauterine device, brain abscess, and a disseminated form of the disease with multiple sites of visceral and cutaneous involvement.

FIGURE 301.3. Sulfur granules of actinomycosis as they appear on a gauze bandage. They are light yellow and represent large clumps of organisms that have grown as a single mass.

Therapy for actinomycosis is penicillin. Cephalosporins, tetracycline, and clindamycin are good alternative agents for infections that do not include the central nervous system. Chloramphenicol is the alternative therapy for brain abscess. Penicillin usually is given in high intravenous doses (10 to 20 million units per day) until disease control is obtained. Then high-dose oral therapy (2 to 4 g per day) can be administered. The average duration of therapy is 3 months for cervical-facial disease and 6 to 12 months for pulmonary or disseminated disease. Surgical debridement is important, especially when an abscess forms.

CHAPTER 302: INFECTIONS CAUSED BY DIMORPHIC FUNGI

THOMAS F. PATTERSON

[Histoplasmosis](#)
[Coccidioidomycosis](#)
[Blastomycosis](#)
[Paracoccidioidomycosis](#)
[Sporotrichosis](#)
[Penicilliosis](#)

The dimorphic fungi are soil-growing organisms that exist in a mycelial form in the environment but grow as a yeast or yeast-like form at body temperature (37°C). The major infections caused by these fungi are histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, sporotrichosis, and penicilliosis. All occur in distinct epidemiologic settings or in specific endemic regions ([Fig. 302.1](#)). Clinical manifestation of these infections depends on the immune status of the host. Among hosts with normal immune status, clinical infection may be minimal. Patients with altered host defenses, including patients with AIDS, may have overwhelming disseminated infection. The large number of persons with suppressed immune systems, including patients with HIV and patients undergoing immunosuppressive therapy, has increased the clinical relevance of dimorphic fungal infection. Although the use of highly active antiretroviral therapy has reduced the incidence of these mycoses among persons with HIV infection, patients not receiving or effectively responding to this therapy continue to be at high risk of infection with these organisms. An approach to antifungal therapy is discussed in [Chapter 336](#).

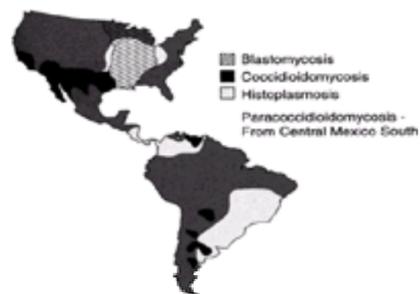

FIGURE 302.1. Endemic zones of dimorphic fungi in the Americas. (Adapted from Graybill JR. Opportunistic fungal infections in patients with AIDS. *Clin Courier* 1995;12:2, with permission.)

HISTOPLASMOSIS

The dimorphic fungus *Histoplasma capsulatum* is the etiologic agent of histoplasmosis, a disease endemic to the Ohio River and Mississippi River valleys. The clinical manifestations range from asymptomatic infection to chronic pulmonary disease and disseminated infection.

INCIDENCE AND EPIDEMIOLOGY

Most cases of histoplasmosis occur in endemic regions in North America and Latin America ([Fig. 302.1](#)). The attack rate approaches 100% in certain areas, but most cases remain asymptomatic and are detected only with skin testing. The organism is found in soil contaminated with droppings from fowl, including pigeons, starlings, and chickens, and is associated with bird roosts, caves, and decaying buildings. Urban outbreaks of histoplasmosis have been linked to soil disturbances. Children have high attack rates in outbreaks because of lack of immunity, as do persons who live on the edges of the endemic regions. Reactivation of infection can occur among immunosuppressed patients, such as those undergoing chemotherapy and patients with AIDS.

PATHOGENESIS

The usual route of infection is inhalation of microconidia, which germinate into yeasts that can disseminate through the blood and lymphatic system. Host cells, including neutrophils, macrophages, and natural killer cells control the organism. Circulating yeasts are cleared by reticuloendothelial cells. Specific cell-mediated immunity to activate macrophages fungicidal to the organism develops within 2 to 3 weeks. Persons with deficient T-cell immunity cannot contain the organism, and severe infection is more likely. Risk factors for failure of cell-mediated immunity include AIDS, organ transplantation, malignant disease, and steroid use. Immunity is not complete, and reexposure may cause clinical infection, particularly if the inoculum is heavy. Host response to the organism results in a granulomatous inflammatory lesion associated with necrosis. The lesion can contain latent organisms that serve as a source of endogenous reactivation if host immunity is impaired.

CLINICAL FINDINGS

The clinical spectrum of histoplasmosis depends on underlying host defenses, the intensity of exposure, and previous immunity. After low-intensity exposure, symptomatic infection develops in only 1 in 100 people ([Table 302.1](#)). After a heavy inoculum, most infections are symptomatic. The acute self-limited illness of histoplasmosis is characterized by a flulike illness with fever, chills, headache, myalgia, anorexia, nonproductive cough, and chest pain. Chest radiographs may show enlarged hilar or mediastinal lymph nodes with patchy infiltrates. After a heavy inoculum, more extensive pulmonary disease may occur, including adult respiratory distress syndrome.

Clinical Manifestation	Heavy inoculum (%)	Light inoculum (%)
Asymptomatic	50	99
Self-limited	50	1
Pulmonary (80% symptomatic)		
Arthritis-erythema nodosum (10%)		
Pericarditis (10%)		
Mediastinal granuloma (unknown)		
Disseminated	Unknown	0.05
Chronic pulmonary	Unknown	0.05
Inflammatory manifestation		
Fibrosing mediastinitis	Unknown	0.02

Source: Adapted from Wheat LJ. *Histoplasma capsulatum*. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious diseases*. Philadelphia: WB Saunders, 1992:1905–1912, with permission.

TABLE 302.1. CLINICAL MANIFESTATIONS OF HISTOPLASMOSIS

Inflammatory complications may accompany acute symptomatic infection in approximately 10% of patients and may include arthritis or severe arthralgia accompanied by erythema nodosum. These symptoms can last for months and are best managed with anti-inflammatory drugs. Viral-like pericarditis also may develop. Chest radiographs may show mediastinal lymphadenopathy as a clue to diagnosis of histoplasmosis. Most cases of acute histoplasmosis resolve without therapy, but

residual calcified granulomas in the lung are commonly identified on chest radiographs of persons who reside in the endemic zones.

In approximately 1 in 2,000 cases, progressive pulmonary histoplasmosis follows acute infection. This condition is characterized by chronic pulmonary symptoms associated with apical lung cavities and fibrosis. Chronic pulmonary histoplasmosis is caused by the immune response to the inhaled organism and is more likely to develop in patients with preexisting lung disease, elderly patients, men, whites, and persons with suppressed immune systems. Clinical symptoms resemble those of other granulomatous infections. Fewer than one-third of the lesions heal spontaneously. More commonly, persistence of the organism leads to chronic infection and fibrosis; progressive infections occur among more than 50% of patients.

Disseminated histoplasmosis develops among approximately 1 in 2,000 patients with acute infection and also can be caused by reactivation of disease. Disseminated infection is more likely to occur among patients with advanced AIDS, organ transplant recipients, patients receiving steroids or chemotherapy, patients younger than 1 year, and patients with debilitating medical conditions. Severe disease is more likely to develop among the very young and among patients with suppressed immune systems, including patients with AIDS. Fever, pulmonary infiltrates (including adult respiratory distress syndrome), and a syndrome resembling septic shock are more likely to occur. Disseminated infection can include gastrointestinal ulcerations and bleeding, skin lesions, oropharyngeal ulcerations, adrenal insufficiency, meningitis, and endocarditis. Signs and symptoms of disseminated infection are nonspecific and can include fever, weight loss, hepatosplenomegaly, and lymphadenopathy. Chest radiographs usually depict a diffuse interstitial or reticulonodular infiltrate. Bone marrow involvement is common and can be suggested by leukopenia, thrombocytopenia, and anemia. A markedly elevated serum lactate dehydrogenase level can be an important clue to the disease.

LABORATORY FINDINGS

The diagnosis of histoplasmosis is established by means of culture, histopathologic examination, or serologic testing ([Table 302.2](#)). Skin tests for histoplasmosis are not useful to establish a diagnosis because most patients in endemic zones have skin test reactivity, and cross-reactions with other fungi are common. Patients with disseminated histoplasmosis may have a negative skin test reaction. Cultures are limited by the lack of positivity in self-limited disease and slow growth of the organism. Cultures are more rapidly positive among patients with a heavy organism burden, as occurs among patients with AIDS. More than 75% of patients with disseminated disease have positive cultures of blood, bone marrow, or urine. Identification of the organism requires conversion of the mold to a yeast and back to the mold, but exoantigen testing is used to establish the diagnosis. Almost two-thirds of patients with chronic pulmonary histoplasmosis have positive sputum culture results, although multiple samples may be needed. Histopathologic analysis of tissues, including bone marrow, skin lesions, and buffy coat smears of blood, is useful for a rapid diagnosis through demonstration of budding intracellular yeasts.

Test	Positive Results (%)		
	Self-Limited	Cavitary	Disseminated
Antibody			
Immunodiffusion	75	100	63
Complement fixation	85	93	63
Either immunodiffusion or complement fixation	95	100	71
Antigen detection	40-75	21	52
Culture	15	85	85

TABLE 302.2. DIAGNOSTIC TESTS IN HISTOPLASMOSIS

Detection of antibody to yeast- and mycelial-phase antigens is used to diagnose acute infection. Antibody is uncommonly detected among persons with remote exposures, but cross-reactions with other fungi can occur. Antibodies develop within 4 to 6 weeks after infection and gradually decrease over a 2- to 5-year period. Antibody develops in most people with acute symptomatic infection. A fourfold rise in complement fixation (CF) titers or a titer of at least 1:32 suggests active infection. In chronic pulmonary histoplasmosis, titers usually are lower. The immunodiffusion (ID) test is used to measure H and M band antibody. Whereas the H band is more specific for the diagnosis, the M band is more sensitive. The diagnostic yield is increased with use of both the ID and the CF test.

A radioimmunoassay and an enzyme immunoassay were developed by Wheat et al. for detecting *Histoplasma* polysaccharide antigen in serum and urine. This method is particularly sensitive in detecting disseminated infection. Serial measurement of antigen provides a means for assessing the efficacy of therapy and for establishing relapse of disease. Therapy is discussed in [Chapter 336](#).

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is caused by the fungus *Coccidioides immitis*, a soil organism that is endemic in the southwestern United States, Mexico, and South America ([Fig. 302.1](#)).

INCIDENCE AND EPIDEMIOLOGY

In the United States, an estimated 100,000 cases of coccidioidomycosis occur annually. The clinical manifestations range from self-limited valley fever to disseminated disease. The number of cases increased in the 1980s and 1990s because of the epidemic of coccidioidomycosis in California and the occurrence of infection among patients with AIDS.

Infection occurs only in the Western hemisphere and primarily in the southwestern United States and Mexico. The semiarid conditions of the southwest United States are particularly favorable to growth of *C. immitis*. Epidemics of *C. immitis* infection in California have been associated with dust storms and soil disturbances from earthquakes. Cycles of drought and rain enhance dispersion of the organism because heavy rains facilitate growth of the organism in the nitrogenous soil wastes. Subsequent drought conditions favor aerosolization of arthroconidia.

PATHOGENESIS

The usual portal of entry for *C. immitis* is inhalation of arthroconidia. Pulmonary macrophages and neutrophils provide initial host defenses. Arthroconidia, endospores, and spherules are resistant to killing by these defenses, which may be related to the outer wall of the organism. Arthroconidia germinate to produce spherules filled with endospores, which is the characteristic tissue phase of the organism ([Fig. 302.2](#)). Spherules rupture to release vast numbers of endospores, which form additional spherules. These spherules are surrounded by neutrophils and macrophages, and this phenomenon leads to granuloma formation.

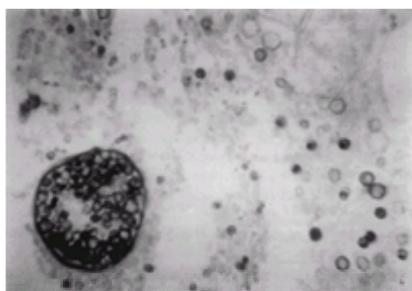

FIGURE 302.2. Periodic acid–Schiff stain of a thick-walled spherule of *Coccidioides immitis* filled with endospores in a tissue specimen.

Cell-mediated defenses with T lymphocytes are central to the immune response. Deficient cellular immunity is associated with disseminated infection. It occurs among certain groups at high risk of dissemination, particularly Filipinos and blacks, and immunosuppressed populations, such as organ transplant recipients, patients receiving steroid therapy or chemotherapy, and patients with AIDS. In certain endemic areas, 10% of patients with HIV infection contract coccidioidomycosis each year; the infection can be primary or reactivated. Male patients have higher rates of dissemination than do women, with the exception of pregnant women, among whom dissemination is common.

CLINICAL FINDINGS

Coccidioidomycosis is asymptomatic among 60% of persons with the infection. The presence of infection is indicated by a positive skin test reaction. The other 40% have a self-limited, influenza-like illness that develops 1 to 3 weeks after exposure. The illness is characterized by a dry cough, pleuritic chest pain, myalgia, arthralgia, fever, sweats, anorexia, and weakness. Patients with primary infection may have a variety of immune complex complications, including an erythematous macular rash, erythema multiforme, and erythema nodosum. Acute infection usually resolves without therapy, although symptoms may last for several weeks. Approximately 5% of patients have pulmonary residua, including nodules and cavities. Chronic progressive pulmonary infection is characterized, particularly among immunocompromised patients, by the development of extensive thin-walled cavities that may be complicated by cavity rupture, bronchopleural fistulas, and empyema.

Extrapulmonary disease develops in 1 in 200 patients and involves the skin and soft tissues, bone, and meninges. Among patients with meningitis, the mortality without therapy is greater than 90% after 1 year, and lifelong infection is common. Cerebrospinal fluid (CSF) findings include mononuclear pleocytosis associated with low glucose and elevated protein levels. CSF cultures frequently have negative results. The diagnosis is made through detection of complement-fixing antibodies in the CSF. Hydrocephalus is a common finding and may necessitate surgical intervention.

Dissemination to the skin is common. Lesions include verrucous, wart-like papules or plaques. Bone and joint dissemination also is common. The spine is the most frequent site of dissemination, but the typically lytic lesions also occur in the skull, hands, feet, and tibia. Joint involvement usually is monoarticular and occurs most commonly in the ankle and knee.

LABORATORY FINDINGS

Spherules are readily seen in histopathologic specimens and are diagnostic of coccidioidomycosis. *C. immitis* organisms are cultured within 3 to 4 days from clinical specimens. Large-volume CSF cultures may increase the yield from spinal fluid. The mycelial form of the organism grows as a white mold and is not distinctive. However, cultures are extremely infectious and should be handled with caution if the presence of *C. immitis* is suspected.

Serologic study is useful in establishing a diagnosis of coccidioidomycosis and in determining prognosis. IgM antibody may be detected within the first few weeks of infection with a tube precipitin test. IgG is detected after a few weeks of infection. One test combines ID and CF (IDCF). A positive IDCF result is highly suggestive of infection, and titers greater than 1:16 commonly indicate dissemination. Serum IDCF titers can be normal with single-site extrapulmonary infection. A positive CSF IDCF result is useful in the diagnosis of meningitis because results of culture of CSF rarely are positive. Serial titers can be used to assess the efficacy of therapy. Skin tests for coccidioidin are of limited utility. A positive result occurs with exposure, but the result may be negative in disseminated disease. Failure to develop a positive skin test reaction has been associated with poor response to therapy. Treatment is discussed in [Chapter 336](#).

BLASTOMYCOSIS

Blastomyces dermatitidis, the etiologic agent of blastomycosis, is endemic in the central United States and causes disease that ranges from pulmonary to disseminated infection. The skin is especially susceptible to dissemination.

EPIDEMIOLOGY AND PATHOGENESIS

B. dermatitidis exists in nature as a mold. At body temperature it appears as a large, broad-based, budding yeast (8 to 30 μm) with a thick, refractory cell wall. The endemic zone for blastomycosis overlaps that of histoplasmosis. Most cases occur in the midwestern and southeastern United States, the Canadian provinces of Ontario, Quebec, and Alberta, and sporadically worldwide ([Fig. 302.1](#)). Dogs are also susceptible to infection with the organism.

Infection has been associated with soil exposure. The organism has been isolated from soil containing decayed vegetation or decomposed wood. Warm, humid temperatures and proximity to water or recent rains seem to facilitate growth of the organism. Occupational or recreational contact with soil has been associated with outbreaks of infection.

The usual route of infection is inhalation of conidia. In the alveoli, the organism transforms into yeasts and induces an acute inflammatory response that includes neutrophils and macrophages with granuloma formation. Once converted to a yeast, the organism is relatively resistant to phagocytosis and killing. Cell-mediated immunity is the principal acquired host defense against the organism and is critical in preventing dissemination. Blastomycosis is not a common opportunistic infection among immunocompromised hosts and is an uncommon late complication among patients with AIDS.

CLINICAL AND LABORATORY FINDINGS

An estimated 50% of persons with blastomycosis have symptoms, which are nonspecific and mimic influenza or bacterial infection with an abrupt onset of fever, chills, cough, myalgia, and arthralgia. Chest radiographs may show lobar or segmental consolidation, although a nodular pattern may be seen with chronic disease. The acute pulmonary symptoms may resolve but can cause progressive pulmonary disease or disseminated infection. The skin is the most frequent site of dissemination. Verrucous or ulcerative lesions appear on exposed areas of the body and may be mistaken for squamous cell carcinoma. Other extrapulmonary sites of infection include subcutaneous abscesses that may ulcerate, bones (particularly long bones, vertebrae, and ribs), genitourinary tract (prostate and epididymis), and central nervous system.

The diagnosis is established by means of demonstration of the organism on wet preparations or by means of histopathologic study. The organism can be differentiated on the basis of size and the presence of a refractile cell wall and broad-based buds. The organism is cultured, but the presence of the mycelial form is not evidence to confirm a diagnosis before conversion to a yeast. Serologic study is less reliable in establishing a diagnosis because of the lack of sensitive and specific antigens. Serum CF tests are less sensitive and specific than ID tests with A antigen. Positive test results occur among as many as 80% of patients and suggest the diagnosis. Negative test results, however, should not exclude the diagnosis, particularly if infection is disseminated. Klein et al. described specific antigens that may enhance serodiagnosis. Treatment is discussed in [Chapter 336](#).

PARACOCCIDIOIDOMYCOSIS

Paracoccidioides brasiliensis, the etiologic agent of paracoccidioidomycosis (South American blastomycosis), is the principal dimorphic fungal infection in Latin America ([Fig. 302.1](#)).

EPIDEMIOLOGY AND PATHOGENESIS

P. brasiliensis produces a characteristic pilot-wheel appearance in tissues; 2- to 4- μm buds surround a central mother cell. Infection occurs only in Latin America but spares some areas, including the Caribbean region and Chile. Infection occurs among men older than 30 years and among patients with soil exposure, although the organism has only rarely been isolated in nature. The organism is inhaled and converts into yeasts. From the lung, the organism disseminates to regional lymph

nodes.

CLINICAL AND LABORATORY FINDINGS

Infection ranges from self-limited acute infection to chronic pulmonary disease and dissemination. The lungs are the primary site of infection, and most patients never have symptoms. In those patients, however, the organism may remain dormant and later cause clinical disease if host defenses are impaired. Among patients younger than 30 years, a juvenile form of infection occurs that is subacute and has a severe prognosis. It also occurs among patients with AIDS. These patients have minimal pulmonary symptoms. The major manifestations of infection involve the reticuloendothelial system. Among adult patients, symptoms can occur years after primary infection. They include a persistent cough, purulent sputum, chest pain, weight loss, weakness, malaise, dyspnea, and fever. The chest radiograph may show interstitial or alveolar infiltrates with nodules, cavitation, or hilar adenopathy. A paracoccidioidoma, a large cavitory mass, also can occur. Infection disseminates to skin and mucosa, including the oropharynx. Ulcerations contain characteristic hemorrhagic spots; oropharyngeal involvement may be associated with hoarseness or dysphagia. Other sites of dissemination are the lymph nodes, especially cervical nodes, adrenal glands, liver, spleen, central nervous system, and bones.

The diagnosis of paracoccidioidomycosis is established through examination of tissues or infected specimens for the characteristic pilot-wheel shape of the organism. Culture requires conversion to the yeast because the mycelial form is not distinctive. Detection of antibody by means of ID or CF testing is useful in suggesting the diagnosis and may be used to evaluate response to therapy. ID antibodies may remain positive for years, and cross-reactions with *Histoplasma* antigens are common with CF. Skin tests are not a reliable means to establish the diagnosis. Treatment is discussed in [Chapter 336](#).

SPOROTRICHOSIS

Sporotrichosis is caused by the soil fungus *Sporothrix schenckii* and is characterized by skin lesions, although pulmonary and disseminated infection occurs.

EPIDEMIOLOGY, PATHOGENESIS, AND CLINICAL FINDINGS

Infections with *S. schenckii* occur by means of direct skin inoculation from contaminated soil or plants, especially thorned plants such as roses. Outbreaks of infection have been associated with exposure to contaminated plant material such as straw, wood, hay bales, and sphagnum moss. Most cases are associated with vocational or recreational exposures, and the disease occurs worldwide. Sporotrichosis is uncommonly associated with immunosuppression and is rare among patients with AIDS.

After an incubation period of 1 to 10 weeks or longer, reddish-purple, necrotic, nodular cutaneous lesions appear that follow the lymphatic vessels and commonly ulcerate. Involvement of distal extremities may be related to the intolerance of some strains to temperatures of 37°C. The organism sometimes spreads directly to joints or bones. Disseminated infection is uncommon, as is pulmonary infection, which occurs most often among patients with alcoholism.

LABORATORY FINDINGS

The diagnosis of sporotrichosis is established by means of culture of the organism from pus or cutaneous lesions. Growth of the organism may occur within 3 to 5 days. Histopathologic analysis demonstrates typical cigar-shaped yeasts that may be surrounded by a stellate material that is positive at periodic acid–Schiff staining and is known as an *asteroid body*. Serologic testing may be useful to detect extracutaneous infection such as meningitis, but antibodies may be present without the disease. Treatment is discussed in [Chapter 336](#).

PENICILLIOSIS

Penicillium marneffe has emerged as an important dimorphic pathogen in Southeast Asia. It produces chronic disseminated infection in immunosuppressed hosts. The fungus is endemic to Southeast Asia and is associated with exposure to the bamboo rat. Infections have been reported in northern Asia, throughout China, and as imported cases in Europe and Texas. Most cases have occurred among patients infected with HIV.

The organism is acquired through inhalation, and disseminated infection develops. Signs and symptoms mimic those of disseminated histoplasmosis or coccidioidomycosis. They include fever, weight loss, cough, hepatosplenomegaly, lymphadenopathy, and skin lesions. Pulmonary infiltrates, anemia, and thrombocytopenia are common. The diagnosis is established with smears of bone marrow, ulcerative skin lesions, or buffy coat of blood. Examination of the smears show elliptic yeasts that resemble *H. capsulatum* organisms except that prominent cross-walls are present. The walls develop when the organism divides through fission. On culture, the mold colony produces a distinctive red pigment. Treatment is discussed in [Chapter 336](#).

CHAPTER 303: OPPORTUNISTIC FUNGAL INFECTIONS

JOHN E. EDWARDS, JR.

[Candida Species, Including Candida Glabrata](#)
[Cryptococcal Infections](#)
[Aspergillosis](#)
[Zygomycosis \(Mucormycosis\)](#)
[Emerging Opportunistic Fungi](#)

CANDIDA SPECIES, INCLUDING CANDIDA GLABRATA

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Although more than 150 species of *Candida* exist, only *Candida albicans*, *C. tropicalis*, *C. guilliermondii*, *C. parapsilosis*, *C. stellatoidea*, *C. pseudotropicalis*, *C. krusei*, and *C. glabrata* infect humans with frequency. The numbers of infections caused by *C. lusitanae* is increasing. The importance of *C. lusitanae* is its resistance to amphotericin B. The rate of infection with *C. dubliniensis* is increasing among patients with AIDS. *C. glabrata*, formerly called *Torulopsis glabrata*, is capable of infecting the urinary tract and disseminating to major organs in immunocompromised patients. The manifestations are similar to those associated with the other species. Recovery of *C. glabrata* organisms from the gastrointestinal tract, genitourinary tract of women, and blood has increased considerably.

Candida organisms are ubiquitous. They are normal commensals of humans and some animals, usually inhabiting mucous membranes or damaged skin. Evidence indicates that many health care workers carry the organisms on their hands. Most species exist in three forms in tissue: yeast, which can bud, hyphae, and pseudohyphae. The organisms are partially gram-positive and grow well in aerated blood culture bottles, lysis centrifugation isolators, and routine culture media.

PATHOGENESIS

Severe candidal infections usually are iatrogenic complications of modern therapeutics. The organism is emerging as a highly important nosocomial pathogen. The two most important predisposing factors are exposure to broad-spectrum antimicrobial agents and neutropenia. Neutropenia, however, is not requisite for disseminated candidiasis. About one-half of cases continue to occur among patients with complicated postoperative courses unrelated to underlying neoplastic diseases. *Candida* organisms are the fourth most commonly isolated microorganisms and the third most common pathogen in blood cultures of hospitalized patients. Several virulence factors of *Candida* have been studied, including the morphologic forms of the organism (especially germ tubes and hyphae), extracellular enzymes (e.g., protease and phospholipases), and its ability to interfere with host defense mechanisms.

CLINICAL FINDINGS

Skin and Mucous Membranes

Intertrigo on the warm, moist areas of the skin occurs among obese persons and those with diabetes. Infection of the hair follicles occurs among both healthy persons and addicts. Paronychia occurs among persons who immerse their hands in water for long periods. Candidal diaper rash is one of the most common cutaneous infections of infants. Chronic mucocutaneous candidiasis is a long-standing, severe mucocutaneous disease of patients with lymphocyte-mediated immune response deficiency. Among immunocompromised hosts, the macronodular lesions of disseminated candidiasis, which contain the organisms, are important in ascertaining the presence of widespread dissemination in the visceral organs. These lesions are raised and frequently have a hemorrhagic base. Results of biopsy with both culture and section for histopathologic study establish the cause.

Candidal infection of the mouth, or thrush, occurs among patients who have taken antibiotics or inhaled steroids, among neonates, among denture wearers, and among severely debilitated or immunocompromised patients. It is one of the most frequent manifestations of AIDS. Any person who has thrush without an identifiable predisposing factor should be evaluated for AIDS.

Candidal infections of the gastrointestinal tract have become common among immunocompromised patients. Candidal esophagitis occurs frequently among patients receiving cytotoxic chemotherapy and among patients with AIDS. Swallowing is painful, and white plaques on the esophageal mucosa can be identified with endoscopy. Because herpesvirus and cytomegalovirus infections are in the differential diagnosis, biopsy is necessary. Before a definitive diagnosis is made for selected patients, however, a therapeutic trial with antifungal agents is acceptable. Biopsy specimens of gastric ulcers have been found to contain *Candida* organisms. Therapy for the ulcer usually is successful without specific anti-*Candida* therapy. In refractory cases, however, antifungal therapy should be tried when *Candida* has infected the ulcer base. In severely neutropenic hosts, *Candida* may cause ulcers throughout the gastrointestinal tract and may disseminate from these sites.

Genitourinary Tract

Candida species are found in the urine of 8% of healthy male and 12% of healthy female subjects. Candiduria, however, may signify cystitis, pyelonephritis, papillary necrosis, perinephric abscess, fungus balls, and emphysematous cystitis. A common problem is prolonged colonization of the bladders of patients with indwelling Foley catheters. Among most patients, the candiduria is self-limited, but some patients may need an amphotericin B bladder washout or treatment with oral fluconazole. There is concern that urinary tract colonization can cause dissemination, so the threshold has lowered for treating hospital patients for urinary colonization and infection.

Blood Vessels

About 2% of cases of endocarditis are caused by *Candida* organisms, and 50% of these are complications of cardiac surgery. Heroin addicts also are prone to the development of candidal endocarditis, usually with *C. parapsilosis*. The hallmarks of candidal endocarditis are large vegetations and occlusion of large vessels. Of particular importance is the increasingly common occurrence of candidal intravascular infection at sites of peripheral indwelling intravascular lines. Fungus balls in the right atrium have occurred as complications of the presence of indwelling central catheters. Persistent candidemia may be caused by these intravenous infections.

Central Nervous System

The most common candidal infection of the central nervous system (CNS) is microabscess of the brains of patients with widespread hematogenous candidiasis. A large percentage of biopsy specimens from such patients have shown brain involvement. The most common form of infection is multiple microabscesses and small macroabscesses. Larger parenchymal abscesses, granulomatous vasculitis, and meningitis also have been described. Other CNS conditions associated with cerebral candidiasis include complications of chronic otitis, cerebral trauma, neurosurgical procedures, and presence of indwelling intracranial devices, such as ventricular fluid shunts. A small number of patients have had candidal meningitis that occurred de novo. The leukocytosis in candidal meningitis may be predominantly polymorphonuclear or predominantly mononuclear. The most effective treatment is a combination of amphotericin B and 5-fluorocytosine.

Pulmonary System

Candidal pneumonia is uncommon. When it occurs, the most common form is diffuse miliary abscesses in the preterminal course of severe neutropenia. In rare instances *Candida* organisms may superinfect the lung parenchyma damaged by preceding bacterial pneumonia. Progressive, necrotizing, localized pneumonia may evolve. Because *Candida* organisms frequently are present in the sputum of ill patients previously treated with antibiotics, simple recovery of the organism does not prove pneumonia. Histopathologic demonstration of invasion of tissue is definitive.

Other Candidal Infections

Additional candidal infections are osteomyelitis, arthritis, pancreatitis, biliary infection with fungus ball formation in the gallbladder and biliary ducts, postoperative infection of sternotomy sites, infection of prosthetic implants, peritonsillar abscesses complicating thrush, sinus and otic infections, peritonitis, especially during long-term ambulatory dialysis, and infection of the skeletal muscle with severe pain. Candidal endophthalmitis is an important complication of hematogenous dissemination and an important clue to infection of other organs. Ocular candidal infection can occur as a complication of ophthalmic surgery. Numerous patients have had hepatosplenic candidiasis with focal abscesses in both organs. It usually requires prolonged antifungal therapy. The abscesses can be seen on computed tomographic scans, and percutaneous biopsy can be performed.

Syndrome of Disseminated Candidiasis

Widespread disseminated candidiasis occurs most frequently among patients with neutropenia and among patients with prolonged and medically complicated postoperative courses, not necessarily related to the presence of a neoplasm. Low-birth-weight neonates also are at risk. Predisposing factors include use of antibiotics, neutropenia, presence of indwelling intravascular catheters, hyperalimentation fluids, and steroids. *Candida* is one of the most common organisms recovered from blood cultures in major medical centers, usually within the top 5 to 10 organisms. A strong consensus has evolved to treat all patients who have candidemia with an antifungal agent.

Beginning in the 1980s, a syndrome called the *yeast connection* or *Candida-related complex* was described in the general press. The purported pathogenesis is overgrowth of *Candida* on mucous membranes, especially in the gastrointestinal tract. This overgrowth is said to be induced through use of antibacterial drugs and environmental toxins. The *Candida* organisms are said to be capable of producing toxins that inhibit the immune system. The publications claim that weakness of the immune system causes a diversity of general symptoms, including fatigue, irritability, poor memory, and many other similar nonspecific conditions. Treatment is supposedly antifungal agents and avoidance of yeast-containing foods. Because the reports appeared in the general press, many persons are convinced they have this condition. At least three medical societies have published position statements expressing skepticism about the syndrome and advising caution in the use of potentially toxic antifungal agents for treatment.

LABORATORY FINDINGS AND DIAGNOSIS

It is difficult to determine whether a positive blood culture result is related to the presence of an indwelling catheter and the infection may resolve with removal of the catheter or whether the result reflects underlying disseminated disease. The problem is compounded by the lack of any reliable serodiagnostic tests. A strong consensus has evolved that all patients with candidemia should be treated with an antifungal agent. Any patient prone to disseminated candidiasis because of exposure to the known predisposing factors needs serial blood cultures and a physical examination to detect evidence of renal, cardiac, or cerebral infection. The diagnosis of candidal infection of deep organs requires biopsy evidence of the organism that is invading the tissue. Determining whether macronodular skin lesions, candidal endophthalmitis, or candidal myositis is present is valuable because the presence of these infections is highly correlated with involvement in the brain, heart, or kidney. The diagnosis of candidal infection of the mucous membranes can be established on the basis of the clinical appearance of the lesions and recovery of the organism from scrapings of the infected area. There are no serodiagnostic tests for invasive candidiasis that are well accepted or widely used.

STRATEGIES FOR OPTIMAL CARE

Until further studies are completed, therapy for life-threatening candidal infection is amphotericin B. Studies have shown that fluconazole is acceptable for patients without neutropenia and patients with neutropenia and candidemia who do not have life-threatening infection. Mucocutaneous infections have been successfully controlled with azole antifungals, including fluconazole, itraconazole, and ketoconazole. Removal of as many predisposing factors as possible is critical. The consensus is that removal of a catheter and changing all intravenous lines is highly desirable whenever logistically feasible.

CRYPTOCOCCAL INFECTIONS

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Within the genus *Cryptococcus*, *C. neoformans* is the dominant species; infection with non-*neoformans* species is rare. The organism is a ubiquitous, encapsulated yeast of worldwide distribution, found in soil, on fruit, in pigeon droppings, on eucalyptus trees, and in animals, including cats. It occurs predominantly in the yeast phase, and its capsule is easily seen in specimens of body fluids with the aid of india ink or nigrosin. Cryptococcosis is an aerosol-borne mycosis. Either overt or subclinical infection of the lungs occurs after inhalation of contaminated dust. Most patients with the infection do not give a history of unusual exposure to dust or pigeons. CNS infection is caused by hematogenous seeding. Direct human-to-human or animal-to-human infection is not known to occur.

PATHOGENESIS

Many patients with cryptococcosis have no known host defense defect or predisposing condition. Only limited clinical observations and data from experiments with mice suggest the possibility of a genetic predisposition to infection in these circumstances. Predisposing factors for cryptococcal infection include AIDS, lymphoma, use of corticosteroids, sarcoidosis, diabetes, cytotoxic antineoplastic therapy, and renal transplantation. The disease is substantially more frequent among men and more common among whites than other races.

CLINICAL FINDINGS

Central Nervous System

Involvement of the CNS is the most serious and frequent form of cryptococcosis. Certain host factors may be responsible for this common CNS localization, such as lack of an inflammatory response in the brain and meninges and the growth-supportive nature of the cerebrospinal fluid (CSF). Hematogenous seeding of the meninges usually causes subacute symptoms, including headache, meningism, and low-grade fever. However, approximately one-half of patients who do not have a recognizable immunocompromising condition do not have a fever when they come to medical attention. Some patients with AIDS may have almost no symptoms. Although uncommon, neuropathy and papilledema may occur. Because of the possibility of a brain abscess or other space-occupying lesion, computed tomography scan of the head is advisable before a spinal tap. Abnormal CSF values include elevated opening pressure, depressed CSF glucose levels, elevated protein levels, and pleocytosis with lymphocyte predominance. Many or all of these abnormalities can be absent among patients with AIDS. In about one-half of cases, cryptococci can be seen with a microscope in india ink or nigrosin preparations of the CSF. During the evolution of the AIDS epidemic, patients were in stable clinical condition at admission and had rapid herniation after therapy was begun. Whether therapy accelerated decompensation is related to initiation of antifungal therapy is speculative. In general, the prognosis among patients with AIDS has been poor, and the relapse rate has been high. Many patients have come to attention with only minimal or no neurologic signs or symptoms.

Pulmonary System

Healthy people may harbor cryptococci as part of the natural flora of the tracheobronchial system. Simple recovery of the organism does not define infection. Asymptomatic pulmonary nodules may occur. Cryptococcal pneumonia occurs most frequently among immunocompromised persons and is usually a subacute necrotizing process that tends to be lobar in distribution. Some patients with AIDS have radiographic findings indistinguishable from those of pneumocystic pneumonia.

Other Forms of Cryptococcal Infection

Subcutaneous, painless nodules have been associated with widespread hematogenous cryptococcal infection. Biopsy with visualization of the organism has established the presence of dissemination in some patients. Cellulitis, lesions resembling molluscum contagiosum (among patients with AIDS), and ulcerations have been described. Cryptococcal prostatitis has emerged as an important problem among patients with AIDS. Cryptococemia is associated with a poor prognosis. Other sites of cryptococcal infection include the oral mucosa, kidney, bone, eye (chorioretinitis), heart, pericardium, mediastinum, liver, peritoneum, joints, and muscle.

Myocardial involvement is an important complication among patients with AIDS and may be considerably underreported.

LABORATORY FINDINGS AND DIAGNOSIS

The definitive diagnosis of cryptococcal infection is made by means of detecting the organism in biopsy specimens. Finding the organism in india ink or nigrosin preparations is nearly enough information to confirm a diagnosis because of the small incidence of false-positive results when experienced personnel perform the test. Detection of cryptococcal polysaccharide antigen by means of latex agglutination is an important adjunct to diagnosis when controls are in place for the presence of rheumatoid factor. Sensitivity and specificity are high. The results of the test are not definitive, however, and finding the organism in a biopsy specimen or culture from the appropriate source remains the definitive diagnostic procedure. Antigen testing should be performed on both blood and CSF. Positive results are more frequent when the test is performed on CSF. Some patients with AIDS have extremely high antigen titers.

STRATEGIES FOR OPTIMAL CARE

The management of cryptococcal CNS infection is controversial and is under study. Amphotericin B in combination with 5-fluorocytosine or amphotericin B alone for 6 to 10 weeks (depending on clinical response) is considered standard therapy. Some patients who respond well to initial treatment can undergo a 2-week consolidation course with amphotericin B and 5-fluorocytosine followed by fluconazole for 10 weeks. Because of the improved prognosis for patients with AIDS in general, more aggressive therapy is now being used. The consensus is to treat patients with AIDS with a combination of amphotericin B and 5-fluorocytosine for 2 weeks followed by treatment with fluconazole for a minimum of 10 weeks at 400 mg per day. These patients then undergo maintenance therapy for 12 to 18 months taking fluconazole at 200 to 400 mg per day. If the patient is doing poorly, a 6- to 10-week course of combined amphotericin B and 5-fluorocytosine may be preferable. It has become popular to use fluconazole to control cryptococcal infection outside the CNS that is not life threatening. A consensus also has been established to remove CSF fluid to correct increased intracranial pressure.

Patients intolerant of fluconazole may be given itraconazole, but there is concern that itraconazole may be less effective than fluconazole. Data are accumulating that suggest the lipid formulations of amphotericin B may be alternatives for those patients who are especially intolerant of the standard preparation.

ASPERGILLOSIS

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Aspergillus organisms are among the most ubiquitous microbes. Interpretation of positive culture results from clinical specimens must be critical because contamination by dust particles is common at collection and during the culture procedure. The ubiquitous nature of the organism also presents important considerations with regard to the hospital environment. Hospital air conditioning systems may be contaminated with *Aspergillus* organisms, which probably causes regional differences in infection rates. At least 10 species of *Aspergillus* are known to be pathogenic for humans. Of these, *A. fumigatus* and *A. niger* are the most common. The organism is readily grown on standard fungal culture media.

PATHOGENESIS

Neutrophils, monocytes, and macrophages are important host defense mechanisms, and functioning of these cells is enhanced through complement. Like the organisms that cause the zygomycoses, *Aspergillus* organisms are angiotropic. They invade vascular walls and cause thrombosis, vascular occlusion, and infarction.

CLINICAL FINDINGS

Disseminated Aspergillosis in an Immunocompromised Patient

Neutropenia and use of steroids are the most important predisposing factors for an immunocompromised host. *Aspergillus* organisms usually enters through the sinuses or lungs and seed hematogenously to almost any organ. Severe, necrotizing pneumonia may occur and can cause cavitation or infarction. The hallmark of aspergillosis among immunocompromised hosts is tissue infarction. Lung, liver, and brain are the most common examples, but skin, gastrointestinal tract, eye, and bone involvement also occur. *Aspergillus* infection can cause esophagitis or ulceration in other segments of the gastrointestinal tract. Sinus involvement may be extensive, and necrosis of the nasal septum can occur. Blood cultures rarely are positive in disseminated aspergillosis, and generalized meningitis is rare.

Pulmonary System

The syndrome of allergic bronchopulmonary aspergillosis occurs among persons with asthma who have an immediate-type skin response to *Aspergillus* antigens, anti-*Aspergillus* antibodies, elevated IgE, transient pulmonary infiltrates from bronchial plugging, and *Aspergillus* organisms in the bronchial tree that contribute to bronchial plugging. Invasion of the pulmonary parenchyma does not occur. A common form of aspergillar pulmonary involvement occurs among patients who have cavitary pulmonary disease from any cause and an *Aspergillus* fungus ball in the cavity. Symptoms may range from none to fatal hemoptysis. Chest radiographs show a superior crescent of air above the fungus ball that shifts with changes in position. Unless complications such as hemoptysis, bronchopulmonary fistula, or recurrent bacterial infection of the cavity occur, aspergilloma is left untreated.

A form of miliary pulmonary aspergillosis occurs among children with normal immune function after they inhale large numbers of *Aspergillus* spores. Deaths have occurred, but spontaneous resolution is the norm. Immunocompromised patients, including children with chronic granulomatous disease, may have severe, necrotizing, cavitating bronchopneumonia associated with pulmonary infarction. Widespread dissemination may result. Resolution of the neutropenia and aggressive amphotericin B therapy are associated with an improved prognosis. In rare instances this form of aspergillar pneumonia occurs among persons with normal immune function.

Other *Aspergillus* Infections

Aspergillus organisms may infect the sinuses of otherwise healthy persons. They also may be recovered from patients with allergic sinusitis. In rare instances fungus balls may form in the involved sinuses. When *Aspergillus* is considered to play a role in chronic sinus infection, extensive irrigation or surgical drainage is necessary. Postsurgical antifungal therapy usually is not needed. For unknown reasons, *A. flavus*, as opposed to *A. fumigatus*, is much more commonly recovered from sinus infections. In rare circumstances, aspergillar sinus infection may have features indistinguishable from those of rhinocerebral zygomycosis. *Aspergillus* may be one of several organisms recovered in culture from ears with chronic otitis externa. Although it rarely causes extensive disease, the organism usually is one of many recovered and does not necessitate specific treatment.

Aspergillus infection can cause endocarditis, but rarely does so. The infection is most common among drug addicts and patients with prosthetic valves. Bone infection can be caused by contiguous extension, especially in the lung. Surgical contamination can occur, particularly in neurosurgical procedures. Infections of the mandible, larynx, tracheobronchial tree, external ear canal, pericardium, myocardium, eye, peritoneum, pericardium, urinary tract, and epiglottis have been reported.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis of invasive aspergillosis is established by means of histopathologic and culture demonstration of the fungus invading tissues. Blood and CSF culture results rarely are positive in hematogenously disseminated aspergillosis in a patient with neutropenia. The infrequent recovery of *Aspergillus* organisms from body fluids (even from the blood of patients with endocarditis), coupled with difficulty in interpreting positive cultures results because of the ubiquitous nature of the organism, make the diagnosis of invasive aspergillosis one of the most difficult among the opportunistic mycoses. The serodiagnostic technology is still experimental; however, an enzyme-linked immunosorbent assay (ELISA) is used in Europe. Detection of anti-*Aspergillus* antibodies, however, is helpful in diagnosing allergic bronchopulmonary aspergillosis.

STRATEGIES FOR OPTIMAL CARE

Amphotericin B is considered standard therapy for *Aspergillus* infection. Itraconazole has been approved for management of aspergillosis, and successful treatment

with this azole has been reported. The lipid formulations of amphotericin B are considered alternatives in the presence of amphotericin intolerance. An experimental triazole, voriconazole, is under evaluation. In selected circumstances, surgery combined with antimicrobial treatment is necessary, as in aspergilloma, enophthalmitis, sinus infection, endocarditis, and selected pulmonary infections that cause massive hemoptysis. A combination of corticosteroids and itraconazole is the preferred strategy to manage allergic bronchopulmonary aspergillosis. The use of inhaled amphotericin B is experimental.

ZYGOMYCOSIS (MUCORMYCOSIS)

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

The term *zygomycosis* will likely replace *mucormycosis* because the latter incorrectly implies infection by organisms of the genus *Mucor*. The term *zygomycosis* is derived from *Zygomycetes*, which is the subclass of fungi that produce zygospores. Within the order Mucorales, consisting of the four genera *Rhizopus*, *Absidia*, *Mucor*, and *Cunninghamella*, are most of the organisms that cause infection in an immunocompromised host. There has been increased reporting of infections caused by *Apophysomyces elegans*. Some of these infections have occurred in normal hosts.

Zygomycetes species are ubiquitous. Decaying organic material is their most frequent site. They occasionally are recovered from healthy persons. The spores can easily disseminate through the air, and in infected tissue, they form broad, thick-walled, nonseptate hyphae that branch at nearly right angles. The various species cannot be differentiated by means of histopathologic examination, nor can Zygomycetes species be reliably differentiated from other fungi on this basis.

The two most important factors of predisposition are any disease that causes systemic acidosis (not the hyperglycemia of diabetes) and neutropenia associated with cytotoxic chemotherapy. The use of deferoxamine in the care of dialysis patients has been a well-defined predisposing factor. The neutrophil is capable of damaging *Mucor* hyphae and probably is an important cell in host defense.

A hallmark of infection with Zygomycetes species is invasion of vascular walls. Black, necrotic debris frequently is present in pus from infected areas. The pertinent clinical signs and symptoms coupled with the finding of this black debris may facilitate diagnosis of zygomycosis.

CLINICAL FINDINGS

Rhinocerebral Zygomycosis

Rhinocerebral zygomycosis occurs most commonly among patients with diabetes who have ketoacidosis. The infection begins in the nasal sinuses and spreads through the ethmoid sinus into the retroorbital space. The first symptoms and clinical signs frequently are not detected until the retroorbital tissues become infected. Pain, loss of ocular movement, and proptosis usually are the initial manifestations. Headache, visual loss, and periorbital cellulitis may occur. Because of the propensity of the organism to invade vessel walls, direct extension through the apex of the orbit into the brain may occur. A surprising phenomenon is that computed tomographic scans of the orbit may be normal; only rarely is an organized retroorbital mass present. Involved ocular muscles also may appear normal at surgical exploration of the orbital area.

Thoracic Zygomycosis

The most common form of intrathoracic zygomycosis is infection of the lung parenchyma. The pulmonary form of zygomycosis occurs most commonly among immunocompromised patients, usually as a superinfection in an area of pneumonia caused by bacterial infection. Pulmonary infection also can occur from hematogenous seeding to the pulmonary artery with subsequent thrombosis and infarction. The pneumonia caused by Zygomycetes species generally is more indolent than most types of bacterial pneumonia. Bronchopneumonia infiltrates, consolidation, cavitation, and pleural effusions are present, as are fungus balls within cavities. Nonpulmonary intrathoracic forms of zygomycosis are much less common than pulmonary forms. Examples are hematogenous seeding of cardiac valves and of the coronary arteries accompanied by thrombosis and myocardial infarction.

Abdominopelvic Zygomycosis

In nearly all instances, zygomycosis of the gastrointestinal tract occurs in areas of underlying disease such as gastric ulcer, amebic colitis, pellagra, kwashiorkor, *Salmonella* infection, and local trauma from indwelling intragastric devices. Complications such as perforation, obstruction, and peritonitis may occur. Other sites of infection are the kidney, uterus, and bladder.

Cutaneous Zygomycosis

Among immunocompromised patients, cutaneous zygomycosis may occur as subcutaneous, nonspecific nodules or as hematogenous lesions that resemble ecthyma gangrenosum. Burn wounds can be infected with Zygomycetes species and contain black necrotic debris within the pus. The organisms also have infected needle tracks left after organ biopsies or steroid injections.

Widespread Dissemination

Widespread dissemination may occur from any cutaneous site. Most commonly, however, this dissemination occurs in a severely immunocompromised host treated with cytotoxic chemotherapy for leukemia or lymphoma. When hematogenous dissemination occurs, infarction of the infected organs may be a clinical clue to disseminated zygomycosis or aspergillosis if the patient has a fever and neutropenia. Patients with rhinocerebral zygomycosis associated with acidosis may have hematogenous dissemination to the lungs, coronary arteries, and other organs.

Miscellaneous Infections

Zygomycosis of the ear, venous grafts, bone (hematogenous osteomyelitis), renal cysts, heart valves, and prosthetic material used for breast implants has been described.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis of disseminated zygomycosis frequently is difficult because patients usually have severe multisystem disease, drug toxicity, and almost never have positive results of blood cultures. There also is no satisfactory serodiagnostic test. The diagnosis is obtained when methenamine silver or periodic acid–Schiff staining of a biopsy specimen shows the organism invading tissue. Precise diagnosis depends on recovery of the organism from culture of the biopsy specimen, because the species cannot be identified on the basis of the appearance of histopathologic sections.

None of the signs or symptoms of zygomycosis is specific. Entities commonly included in the differential diagnosis are tumor, pyogenic retroorbital infection, Graves' ophthalmopathy, infection with non-Zygomycetes fungi, bacterial bronchopneumonia, or colonization with the organism without its causing infection. Laboratory contamination of specimens can occur because these organisms are ubiquitous. When a culture for zygomycoses is requested, alerting the laboratory is beneficial so that the technologist does not use media that contain cycloheximide. There are no useful serodiagnostic tests.

STRATEGIES FOR OPTIMAL CARE

Standard therapy for rhinocerebral zygomycosis is amphotericin B in combination with a surgical procedure. At one time, radical surgical intervention was routine. Today a more selective surgical procedure combined with amphotericin B therapy has become the standard approach. The importance of the operation cannot be overemphasized, because many strains of the organism are resistant to amphotericin B. The use of other antifungal agents in combination with amphotericin B is controversial. Although no systematic studies have been performed, the lipid formulations of amphotericin B may be important for management of zygomycosis, because many patients need large amounts of amphotericin B and relatively rapid acceleration of dosage schedules.

EMERGING OPPORTUNISTIC FUNGI

A large number of rare fungal organisms are emerging as an important group of pathogens in immunocompromised hosts. Reported fungi (incomplete list) include *Trichosporon beigelii*, *Malassezia furfur*, *Fusarium* species, *Geotrichum candidum*, *Curvularia* species, *Drechslera* species, *Pichia farinosa*, *Torulopsis pintolopesii*, *Saccharomyces cerevisiae*, *Cunninghamella bertholletiae*, *Penicillium* species, *Rhodotorula rubra*, *Scedosporium inflatum (prolificans)*, and *Alternaria* species. When these organisms are recovered from immunocompromised patients, the possibility of dissemination has to be carefully evaluated, rather than their being considered contaminants or inconsequential. Many of these species may be relatively resistant to amphotericin B. Some may be partially resistant to fluconazole. This list will continue to grow in parallel with the growth in the population of immunocompromised hosts.

[Strategies for Optimal Care and Prevention](#)

DEFINITION

The human pathogens in the genera *Rickettsia*, *Ehrlichia*, *Orientia*, and *Coxiella*, are fastidious, pleomorphic gram-negative bacteria that grow in association with eukaryotic cells. These organisms cause a number of different diseases and clinical syndromes ([Table 304.1](#)). All are zoonoses; the natural history requires an animal reservoir and, with the exception of Q fever, an arthropod vector. The epidemiology and geographic distribution of each disease are related to the distribution of these reservoirs, vectors, and humans who come into contact with them. The bacteria discussed in this chapter were formerly included the family Rickettsiaceae but have recently undergone substantial reclassification. They are considered together because of their historical, pathophysiologic, clinical, and therapeutic similarities.

Genus and Group	Etiologic Agent	Disease
<i>Rickettsia</i>		
Spotted fever group	<i>R. rickettsii</i>	Rocky Mountain spotted fever
	<i>R. conorii</i>	Mediterranean spotted fever
	<i>R. sibirica</i>	Siberian tick typhus
	<i>R. japonica</i>	Japanese or Oriental spotted fever
	<i>R. africae</i>	African tick bite fever
	<i>R. australis</i>	Queensland tick typhus
	<i>R. helmsi</i>	Florida island spotted fever
	<i>R. akari</i>	Two-spot fever
	<i>R. mongolotimonae</i>	Five-spot fever
	Israeli tick typhus Rickettsia	Israeli spotted fever
	<i>R. slovaca</i>	Carpathian flu-like illness
	<i>R. alberta</i>	Rickettsial pox
	Not named	Arborea fever
Typhus group	<i>R. typhi</i>	Murine typhus
	<i>R. prowazekii</i>	Sylvatic typhus, Brill-Zinsser disease, flying squirrel-associated typhus
<i>Orientia</i>	<i>O. tsutsugamushi</i>	Southern tick-tick fever
<i>Coxiella</i>	<i>C. burnetii</i>	Q fever
<i>Ehrlichia</i>	<i>E. chaffeensis</i>	Human monocytic ehrlichiosis
	<i>E. phagocytophila</i> or <i>E. equi</i>	Human granulocytic ehrlichiosis
	<i>E. ewingii</i>	Severe ehrlichiosis

SPOTTED FEVER GROUP *RICKETTSIA*

ROCKY MOUNTAIN SPOTTED FEVER, BOUTONNEUSE FEVER

Incidence and Epidemiology

Rocky Mountain spotted fever (*Rickettsia rickettsii*) was originally recognized in the early 1900s in the Bitterroot Valley of Montana. Most of the approximately 500 cases reported each year in the United States occur in the south central states, especially Oklahoma, and along the Atlantic seaboard, especially North Carolina, but cases are reported from many other states ([Table 304.2](#)). Rocky Mountain spotted fever also occurs in other countries in the Western Hemisphere, from Canada to Brazil. Boutonneuse fever (*R. conorii*) follows exposure to infected *Rhipicephalus* ticks and is endemic throughout Africa, the Middle East, and southern Europe. These disease are most common among boys and men younger than 20 years. A history of tick bite, attachment, or exposure can be elicited from about 60% of patients. For Rocky Mountain spotted fever, tick exposure usually occurs in rural wooded or brushy areas but can also follow exposures in parks and other less-developed parts of large cities, New York, for example.

TABLE 304.2. COMPARISON OF CLINICAL AND EPIDEMIOLOGIC FEATURES OF RICKETTSIAL DISEASES FOUND IN THE UNITED STATES

Clinical Findings

Rocky Mountain spotted fever and the Eastern Hemisphere spotted fever group infections are similar in most aspects. Illness begins 2 to 14 (usually 6 to 8) days after exposure. For most patients, the first symptoms are high fever, usually 39°C, severe headache, myalgia, and rash; about one-half of patients report nausea, abdominal pain, and vomiting. A macular rash, which often begins on the wrist and ankles, appears by day 5 among 75% of patients, spreads centripetally, and becomes petechial. About 50% of patients with spotted fever group infections other than Rocky Mountain spotted fever have a red papule appears at the bite site. The papule develops into a painless, punched-out ulcer covered by a dark crust (tache noire, eschar). Central nervous system signs, pulmonary and peripheral edema, hypotension, adult respiratory distress syndrome, hepatomegaly and jaundice, and renal failure indicate serious organ system involvement, occur in severe forms of the disease, and are poor prognostic signs. Some patients have permanent sequelae. If the patient is not treated, the disease lasts 2 to 3 weeks. About 3% to 5% of patients die. The risk of death increases with age and duration from onset of symptoms to initiation of treatment with tetracycline.

Laboratory Findings

Because no laboratory test has a consistently positive result during the first 2 weeks of illness, the initial diagnosis of spotted fever group infections must be based on epidemiologic and clinical features. Thrombocytopenia, anemia, leukopenia, abnormal hepatic aminotransferase levels, and hyponatremia are present toward the end of the first week of illness among about one-third of patients. A definitive diagnosis of most spotted fever group infections can sometimes be made early in the illness by means of polymerase chain reaction in a variety of specimens or immunologic detection of *Rickettsia* organisms in involved skin by means of direct fluorescent antibody technique. The diagnosis is best established with tests of both acute and convalescent phase sera. A fourfold rise in titer confirms the diagnosis; tests of single sera samples should be interpreted with caution. Indirect immunofluorescence assay is the standard serologic test, although a number of other detection

systems are satisfactory. The Weil–Felix test lacks specificity.

STRATEGIES FOR OPTIMAL CARE AND PREVENTION

Early suspicion of spotted fever group infections is particularly important because delay in initiation of effective treatment increases the risk of complications and death. Infection with all *Rickettsia* species responds to doxycycline (100 mg every 12 hours) or tetracycline, 25 to 50 mg per kilogram per day for 10 to 14 days. Seriously ill patients should receive the drugs parenterally. Fever should begin to subside within 24 to 48 hours, and defervescence should be complete within 3 to 5 days. Although chloramphenicol has long been an alternative treatment, outcomes may be better with tetracycline or doxycycline. Avoiding tick-infested areas and animals, especially dogs, best prevents Rocky Mountain spotted fever and boutonneuse fever. When this is not practical, protective clothing should be worn, a tick repellent used, the body inspected for ticks twice a day, and ticks removed with a tweezers. No vaccine is available.

Rickettsial Pox

Rickettsial pox (*R. akari*) is transmitted to humans by mites of house mice. The first sign may be a painless red papule that forms 7 to 10 days after the bite, becomes vesicular and slowly forms an eschar that lasts for weeks. About 1 week later, fever, chills, headache, myalgia, and 5 to 100 discrete papulovesicles develop. Therapy is the same as for Rocky Mountain spotted fever.

California Flea Rickettsiosis

California flea rickettsiosis (*R. felis*) is a spotted fever group rickettsial infection that resembles murine typhus clinically and epidemiologically.

TYPHUS GROUP RICKETTSIA: EPIDEMIC TYPHUS

INCIDENCE AND EPIDEMIOLOGY

Epidemic typhus (*R. prowazeki*) may have caused more deaths in the twentieth century than any other infectious disease. The disease occurs where war, famine, cold, poverty, poor hygiene, and crowding promote infestation and proliferation of body lice (the vector) on humans (the reservoir). Epidemic typhus became rare after the introduction of insecticides (especially DDT) effective against lice and antibiotics effective against the disease. The continued threat, however, is evidenced by outbreaks and endemic foci in Africa (Ethiopia, Uganda, Rwanda, and Burundi) and the highlands of the Americas (Peru). Brill–Zinsser disease, a recrudescent form, can occur decades after the primary infection. Acute infection has been found sporadically during the winter months in the eastern and southern United States. It appears to be associated with contact with the ectoparasites of flying squirrels, the sylvan reservoirs.

CLINICAL AND LABORATORY FINDINGS

In acute infection, an incubation period of 7 to 12 days is followed by an abrupt onset of symptoms. The patient appears seriously ill. Symptoms are similar to those of Rocky Mountain spotted fever, but the rash is an ill-defined macular one that appears on the fourth to seventh day in the axillae or sides of the torso, becomes hemorrhagic and generalized, but spares the face, palms, and soles. Untreated epidemic typhus is a serious infection. The case-fatality ratio reaches 50%. Patients with flying squirrel–associated typhus and Brill–Zinsser disease become quite ill but less so than patients with epidemic typhus. Thrombocytopenia, abnormal results of liver function tests, and microscopic hematuria and proteinuria are common laboratory abnormalities. Definitive diagnosis is best made by means of analyzing acute- and convalescent-phase sera in a test in which typhus group antigen is used.

STRATEGIES FOR OPTIMAL CARE AND PREVENTION

A single dose of doxycycline (100 to 200 mg) is as effective as the extended regimens used for Rocky Mountain spotted fever. Prevention efforts are directed at delousing the infested populations and improving living conditions that facilitate infestation.

TYPHUS GROUP RICKETTSIA: MURINE TYPHUS

Murine typhus (*R. typhi*) and California flea rickettsiosis (*R. felis*) are transmitted to humans by fleas. Murine typhus is endemic in many warm parts of the world where poor living conditions and flea-infested rats coexist. Although improved sanitation and rodent control programs have markedly reduced the incidence of this disease in the United States, recent cases in California and Texas have been associated with flea-infested free-ranging cats, dogs, and opossums.

Although milder than that of epidemic typhus, the onset of murine typhus can be abrupt. Fever more than 39°C, headache, chills, myalgia, and nausea are common. Only about 20% of patients have a rash when they seek medical attention. The rash usually is macular and appears on the torso, legs, or arms. Splenomegaly or hepatomegaly may be present. Laboratory abnormalities include mild depression of platelets, elevated hepatic aminotransferase levels, and hypoalbuminemia. Death (1% of cases) and complications are associated with delayed treatment and advanced age. Diagnosis requires a high index of suspicion because only a few patients report rodent contact or flea bites. Specific diagnostic tests are the same as those for suspected *R. prowazeki* infection. The therapeutic regimens are the same as those for spotted fever group infections. Relapses have occurred among patients treated with chloramphenicol. Infection can be prevented by means of avoiding flea-infested rats or using vector and rodent control measures. No vaccine is available.

ORIENTIA

SCRUB TYPHUS

Caused by *Orientia tsutsugamushi*, scrub typhus is found in Asia, Australia, and the South Pacific, where it can be a common cause of febrile illness. The reservoir and vector for humans are trombiculid mites (chiggers). Humans become infected when they intrude on the areas of transition (scrub) vegetation where the vectors thrive. Soldiers and agricultural workers are therefore especially likely to be infected. After a prodrome of headache, chilliness, and anorexia, almost all patients have a fever, headache, and chills. Most patients have generalized lymphadenopathy. About one-half of patients have an eschar, splenomegaly, and a maculopapular rash. Absolute lymphocytosis is often present, suggesting the diagnosis of mononucleosis. Without treatment, the fever lasts about 2 weeks. Complications include pneumonitis, meningoencephalitis, renal failure, and jaundice. About 10% of cases die. Unlike other rickettsial diseases, reinfection can occur with one of the multiple serotypes of this organism. The Weil–Felix test is of some diagnostic utility. The sensitivity and specificity are approximately those of the indirect immunofluorescence assay for this disease. Treatment with tetracycline results in rapid defervescence, but antibiotic resistance has been reported.

COXIELLA

Q FEVER

Incidence and Epidemiology

Q fever has been reported from at least 51 countries on 5 continents. Q fever is the only rickettsial infection transmitted in nature by aerosols. Because *Coxiella burnetii*, the etiologic agent, is extremely resistant to desiccation and physical and chemical agents and a single organism can cause infection, *C. burnetii* is a threat in a variety of natural settings and in health and research institutes. It also has been considered as an agent of bioterrorism. Although *C. burnetii* has been transmitted to humans from many species of domestic animals, most cases occur in association with exposure to livestock or livestock products and domestic cats. The disease usually is transmitted through aerosols from contaminated environments, but infection also can occur after direct contact with these animals, their birth products, milk, urine, and feces. Outbreaks of up to several hundred cases, sometimes of obscure origin, have occurred. Chronic Q fever occurs 1% to 10% of infections.

Clinical and Laboratory Findings

Asymptomatic infection is common. Acute Q fever can appear as pneumonia, a nonspecific febrile illness, as hepatitis, or as a combination of these diseases. *C.*

burnetii infection has been associated with spontaneous abortion among humans. After an incubation period that ranges from 2 to 5 weeks, the onset usually is somewhat sudden with rigors and fever to 40°C or more. Other, nonspecific symptoms include fatigue, headache, myalgia, arthralgia, retrobulbar pain, chest pain, cough, nausea, and vomiting. Physical examination abnormalities are limited to evidence of pulmonary consolidation and, occasionally, hepatomegaly, splenomegaly, and generalized or focal neurologic signs. Liver function test results frequently are abnormal. As in other rickettsial diseases, diagnosis is best established by means of testing acute and convalescent serum specimens. In granulomatous hepatitis, liver biopsy reveals doughnut granulomas.

Chronic Q Fever

The chronic form of Q fever usually becomes manifest as culture-negative bacterial endocarditis in a patient with underlying rheumatic valvular disease or vascular aneurysms. About one-half the cases occur among persons with prosthetic aortic valves. The initial symptom also may be a fever of unknown origin.

STRATEGIES FOR OPTIMAL CARE AND PREVENTION

Although acute Q fever almost always resolves without treatment, tetracycline reduces the duration of fever if administered during the first 3 days of illness. This drug is the treatment of choice. Quinolones, rifampin, and chloramphenicol may be effective. Effective control of Q fever endocarditis is extremely difficult. The antibiotics available are rickettsiostatic only in the face of a deep-seated infection and should be used in combination. Valve replacement is indicated if infection cannot be controlled or if there is hemodynamic instability. A vaccine is available in a number of countries and as an investigational new drug in the United States. Vaccination should be considered for persons at high risk of exposure and who have no demonstrated sensitivity to Q fever antigen.

EHRlichia

HUMAN MONOCYtic EHRlichiosis AND HUMAN GRANULOCYtic EHRlichiosis

Ehrlichia species are members of the Rickettsiaceae family characterized by parasitism of macrophage-monocytes and the granulocytic cell line, which they invade by means of phagocytosis. Human monocytic ehrlichiosis (HME), a tick-borne infection caused by *E. chaffeensis*, was first recognized in the United States in 1986. Human granulocytic ehrlichiosis (HGE), caused by organisms similar or identical to the veterinary pathogens *E. phagocytophila*, *E. equi*, and *E. ewingii*, was first reported in 1994. Clusters (morulae) of *Ehrlichia* organisms, sparse perivascular infiltrates, reticuloendothelial hyperplasia, and focal necrosis can be found in bone marrow, liver, spleen, and other organs.

Incidence and Epidemiology

E. chaffeensis infection has been recognized in the south central and southern United States as well as in Europe and Africa. Patients often are exposed to Lone Star ticks (*Amblyomma americanum*) during outdoor activities in brushy or woody areas. HGE, a clinically similar infection, is transmitted by black-legged ticks (*Ixodes scapularis*) in the upper midwestern and northeastern United States and *I. pacificus* in California. The disease also is found in western Europe and Slovenia. The incubation period usually is 1 to 2 weeks. Incidence rates of both forms of ehrlichiosis are higher among men and increase with age through 60 to 69 years.

Clinical and Laboratory Findings

The clinical spectrum varies from asymptomatic to life threatening. The onset usually is gradual, but it may be sudden. Early symptoms include malaise or myalgia. Fever often is higher than 39°C. Other common symptoms include headache, chills, and gastrointestinal symptoms. A rash occurs among only about one-third of patients and frequently is fleeting.

Both HME and HGE are suggested when leukopenia or thrombocytopenia is present during the first week of an otherwise unexplained febrile illness. Anemia and abnormalities in hepatic aminotransferase levels and renal function are common. Coagulopathy and cerebrospinal fluid pleocytosis also have occurred. Neutrophilic inclusions (morulae) occur among about 80% of patients with HGE and are a practical screening criterion, but inclusions are rare in HME. Serologic testing is performed with sera from the acute and convalescent periods. Indirect immunofluorescence assay is performed with the antigen of *E. chaffeensis* for HME and that of *E. equi* for HGE.

STRATEGIES FOR OPTIMAL CARE AND PREVENTION

HME and HGE respond best to tetracycline and doxycycline. The dosages are the same as for infections with spotted fever group rickettsiae. Preventive measures are the same as for Rocky Mountain spotted fever.

CHAPTER 305: INFECTIONS CAUSED BY *MYCOPLASMA PNEUMONIAE* AND THE GENITAL MYCOPLASMAS

CHARLES M. HELMS

[Definition](#)
[Infections Caused by Mycoplasma Pneumoniae](#)
[Infections Caused by Genital Mycoplasmas](#)

DEFINITION

Mycoplasmas belong to the class Mollicutes, eubacteria that have evolved regressively from low G + C–containing gram-positive ancestors by means of genome reduction. Mycoplasmas are the smallest of the free-living organisms, about 200 nm in greatest dimension. They are pleomorphic and bounded by a single triple-layered membrane. The genome (500 to 1,000 kd) is only half that of the smallest bacterium. Unlike viruses, mycoplasmas are capable of cell-free growth in artificial media and are susceptible to some antibiotics. Unlike classic bacteria, mycoplasmas have no cell wall because they are genetically incapable of synthesizing cell wall precursors.

Several *Mycoplasma* species have been isolated from humans, but only three appear to be frequent human pathogens: *M. pneumoniae* is a respiratory pathogen, and *M. hominis* and *Ureaplasma urealyticum* are urogenital pathogens. *M. genitalium* is believed to be a genital pathogen. *M. fermentans*, *M. pirum*, and *M. penetrans* have been isolated from patients with HIV infection, but the pathogenic role of these organisms in association with AIDS is unclear. *M. salivarium*, *M. orale*, *M. buccale*, *M. faucium*, *M. lipophilum*, *M. primatum*, *M. spermatophilum*, *Acholeplasma laidlawii*, and *A. oculi* are isolated from humans but do not clearly or commonly cause disease.

INFECTIONS CAUSED BY *MYCOPLASMA PNEUMONIAE*

INCIDENCE AND EPIDEMIOLOGY

Infections with *M. pneumoniae* occur worldwide in all seasons. Pneumonia epidemics tend to occur at 4- to 8-year intervals, usually in the summer and fall. Infections are particularly troublesome among military recruits and college students, among whom the prevalence of *M. pneumoniae* pneumonia may be as high as 44%. In communities the overall prevalence is about 15%. Infection rates are highest among school-aged children and young adults. Illness tends to occur primarily among those 5 to 40 years of age. Thirty percent to 60% of cases of pneumonia that occur among these age groups are caused by *M. pneumoniae*. Although *M. pneumoniae* infections occur among the very young and in the elderly, serious illness appears to be uncommon. Humans are the only known reservoir of *M. pneumoniae*. Infection is spread in respiratory secretions, especially when contact is close. Infection among families usually is introduced by a school-aged child and spreads slowly but extensively.

ETIOLOGY, PATHOGENESIS, AND IMMUNITY

M. pneumoniae organisms are small (10 × 200 nm), filamentous, and motile. A key step in pathogenesis is binding of the organism to glycoprotein receptors on the luminal surface of ciliated respiratory epithelial cells. A specialized terminal attachment tip in the membrane binds the organism to the cell ([Fig. 305.1](#)). The tip contains a 170-kd cytoadhesin (P1 protein) and accessory proteins that facilitate cytoadherence. Antibodies directed against the P1 protein inhibit attachment and reduce histologic evidence of disease in hamsters. After attachment to host respiratory epithelium, ciliostasis occurs. This injury appears to be mediated through a complex array of virulence determinants, including hydrogen peroxide and superoxide radicals produced by the organism. Overt destruction of epithelial cells follows ciliostasis, and marked superficial disruption of the respiratory mucosa occurs.

FIGURE 305.1. Electron photomicrograph shows *Mycoplasma pneumoniae* organisms attached to ciliated epithelial cells of a human fetal trachea organ culture. The specialized attachment tip of *M. pneumoniae* is indicated by an arrow. (From Collier AM. Pathogenesis of *Mycoplasma pneumoniae* infection as studied in the human foetal trachea in organ culture. *Ciba Found Symp* 1972:307, with permission.)

The pathologic changes associated with *M. pneumoniae* infection likely involve host cellular immune processes and processes attributable directly to *M. pneumoniae*. The characteristic histopathologic host response involves peribronchial lymphocytes and plasma cells. Neutrophils and macrophages are present in the peribronchial area and within the bronchial lumen. Bronchitis, bronchiolitis, alveolitis, and interstitial infiltrates have been described. The organism induces a broad range of immunoregulatory events, among them T-cell and B-cell activation and cytokine production.

In recovering from respiratory infection with *M. pneumoniae*, the host produces specific local and systemic antibodies to the organism. Local antibodies may inhibit cytoadherence, promote opsonization, or allow antibody-complement-mediated lysis. The presence of local and systemic antibodies has been related to resistance to infection. Immunity to *M. pneumoniae* infection increases with age but is not complete. There are well documented cases of second infection.

CLINICAL FINDINGS

Infections caused by *M. pneumoniae* are manifest most commonly as respiratory tract illnesses. Pneumonia, rhinitis, pharyngitis, otitis media, bullous myringitis, sinusitis, tracheobronchitis, bronchitis, and bronchiolitis are seen. Sometimes *M. pneumoniae* infection manifests itself primarily in extrapulmonary disease. A causal relation exists between *M. pneumoniae* infection and meningoencephalitis. Erythema multiforme (Stevens–Johnson syndrome), meningitis, mononeuritis and polyneuritis, myocarditis, pericarditis, arthritis, and pancreatitis have been reported in association with *M. pneumoniae* infection. The advent of DNA probes and polymerase chain reaction methods promises a better understanding of the etiologic relation between *M. pneumoniae* infection and many of these extrapulmonary manifestations.

For most cases of *M. pneumoniae* pneumonia, the incubation period ranges from 9 to 21 days. Onset is typically insidious with a prodrome of headache, malaise, fever, and upper respiratory tract symptoms. Cough is present in nearly all cases and is initially prominent and nonproductive. Temperature of at least 37.8°C (100°F) is present in 94% of cases and is at least 38.9°C (102°F) in 77% of cases. Chills occur in 58% of cases, but frank rigors are unusual. The patient usually is not toxic, and the physical examination except for rales often is not helpful. Bullous myringitis and rash occur in fewer than 20% of cases. Chest radiographic findings are nonspecific; the findings in as many as 25% of cases are those of segmental bronchopneumonia in the lower lobe or lobes and a small effusion. Leukocytosis is variable (more than 10,000 cells per microliter in only 27% of cases). An elevated cold agglutinin titer may be found in 50% of cases by the second week of illness.

Sputum Gram stain does not show a predominant organism. The course of the typical case of *M. pneumoniae* pneumonia, even if untreated, is self-limited and rarely fatal. Nevertheless, uncontrolled illness often persists for 3 to 6 weeks or more and may cause considerable debilitation. Only about 2% of patients with pneumonia need admission to a hospital.

Although the usual case of *M. pneumoniae* pneumonia is mild and easily managed in the ambulatory setting, severe illness requiring hospitalization does occur. The hospitalized person may be previously healthy, have an underlying disease, such as sickle cell disease, or be immunocompromised. Complications occur among 2% to 10% of hospitalized patients. Respiratory complications include relapse, respiratory insufficiency, pneumatocele, lung abscess, bronchiectasis, and bronchiolitis obliterans organizing pneumonia. Extrarespiratory complications include erythema multiforme, meningoenzephalitis, meningitis, mononeuritis and polyneuritis, myocarditis, pericarditis, and arthritis. Varied rashes, nephritis, hepatitis, intravascular hemolysis, disseminated intravascular coagulation, thrombocytopenic purpura, Raynaud's phenomenon, cerebellar ataxia, psychosis, transverse myelitis, postinfectious leukoencephalitis, optic neuritis, sudden deafness, and polymyositis have been reported.

Mechanisms underlying extrarespiratory findings in *M. pneumoniae* infection are not clear. Autoimmune mechanisms and toxins have long been postulated. Extrarespiratory spread and tissue invasion seem likely, however. Case reports of accumulate describing isolation of *M. pneumoniae* organisms from skin lesions, from cerebrospinal, pleural, pericardial, and synovial tissues and fluids, and from blood.

LABORATORY FINDINGS

The diagnosis of *M. pneumoniae* requires a careful history and physical examination. Elements of the epidemiologic and clinical history that may implicate the organism must be elucidated. Radiographic evidence of an infiltrate is critical to the diagnosis of pneumonia. The differential diagnosis of mycoplasmal pneumonia is extensive and includes infection with most bacterial and nonbacterial pathogens. The presence of cold agglutinins of the IgM class with anti-I specificity strengthens clinical suspicion, but is not sufficiently specific to confirm a clinical diagnosis of *M. pneumoniae* pneumonia. Infections caused by measles virus, Epstein–Barr virus, adenoviruses, and some tropical parasites have been associated with elevated cold agglutinin antibody titers. Likewise, the absence of cold agglutinins is not a sufficiently sensitive negative finding to exclude the diagnosis of *M. pneumoniae* pneumonia, because only about one-half of cases of *M. pneumoniae* pneumonia are associated with elevated titers of cold agglutinins.

Definitive diagnosis of mycoplasmal pneumonia involves isolation of *M. pneumoniae* on selective media from respiratory exudate. This usually takes 7 to 10 days. DNA probes and polymerase chain reaction methods can be sensitive, specific, and more timely. A fourfold or greater rise in specific antibody titer in convalescence also confirms the diagnosis. Antibodies usually are assayed with the complement fixation or enzyme-linked immunosorbent assay method with sera from the acute and convalescent phases, the latter obtained 4 to 6 weeks after onset of illness. None of the serologic approaches allows easy or rapid diagnosis of *M. pneumoniae* pneumonia.

STRATEGIES FOR OPTIMAL CARE

Because of diagnostic limitations, the decision to initiate therapy for most cases of *M. pneumoniae* pneumonia is empiric. Erythromycin, clarithromycin, azithromycin, ofloxacin, levofloxacin, sparfloxacin, and tetracycline are used for management of *M. pneumoniae* pneumonia. β -Lactam and other antibiotics active on cell wall synthesis are ineffective against *M. pneumoniae* infection because the organism lacks a cell wall.

Erythromycin and tetracycline have proved effective in controlled trials among military recruits and college students in shortening the morbidity of illness and the duration of hospitalization associated with *M. pneumoniae* pneumonia. Erythromycin or tetracycline in dosages of 0.25 to 0.5 g orally every 6 hours is recommended for treatment of selected patients. Intravenous therapy may be used if the patient has severe illness. Tetracycline should not be used to treat children younger than 8 years or pregnant women. Two or 3 weeks of erythromycin or tetracycline therapy is recommended to prevent relapse. Resistance to erythromycin and tetracycline has not emerged as a clinical problem.

Antibiotic therapy is not used for *M. pneumoniae* respiratory illnesses other than pneumonia unless the etiologic diagnosis is clear and the clinical course necessitates intervention. The course of extrarespiratory complications of *M. pneumoniae* infection seems unaffected by antibiotic therapy. There is no vaccine for the prevention of *M. pneumoniae* pneumonia.

INFECTIONS CAUSED BY GENITAL MYCOPLASMAS

INCIDENCE AND EPIDEMIOLOGY

U. urealyticum and *M. hominis* are the two species of *Mycoplasma* most frequently isolated from the human genitourinary tract. Both have been associated with a number of urogenital and reproductive diseases. Causal relations have been difficult to establish, however, because both agents may be isolated from healthy and from sick people. Nevertheless, a consensus has emerged that etiologically links these two species of genital *Mycoplasma* with selected urogenital infections and systemic infections among immunocompromised hosts.

Colonization of infants with genital mycoplasmas occurs during passage through the birth canal. Colonization rates then decrease until puberty, when they rise again in direct relation to sexual activity and the number of sexual partners. Colonization rates are higher among women than among men. Pregnancy may predispose a woman to colonization. Race or socioeconomic status may contribute to the higher colonization rates found among blacks than among whites and among patients attending municipal clinics rather than private clinics.

ETIOLOGY AND PATHOGENESIS

Results of inoculation studies with human and primate subjects have firmly established *U. urealyticum* as a cause of nongonococcal urethritis. At least 10% of cases of nongonococcal urethritis are caused by this organism. *M. genitalium* may also be a pathogen in this setting. Serologic examinations of some patients with pelvic inflammatory disease and its complications implicate *M. hominis* as an etiologic agent. In experiments in monkeys, isolates of *M. hominis* have produced salpingitis.

A causative role for *M. hominis* in postabortal and postpartum fever is supported by results of serologic studies and isolation of the organism from the blood. A probable role for *U. urealyticum* in chorioamnionitis is suggested by the results of serologic studies, isolation of the organism in pure culture from amniotic fluid, and isolation from the blood. Both *M. hominis* and *U. urealyticum* have been isolated from urine in cases of lower urinary tract disease, but only *M. hominis* has been implicated etiologically with culture and serologic data as an agent in acute pyelonephritis.

There are well-documented reports of associations between *U. urealyticum* and *M. hominis* and septic arthritis in settings of hypogammaglobulinemia and immunosuppression. *M. hominis* and *U. urealyticum* organisms have been isolated from cultures of pericardial fluid and tissue in cases of pericarditis. *M. hominis* infection also has been associated with neonatal meningitis, meningoenzephalitis, brain abscess, fever among burn and trauma patients, sternotomy infections, and extragenital infections among recipients of solid-organ transplants.

The pathogenetic mechanisms of the genital mycoplasmas are not well understood. Both *U. urealyticum* and *M. hominis* appear capable of adsorbing to the surface of mammalian cells and replicating. Subsequent structural and functional changes in sperm and fallopian ciliary cells have been found. The cytopathic effect induced by *U. urealyticum* has been related to its urealytic activity and subsequent release of ammonium ions. *M. genitalium* appears to have a specialized terminal attachment structure and a cytoadhesin resembling the *M. pneumoniae* P1 protein.

CLINICAL AND LABORATORY FINDINGS

Genital mycoplasmal infection has been etiologically associated with nongonococcal urethritis, pelvic inflammatory disease and its complications, chorioamnionitis, postpartum and postabortal fever, and pyelonephritis. The clinical presentations of these infections are discussed in detail in [Chapter 272](#). Exclusion of other, more common pathogens associated with a given urogenital clinical syndrome, such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in urethritis, is a crucial part of diagnosis.

Definitive diagnosis requires laboratory isolation of the organism from the infection site in the absence of other pathogens. Culture techniques for isolation of genital mycoplasmas can be performed in many hospital microbiology laboratories. Isolation of genital mycoplasmas is optimized by immediate inoculation of the specimen into appropriate selective media and rapid transport to the laboratory for incubation. Unlike *M. pneumoniae* organisms, which have a long incubation time, genital mycoplasmas grow in culture within 1 to 3 days.

In interpreting culture results, it is important to remember that sexually active persons often are colonized with genital mycoplasmas. These colonize the urethral mucosa of men and may be found under the foreskin. In women, the organisms are found most frequently in the vagina but also are present in the endocervical canal and periurethral area.

STRATEGIES FOR OPTIMAL CARE

Even when diagnostic techniques to detect mycoplasmal urogenital infections are available, they may not be clinically useful because of the time inherent in culturing the organisms. Therapy for these infections therefore is almost inevitably empiric. It is in the clinical setting of antibiotic failure in the management of presumed bacterial urogenital infection that culturing of blood or the genital site for mycoplasmas may be most helpful in patient care.

Tetracycline and erythromycin continue to be the mainstays of therapy for presumed genital mycoplasmal infections. Azithromycin, other new macrolides, and fluoroquinolones are of increasing therapeutic value, however, because the prevalence of clinically significant tetracycline resistance is increasing among persons with *U. urealyticum* or *M. hominis* infection. Tetracycline should not be used to treat pregnant women or children younger than 8 years or in situations in which tetracycline resistance is suspected.

Erythromycin may be used as therapy for suspected or proven *U. urealyticum* infections when tetracycline is contraindicated. Clindamycin may be used as alternative therapy for suspected or proven *M. hominis* infection. In vitro tests of antibiotic susceptibility may be used to guide therapy for genital mycoplasmal infections in which antibiotic resistance is a factor. The routine use of antimycoplasmal agents in empiric therapy for urogenital or other conditions in which a mycoplasmal cause has not been proved is not recommended.

CHAPTER 306: CHLAMYDIAL INFECTIONS

ROBERT B. JONES

[Definition](#)
[Incidence and Epidemiology](#)
[Pathogenesis](#)
[Clinical and Laboratory Findings](#)
[Diagnosis and Strategies for Optimal Care](#)

DEFINITION

The order Chlamydiales contains only a single genus, *Chlamydia*, and four species ([Table 306.1](#)) only three of which are associated with infection among humans—*C. psittaci*, *C. trachomatis*, and *C. pneumoniae*. Organisms in all three species are obligate, intracellular parasites with a relatively complex life cycle ([Fig. 306.1](#)). The extracellular forms (elementary bodies) attach to susceptible cells and induce their own ingestion but are able to inhibit fusion of lysosomes with the endocytic vacuole. Thus they escape intracellular destruction and live in a protected environment inside the cell, where they reorganize into their replicative forms (reticulate bodies) and divide by means of binary fission. They are energy parasites in that high-energy phosphate compounds, as well as essential amino acids, are supplied by the host cell. Continuing replication results in an intracytoplasmic inclusion that ultimately fills the infected cell. The reticulate bodies then reorganize into elementary bodies, and the inclusion is either extruded from the cell or the cell is lysed to allow the cycle to continue. Despite many biologic similarities, there is less than 10% DNA homology among the three species.

Species	Biovar/Serovar	Primary Host	Associated Diseases in Humans
<i>C. psittaci</i>	Many unclassified serovars	Typical birds, domestic fowl, mammals	Atypical pneumonia, culture-negative endocarditis
<i>C. pneumoniae</i>	Single strain, TWAR	Humans	Pharyngitis, bronchitis, and atypical pneumonia
<i>C. trachomatis</i>	Lymphogranuloma venereum biovar Serovars L ₁ , L ₂ , L ₃	Humans	Lymphogranuloma venereum, proctocolitis
	Trachoma biovar Serovars A-C, D ₉ Serovars D ₁ -D ₈	Humans	Trachoma Inclusion conjunctivitis, urethritis, cervicitis, epididymitis, endometritis, salpingitis, proctitis, infant pneumonia
	Whose presence in biovar single strain recognized	Mice	None
<i>C. pecorum</i>	Many unclassified serovars	Swine, ruminants, marsupials (kangaroo)	None

TABLE 306.1. CLASSIFICATION OF *CHLAMYDIA* SPECIES

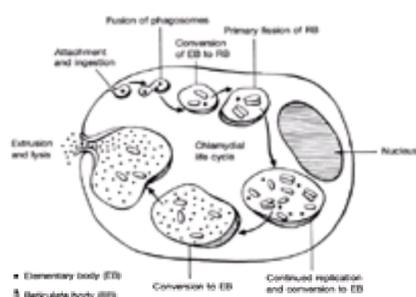

FIGURE 306.1. Schematic of life cycle of *Chlamydia trachomatis* organism. *C. psittaci* and *C. pneumoniae* organisms have similar life cycles but often have multiple cytoplasmic inclusions in each infected cell, unlike the one large inclusion of *C. trachomatis*.

Multiple strains of *C. psittaci* cause a wide variety of diseases among birds and other animals. TWAR is the only recognized strain of *C. pneumoniae*. *C. trachomatis* contains two biovars that infect humans. On the basis of degree of antigenic relatedness, these have been subdivided into 15 well-characterized serovars or strains ([Table 306.1](#)).

INCIDENCE AND EPIDEMIOLOGY

PSITTACOSIS

Most cases of psittacosis among humans are caused by contact with infected birds, especially members of the parrot family (psittacine), such as parakeets or cockatiels. However, outbreaks also have been associated with exposure to turkeys in poultry-processing plants. *C. psittaci* can be recovered from the tissue, feathers, and droppings of infected birds. Humans are infected as a result of handling the sick birds or being exposed to aerosols of their excreta. Less than 500 cases per year are reported in the United States.

CHLAMYDIA PNEUMONIAE INFECTION

Clustering of cases suggests human-to-human transmission for what appears to be a fairly common cause of mild lower respiratory disease. Moreover, a growing body of evidence suggests that *C. pneumoniae* also may cause more severe disease, including pneumonia, either as a primary or a copathogen with other bacteria. Reinfection appears to be common. Epidemiologic and anatomic evidence suggests that chronic *C. pneumoniae* infection may play a role in the pathogenesis of atherosclerosis and coronary artery disease.

OCULOGENITAL INFECTIONS

C. trachomatis infection is among the most prevalent sexually transmitted diseases. In industrialized nations infection occurs among a substantial proportion of sexually active adults in both symptomatic and asymptomatic forms ([Table 306.2](#)). Infection is epidemiologically linked to younger age, nonwhite race, and level of sexual activity as determined by frequency of intercourse or number of partners. Transmission among adults is almost entirely a result of sexual activity, although ocular infection can occur as a result of autoinoculation with infected genital secretions. Untreated chlamydial urethritis or cervicitis resolves over a few weeks in most instances, although the organism can persist for years in the absence of effective therapy. Identification of the organism does not always mean recent acquisition of infection. Presence of the organism alone should not be interpreted as prima facie evidence of recent sexual activity with a new partner. Among 20% to 30% of untreated women, the infection progresses to symptomatic salpingitis, and among an unknown proportion to asymptomatic endometritis or salpingitis. There is compelling evidence that urogenital infection with *C. trachomatis* is a risk factor for transmission or acquisition of HIV among both men and women. Serologic studies indicate that approximately 70% of infants born to infected women acquire the organism during passage through the infected birth canal. Ten percent to 30% contract inclusion conjunctivitis, pneumonia, or both.

Presentation	Prevalence (%)
Men	
Nongonococcal urethritis	~40
Gonococcal urethritis	~20
No or ignored symptoms*	10–28
Women	
Gonorrhea	30–50
Sexual contact with partner with urethritis (gonococcal or nongonococcal)	31–66
Clinical diagnosis of pelvic inflammatory disease	20
Routine examination	
Family planning clinic	5.2–9
Adolescent clinic	9–28
College student health service	8–9

* Screening examination for condition not related to urogenital tract.

TABLE 306.2. PRESENTATION AND APPROXIMATE PREVALENCE OF *CHLAMYDIA TRACHOMATIS* INFECTION IN SEXUALLY ACTIVE POPULATIONS

PATHOGENESIS

PSITTACOSIS

Infection of human usually is a result of inhalation of infective elementary bodies. Progressive localized pneumonia can then occur. More frequently, however, the organism spreads hematogenously to the liver and spleen and, after additional growth at these sites, infects the lungs and other organs. Carditis, pericarditis, or endocarditis may occur. When pulmonary involvement is minimal, endocarditis may be the predominant manifestation.

OCULOGENITAL INFECTIONS

C. trachomatis is capable of infecting transitional and columnar epithelial cells of the conjunctiva, respiratory tract, and urogenital tract. Strains of the lymphogranuloma venereum (LGV) biovar are capable of infecting monocytes and macrophages. Primary infection with the trachoma biovar of *C. trachomatis* causes a polymorphonuclear leukocytic response of variable duration followed by infiltration of mononuclear cells and local lymphoid hypertrophy. Uncontrolled infection may resolve spontaneously or progress to low-grade persistent infection. In either case, it usually does not produce serious sequelae unless it is reactivated or reinfection occurs. In hyperendemic areas of ocular trachoma, reinfection is common. Reactivation also is a result of bacterial conjunctivitis. Flies play a major role in transmission. Findings characteristic of ocular trachoma include lymphoid follicular conjunctivitis with scarring, keratitis, and vascular pannus formation (pannus is a fibroid vascular infiltration across the limbus). Pannus formation and scarring cause distortion of the lid margins such that the eyelashes can turn in and scrape the bulbar conjunctiva, causing further scarring and blindness.

The urethra or endocervix usually is the initial site infected in the genital tract. The resulting degree of inflammation is variable, and the infection may resolve spontaneously, progress to more severe disease, especially in women, or evolve into a low-grade, persistent infection. In many if not all cases of endocervical infection, there is concurrent or subsequent involvement of the endometrium and fallopian tubes. The intensity of the inflammatory response is presumed to be a function of the host's earlier experience with the organism and the resulting immune status. Chlamydial endometritis is characterized by a plasma cell infiltrate with associated lymphoid hypertrophy. When the fallopian tubes are involved, clinically apparent or subclinical salpingitis may develop, and scarring, distortion, and blockage of the tubes occur. Such changes can lead to ectopic pregnancy or infertility.

The pathogenesis of adult or infant inclusion conjunctivitis is similar to that of initial infection in ocular trachoma. Repeated cycles of reinfection or reactivation of persistent infection do not occur, however, and serious sequelae are uncommon.

LYMPHOGRANULOMA VENEREUM

Although there frequently is a lesion at the site of initial inoculation, the primary manifestations of LGV infection are lymphangitis in the regional nodes draining the inoculation site. Among men, these usually are the inguinal nodes, and the enlarged, fluctuant nodes are called *buboes*. These may break down and drain spontaneously, producing cutaneous fistulas. Among women, the regional nodes frequently are sacral and perirectal. When these nodes suppurate and drain, they may produce rectal strictures and rectal or vaginal fistulas.

CLINICAL AND LABORATORY FINDINGS

PSITTACOSIS

Psittacosis usually begins suddenly with chills and a high fever 7 to 15 days after exposure. Severe headache, myalgia, and a persistent, dry cough are common. Physical findings usually are minimal and may consist only of rales in the lower lung fields. Nontender hepatomegaly is frequent, and palpable splenomegaly is present in 10% to 70% of patients. A pulse-temperature dissociation (a normal or slow heart rate at the time of a high temperature) is a frequent observation. Routine laboratory studies usually are not helpful. A chest radiograph usually reveals a patchy interstitial infiltrate, although lobar infiltrates also occur. The disease should be considered when there is a history of contact with pet birds or the patient is a poultry worker, has culture-negative endocarditis, or has non-hospital-acquired pneumonia not responsive to cell wall-active antibiotics, such as penicillin or cephalosporins.

CHLAMYDIA PNEUMONIAE INFECTION

Symptoms associated with *C. pneumoniae* infection of the respiratory tract include fever, cough, and sore throat (often with laryngitis). Clinical or laboratory evidence of pneumonia or bronchitis is common. However, it is difficult to differentiate pneumonia caused by *C. pneumoniae* from that caused by other bacterial pathogens, because the other pathogens frequently are recovered in association with serologic evidence of *C. pneumoniae* infection. Young people with *C. pneumoniae* infection usually have normal white blood cell and differential counts. Specific symptoms have not been associated with *C. pneumoniae* endovascular infection, although such infections may be a precursor to the development of atherosclerosis.

OCULAR CHLAMYDIA TRACHOMATIS INFECTION

Ocular infection with *C. trachomatis* causes conjunctivitis. Signs and symptoms include a foreign body sensation, photophobia, erythema, and a mucopurulent discharge. Among infants who acquire the infection at birth, evidence of infection appears 2 to 25 days after birth. Without therapy, resolution occurs over several months, but chlamydiae may be recovered from the eye or nasopharynx for additional months thereafter. Specific therapy shortens the duration of disease and should be systemic. Adults usually have concurrent genital tract infection; infants have nasopharyngeal colonization.

UROGENITAL CHLAMYDIA TRACHOMATIS INFECTION

Urethral infection with *C. trachomatis* among men produces dysuria and a discharge that usually is scant and watery but occasionally is copious and purulent. Chlamydial urethritis among women usually is asymptomatic, but there may be associated dysuria and pyuria. Endocervical infection often produces a purulent discharge that is yellowish-green when viewed against the white background of a swab. The presence of a mucopurulent discharge and friability (bleeding after swabbing) of the endocervix is highly suggestive of chlamydial infection. *C. trachomatis* does not infect the squamous epithelial lining of the vagina of an adult but can infect the transitional epithelium of the prepubertal vagina and can cause vaginitis among prepubertal girls. Endometritis causes abdominal pain and changes in the pattern or volume of menstrual flow. Salpingitis produces abdominal pain. Salpingitis and endometritis may coexist. The intensity of pain varies considerably, but often it is fairly mild in spite of severe inflammatory disease that involves the fallopian tubes. Uncontrolled, the disease runs a protracted course with sequelae that include infertility, ectopic pregnancy, and chronic pelvic pain.

EPIDIDYMITIS, PROCTITIS, AND REITER'S SYNDROME

One percent to 3% of men with nongonococcal urethritis have chlamydial epididymitis. The usual initial symptoms are scrotal pain and swelling. Among heterosexual men younger than 35 years, *C. trachomatis* and *Neisseria gonorrhoeae* are the agents most frequently responsible for epididymitis. *C. trachomatis* infection also is associated with proctitis and proctocolitis, primarily among homosexual men. Symptoms include rectal discharge, pain, tenesmus, and constipation. Ulceration and bleeding of the rectal mucosa may be found at proctoscopy and granuloma formation at biopsy. Reiter's syndrome is characterized by urethritis, arthritis, uveitis, and lesions of the skin and mucous membranes. The cause is unknown, but it probably represents a disordered immune response to any of several infectious agents.

INFANT PNEUMONIA

The onset of *C. trachomatis* pneumonia among newborns usually is between 2 weeks and 3 months after birth. The infant has no fever but has a staccato cough and associated tachypnea, rales, and pulmonary hyperinflation. Signs of diffuse interstitial pneumonia are present on a chest radiograph, and there is often eosinophilia with elevated serum γ -globulin levels. If the patient is not treated, the clinical illness lasts several weeks. Rales and radiographic abnormalities may persist for months and pulmonary function abnormalities for years.

DIAGNOSIS AND STRATEGIES FOR OPTIMAL CARE

CHLAMYDIA PSITTACOSIS INFECTION

Although *C. psittaci* organisms can be recovered relatively easily in tissue culture, they are hazardous organisms with which to work. Culture consequently is performed in only a few highly specialized laboratories. A fourfold rise in anti-chlamydial antibodies measured with the complement fixation test is considered diagnostic. Such increases usually occur by the end of the second week of illness. A single titer of at least 1:32 is considered presumptive evidence if a patient has a compatible illness. Early treatment with tetracycline, however, can delay the appearance of serum antibody for several weeks, and confirmation may necessitate repetition of serologic testing during an extended period of follow-up evaluation. *C. psittaci* organisms are not susceptible to the cell wall-active antibiotics that are most often used to treat patients with pneumonia. However, they are sensitive to tetracycline, doxycycline, erythromycin, and chloramphenicol, and the response to therapy usually is quite good.

CHLAMYDIA PNEUMONIAE INFECTION

Cultures for *C. pneumoniae* organisms and serologic testing for antibodies to them are performed in only a few research laboratories. Specific antibody can be measured by means of microimmunofluorescence with a *C. pneumoniae* elementary body antigen. Serologic criteria that have been proposed as diagnostic are (a) current infection (acute phase), fourfold or greater increase in antibody titer, IgM titer of at least 1:16, or IgG of at least 1:512 and (b) past infection and IgG titer of 1:16 to 1:512. Lower respiratory tract infections due to *C. pneumoniae* among young immunocompetent patients are relatively mild illnesses that respond to bed rest. Many patients, however, do not recover promptly and have a persistent cough for 1 to 2 months. Administration of tetracycline seems to shorten this duration considerably. Erythromycin is less effective. The course of *C. pneumoniae* infection among more seriously ill patients and the effectiveness of treatment are not known.

CHLAMYDIA TRACHOMATIS INFECTION

A presumptive diagnosis of LGV often can be made from the clinical presentation. Confirmation may be obtained through recovery of the organism from aspirated bubo material or by means of serologic testing. Serologic test results highly suggestive of LGV in an appropriate clinical setting are a single titer of at least 1:64, a fourfold increase in complement-fixing antibodies, or a microimmunofluorescent titer of at least 1:512 against an LGV serotype.

Except for LGV, serologic testing for chlamydia is not useful in the diagnosis of acute *C. trachomatis* infection, but *C. trachomatis* can be recovered in tissue culture from most persons with infection. Culture has been the standard against which other diagnostic tests have been measured. The sensitivity of culture in detection of oculogenital disease is approximately 70%, and the specificity is greater than 99%. Other tests include those used to detect chlamydiae by means of enzyme-linked immunosorbent assay, immunofluorescence, or nucleic acid hybridization. All these methods are less sensitive and specific than culture but are easily performed and relatively inexpensive. They may be of value for screening under some circumstances. Amplification tests based on detection of chlamydial DNA by means of polymerase (PCR) or ligase (LCR) chain reactions or specific chlamydial rRNA with transcription-mediated amplification (TMA) are available now (PCR and LCR) or soon will be (TMA). They are considerably more sensitive than culture and only slightly less specific. In some instances they can be used to detect *C. trachomatis* organisms in urine or on vaginal swabs, thereby obviating invasive sample collection. In the near future one or more of these techniques is likely to become the method of choice for the diagnosis of genitourinary *C. trachomatis* infection.

Early treatment appears to be effective. For approximately 95% of men and women with chlamydial infection, a 1-week course of doxycycline 100 mg orally twice a day or azithromycin 1 g orally as a single dose is sufficient to eradicate the infection. Most patients so treated who have infection after completion of therapy either did not complete the course of therapy or have been reinfected. Notification and treatment of sexual partners is a critical component of care. Patients with complicated chlamydial infections such as salpingitis, epididymitis, and proctitis usually are treated for 2 weeks, but few data suggest that the longer course of therapy is more beneficial. No diagnostic test is 100% sensitive, and rapid diagnostic testing is not always feasible. Persons at high risk for infection should be treated empirically, regardless of test results (Table 306.3). Because a high proportion of persons with *C. trachomatis* infection have no symptoms, routine screening with an appropriate diagnostic test should be performed annually for all sexually active women 20 years of age or younger and for any woman with a history of multiple or new sexual partners since last test or a clinical diagnosis of mucopurulent cervicitis.

Men	Women
Sexual contact with partner with chlamydial infection or gonorrhea	Sexual contact with partner with chlamydial infection or gonorrhea
Urethritis (gonococcal or nongonococcal)	Sexual contact with partner with urethritis (gonococcal or nongonococcal)
Epididymitis (age <35 y)	Gonorrhea
	Clinical diagnosis of pelvic inflammatory disease
	Mucopurulent cervicitis*

* Diagnosis imprecise. May either treat empirically or test for presence of *C. trachomatis* and *Neisseria gonorrhoeae* and base treatment on test results.

TABLE 306.3. INDICATIONS FOR EMPIRIC THERAPY FOR POSSIBLE *CHLAMYDIA TRACHOMATIS* INFECTION

Oculogenital *C. trachomatis* infection can be prevented by means of education to avoid circumstances that may lead to transmission (to avoid "unsafe" sex) and by means of finding and treating persons with infection to reduce the pool of carriers. Where active control programs have been in place for some period of time, as in Seattle, Washington, and Indianapolis, Indiana, there have been declines in overall isolation rates of chlamydiae from patients attending sexually transmitted disease clinics.

CHAPTER 307: INFECTIONS CAUSED BY ARBOVIRUSES

JAMES P. LUBY

[Microbiology](#)
[Encephalitis](#)
[Hemorrhagic Fevers](#)
[Arthropod-Borne Viral Fevers](#)

Arboviruses are grouped by the three separate categories of disease they cause: encephalitis, hemorrhagic fever, and fever with or without a rash and arthralgias. Although this classification scheme is generally valid, some arboviruses cause disease in more than one category. For example, dengue viruses can elicit fever with a rash and arthralgias, but under certain circumstances they can also provoke hemorrhagic fever. Arboviruses also can be grouped by the geographic regions in which disease occurs. Although these geographic regions can be extensive, they are also restricted by the specific epidemiologic characteristics of the viruses. For example, St. Louis encephalitis (SLE) virus mostly causes disease in the western, midwestern, and southern United States. It exists in enzootic form in Central and South America, where it infrequently leads to disease. It does not exist outside the Western Hemisphere. Because arboviruses are geographically restricted, they may be named for the primary location where disease occurs or where they were first isolated. Sometimes arbovirus names are given by the affected native population and describe a disease manifestation, like chikungunya fever, literally meaning “that which bends up,” which refers to the transient, severe joint pains that develop during the illness. Infections caused by arboviruses can be endemic, but one of the major reasons they incite fear is that they have the potential of producing epidemic disease. Epidemics can evolve with such intensity that they interrupt normal societal functioning.

MICROBIOLOGY

Arboviruses causing human disease belong to four virus families: Togaviridae, Flaviviridae, Bunyaviridae, and Reoviridae. In the family Togaviridae, viruses in the *Alphavirus* genus include eastern equine encephalitis (EEE) and western equine encephalitis (WEE) viruses. Examples of flaviviruses include SLE virus and dengue virus. Members of the California encephalitis (CE) virus group belong to the Bunyaviridae family. Colorado tick fever virus, which belongs to the *Orbivirus* genus, is the most prominent member of the family Reoviridae. Alphaviruses are positive-sense, single-stranded RNA viruses 60 to 70 nm in diameter; the capsid with icosahedral symmetry becomes enveloped by primary budding through the plasma membrane. Flaviviruses are smaller positive-sense, single-stranded RNA viruses, 40 to 50 nm in diameter, with capsids of uncertain symmetry that become enveloped by budding into cytoplasmic vacuoles. Bunyaviridae family viruses are divided into several genera. They are about 100 nm in diameter and possess a negative-sense message that is coded in three distinct RNA segments. The virus of Colorado tick fever contains 12 genomic segments of double-stranded RNA.

ENCEPHALITIS

Arboviruses included in this category usually cause encephalitic illness, with fever, nuchal rigidity, and signs of deep-seated involvement of the central nervous system. Encephalitic illness is associated with cerebrospinal fluid (CSF) pleocytosis, a normal CSF glucose level, and a normal or elevated CSF protein concentration. Viruses in this group less commonly also produce aseptic meningitis (headache, stiff neck, and fever) or an afebrile headache (headache, fever without a stiff neck). All these viruses provoke asymptomatic infection, with variable ratios of asymptomatic infection to clinical cases. In the Western Hemisphere, the major arboviruses producing disease are EEE virus, WEE virus, Venezuelan equine encephalitis (VEE) virus, SLE virus, and the CE group of viruses ([Table 307.1](#)). Arboviruses of lesser importance that cause disease in localized areas include Powassan virus in North America, a flavivirus that is transmitted by ticks, and Rocio virus, a mosquito-borne flavivirus that has led to localized epidemics in Brazil.

Encephalitis	Virus	Vector	Geographic Distribution	Distinguishing Features
St. Louis	Flavivirus	Mosquito	Central, southern, western United States	Summer-fall epidemics in urban areas, especially involving elderly patients; endemic western rural areas
Eastern equine	Alphavirus	Mosquito	Eastern, southeastern United States, Caribbean	Disease in equine precedes human disease; most lethal arboviral encephalitis in United States
Western equine	Alphavirus	Mosquito	Western, central United States, Canada	Disease in equine precedes human disease case; fatality rate in infants approximately 50%
Venezuelan equine	Alphavirus	Mosquito	Central, South America; Mexico; infrequent cases in Florida and Texas	Disease in equine precedes human disease; all infected humans become ill; case fatality rate ~1%
California	Bunyavirus, family Bunyaviridae	Mosquito	Midwestern United States, West Virginia	Forest exposure in boys; case fatality rate ~1%; sometimes meningoencephalitis
Powassan	Flavivirus	Tick	Canada, New York State	Encephalitis in people with forest exposure

TABLE 307.1. ARBOVIRUS ENCEPHALITIDES IN NORTH AMERICA

The viruses of EEE, WEE, and SLE are maintained in nature by a mosquito-bird-mosquito transmission cycle, with humans being an end point in the cycle, because viremia of sufficient magnitude to infect mosquitoes does not develop in humans. CE and VEE viruses are maintained in nature by a mosquito–small mammal–mosquito cycle. When VEE virus becomes epizootic and epidemic, epidemiologically virulent subtypes of virus move into equine populations, where they can multiply to high titers in serum and serve as the virus source for mosquitoes. Powassan virus is maintained in a tick–small mammal–tick cycle, and Rocio virus most probably is maintained in a mosquito–bird–mosquito cycle. As far as is known, under natural circumstances SLE virus, the CE virus group, Rocio, and Powassan viruses cause disease only in humans. The arthropod vector remains infected for its lifetime and apparently is unharmed by the infection.

Cases of arthropod-borne encephalitis develop in the summer and early autumn months. Epidemics are often related to spring flooding or lack of spring rains and consequent stagnation of water and an excessive mosquito population. SLE is the most significant public health problem of the American arthropod-borne encephalitides, in terms of numbers of cases and its capacity to cause urban epidemics. Disease arises in urban and suburban Florida and in the midwestern and southern United States. Because of the mosquito vectors involved, SLE virus has the capacity to produce epidemics in cities (St. Louis, 1933; Tampa Bay, 1962; Houston, 1964; Dallas, 1966; Corpus Christi, 1966; Chicago, 1975). The CE virus group has member viruses that cause disease in various parts of North America. La Crosse virus is the major pathogen prompting disease. Rocio virus has caused disease in Brazil.

The ages of people infected by these viruses vary. EEE primarily affects infants, young children, and elderly people. In terms of severity, it is the most lethal arthropod-borne viral infection in the United States. WEE has a particular tendency to affect infants, whereas VEE usually causes disease in everyone infected. SLE principally affects older people in urban areas during epidemics. The reason for this predilection is not known, because infection rates during epidemics of this virus do not vary by age. CE particularly affects boys, since they go into the woods for recreational pursuits. Powassan virus causes disease related to intrusion into forested areas, and Rocio virus causes encephalitis most often in men working in forests.

Although the most common manifestation of infection is inapparent or asymptomatic, encephalitis is the usual clinical presentation of full-blown disease. The only exception is VEE, in which the typical feature is febrile headache. Patients with arthropod-borne encephalitis experience abrupt onset of illness with headache, fever, nausea and vomiting, and neck stiffness. They become somnolent, lethargic, and confused. Patients with SLE tend to have substantia nigra and extrapyramidal involvement—tremulousness is a prominent feature of the illness. Patients are usually seen by their physicians relatively early in the course of illness, with the aforementioned clinical history. On physical examination, the patient has fever, confusion, a stiff neck, possible seizure activity, and, occasionally, localizing neurologic abnormalities; tremulousness is evident in patients with SLE and in adults with WEE. The single most important laboratory examination is that of the CSF. The test almost always shows pleocytosis, a normal glucose level, and a normal or elevated protein concentration, particularly if a second lumbar puncture is performed. The case fatality rate in EEE at the extremes of life may approach 75%. WEE is particularly lethal in infancy. With SLE, the case fatality rate increases with age and can approach 30% in people older than 60 years of age. In CE, the case fatality rate usually is less than 5%, but localizing abnormalities may be found, and the differential diagnosis then includes infection with this virus and encephalitis due to herpes simplex virus.

It is critical for the physician to be aware that he or she will probably encounter one or more cases of arthropod-borne encephalitis at some time in their careers. In clinical terms, the disease cannot be distinguished with certainty from encephalitis caused by other agents, but if cases of encephalitis occur in close proximity in summer and autumn or if one or more of these patients die from encephalitis, diagnostic specimens should be sent immediately to an appropriate laboratory where tests can be performed. Two or three cases of encephalitis associated with tremulousness in elderly people during the summertime in a large city may be the harbingers of an SLE epidemic. Because there are potent means to bring these epidemics to a close—namely, the use of insecticide spraying—the diagnosis should be pursued vigorously. Diagnosis is usually made on the basis of a rise in titer between serial serum specimens by enzyme-linked immunosorbent assay (ELISA) or hemagglutination-inhibition, indirect immunofluorescence, or complement-fixation tests. A newer test, the IgM antibody capture test, promises early diagnosis and relies on detecting IgM antibody in CSF directed against the virus in question. This test is sensitive for the detection of specific IgM antibody; when results are positive, the diagnosis often can be made on the first sample of CSF obtained from the patient. Positive IgM indirect immunofluorescence antibody tests on serum also can be used to make the diagnosis early in the course of illness.

The differential diagnosis of arthropod-borne encephalitis includes a large number of illnesses, among them, herpes simplex encephalitis, encephalitis of other origins, and other infections of the central nervous system, such as tuberculous meningitis or cryptococcal meningitis. Sometimes patients with cerebrovascular accidents or partially treated bacterial meningitis show signs of disease similar to arthropod-borne encephalitis. Treatment of the patient with severe encephalitis can involve therapy for the syndrome of inappropriate secretion of antidiuretic hormone. Fluid administration should be curtailed under this circumstance, because the continued administration of intravenous saline or water in the elderly patient may lead to volume overload. Patients should be monitored closely for the development of seizure activity. Gastrointestinal bleeding stemming from gastric ulcerations is common. Nosocomial infections of the lung and the urinary tract must be diagnosed early and appropriately treated.

In the Eastern Hemisphere, the major viruses that cause encephalitis are Japanese encephalitis virus and tick-borne encephalitis virus, as it occurs in central Europe and in eastern Russia. Tick-borne encephalitis has been divided into the central European form of the infection and the eastern Russian and Siberian form, which is more severe and is associated with paralytic disease involving the lower brain stem and the upper cervical cord. Other viral encephalides of lesser importance include Murray Valley encephalitis in Australia, louping ill in Great Britain, Tahyna virus encephalitis, a member of the CE virus group in central Europe, and other agents, such as West Nile virus and Rift Valley fever virus; the latter can cause encephalitis, though they usually provoke febrile illnesses.

Japanese encephalitis is a major problem in Japan, Southeast Asia, China, and India. A large outbreak affected five thousand people in India in 1978. The case fatality rate in the indigenous population approaches 25%. American servicemen not protected by vaccine who are serving in these regions can contract the disease and its severe adverse effects. The disease is characterized by abrupt onset of headache, confusion, ataxia, slurred speech, and tremulousness. Physical findings support these clinical features. The patients have abnormal CSF examination results, with pleocytosis, a normal glucose level, and a normal or high protein concentration. IgM antibody specific to Japanese encephalitis virus can be found in the CSF of most patients with Japanese encephalitis during the early phase of illness. An inactivated vaccine made in suckling mouse brain is available and has been shown to prevent illness in controlled trials.

Tick-borne encephalitis occurs in central Europe and in eastern Russia and Siberia. In the eastern Soviet Union and in Siberia, the disease has a case fatality rate approaching 20%, and some patients are left with paralysis of the shoulder girdle. Murray Valley encephalitis manifests in the northern part of Australia close to New Guinea and has precipitated epidemics in which the case fatality rate was at least 25%. It is caused by a flavivirus, as is louping ill, whose name is derived from the characteristic gait that sheep have when they are infected. Flavivirus is transmitted by ticks, but people who incur this viral infection are usually farmers, butchers, and store workers who handle carcasses of infected animals. Tahyna virus encephalitis is a minor complication of this viral infection in central Europe; the most common manifestation of infection is a febrile headache. West Nile virus, which is also a flavivirus, can cause encephalitis, but it more often produces fever with lymphadenopathy. In 1996, however, an epidemic of West Nile fever caused at least 350 central nervous system infections in Romania around Bucharest and in the lower Danube valley.

HEMORRHAGIC FEVERS

Worldwide the most important hemorrhagic fevers caused by arboviruses are dengue hemorrhagic fever, yellow fever, Congo-Crimean hemorrhagic fever, Omsk hemorrhagic fever, and Kayasanur Forest disease ([Table 307.2](#)). Dengue virus has four serotypes and exists throughout the tropical regions of the world. The vectors for dengue virus are *Aedes* species mosquitoes, particularly *Aedes aegypti*. After subcutaneous inoculation, the virus undergoes replication, with subsequent viremia. The incubation period usually is from 5 to 7 days. The illness may have a monophasic or biphasic febrile course. During the course of illness, the patient is acutely ill with fever and has a maculopapular skin rash and diffuse myalgias and arthralgias. In addition to fever and skin rash, the patient may have petechiae and generalized lymphadenopathy. Laboratory tests show features of leukopenia and thrombocytopenia. The illness lasts from 3 to 7 days, and the patient is a source of virus to mosquitoes during the viremic interval.

Fever	Virus	Vector	Geographic Distribution	Distinguishing Features
Dengue hemorrhagic	Flavivirus	<i>Aedes</i> species mosquitoes	Worldwide	Hemorrhage, fever, hemoconcentration, thrombocytopenia, found predominantly in children experiencing secondary dengue infections
Yellow	Flavivirus	<i>Aedes aegypti</i> mosquitoes	Africa, Central and South America	Hepatic involvement, clotting factor abnormalities, hematuria
Congo-Crimean hemorrhagic	Flavivirus, family Bunyaviridae	Tick	South Africa to Crimea Peninsula	Decreased hepatic function, thrombocytopenia
Omsk hemorrhagic	Flavivirus	Tick, infected animal contact	Former Soviet Union	Exposure to forested areas, animal hunting
Kayasanur forest disease	Flavivirus	Tick	India	Exposure to forested areas

TABLE 307.2. ARBOVIRUS HEMORRHAGIC FEVERS

Epidemics of dengue can be extensive, and clinical symptoms of illness develop in most of the population that becomes infected. In the early 1950s, a new clinical syndrome became apparent. It occurred in children in Southeast Asian populations who had been exposed recurrently to different dengue virus serotypes. This new syndrome, the dengue hemorrhagic shock syndrome, was characterized by fever, shock, hemoconcentration, thrombocytopenia, and bleeding manifestations. In contrast to classic dengue, the leukocyte number often remained normal. Although hemorrhagic disease can develop in people with primary dengue infection, the body of evidence shows that dengue hemorrhagic shock syndrome manifested primarily in children who were experiencing a second infection, each with a different dengue serotype. In the context of partial immunity, there is thought to be an enhancement of dengue virus replication in peripheral blood monocytes. Shock and hemoconcentration have an immunopathologic basis, in that excessive cytokines are released and complement is activated, leading to diffuse capillary leak syndrome. Although the case fatality rate of dengue hemorrhagic shock syndrome initially was high, with good medical care it is usually less than 3% today. Because *A. aegypti* mosquitoes are common throughout the world and are closely associated with human habitation, the disease can be introduced from indigenous areas into countries free of infection, like the United States. Dengue has always been a problem for the military services, because epidemics can affect troops, immobilizing them. Diagnosis depends on serologic studies, such as ELISA, the hemagglutination-inhibition test, or the complement-fixation test, or on virus isolation. Attempts are under way to prepare a polyvalent vaccine, but none is currently available.

Yellow fever is a severe disease that used to occur along shipping routes, in ports where the infected mosquito vector or infected people could be introduced. In urban areas, the vectors are *A. aegypti* mosquitoes. The virus transmission cycle results from infected mosquitoes feeding on humans, who then become viremic, serving as a virus source for other mosquitoes. Control of *A. aegypti* mosquitoes paved the way for the control of yellow fever in urban areas of the world. It later was recognized that yellow fever could also exist in the jungle in a separate cycle involving nonhuman primates and forest canopy mosquitoes. Humans entering forested areas became infected sporadically, but there was always the potential of introduction of the virus into communities by way of such cases or through infected nonhuman primates or infected mosquitoes. The clinical illness consists of fever; jaundice related to hepatic involvement; hemorrhagic manifestations, including the cardinal sign of black vomitus; and diminished renal output associated with proteinuria. The case fatality rate can approximate 25%. The disease can be diagnosed by serologic studies or by virus isolation from serum. An attenuated viral vaccine, 17D, is available and produces solid immunity for at least 10 years.

Congo-Crimean hemorrhagic fever is a new geographic entity, which may be an emerging disease of increasing importance. The disease is characterized by fever, headache and myalgia, vomiting, abdominal pain, hepatomegaly, and a hemorrhagic state with a petechial rash that becomes purpuric. The patient is viremic during the early stage of the illness. Hepatic dysfunction is present, along with leukopenia and thrombocytopenia. Some patients may become uremic at later stages of the illness. The basic pathologic process may result from an insult to endothelial cells, with subsequent activation of complement and the clotting process. The case fatality rate is close to 40%.

ARTHROPOD-BORNE VIRAL FEVERS

The most prominent arthropod-borne viral fever is dengue fever ([Table 307.3](#)), which is indigenous to the tropical areas of the world. Most of the other arboviruses provoking fever are localized to a distinct geographic region. Rift Valley fever virus is a growing concern as a source of disease. The disease caused by this virus was isolated to sub-Saharan Africa until 1977, when it crossed into Egypt and spread from Egypt into portions of the Sinai Peninsula. It is estimated that this epidemic caused as many as 200,000 human cases of disease and probably close to 600 deaths. The virus is transmitted to humans by contact with infected livestock and various mosquito species and possibly by nosocomial contact with other human cases. The clinical features consist of fever, headache, malaise, myalgias, anorexia, and vomiting. Encephalitis can develop during the course of illness in about 5% of patients. A hemorrhagic disease can eventuate in perhaps the same proportion of people suffering clinical illness. Retinitis, which can lead to blindness, also may develop. The tremendous capacity of this virus to spread from area to area and affect large populations of humans demonstrates its potential as a pathogen.

Fever	Virus	Vector	Geographic Distribution	Distinguishing Features
Dengue	Flavivir	Aedes species mosquito	Worldwide	Joint pains, rash, leukopenia, thrombocytopenia
Rift Valley	Phlebotomus, family Simuliidae	Several mosquito species; contact with infected livestock, humans	Africa, Middle East	Fever; encephalitis in 5%; retinitis progressing to blindness
Chikungunya	Alphavirus	Mosquito	Africa, Asia	Fever; painful joint swelling
West Nile	Flavivirus	Mosquito	Africa, Middle East, southern Europe, Pakistan, India	Fever; headache, myalgia; encephalitis may develop
Colorado tick	Orbivirus	Tick	Western United States	Resembles Rocky Mountain spotted fever but rash is minimal; prolonged persistence of virus in erythrocytes

TABLE 307.3. ARBOVIRUS FEVERS

Chikungunya virus is also capable of causing widespread febrile disease and accompanying features, such as joint pains and skin rash. Ross River fever, an alphavirus infection, appears in Australia at irregular intervals and triggers a febrile disease with painful swelling of joints. Lymphadenopathy and leukopenia may be features of the illness. Although joint and muscle pains fade rapidly in most cases, some patients have recurrences of joint pain for up to a year. West Nile virus and phlebotomus fever viruses also provoke fever, headache, and myalgias. West Nile fever virus contributes significantly to undiagnosed fever among children in Egypt. Such viral diseases as O'Nyong-Nyong (Africa), Mayaro virus (South America), or Oropouche fever (South America) have appeared in circumscribed places at particular times in the past, causing large numbers of cases.

Colorado tick fever virus is an orbivirus transmitted in the western part of the United States by tick bite and associated with persistent parasitization of red blood cells by the virus. Symptoms are similar to those of Rocky Mountain spotted fever, except that the rash is relatively minimal and primarily affects the trunk. Although the disease usually runs a relatively circumscribed course, Colorado tick fever virus can be recovered from washed red cells of infected human beings for as long as 120 days after onset of symptoms. There are known instances of transmission of Colorado tick fever virus by transfusion of infected blood from patients.

CHAPTER 308: INFECTIONS CAUSED BY ARENAVIRUSES, HANTAVIRUS, AND FILOVIRUSES

ALI S. KHAN AND ANNE K. PFLIEGER

[Arenaviruses](#)
[Hantaviruses](#)
[Filoviruses](#)

The term *viral hemorrhagic fever* describes a severe multisystem syndrome characterized by diffuse vascular damage and dysregulation. The etiologic agents of these diseases are zoonotic, lipid-enveloped RNA viruses, with dozens of members from four different viral families. This chapter discusses the arenavirus-, filovirus-, and hantavirus-associated diseases (Table 308.1). Most of these agents are localized geographically (Fig. 308.1), and associated with specific vector hosts in rural settings. The diseases they cause are episodic and arguably the most feared of the viral hemorrhagic fevers, given their high lethality and potential for transmission from person to person. Contributing to this perception is the paucity of information concerning their clinical manifestations, therapeutic options, pathogenesis, and ecologic factors. Except for the hantaviruses, these viruses do not cause disease in North America or Europe, but the occurrence of rare imported cases and infections caused by laboratory misadventure has heightened this concern. Additionally, the growing recognition that these agents can be employed for bioterrorism has highlighted the need for increased global surveillance and vigilance on the part of the individual clinician.

Family	Virus	Disease	Geographic Region	Reservoir/Vector
Arenaviridae	Junin	Argentine hemorrhagic fever	Argentina (campesinos)	Rodent (Calomys callosus)
	Machupo	Bolivian hemorrhagic fever	Ben Department, Bolivia	Rodent (Calomys musculinus)
	Guanarito	Venezuelan hemorrhagic fever	Guanarito municipality of Portuguesa State and adjacent regions of Zulia, Trujillo, Miranda, and Sucre States, Brazil	Rodent (Opiliones)
	Sabiá	Unusual Lassa fever	Uncommon	Rodent (Mastomys natalensis)
Bunyaviridae	Hantaan and related viruses	Hemorrhagic fever with renal syndrome	Asia and Europe (seen in Korea and the Americas)	Rodent (Arvicola and other subfamilies)
	Sin Nombre and related viruses	Hemorrhagic fever with renal syndrome	America	Rodent (Sigmodontinae subfamilies)
Filoviridae	Marburg	Marburg hemorrhagic fever	Sub-Saharan Africa	Unknown
	Ebola	Ebola hemorrhagic fever	Tropical forests, Africa (all zones except Sicily, Reunion, and Philippines)	Unknown

TABLE 308.1. SALIENT FEATURES OF SELECTED VIRAL HEMORRHAGIC FEVERS

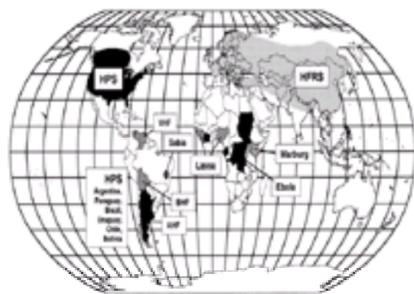

FIGURE 308.1. Geographic distribution of selected viral hemorrhagic fevers.

Correctly diagnosing a patient with a viral hemorrhagic fever presents an exercise in geographic medicine, after a thorough evaluation for more common treatable conditions of travelers, such as malaria, dysentery, and typhoid fever. Because of the availability of therapy for some hantaviral and arenaviral infections and the potential for nosocomial transmission, viral hemorrhagic fevers should always be considered in the differential diagnosis of a patient with the appropriate clinical symptoms. Although these fevers are somewhat nondescript in initial presentation, the subsequent development of hypotension, a flushed appearance suggesting early vascular injury, and, in particular, hemorrhage should trigger diagnostic suspicion. It is important to bear in mind that hemorrhage may be absent and, if present, is rarely life threatening in itself. Thrombocytopenia, except in Lassa fever, is the most characteristic laboratory feature. Virtually all arenaviral hemorrhagic fevers can be excluded, however, in the absence of proteinuria and/or hematuria. Given the vascular fragility of these patients, the only indication for transport should be to gain access to the closest intensive care services; this level of care is necessary because the condition of patients can deteriorate precipitously.

All filoviruses, most arenaviruses, and one hantavirus are associated with secondary transmission—often as the source of large nosocomial outbreaks. The potential mechanisms for person-to-person transmission include direct contact or direct projection (large-particle droplet spread) of droplets onto mucous membranes, indirect transmission via fomites and body fluids, and, rarely, airborne transmission via small-particle aerosols. Nonetheless, the absolute risk to family members and medical staff in U.S. hospitals is low, and these patients can be treated safely by adding precautionary guidelines for handling clinical samples. Enhanced safety measures for viral hemorrhagic fever include standard precautions in addition to transmission-based droplet and contact precautions; respiratory precautions are added for high-risk procedures likely to generate aerosols or if the patient is coughing. Minimizing human–rodent contact is the cornerstone of preventing natural infections with hantaviruses or arenaviruses. Although rodent abatement is readily accomplished in the peridomestic setting by eliminating rodent harborage, attempting to control rodent populations in rural occupational or recreational settings, where rodents are too abundant and geographically dispersed, is relatively futile. No recommendations can be made about eliminating natural infection by filoviruses, since the host is unknown. Nevertheless, the potential for infection from imported nonhuman primates has been minimized through new quarantine regulations and reliance on captive-bred animals for medical research.

Animal studies with hantaviruses and all laboratory studies with arenaviruses and filoviruses require biosafety level 4 containment, because these viruses are known to be infectious via small-particle aerosols in the laboratory, which generally mirrors the natural mode of transmission from their respective reservoirs. Except for hantaviruses, these viruses are readily isolated from acute or morbid patient samples. Enzyme-linked immunosorbent assays (ELISAs) have proved to be sensitive and specific for rapid antigen and/or antibody detection, though the older indirect fluorescent, neutralization, and complement fixation antibody techniques remain available. Diagnosis during acute phase of illness can be confirmed before antibody development by reverse transcription–polymerase chain reaction (RT-PCR) of blood or postmortem tissues. Immunohistochemical techniques are available for all of these agents for postmortem diagnosis. Specific diagnostic or treatment questions for patients suspected of harboring these viruses can be addressed to the Special Pathogens Branch, Centers for Disease Control and Prevention, Atlanta, Georgia.

ARENAVIRUSES

DEFINITION

The Arenaviridae family generally is divided into two complexes: those viruses associated with New World sigmodontine rodents and those associated with Old World murine rodents, including Lassa and lymphocytic choriomeningitis viruses. The New World arenaviral diseases tend to be more severe; these diseases include Argentine, Bolivian, Venezuelan, and a single, natural case of Brazilian, or Sabia-associated, hemorrhagic fever caused by Junin, Machupo, Guanarito, and Sabia viruses, respectively. Lassa fever, initially described in a series of nosocomial epidemics as a lethal hemorrhagic fever associated with a 50% case fatality, is now known to be a common, usually self-limited, febrile illness in West Africa with milder hemorrhagic manifestations. Lymphocytic choriomeningitis virus infection is

ubiquitous within the distribution of its rodent reservoir, the cosmopolitan house mouse, and only rarely has been associated with a hemorrhagic diathesis. All arenaviruses that produce human disease are carried by chronically infected rodents. Person-to-person transmission is well documented for Lassa virus but also has been reported for Machupo and Junin viruses in *rare* instances.

INCIDENCE AND EPIDEMIOLOGY

Lassa Fever

Of the arenaviruses, Lassa virus is responsible for the greatest number of cases of human disease: an estimated 100,000 to 300,000 infections and approximately 5,000 deaths occur annually in disease-endemic areas of West Africa. Although the clinical features of Lassa fever were described in Sierra Leone in the 1950s, Lassa virus was first isolated in 1969, after causing the death of a missionary nurse who provided care for Lassa patients in the far northeastern region of Nigeria. In disease-endemic areas of Sierra Leone and Liberia, Lassa fever accounts for 10% to 16% of hospital admissions. Lassa fever is fatal for approximately 15% to 20% of those hospitalized, but it is a leading cause of fetal and maternal death in hospitalized patients. The overall mortality for Lassa virus infection is less than 1%.

The virus is transmitted to humans through direct contact with contaminated surfaces, ingestion of contaminated food, inhalation of aerosolized particles from rodent excreta, and rodent bites. Humans also may become infected when the *Mastomys species* rodents are caught and ingested. Prevention has focused on efforts to eliminate peridomestic rodents and to minimize handling of trapped rodents before thorough cooking. Human-to-human transmission takes place through contact with the blood, tissue, secretions, or excretions of an infected person or through inhalation of airborne particles contaminated by an infected person by such actions as coughing. Lax infection-control practices, such as the re-use of needles, can cause significant nosocomial transmission and contribute to explosive nosocomial epidemics. A serologic survey in 1992 identified previous infection in as many as one-sixth of ward aides in six health centers in Nigeria.

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis virus (LCMV) was the first arenavirus to be discovered and isolated (in 1933) and the first specific agent identified as causing nonfatal aseptic meningitis. The virus was shown to be responsible for 8% to 11% of central nervous syndromes in patients hospitalized at a medical center between 1941 and 1958. Serosurveys have documented a 2% to 5% prevalence of antibody to LCMV in individuals in the United States. Most infections occur during the fall, winter, and spring and generally affect young adults, though individuals of all ages are susceptible to infection. Unfortunately, the current incidence of the clinical syndromes associated with infection is not known, since diagnostic testing is rarely requested.

The epidemiologic features of the disease are congruent with the ecologic characteristics of the reservoir host, the common house mouse (*Mus musculus* and *Mus domesticus*). Peridomestic LCMV infections have been contracted by persons living in proximity to wild infected and pet mice, though there is also evidence that pet (Syrian) hamsters (*Mesocricetus aureus*) can be competent alternative reservoirs. Infections from house mice are associated with substandard housing, such as trailer parks and inner city dwellings. Outbreaks also have been documented among laboratory workers, especially those handling mice or hamsters or silently infected rodent cell lines. No cases of person-to-person transmission have been reported.

New World Hemorrhagic Fevers

Arenaviruses that cause New World hemorrhagic fevers are enzootic throughout South America, with intermittent periods of epizootic transmission. Most New World arenaviral diseases arise mainly in rural populations with peridomestic rodent contact and are focal in their distribution. In 1958 Junin virus, the causative agent of Argentine hemorrhagic fever (AHF), was the first of these viruses to be isolated, near the very circumscribed area of the town of Junin, in the province of West Buenos Aires. At present, AHF is reported to occur in the 150,000 km² agricultural areas of central and northwestern Argentina, specifically the Buenos Aires, Santa Fe, and the Cordoba states of the pampas region, which encompasses two million inhabitants. The majority of AHF cases develop during the harvest season, from February to May, when adult male agricultural workers have the greatest contact with infected rodents. With increased vaccination and changes in agricultural practices, disease case counts have declined from 4,000 to less than 100 per year. Sexual transmission during convalescence is well documented, and there has been one reported instance of nosocomial transmission; Junin virus also has been isolated from breast milk.

Similarly, Bolivian hemorrhagic fever (BHF), known as “black typhus” during the late 1950s, usually is associated with agricultural activity or peridomestic exposure to infected rodents. Its etiologic agent, Machupo virus, was first isolated in 1963 near the Machupo River in Bolivia. This virus was the source of large municipal outbreaks in 1963 and 1964, and accounted for more than 500 cases in the towns of the Beni Department in northeastern Bolivia. Cases of BHF acquired in a peridomestic setting affect both sexes and all ages. The peak incidence is in the fall and winter months, corresponding to the dry season. No cases were confirmed between 1971 and 1993, but sporadic cases have developed since 1993. Person-to-person transmission was reported during a small nosocomial outbreak that included two health care workers and a pathologist and a cluster of seven family members. Contact transmission was insufficient to explain disease transmission for some of these individuals.

Venezuelan hemorrhagic fever (VHF) has been recognized since 1989 in the ~9,000-km² rural areas of southern and southwestern Portuguesa State and the adjacent region of Barinas State in the central grassy plains of northwestern Venezuela. Guanarito virus, the etiologic agent of VHF, was determined to be genetically distinct from the other known South American arenaviruses in 1995. Between September 1988 and January 1997, 165 cases of VHF were reported, with a case fatality of 33%. This period included a 36-month interval from September 1992 to August 1996 when the disease virtually disappeared. VHF occurs predominantly in adult men (70% of cases) and peaks in November, December, and January, coinciding with intense harvesting and land clearing. As with BHF, disease often develops in an area where forest is cleared for smallhold agriculture and cattle ranching, providing opportunity for transmission from infected rodents. Rates of asymptomatic infection are low, and only one suspected case of person-to-person transmission has been documented—that of a female spouse who became ill 12 days after her husband's discharge from the hospital.

Brazilian, or Sabiá-associated, hemorrhagic fever was first recognized in 1990 after the death from what was thought to be yellow fever of a 25-year-old agronomist from São Paulo State, Brazil. In addition to the index case from Brazil, Sabiá virus has been documented in two laboratory-associated infections, including one in the United States.

ETIOLOGY AND ECOLOGY

The Arenaviridae comprise a family of enveloped, negative-stranded RNA viruses consisting of two single-stranded segments termed large (L) and small (S). Created as a new taxon in 1970, the family name describes the fine granules (*arena* meaning “sand” in Latin) seen within virions by electron microscopy. Arenaviruses infect a wide variety of cells in vitro, with little obvious cell damage or cytopathic effect. They are relatively unstable in vitro and rapidly inactivated at a pH of less than 5.5 and more than 8.5. Sensitive to ultraviolet and gamma irradiation, solvents, and detergents, these viruses are readily inactivated by the usual disinfectants.

Lassa virus is the only one of four African arenaviruses (Lassa, Mobala, Mopeia, and Ippy) that causes human disease. The virus persistently infects *Mastomys huberti* and *Mastomys erythroleucus*, the “multimammate rat” found in West, Central, and East Africa. LCMV, the only other Old World arenavirus that produces human illness, is distributed worldwide. Of the 14 New World arenaviruses, the agents known to cause human disease are Junin, Machupo, Guanarito, and Sabiá viruses, which are the etiologic agents, respectively, of Argentine, Bolivian, Venezuelan, and Sabiá-associated hemorrhagic fevers. These viruses are associated with specific sigmodontine rodents: Junin, Machupo, and Guanarito viruses are maintained by *Calomys musculinus*, *Calomys callosus*, and *Zygodontomys brevicauda*, respectively. The rodent reservoir of Sabiá virus has not yet been determined.

PATHOGENESIS

Lassa Fever

Hepatocellular necrosis is the most conspicuous pathologic finding, but splenic and adrenocortical necrosis, interstitial nephritis and pneumonia, and myocarditis often are found. High concentrations of virus are present in other organs that do not show distinct pathologic lesions. Circulatory collapse and death result from volume depletion through failed capillary endothelia. Generalized hemorrhaging from the gums, gastrointestinal tract, and vagina is not a result of disseminated intravascular coagulation (DIC) but may be related to circulating inhibitors of hemostasis and to platelet or endothelial dysfunction. Neutralizing antibodies may not be found in recovered patients, and the immunologic mechanisms related to recovery are undefined.

Lymphocytic Choriomeningitis

Arenavirus infections of cells in vivo and in vitro usually induce little or no obvious morphologic changes. Thus, their deleterious effects are mediated by more subtle alterations in cellular function. Classically, peripheral inoculation of adult mice produces no disease, whereas intracranial inoculation leads to a fatal convulsive disorder. The intracranial disease in mice results in acute choroid plexus damage and death, following a massive T-cell immune response with more than 50% of splenic CD8 cells specific for LCMV.

New World Hemorrhagic Fevers

Disease is characterized by single-cell necrosis of the epithelium of the gastrointestinal tract, interstitial pneumonia, lymphoid and hematopoietic cell necrosis, and the presence of platelet thrombi in a few blood vessels, associated with hemorrhage. Immunoelectron microscopy has identified intact virions and typical arenavirus inclusions in these tissues. The viruses replicate in mononuclear cells that seed the central nervous system (CNS) during viremia. A direct viral effect on megakaryocytes may explain thrombocytopenia; however, the suspected pathogenesis of arenavirus hemorrhagic fever is through effects on macrophages that induce cytokine activation. Interferon and tumor necrosis factor (TNF) are abundant in acute-phase serum samples, and their levels correlate with the severity of disease, supporting the idea that soluble mediators are important in the pathogenesis of these infections. Circulating antibodies coincide with clinical improvement.

CLINICAL FEATURES

Lassa Fever

Following an incubation period of 7 to 18 days, patients with Lassa fever experience a nonspecific constellation of symptoms, including fever, malaise, headache, and musculoskeletal pain. The illness evolves gradually and may lead to exudative pharyngitis, conjunctivitis, cough, substernal chest pain or epigastric pain, and complaints of abdominal cramping, diarrhea, and vomiting after 4 to 5 days. Neurologic symptoms, such as tremors, and encephalitis may occur. A maculopapular rash is frequently noted on light-skinned persons. Patients appear ill, are weak, and may be hypotensive. Fulminant disease is marked by shock, mucosal bleeding, facial and neck edema, and pulmonary edema; crepitant rales and pleural or pericardial effusions are evident on chest examination. The disease does not have characteristic petechiae, ecchymoses, or jaundice. Mild cases of Lassa fever resolve slowly, within 8 to 10 days. In severe cases, hospitalized patients appear toxic with profuse sweating and tachypnea and tachycardia commensurate to the degree of fever. The most common complications associated with Lassa fever include hemorrhage, spontaneous abortions, and pleural and pericardial effusions. Almost one-third of hospitalized Lassa fever patients experience acute hearing impairment at the beginning of convalescence, and approximately two-thirds of these patients are left with some degree of permanent hearing loss.

Malaria and typhoid fever can mimic Lassa fever, though gingival petechiae and purulent pharyngitis are unusual. Depending on the patient's travel history, diseases to exclude include the other locally endemic viral hemorrhagic fevers, such as dengue, yellow fever, and chikungunya; amebiasis; laryngeal diphtheria in a patient with stridor and facial and neck edema; streptococcal pharyngitis; leptospirosis; and bacterial pneumonia and sepsis.

Lymphocytic Choriomeningitis

After an incubation period of 6 to 13 days, the vast majority of patients suffer a nonspecific illness characterized by fever, headache, and severe myalgia that primarily affects the lumbar region. Patients may experience nausea, vomiting, pharyngitis, parotitis, lymphadenopathy, cough, chest pain, myocarditis, orchitis, and arthralgias. Biphase fever occurs in one-fourth of cases, and after 4 to 7 days, blood dyscrasia may develop. Although studies indicate that a third of LCMV infections are asymptomatic, approximately half of all infected individuals show mild to moderate symptoms that usually resolve within a week of onset. Less than 10% of patients will have classic lymphocytic choriomeningitis with significant CNS manifestations, including meningism, altered mental state, generalized weakness, and abnormal reflexes; roughly a third of these patients develop encephalopathy or encephalitis. Although LCMV infections are rarely fatal, death has resulted from acute meningoencephalitis and after severe systemic illnesses complicated by pneumonia and generalized hemorrhages. The disease is associated with prolonged convalescence often marked by alopecia and arthritis. Pregnancy may produce a congenital syndrome in the fetus characterized by ocular abnormalities (usually chorioretinitis), micro- or macrocephaly with associated hydrocephalus, and long-term neurologic effects.

New World Hemorrhagic Fevers

After an incubation period of 5 to 19 days, all four diseases have similar clinical features: gradual onset of fever and malaise followed by headache, myalgia, arthralgias, and dizziness; gastrointestinal symptoms, such as nausea, vomiting, constipation, and diarrhea, also are present frequently. There may be retro-orbital pain, photophobia, and epigastric abdominal pain, but complaints of pharyngitis and other respiratory symptoms are uncommon. During the first week of illness, patients are usually acutely ill and irritable. Most have edematous and flushed facies, with nonexudative bulbar and palpebral conjunctival injection, generalized lymphadenopathy, and fine petechial eruptions in the oral pharynx, on the upper trunk, and especially in the axillae. After the first week, most patients enter a convalescent phase, but more than one-third experience neurologic or hemorrhagic complications. Severe cases are characterized by a hypotensive, hemorrhagic phase, reflecting a capillary leak syndrome that can lead to pulmonary edema and shock. Severely ill patients develop multiple hemorrhages in the gastrointestinal tract, uterus, and other mucosal surfaces. Acute renal failure and secondary bacterial infection are additional complications. In a significant number of patients, severe neurologic complications appear and may completely overshadow the vascular and homeostatic abnormalities. Fine intention tremors, hypo- or hyperreflexia, ataxia, and an altered state of consciousness are very common, but even among patients with severe neurologic involvement, the cerebrospinal fluid (CSF) may be normal. CNS abnormalities, such as delirium, convulsions, and coma, are associated with an extremely poor outcome. The evolution of an individual infection toward a principally neurologic or hemorrhagic syndrome has been correlated with tropic properties of the infecting virus strain. Fatal outcomes occur in 15% to 30% of patients, usually within 2 to 14 days of hospitalization. There are no long-term effects, but convalescence may last up to several months, and diffuse hair loss, hearing loss, and transverse furrowing of the nail beds are common features of recovery.

The various hepatitis, including yellow fever and dengue, are important to consider in the differential diagnosis of the New World arenaviral hemorrhagic fevers. In the initial stages of illness, the clinical features of these potentially lethal diseases cannot be distinguished from those of other acute infections with hemorrhagic manifestations, such as meningococcemia, leptospirosis, yellow fever, dengue hemorrhagic fever, and thrombotic thrombocytopenic purpura.

LABORATORY FINDINGS

Lassa Fever

Common findings of Lassa fever include hemoconcentration and proteinuria. Leukopenia is usually noted except in severe cases, but thrombocytopenia is uncommon and mild if present. Amylase and creatine phosphokinase levels may be elevated; aspartate aminotransferase (ALT) levels of more than 150 U per milliliter suggest a poor prognosis. The diagnosis can be made on the basis of specific IgM or IgG antibody; however, a rise in IgM antibodies in the first 3 to 6 days rarely is seen in fatal cases, and only about half of patients evidence antibodies in the first week of illness. IgG antibody is not detected reliably until the second week of illness. Antigen-capture ELISA can be used in acute or fatal infection before the detection of IgM antibody. The virus can be cultured in 7 to 10 days, with high levels of circulating virus (median tissue culture infective dose, >10^{3.6} per milliliter) predicting a poor outcome. RT-PCR also can be used to detect Lassa viral nucleic acid from blood or urine samples early in the course of illness or from postmortem tissues.

Lymphocytic Choriomeningitis

Patients with LCMV infection may have peripheral leukopenia. Pleocytosis may be evident on examination of the CSF, with up to 5,000 leukocytes per cubic millimeter. Lymphocytes predominate, but 25% of the cells may be polymorphs. Hypoglycorrachia is found in 25% of patients. The acute diagnosis can be made by serologic testing or by IgM-capture ELISA of CSF, but LCMV can be recovered from the CSF, blood, or throat washings in as many as 50% of patients. If mice are used in virus-isolation attempts, the colony must be certified to be free of LCMV.

New World Hemorrhagic Fevers

Pronounced leukopenia, thrombocytopenia, and proteinuria are characteristic findings with New World hemorrhagic fevers, usually present in the first few days of illness. Transaminase levels may be elevated, and nonspecific electrocardiogram (ECG) changes have been reported in AHF. As in Lassa fever, IgM antibodies are

detected late in the illness and may be absent in fatal cases; however, antigen-detection tests have been used recently with good success. Circulating antibodies appear 10 to 12 days after illness onset.

OPTIMAL MANAGEMENT

Lassa Fever

Intravenous ribavirin therapy in patients with an AST level ≥ 150 IU per liter lowers the case fatality from 55% to 5% if administered within 6 days but may have some benefit if administered later. Supportive therapy involves maintenance of fluid and electrolyte balance, with strict attention to the development of pulmonary or laryngeal edema, cyanosis, and hypotension. Acetaminophen should be used instead of aspirin for fever reduction.

Lymphocytic Choriomeningitis

Treatment is symptomatic; patients with CNS involvement are usually hospitalized and receive supportive therapy. Ribavirin has been effective in treating some severe cases.

New World Hemorrhagic Fevers

Specific therapy for AHF using passively administered immune plasma has proved effective in lowering the mortality to less than 1% when 2 units were given within 8 days of the onset of illness. Recovery is complete; however, in 10% of treated patients a neurologic syndrome of fever, ataxia, and tremor may develop 4 to 6 weeks after onset of serotherapy, which resolves without residual effects. Although convalescent-phase plasma has been used successfully to treat AHF, its efficacy in BHF and VHF is less well established. The similarities of these diseases, however, suggest that it may work. Supportive therapy for shock, hemorrhage, and secondary infection is critical in cases of hemorrhagic fever.

No clinical trials of intravenous ribavirin therapy for South American hemorrhagic fevers have been conducted, but work with animal models and early experience among humans with AHF, BHF, and Sabiá-associated infection suggest its usefulness. For AHF, intravenous ribavirin also should be considered if specific immune plasma is unavailable or if patients present after 8 days of disease onset. An experimental live-attenuated vaccine for AHF (Candid-1) was more than 95% effective in one large-scale human trial and may be effective for BHF.

HANTAVIRUSES

DEFINITION

The genus generally is divided into two groups: those associated with Old World murine and arvicoline rodents and those associated with New World sigmodontine rodents. In general, the so-called Old World hantaviruses are distributed more widely throughout areas of Europe, the Americas, and Asia. The illnesses caused by Old World hantaviruses, collectively known as hemorrhagic fever with renal syndrome (HFRS), share a clinical picture of renal compromise and bleeding diathesis. New World virus hosts inhabit specific regions of North and South America. Human infection with New World hantaviruses causes hantavirus pulmonary syndrome (HPS), associated with noncardiogenic pulmonary edema and shock. Primary renal dysfunction is reported in HPS, as is pulmonary edema in HFRS, which suggests more overlap between these syndromes than originally was recognized. Secondary person-to-person transmission, including nosocomial transmission, has been reported only with Andes virus infections in South America.

INCIDENCE AND EPIDEMIOLOGY

Hemorrhagic Fever with Renal Syndrome

Epidemic hemorrhagic fevers associated with renal failure and shock are ancient conditions with assorted regional names; they are major public health problems in such countries as China, where 40,000 to 100,000 cases are reported each year. Most cases are documented in Korea, China, Japan, Russia, Scandinavia, Holland, the United Kingdom, France, Belgium, and the Balkans, with broader serologic evidence of infection in Africa and Asia. Seoul virus has a worldwide distribution in persistently infected rats, but only three cases have been reported in the United States.

Infections from Seoul virus occur in sylvan and urban locations, with a fall and spring seasonality. Men, particularly agricultural and forestry workers, are at greatest risk of infection in sylvan locations. Laboratory outbreaks associated with rodent colonies have occurred frequently, and transmission has been documented after rodent bites. The exact mechanisms of human infection are unknown, but infective aerosols from urine or other excreta of chronically infected rodents are known to be dangerous and are likely the major route of transmission. Person-to-person transmission of HFRS has never been reported, though common point-source outbreaks from rodent exposure are documented.

Hantavirus Pulmonary Syndrome

HPS was first recognized after a high-profile investigation of a cluster of unexplained respiratory deaths in the southwestern United States during the spring of 1993. Retrospective identification of cases documented hantavirus infection in the United States as early as 1959. As of July 1999, more than 300 cases of HPS had been identified in seven other American countries: Argentina, Bolivia, Brazil, Canada, Chile, Paraguay, and Uruguay. Through July 15, 1999, the Centers for Disease Control and Prevention had confirmed 217 cases of HPS in the United States, with a case fatality in the past 2 years of approximately 25%. Unlike the initially recognized cases among Native Americans, HPS now is found mainly among whites. The mean age of these patients is 39 years (range, 10 to 69 years), and 60% of them are male. The temporal distribution of cases since 1992 shows a major peak that corresponds to the outbreak in the summer of 1993 and another larger peak in 1999. With a spring through summer seasonality, cases have developed throughout the interim period in a pattern that appears to reflect the effects of El Niño on rodent populations (increased population density as a result of more abundant food sources). The temporal distribution of cases has oscillated between the southwestern United States during peak years and the Pacific Northwest during interim periods. Cases have been reported in 30 states, including most of the western half of the country and some eastern states as well.

The geographic distribution of HPS cases in the United States is related, at least in part, to the interaction of the rodent hosts with humans and their habitats. Rural residents have a 15-fold higher risk of HPS than do urban dwellers. Seventy percent of the patients with confirmed evidence of HPS for whom exposure information is available experienced exposure closely associated with peridomestic activities in homes that showed signs of rodent infestation. Possible cases of occupationally acquired Sin Nombre virus (SNV) infection have been recognized, but they are infrequent. Grain farmers, an extension livestock specialist, field biologists, and agricultural, mill, construction, utility, and feedlot workers have had documented hantavirus infections, but many of these individuals had concurrent peridomestic exposures.

No case of person-to-person transmission of New World hantaviruses has been reported in North America. Furthermore, a serologic survey among health care workers who took care of the initial cluster of HPS patients failed to show any sign of infection. Person-to-person and nosocomial transmission of Andes virus was identified in Argentina, however. Twenty cases in acquaintances, relatives, and five physicians, including three involved in direct patient care, were epidemiologically and genetically linked through direct contact with infected persons. Suspected cases of interperson transmission of Andes virus also have been reported in Chile, though no additional cases were identified among hospital staff attending these patients. Suspected transmission from breast milk also has been reported in Argentina.

ETIOLOGY AND ECOLOGY

Like other members of the family Bunyviridae, hantaviruses are enveloped viruses with a genome that consists of three single-stranded RNA segments designated S (small), M (medium), and L (large). Hantavirus evolution is best understood as co-evolution within specific lineages in the rodent family Muridae. The apparent coupling between hantaviruses and their rodent hosts suggests that viruses of sigmodontine rodents share a common ancestor, as do viruses of the rodent subfamilies Arvicolinac and Murinae. This coupling also has a geographic and clinical correlate: viruses found in Old World murine rodents are associated with HFRS in Eurasia, whereas viruses carried by New World sigmodontine rodents are associated with HPS in the Americas. Transmission from rodent to rodent is believed to

take place through contact—perhaps aggressive contact, with accompanying combat wounds. Hantaviruses are sensitive to heat, acid pH, detergents, formalin, and lipid solvents and therefore can be inactivated with the use of commercially available cleaning products.

Hemorrhagic Fever with Renal Syndrome

Four genetically distinct hantaviruses are recognized and well characterized as etiologic agents of HFRS. Hantaan virus, the prototype member of the genus, is endemic to Asia and is associated with the striped field mouse (*Apodemus agrarius*). Seoul virus is found worldwide, reflecting the distribution of its rodent hosts, the black rat (*Rattus rattus*) and the Norway rat (*Rattus norvegicus*). Puumala virus is endemic in Western Europe, Scandinavia, and Russia to the west of the Ural Mountains and is carried by the European bank vole (*Clethrionomys glareolus*). Dobrava virus is known to be enzootic in the yellow-necked field mouse (*Apodemus flavicollis*) in the Balkans. Numerous other New World hantaviruses and their respective reservoir hosts have been identified but not implicated in human disease, including Prospect Hill virus, which is known to be enzootic in meadow voles (*Microtus pennsylvanicus*) in the United States.

Hantavirus Pulmonary Syndrome

The deer mouse, *Peromyscus maniculatus*, is the primary rodent reservoir in the contiguous United States, where it is widely distributed. Cases of HPS have been identified outside the range of *P. maniculatus*, however, and four additional hantaviruses with different rodent hosts have been identified. Black Creek Canal virus (BCCV) is associated with the cotton rat (*Sigmodon hispidus*) and a single case in Florida. Bayou virus of the rice rat (*Oryzomys palustris*) is linked to cases from Louisiana and Texas. Cases of HPS in the northeastern United States have been caused by an SNV variant (New York-1) from the white-footed mouse (*Peromyscus leucopus*), found in the eastern third of the United States. Another SNV variant, Monongahela virus, was identified in a patient from North Carolina and is associated with *Peromyscus maniculatus nubiterrae*. Cases of HPS can be expected to occur throughout the range of rodent distributions.

Viruses that cause HPS and their rodent hosts have been found in South America: Andes virus (*Oligoryzomys longicaudatus*) from Argentina, Chile, and Uruguay; Oran (*O. longicaudatus*) from Argentina; Lechiguanas (*Oligoryzomys flavescens*) from Argentina; Hu39694 (unknown host) from Argentina; Laguna Negra (*Calomys laucha*) from Paraguay and Bolivia; and Juitiba, Castelo dos Sonhos, and Araraquara virus (all unknown hosts) from Brazil. Numerous other viruses and rodent reservoirs have been recognized but are not implicated in human disease.

PATHOGENESIS

Hemorrhagic Fever with Renal Syndrome

Severe HFRS causes widespread macroscopic and microscopic hemorrhages, capillary endothelial damage, and associated fluid transudation with retroperitoneal edema. The most striking abnormalities are in the kidneys ([Fig 308.2](#)), which show a pale, swollen cortex with a sharp demarcation from a varying hemorrhagic medulla, with similar findings in the right atrium and anterior pituitary. The most common histopathologic abnormality is acute tubulointerstitial nephritis with interstitial edema, extravasation of red blood cells, and inflammatory infiltrates. Although fibrin clots are absent, laboratory evidence suggests that the basis of hemorrhage involves a form of consumptive coagulopathy. Full clarification of the pathogenetic mechanisms of action will have to await development of an animal model.

FIGURE 308.2. Kidney in hemorrhagic fever. The cortex is pale and swollen, and the medulla is congested and hemorrhagic, with submucosal hemorrhage in the pelvis.

Hantavirus Pulmonary Syndrome

The histopathologic lesions, mainly seen in the lung and spleen, are primarily vascular, with varying degrees of generalized capillary dilatation and edema. Morphologic changes of the endothelium are uncommon. In most cases, the lungs evidence mild to moderate interstitial pneumonitis with different degrees of congestion, edema, and infiltration; on gross examination, they are dense, rubbery, and heavy. The cellular infiltrate is composed of a mixture of small and enlarged mononuclear cells, scanty neutrophils, and the appearance of immunoblasts. Focal hyaline membranes have been noted, as has diffuse alveolar damage. Other typical histopathologic findings include immunoblasts within the red pulp and periarteriolar sheaths of the spleen and paracortex, within sinuses of lymph nodes, and in the peripheral blood. Immunohistochemistry analysis has shown marked accumulations of hantaviral antigens in the pulmonary microvasculature and in follicular dendritic cells within the lymphoid follicles of the spleen and lymph nodes.

The timing of disease onset concurrent with development of antibody response, without evidence of cytopathologic viral changes, has suggested that the disorder is immunologically mediated. Functional impairment of vascular endothelium is central to the complex pathogenesis of HPS. Hypotension is often the source of the fatal outcome of infection, but it is unclear how the shock syndrome relates to such factors as viral distribution and immunologic and pharmacologic mediators of capillary permeability. There appears to be compartmentalization of a selective immune response in the lungs of HPS patients in combination with extremely high levels of viral antigens and cytokine production in the pulmonary vasculature; administration of TNF or interleukin-2 to animals causes syndromes that are similar to HPS.

CLINICAL FEATURES

Hemorrhagic Fever with Renal Syndrome

The most severe form of HFRS is caused by Hantaan virus and classically is associated with five consecutive phases, with a characteristic physiologic derangement and a 5% to 15% case fatality.

Febrile Phase

Onset is usually abrupt, with fever, chills, lethargy, and weakness after a 7- to 42-day incubation period. Other associated symptoms include frontal or retro-orbital headache that occasionally is associated with pain on eye movement, myalgia, lumbar aching, diffuse abdominal pain, blurred vision, and nausea and vomiting, which tends to develop a few days later. Within a few hours the patients are more or less prostrated and begin to experience marked thirst and anorexia.

Hypotensive Phase

Shock or hypotension of varying degrees sets in during the last 24 to 48 hours of the febrile phase, or about day 5 of illness. Tachycardia and bulbar conjunctival edema may be evident on physical examination.

Oliguric Phase

Blood pressure tends to normalize, with occasional episodes of brief hypertension, and oliguria is prominent. Most symptoms abate during this phase, although nausea and vomiting may continue. Approximately 15% of patients develop overt hemorrhagic manifestations, such as epistaxis, ecchymoses, and subconjunctival hemorrhage and, less often, gross hematuria, hemoptysis, and CNS and gastrointestinal bleeding. This phase reflects the overall severity of the illness and is associated with major electrolyte, fluid, and CNS abnormalities in addition to serious pulmonary complications.

Diuretic Phase

Progressive improvement is heralded by the onset of diuresis, usually within 2 weeks of onset of symptoms.

Convalescent Phase

Convalescence is marked by polyuria and loss of urine-concentrating ability. Rare reports have suggested long-term renal complications, such as renal tubular acidosis, renal hypertension, proteinuria, and end-stage renal disease. A residual inability to concentrate the urine may be permanent, and studies in the United States have suggested an association with hypertensive renal disease.

Patients with severe HFRS appear acutely ill; their symptoms include an erythematous flush of the face and upper torso, with blanching on pressure and dermatographia. Petechiae are present in axillary and waist folds and occasionally on the face and upper torso. Conjunctival injection is common; conjunctival petechiae and hemorrhage develop during days 3 to 5 in some patients. The soft palate also is intensely and diffusely reddened, with mild generalized lymphadenopathy noted on day 2. Splenomegaly, jaundice, and a maculopapular rash have not been reported.

The incidence and severity of clinical manifestations of hantavirus infection vary considerably, and the individual phases may overlap. This is most apparent in Puumala virus infections, in which shock does not develop and skipping of phases is common. The mildest form of this syndrome, known as nephropathia epidemica, is characterized by a mild degree of renal insufficiency without significant overt hemorrhage. Epistaxis, macroscopic hematuria, and mild gastrointestinal bleeding may occur in 5% of these patients in association with petechiae, but most patients experience only febrile gripe with proteinuria and an extremely low case fatality of 0.2%. Blurred vision and photophobia are typical findings, as is a myopic shift with narrowing of the anterior chamber and thickening of the crystalline lens. Puumala virus infection also has been associated with Guillian-Barré syndrome. Pulmonary edema is another classic feature, not just in the more severe Hantaan virus infections but in the much milder Puumala virus infections. Features of disease caused by Seoul virus infection are intermediate in nature between these two clinical pictures, whereas Dobrava virus infection appears to be more Hantaan-like. Hepatic involvement is more likely with Seoul virus.

Although it is difficult to mistake HFRS with classic polyphasic manifestation, this syndrome can be confused with Waterhouse–Friderichsen syndrome, acute glomerulonephritis, pyelonephritis, leptospirosis, scrub typhus, dengue fever, thrombocytopenic purpura, or acute renal vein thrombosis. Nephropathia epidemica cannot be distinguished clinically from other viral gripes. Consider these diseases in the differential diagnosis of all patients with unexplained febrile nephropathy with isosthenuria and proteinuria.

Hantavirus Pulmonary Syndrome

Hantaviral infection may be asymptomatic or mild or may cause severe disease (HPS). After a 1- to 5-week incubation period, patients usually experience a brief, 4-day prodrome characterized by malaise, diarrhea, and headache. Fever, chills, myalgia, nausea or vomiting, and cough develop one day later. Dizziness or lightheadedness is also reported by approximately one-fourth of patients, whereas arthralgias, back pain, and abdominal pain are reported less frequently. Patients often are misdiagnosed during this early stage because differentiating characteristics, such as cough and tachypnea, generally do not develop until the end of the prodromal phase. Within 24 hours of initial evaluation, most patients abruptly enter the characteristic cardiopulmonary phase, with some degree of hypotension and progressive evidence of pulmonary edema and hypoxia, usually requiring mechanical ventilation. Patients who do not survive have severe hypotension frequently terminating with sinus bradycardia, electromechanical dissociation, or ventricular tachycardia or fibrillation. This terminal hemodynamic compromise can be independent of oxygenation status and occurs a median of five days after onset of symptoms. Multiorgan dysfunction syndrome is rarely seen. About 90% of patients are intubated by day 5 of illness. The disease resolves rapidly, usually preceded by or concurrent with a diuretic phase. Atypical clinical pictures of prominent renal insufficiency and myositis have been documented with Black Creek Canal, Bayou virus, and Andes virus. The typical length of stay in the hospital is 10 days, though patients may experience fatigue and exercise intolerance for several months. Occasional residual effects under investigation include cognitive impairments, sensorineural hearing loss, and modest small-airway obstruction, and a few patients have mild degrees of proteinuria and pulmonary hypertension.

Physical examination of the patient in the initial stage of infection shows normal results, except for fever, tachypnea, and tachycardia. Rashes, throat or conjunctival erythema, and peripheral or periorbital edema are absent. In South America, Andes virus may produce facial flushing (rubundez), petechiae, and occasionally frank hemorrhage from the gastrointestinal or pulmonary tract. Rarely, there is overt hemorrhage in severe cases in North America, owing to DIC. Rapidly progressive respiratory and hemodynamic compromise reflects the evidence of increasing tachypnea, hypotension, and pulmonary edema and pleural effusions on serial examination.

Initial chest radiographs in almost all patients show abnormal results indicative of interstitial edema, specifically, Kerley B lines, hilar indistinctness, or peribronchial cuffing with normal cardiothoracic ratios. One-third of patients also have evidence of airspace disease on the initial radiograph. By 48 hours, all patients show evidence of interstitial edema, and two-thirds have extensive airspace disease that is initially bibasilar or perihilar in nature, with some degree of pleural effusion ([Fig. 308.3](#)). Evidence of bilateral interstitial pulmonary infiltrates is required for a diagnosis of severe disease. The lack of peripheral distribution of initial airspace disease, the prominence of interstitial edema, and the presence of pleural effusions on radiography early in the disease process distinguish HPS from the acute respiratory distress syndrome (ARDS).

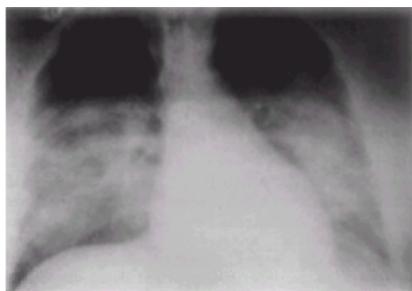

FIGURE 308.3. Chest radiograph of hantavirus pulmonary syndrome, taken 48 hours after admission, showing bilateral interstitial infiltrates.

Diagnostic considerations include sepsis and severe pneumonia. The lack of sore throat and nasal symptoms facilitates differentiation of HPS from influenza, the lack of lobar infiltrates and chest pain distinguishes HPS from pneumococcal pneumonia, and certain laboratory test abnormalities help discriminate HPS from unexplained ARDS. Depending on the patient's history, other diagnoses to exclude are acute pulmonary edema due to myocardial infarction, septicemic plague, tularemia, leptospirosis, Q fever, ehrlichiosis, coccidioidomycosis, histoplasmosis, and diffuse pulmonary hemorrhage.

LABORATORY FINDINGS

Hemorrhagic Fever with Renal Syndrome

Laboratory findings are usually unremarkable at first, but progressive thrombocytopenia and leukocytosis develop during the course of the febrile phase and into the hypotensive phase. Abrupt onset of proteinuria is usually noted on about day 5 of illness, with isosthenuria (urine specific gravity of 1.010) and evidence of

hemoconcentration. Renal insufficiency and electrolyte abnormalities are prominent during the oliguric phase.

Measurement of IgM-specific anti-hantaviral antibodies, using an IgM-capture ELISA or immunofluorescence assay, is the method of choice for the early diagnosis of HFRS. Specific antibodies are usually present on admission, and all patients should have measurable antibodies by day 7 of disease. Hemagglutination or neutralization tests are needed to distinguish hantaviruses serologically. RT-PCR also has been used in clinical diagnosis and to differentiate hantaviral strains. Recovery of virus from blood, various fluids, and tissues has rarely been done and has no diagnostic usefulness.

Hantavirus Pulmonary Syndrome

Notable hematologic findings include neutrophilic leukocytosis with increased myeloid precursors, circulating immunoblasts, thrombocytopenia, and hemoconcentration, especially at the onset of the cardiopulmonary phase. The triad of left-shifted neutrophils, thrombocytopenia, and immunoblasts may help make an early diagnosis. Hypoalbuminemia, proteinuria, and mild elevations of transaminases, creatinine phosphokinase, amylase, and creatinine also have been documented. Other abnormalities mirror hemodynamic and pulmonary involvement—the development of metabolic acidosis, rising serum lactate levels, and prolongation of the prothrombin time and partial thromboplastin time. Critical prognostic indicators include a plasma lactate level greater than 4.0 mmol per liter or a cardiac index of less than 2.2 L per minute per square meter. Elevated fibrin split products and decreased fibrinogen levels suggestive of DIC are uncommon.

Diagnosis can be confirmed rapidly by using ELISA to detect SNV-specific IgM and IgG antibodies in North America and Laguna Negra—specific antibodies in South America. A Western blot assay using recombinant antigens and isotype-specific conjugates for IgM–IgG differentiation is also available. Specific antibodies almost always are present on admission, and all patients should have measurable antibodies by day 7 of disease. Serologic confirmation of hantaviral infections traditionally has been done with neutralizing plaque assays; these assays have been described for SNV, though they are not readily available. IgG antibody is long lasting, but antibody reversions have been reported.

To date, no isolates of SNV-like viruses have been recovered from humans; therefore, virus isolation is not a diagnostic consideration. Detection of hantaviral RNA has been useful for diagnosis when fresh frozen lung tissue, blood clots, or nucleated blood cells are tested by RT-PCR. Serum does not appear to be as useful for amplification of viral RNA. Immunohistochemistry has an important role in the diagnosis of HPS in patients from whom serum samples and frozen tissues are not available for diagnostic testing.

OPTIMAL MANAGEMENT

Hemorrhagic Fever with Renal Syndrome

The principal therapeutic challenge is treatment of renal failure and shock, but pulmonary edema, stroke, primary encephalopathy, myocarditis, hepatitis, and pancreatitis may complicate the illness. The case fatality rate is less than 5% when good supportive care and access to dialysis and advanced intensive care are available. In a double-blind concurrent, placebo-controlled trial, intravenous ribavirin therapy has been shown to result in a seven-fold reduction in Hantaan-virus associated HFRS mortality, if it is administered within 6 days of fever onset to patients >14 years of age. It has been established that steroids ameliorate disease but do not affect fatality. Cyclophosphamide, which presumably inhibits immune-mediated damage, has been used in China outside any controlled trials, with conflicting results. Public health measures have focused on the control of rodents and building rodent-proof homes and grain storage facilities. A number of inactivated Hantaan virus vaccines are commercially available in Korea and China, but no effectiveness data are available. Preliminary human trials using a recombinant vaccine that expresses both the M and S segments for Hantaan virus are under way.

Hantavirus Pulmonary Syndrome

Treatment of patients with HPS also remains supportive in nature. Nevertheless, all patients should be placed on broad-spectrum antibiotics, including tetracycline, until the diagnosis of HPS is well established, since bacterial shock is far more common than hantaviral shock. Early intensive care is important, with prompt correction of electrolyte, pulmonary, and hemodynamic abnormalities. Flow-directed catheterization of the pulmonary artery is helpful not only in intensively monitoring and treating the patient but also in verifying the normal-to-low pulmonary wedge pressure, decreased cardiac index, and increased systemic vascular resistance in patients who progress to shock. This pattern of shock is in contrast to the typical hemodynamic profile for septic shock of increased cardiac index and low systemic vascular resistance. Fluid administration to correct hypotension should be limited, to prevent worsening pulmonary edema, and the early use of inotropic agents, such as dobutamine, is strongly encouraged. Early promising results with extracorporeal membrane oxygenation as salvage therapy for patients with poor prognostic indicators have not been reproduced. An open-label trial of treatment with intravenous ribavirin—which is effective in treating HFRS—failed to document a dramatic improvement in mortality. A single patient had a favorable outcome after inhaled nitric oxide therapy. Therapy with intravenous glucocorticoids has had positive results in South America and is to be tested in a controlled trial.

The thrust of the prevention effort regarding peridomestic rodents is to eliminate their access to domestic settings and to make domestic settings uninhabitable by rodents by properly storing or removing all sources of food and water. Standard precautions coupled with droplet precautions should be reinforced in South American countries, with an upgrade to aerosol precautions as indicated.

FILOVIRUSES

DEFINITION

Marburg and Ebola viruses are the prototypical emerging pathogens. They cause a hemorrhagic disease with a high case fatality associated with explosive outbreaks due to person-to-person transmission. Moreover, they occur unpredictably and have an unknown reservoir. There is no treatment at present. Since their initial discovery in 1967, there have been only a handful of filoviral outbreaks, mostly in remote locations. The documented occurrence of secondary cases in locations far from disease-endemic areas, however, raises the concern that filoviruses have the potential to generate unprecedented outbreaks in the future. This speculation has been validated by the identification of a fatal case of Marburg virus infection traced to the large-scale production of Marburg virus by Biopreparat, the biological weapons program of the former Soviet Union.

INCIDENCE AND EPIDEMIOLOGY

Marburg Viral Hemorrhagic Fever

In 1967, many cases of severe hemorrhagic fever with nosocomial transmission among European laboratory workers led to the identification of Marburg virus. The primary patients had all handled monkey blood, tissues, or cell cultures traced to a shipment of African green (vervet) monkeys (*Cercopithecus aethiops*) exported from Uganda. In 1975, a traveler became infected in Zimbabwe and transmitted the disease to a female companion and a nurse who attended the second victim. In 1980 and 1987, two episodes of Marburg VHF were identified among expatriates in southwestern Kenya, near the area in Uganda that produced the infected monkeys involved in the 1967 outbreak. Indigenous Marburg virus infection among native Africans in rural areas was confirmed during a large 1999 outbreak in Durba, in the northeastern region of the Democratic Republic of Congo, primarily affecting gold miners and with occasional secondary spread. This area had several similar small outbreaks that were termed “Durba syndrome,” with retrospective confirmation of Marburg virus infection in a survivor from 1994.

Ebola Viral Hemorrhagic Fever

The first recognized outbreaks of Ebola VHF took place simultaneously in northern Zaire and southern Sudan in 1976 and were caused by two distinct subtypes. No index case was identified clearly in the Sudan outbreak, though early cases originating in Nzara, Sudan, arose among cotton factory workers. The disease initially spread through nosocomial transmission; the use of nonsterile needles and lack of barrier nursing practice fueled the epidemic. The case fatality in the Sudan outbreak was 53%. A small outbreak in southern Sudan in 1979 was linked to the same cotton factory.

The outbreak in Zaire centered around a Belgian mission hospital in Yambuku, Equateur region. During the 7-week period of the outbreak, 318 cases were confirmed, with a case fatality of 88%. A significant factor in the spread of infection in the hospital was the reuse of syringes and needles. The disease appeared to subside, except for an isolated case in northwestern Zaire in 1977. Then three separate outbreaks caused by an Ebola-Zaire subtype occurred in Gabon over a 3-year period.

In 1994, an outbreak of Ebola VHF occurred north of the provincial capital of Ogooue-Ivindo, which was originally misdiagnosed as yellow fever. In January 1996, another outbreak, near the site of the 1994 outbreak, was linked to the butchering for consumption of a dead chimpanzee. In 1996–1997, there was a 7-month outbreak of 60 cases in Booue Province, Gabon (case fatality of 75%), associated with eight generations of secondary cases, some of which were found in the capital city. A noteworthy case of secondary transmission involved a nurse in Johannesburg who died from the disease after caring for a physician with Ebola VHF. In 1994, a new Ebola subtype was isolated from an infected ethologist in Côte d'Ivoire who had performed a necropsy on a chimpanzee from a group that had lost several members to an unidentified illness. This isolation extended the geographic distribution of known cases to include most of the African rain forest.

Ebola VHF dramatically reemerged in Zaire in 1995, when a total of 315 cases (81% case fatality) developed over 7 months, centered in Kikwit but taking in an additional 20 villages. The earliest documented patient was a charcoal worker, in whom the diagnosis was missed; for 3 months the disease spread from person to person in the community until it was amplified in the hospital setting and finally recognized. Owing to nosocomial transmission, one-fourth of the cases arose among health care workers. The application of basic barrier nursing methods rapidly terminated transmission in the hospital. Two individuals, designated “super-spreaders,” may have been the source of infection for more than 50 cases; the mechanism of heightened transmission was not identified, though contact with a cadaver was implicated strongly.

In contrast to the three pathogenetic subtypes of Ebola virus from the African continent, a subtype of low or no pathogenicity for humans (Ebola-Reston) was recognized in November 1989 at a primate quarantine facility in Reston, Virginia. Unusually high mortality was noted in a shipment of cynomolgus monkeys (*Macaca fascicularis*) imported from the Philippines; the deceased monkeys subsequently were determined to have been infected with Ebola-Reston virus. Four cases of acute filovirus infection were confirmed among the human caretakers, none of whom experienced clinical illness.

The natural epidemiologic characteristics of these infections, besides those documented during internationally recognized outbreaks, are unknown. The latency between occurrence of index cases and the recognition of a subsequent outbreak suggests that sporadic cases of unrecognized filovirus infections are not uncommon. Serologic surveys have found an antibody prevalence of 9% to 10% among gold panners in Gabon and among rural villagers in the Democratic Republic of Congo. The explosive nature of these outbreaks belies the fact that the secondary attack rate is approximately 12% to 16% and close physical contact is necessary for disease transmission. Health care facilities have played a major role in amplifying the disease; the closure of or upgrade of infection control practices in these facilities, coupled with community education, has proved critical to the rapid cessation of these outbreaks.

ETIOLOGY AND ECOLOGY

Filoviruses are classified into a new family of RNA viruses, the Filoviridae, consisting of the single genus *Filovirus*, on the basis of their similarities in size, tubular morphologic features, and distinctive physicochemical properties. The genus contains four subtypes of Ebola virus (Zaire, Sudan, Ivory Coast, and Reston) and a single species of Marburg virus. Infectious virions can be inactivated when exposed to appropriate amounts of lipid solvents (such as detergents), formaldehyde, hypochlorite (bleach), b-propiolactone, quaternary ammonium and phenolic disinfectants, ultraviolet light, gamma irradiation, and prolonged heating at 60°C. Little is known of the geographic and natural distribution of Marburg or Ebola viruses or the circumstances leading to human infection in nature. The discovery of Reston viral infections in macaque monkeys from Asia suggests a wider, possibly global distribution of Ebola-related viruses. The best evidence for the putative host has come from experimental inoculations that have demonstrated replication and circulation of high titers of virus in bats. The similarity of Ebola–Zaire subtypes from widely separated geographic and ecologic areas (northern Zaire, southern Zaire, and Gabon) and collections spanning 20 years suggest an extremely stable virus–host relationship.

PATHOGENESIS

Filoviral infection results in widespread cytopathic effects on parenchymal and endothelial cells and release of immune cell mediators. Several underlying mechanisms of damage have been postulated: suppression of the immune system through infection of fibroblastic reticular cells, the action of structural (spike) glycoproteins via a conserved immunosuppressive motif, and the binding of the secreted form of the Ebola virus glycoprotein to neutrophils. Disease has been characterized by widespread involvement of liver, lymphoid organs, and kidneys. The liver shows extensive eosinophilic degeneration with prominent vacuolar changes and intracytoplasmic viral inclusions. Interstitial pneumonia, interstitial nephritis, and follicular necrosis of the spleen are found frequently, but there is pathologic evidence of pantropic infection. The pathophysiologic features of bleeding and events leading to death are not understood fully. Platelet and endothelial cell dysfunction may be the primary causes of hemorrhage and shock. Tissue factor release from infected monocytes and fragmented tissue factor–rich cell membranes following viral budding and cell lysis have been hypothesized as mechanisms for DIC.

CLINICAL FEATURES

Marburg Viral Hemorrhagic Fever

After an incubation period of 5 to 9 days, the highly characteristic clinical syndrome begins with sudden onset of fever and headache accompanied by profuse vomiting and nonbloody diarrhea with varying evidence of conjunctivitis, myalgia, and lymphadenopathy. This picture is often accompanied by abdominal pain that may be intense enough to suggest a surgical abdomen. Patients frequently appear restless and anxious, and they later become disoriented, drowsy, and stuporous and exhibit other encephalopathic signs, such as lassitude. After 3 to 8 days, a morbilliform, usually confluent, nonpruritic rash starts on the upper trunk and spreads centrifugally to involve the entire body, sparing the face and neck; the rash fades in 48 hours, and desquamation occurs in 2 weeks. The oral cavity is usually dry, with small aphthous-like ulcers with slight posterior pharynx injection. The conjunctiva are only slightly injected and rarely icteric. Examination of the chest commonly shows bibasilar rales; there is no organomegaly on abdominal exam, but epigastric and right subcostal tenderness may be present. Severe hemorrhagic diathesis, with bleeding from the gums, the nose, and puncture sites as well as the gastrointestinal tract, is noted in approximately one-third of patients when the thrombocyte count is lowest, usually between day 6 and day 12. Multisystem failure from pneumonitis, hepatitis, pancreatitis, and tubulointerstitial nephritis combined with intractable hypotension usually leads to death.

Ebola Viral Hemorrhagic Fever

Beginning with a sudden onset of fever, asthenia, headache, and joint and muscle aches, the disease causes initially nonbloody diarrhea (81%), vomiting (59%), pain and dryness of the throat (63%), and abdominal pain. Chest pain (83%) is a characteristic feature of patients infected with Ebola-Sudan virus but uncommon in those infected with Marburg or Ebola-Zaire virus. Patients are usually hospitalized by the fifth day of illness with deep-set eyes, ghostlike expressionless facies, and extreme lethargy. A rubeola-like rash with later desquamation appears in approximately half of the patients at about the fifth day, though it may be difficult to evaluate in dark-skinned people. Hemorrhagic manifestations, usually gastrointestinal and rarely urogenital, are common and may be preceded by apparent improvement. Although hemorrhage is present in only half of all cases, almost all of the fatal cases showed some sign of hemorrhage, which typically is not life threatening in itself. During the 1995 Ebola-Zaire outbreak, 103 cases were studied prospectively and were characterized by a similar biphasic clinical syndrome with asthenia as an early sign and the later evolution of hemorrhagic manifestations, hiccups (15%), and, less frequently, neurologic symptoms. Terminally ill patients had obtundation, anuria, shock, tachypnea, and normothermia.

Convalescence after filoviral infection is prolonged—resolution of fatigue, anorexia, and cachexia takes as long as several weeks, and weight loss is very common. Tender livers and other hepatic abnormalities have been reported in the Marburg VHF patients, but these features may have been due to transfusion-associated hepatitis; relapse also has been described in Marburg patients. Patients infected with the Ebola-Zaire subtype continue to report myalgia and arthralgias 2 years after acute illness, which may be correlated with circulating antibody titers. The differential diagnosis depends on the initial stage of clinical illness and its evolution. Causes of VHFs in addition to those addressed in this chapter include dengue, yellow fever, Congo-Crimean hemorrhagic fever, and Rift Valley fever viruses. The travel and occupational histories of the patient are critical in narrowing the potential diagnoses, as are reports of clusters of illness or person-to-person transmission. Contact with severely ill humans or with sick or dead nonhuman primates and a history of injections in an African hospital are relevant ([Fig. 308.4](#)).

FIGURE 308.4. Approach to suspected cases of viral hemorrhagic fever (VHF).

LABORATORY FINDINGS

Typical findings include thrombocytopenia, normal or depressed white blood cell counts, and the presence of “atypical” lymphocytes, plasma cells, plasmablasts, pyroninophil blast cells, or immunoblasts. Mild to severe elevations in liver transaminases and amylase levels, prothrombin time, partial thromboplastin time, and fibrin degradation products have been reported. Proteinuria and microscopic hematuria are also evident in some patients. Most of the initial Marburg VHF patients had high levels of aspartate aminotransferase (AST) and ALT (ALT greater than AST) and normal bilirubin, alkaline phosphatase, and creatine kinase levels. Elevated amylase also has been reported, and significant rises in blood urea nitrogen and proteinuria are characteristic of the most severe cases. Antibody is detected late (12 to 13 days) among survivors by ELISA and indirect fluorescent antibody techniques; therefore, during the acute phase of illness, serum or blood should be tested for the presence of virus, viral antigen, or viral RNA. Fatal infections are best diagnosed from serum samples using antigen detection by ELISA, from liver touch preps using fluorescent antibodies, or from fixed solid tissue samples by immunohistochemistry and electron microscopy.

OPTIMAL MANAGEMENT

No specific therapy is available for filoviral infections. Extremely limited data suggest that utmost attention to correction of simple fluid and electrolyte abnormalities may diminish the case fatality rate. Studies in cell culture and in nonhuman primates and guinea pigs have shown no efficacy for interferon- α , convalescent-phase plasma, or ribavirin. Heparin has been used with apparent success in two Marburg virus–infected patients for treatment of suspected DIC; this therapy should be attempted only when adequate monitoring of coagulation parameters is available. Filoviruses may remain sequestered for months in protected immunologic sites, such as the uveal and seminal tracts of convalescent patients, and can cause myelitis, uveitis, or orchitis late in convalescence. These patients must take appropriate precautions after hospitalization to prevent secondary transmission. Postinfectious sequelae in these patients often are associated with the recrudescence of residual virus.

CHAPTER 309: POXVIRUS INFECTIONS

BRIAN W. J. MAHY

[Description](#)
[Pathogenesis](#)
[Epidemiology](#)
[Clinical Features](#)

There are nine poxviruses known to cause infection in humans. Six of them produce relatively rare zoonotic infections (cowpox, milker's nodules, monkeypox, orf, tanapox, and yabapox), and two cause specifically human diseases (smallpox [variola] and molluscum contagiosum). The last, the most widely studied, is vaccinia virus (smallpox vaccine). Smallpox is the only infectious disease to have been eradicated globally; the last natural case occurred in Somalia in October 1977. The intensive worldwide campaign to eliminate smallpox began in 1966 and used vaccinia virus as a potent, stable vaccine. Eradication eliminated the need for smallpox vaccination, with enormous economic benefits; the entire cost to the World Health Organization of the 11-year campaign was recovered in 6 months once vaccination was no longer necessary.

DESCRIPTION

The poxviruses of medical importance belong to the subfamily Chordopoxvirinae of the family Poxviridae. Within this subfamily, viruses of four different genera affect humans: *Orthopoxvirus*, *Parapoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus*. Poxviruses consist of large brick-shaped or ovoid virions of complex structure, 220 to 450 nm by 140 to 260 nm in size (Fig. 309.1). There is an outer coat containing tubular lipoprotein subunits that encloses two "lateral bodies" and a core containing the double-stranded DNA genome, 130- to 220-kb pairs in length in different viruses. The genomes of vaccinia virus (191, 636 bp) and variola (smallpox) virus (186, 103 bp) have been sequenced completely and found to specify more than 180 polypeptides, 151 of which are closely similar between the two viruses. In contrast to the other DNA viruses, poxviruses replicate in the cytoplasm, where they may form characteristic inclusions (Guarnieri bodies) detected on histologic examination.

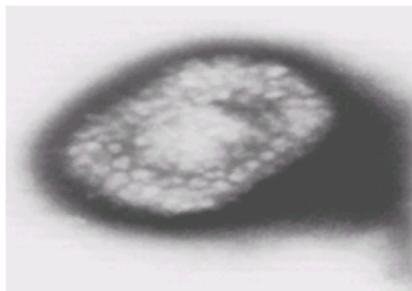

FIGURE 309.1. Smallpox (variola) virus. (Phosphotungstic acid, original magnification $\times 350,000$. Courtesy of Frederick A. Murphy.)

Dozens of enzymes necessary for DNA transcription and replication are encoded in the virus genome, and after entry and uncoating of the virion, DNA transcription is initiated by enzymes contained within the virion itself. Transcription is controlled by the binding of certain viral proteins to promoter sequences on the DNA genome, and it takes place in three stages—early, intermediate, and late. Early genes encode almost 100 proteins needed for replication; once DNA replication begins, intermediate genes are expressed that encode several proteins secreted by infected cells that affect the host immune system. Finally, late genes are triggered that encode late enzymes and virion structural proteins. The entire replication cycle from virus entry to assembly and morphogenesis of progeny virions takes about 20 hours.

PATHOGENESIS

Poxviruses cause lesions on the skin that may be localized or, in more severe cases, generalized. The lesions normally form a pustular rash but can also be proliferative (in molluscum contagiosum). After infection, there is an incubation period of 10 to 14 days before fever, headache, and myalgia develop; the skin lesions appear 2 to 3 days later. In most infections, neutralizing antibodies emerge 4 to 6 days after the onset of clinical symptoms and protect against reinfection. In orthopoxvirus infections, other antibodies are directed against a virus-specific hemagglutinin produced in infected cells. Cell-mediated immune responses also play a critical role in recovery and protective immunity—agammaglobulinemic subjects were found to recover from smallpox provided their cell-mediated immunity was not impaired.

EPIDEMIOLOGY

Transmission of poxvirus infections usually requires close contact with an infected person or animal, although fomites can also disperse the virus. Smallpox was eradicated because (a) there was no animal reservoir for variola virus, (b) immunity after infection was long-lasting and infection did not lead to recurrence, (c) the vaccine (vaccinia virus) was extremely effective, and (d) antigenic variants of variola virus resistant to neutralization were not found. Smallpox was an extremely severe disease that spread worldwide and exacted a high toll in human morbidity and mortality over many centuries. Now that smallpox is extinct, the only human poxvirus disease of global importance is molluscum contagiosum, which is spread by contact with an infected person (or occasionally by fomites) but is quite benign. The zoonotic poxviruses that can be transmitted to humans in a variety of ways are not readily transmissible from human to human and are relatively rare.

CLINICAL FEATURES

HUMAN MONKEYPOX

Monkeypox virus was first recognized as the origin of a disease of captive nonhuman primates, but in 1970 cases of human infection were discovered in West and Central Africa, where smallpox had been eradicated. In the initial reports, six of 36 cases were fatal. The disease has features similar to smallpox—a generalized pustular rash, high fever, and toxemia—and could not be distinguished in clinical terms from smallpox. A mortality rate of about 11% has been recorded among unvaccinated children younger than 9 years of age, but not in adults; vaccination with vaccinia virus protects against monkeypox virus infection. Unlike smallpox, monkeypox is not readily transmissible between humans, and for this reason it is not a serious risk outside the limited disease-endemic area. The true reservoir of monkeypox virus appears to be species of squirrels of the genera *Funisciurus* or *Heliosciurus* that inhabit the tropical rain forest in Zaire and the surrounding regions. Monkeys as well as humans are secondary hosts.

COWPOX

Human infections with cowpox virus have been recorded only in Europe, mostly among farmworkers who have close contact with cattle. The cowpox virus is not enzootic in cattle, however, and it is believed to be maintained in a rodent reservoir, the species of which is not known. Cats frequently become infected with cowpox virus, and human infections from cats have been well documented. Infections in large feline species in zoos also have been reported. In humans, cowpox virus produces ulcerated, pustular lesions on the hands or face that are frequently hemorrhagic and most severe in young children.

PSEUDOCOWPOX (MILKER'S NODULES) AND ORF

Pseudocowpox (milker's nodules) and orf are occupational infections acquired from close contact with cattle or sheep, respectively, and caused by parapoxviruses. Both diseases manifest worldwide and are rare human zoonoses. Orf is the result of human infection with a virus causing contagious pustular dermatitis (scabby mouth) of sheep and goats. Human infections usually consist of a lesion on the finger that begins as an inflammatory papule; enlarges to a relatively painless, granulomatous lesion; and then crusts and regresses without vesicle formation. Many infections are mild, and reinfection is frequent during close contact with infected animals. Pseudocowpox, or milker's nodules, is primarily a disease of cattle, predominantly dairy herds, where it produces lesions on the teats and udder. Humans become infected by handling cattle, and small nodules on the hands are of little consequence and seldom require treatment.

MOLLUSCUM CONTAGIOSUM

The most serious parapoxvirus that affects humans is molluscum contagiosum virus, the only species in the genus *Molluscipoxvirus*. Molluscum contagiosum appears as many discrete, flesh-colored papules in the epidermal layer of the skin. It can arise on many parts of the body, probably as a result of mechanical contact spread; it does not appear to spread through viremia. The painless lesions are firm, usually 2 to 5 mm in diameter, and frequently umbilical with an opening at the top. After several months the lesions regress spontaneously, but they may persist for a year or more, particularly in immunocompromised people, such as patients with acquired immunodeficiency syndrome. The disease has a worldwide distribution and is spread by contact, usually in urban settings associated with public swimming baths, and perhaps through sexual contact. Although the cells in the papular lesions contain masses of virus particles in large cytoplasmic masses known as molluscum bodies, the virus cannot be grown in cell cultures. Confirmatory diagnosis consists of histologic examination for the presence of molluscum bodies; electron microscopic examination easily pinpoints the virus particles themselves.

TANAPOX AND YABAPOX

Tanapox and yabapox are two tropical zoonotic infections that occur mainly in Africa. The primary reservoir of these viruses is unknown, but monkeys become infected and may spread the disease to humans both in the wild and in captive primate colonies. Yabapox virus originally was discovered as the cause of benign fibrous tumors of the head and limbs of rhesus and cynomolgus monkeys in captivity in West Africa. Cases also have been found in primate colonies in other parts of the world. Although once considered a model tumor virus, yabapox virus induces lesions that are nonproliferative and regress as an immune response is mounted.

Tanapox virus was discovered 40 years ago in Kenya, where it is thought to be a zoonotic infection, though the reservoir host is not yet known. Mechanical transmission by arthropods is suspected. The disease frequently is acquired by humans through contact with monkeys, but they are not the primary host. Patients have fever and myalgia before a papule develops at the site of infection. There is thickening of the epidermis to produce a papule about 15 mm diameter that progresses to form an erythematous vesicle. Usually the lesion is solitary, though several lesions sometimes are seen, and healing takes place within a few weeks.

VACCINIA

Vaccinia virus is an attenuated smallpox (variola) virus, the origin of which is obscure. The virus shares 90% homology with smallpox virus and was directly responsible for the global eradication of smallpox. Vaccinia virus caused clinical disease during the smallpox eradication campaign when it was used to vaccinate children with eczema or with various forms of immunodeficiency. Since smallpox was eliminated in 1978, vaccination has ceased worldwide. Some countries (notably the United States) recommend vaccinations for laboratory workers who are conducting experiments using vaccinia virus, because it is preferable to experience primary infection with vaccinia virus after scarification and inoculation into the arm rather than as the result of inadvertent infection at some other site, such as the eye, which may have serious consequences. Some European countries take a different view and prefer not to vaccinate unless exposure to vaccinia virus has been documented.

Vaccinia virus was such a successful vaccine against smallpox that it is being genetically engineered as a vector for other antigens, with a view to developing new vaccines. The US Department of Agriculture has approved a vaccinia-rabies glycoprotein recombinant virus for oral vaccination of wild animal species against rabies virus infection. For human use, much less virulent strains of vaccinia virus are being developed by attenuation using tissue culture passage or by genetically engineered deletion. Vaccinia virus is believed to be identical to buffalopox virus, which may induce lesions on the teats of buffaloes and infect humans in India who milk buffaloes. The virus is now endemic in the Indian buffalo population, but fortunately the human infections are not very serious.

CHAPTER 310: RESPIRATORY VIRAL INFECTION

ROBERT L. ATMAR

[Adenoviruses](#)
[Coronaviruses](#)
[Influenza](#)
[Parainfluenza Virus and Respiratory Syncytial Virus](#)
[Rhinoviruses](#)

Acute respiratory illnesses (ARIs) are among the most common diseases in humans, and respiratory viral infections are the principal cause of ARIs. Several community-based surveillance studies have shown that ARIs occur with the greatest frequency during the first 2 years of life and are common during the first decade of life (five to nine ARIs per year). The frequency of ARIs declines to three to five illnesses per year thereafter. Somewhat higher rates are seen among adults with young children, owing to the introduction of infection into the family by the children.

Acute viral infections can be triggered by a number of different viruses, the most common of which are shown in [Table 310.1](#). Respiratory viral infections are characterized by infection of the respiratory mucosa, though some viruses also can be isolated from tissues outside the respiratory tract. These viruses provoke a variety of clinical syndromes, including the common cold, pharyngitis, influenza-like illness, croup, tracheobronchitis, bronchiolitis, and pneumonia. The typical clinical syndromes associated with respiratory viruses also are listed in [Table 310.1](#), but each of these viruses has been identified in association with most of the other clinical syndromes. Thus, the etiologic agent can be suspected based on the epidemiologic setting and clinical syndrome, but confirmation requires specific viral diagnostic studies. This chapter describes characteristics of the most common respiratory virus infections.

Virus	Number of Types	Common Syndromes	Seasonal Occurrence
Adenovirus	49	Febrile respiratory illness, pharyngoconjunctivitis	Year-round
Coronavirus	2	Common cold	Winter and spring
Influenza virus	3	Febrile respiratory illness with prominent systemic component (myalgia, headache)	Annual winter epidemics
Parainfluenza virus	4	Croup (children)	Fall (types 1 and 2) and year-round (type 3)
Respiratory syncytial virus	2	Bronchiolitis (children), pneumonia	Annual winter epidemics
Rhinovirus	>100	Common cold	Year-round, with increases in spring and fall

TABLE 310.1. CHARACTERISTICS OF COMMON RESPIRATORY VIRUSES

ADENOVIRUSES

DEFINITION

Adenoviruses are nonenveloped, icosahedral viruses 65 to 80 nm in size and containing a genome consisting of double-stranded DNA. The human adenoviruses belong to the genus *Mastadenovirus* and are divided into 49 distinct serotypes. The genus is divided into six subgroups (A to F) on the basis of DNA sequence homology and other characteristics. The adenovirus capsid consists of 240 capsomeres called hexons and 12 pentons. The pentons are located at each of the vertices and have two structural components. The penton base anchors the penton to the capsid, and the fiber extends from the base and is the viral attachment protein. Type-specific and group-specific antigens are found on both the hexons and penton fibers. Adenoviruses can replicate in epithelial cells and lymphoid cells. In epithelial cells, infection results in lysis of the cell and release of infectious virus. Infection of lymphoid cells can result in latent infection. Although some adenoviruses have been shown to cause tumors in rodents, these viruses have not been associated with tumors in humans.

INCIDENCE AND EPIDEMIOLOGY

Adenoviruses induce endemic and epidemic illness. The pattern of infection, mode of transmission, and clinical manifestations vary by serotype. For example, adenovirus types 1, 2, 5, and 6 are endemic, whereas types 4, 7, 14, and 21 more often cause small epidemics. The pattern of disease also can be affected by socioeconomic factors. In developing countries with poor hygienic conditions, adenovirus serotypes that cause conjunctivitis are frequently endemic; in contrast, epidemic illness with these serotypes is more common in developed countries.

Infection rates are highest in young children, in whom up to 5% of ARIs are associated with adenovirus infections. Less than 3% of ARIs in adults are related to adenovirus infection. The average incubation time is 6 to 10 days, but it may be as short as 2 days and as long as 3 weeks. Adenoviruses are transmitted in several ways. Fecal–oral transmission occurs in young children, within families, and with the enteric adenoviruses. Airborne (droplet) transmission is the primary route in outbreaks of acute febrile respiratory illness in closed settings (military barracks), and contact/fomite transmission is a major route for the spread of epidemic keratoconjunctivitis in the community and in nosocomial outbreaks. Infection usually results in the production of type-specific antibodies that are associated with protection against subsequent infection caused by the same serotype.

CLINICAL FEATURES

Adenoviruses prompt a variety of respiratory and nonrespiratory illnesses. In children, common respiratory syndromes associated with adenovirus infection include tonsillitis, otitis media, laryngitis, and pneumonia. These respiratory illnesses cannot be distinguished in clinical manifestations from those caused by other respiratory viruses, and exudative tonsillitis may be confused with tonsillitis caused by *Streptococcus pyogenes*. Pharyngoconjunctival fever, related most frequently to types 3 and 7, is characterized by conjunctivitis with follicular hypertrophy, pharyngitis, and fever. A pertussis-like syndrome, with prolonged cough, has been reported to be produced by several serotypes. Other clinical syndromes seen in children include nonspecific febrile illness, febrile convulsions, hemorrhagic cystitis (type 11), gastroenteritis (types 40 and 41), intussusception in infants, and encephalomeningitis.

In adults, epidemic febrile respiratory illness with symptoms of rhinorrhea, sore throat, and cough was first recognized in military recruits. This acute respiratory disease is associated most frequently with types 4 and 7; its other manifestations include hoarseness, tonsillitis, tracheobronchitis, and a patchy form of interstitial pneumonia. Epidemic keratoconjunctivitis (types 8, 19, and 37) is characterized by conjunctivitis with follicular hyperplasia, lacrimation, ocular pain, and photophobia. Pre-auricular adenopathy is common, and keratitis develops after a few days.

Adenovirus infection can be particularly severe in certain populations. Disseminated infection in neonates is often fatal and is associated with fever, lethargy, hepatomegaly, and pneumonia. Infection in immunocompromised patients, including bone marrow transplant recipients, solid organ transplant recipients, and AIDS patients, elicits a variety of syndromes, ranging from asymptomatic shedding to disseminated disease. Pneumonia, hepatitis, nephritis, colitis, hemorrhagic cystitis, and encephalitis are other complications seen in these patients. Disease may be caused by primary infection, by reactivation of latent infection in the immunocompromised patient, or by reactivation of infection transmitted from a transplanted organ.

LABORATORY FINDINGS

A variety of methods are used to identify adenovirus infections. The virus grows in a number of different cell culture systems, and a cytopathic effect is generally seen within 1 to 2 weeks of inoculation. Hemagglutination assays are used for initial classification into a subgroup, and serotype identification can be performed using

neutralization assays or DNA restriction enzyme analysis. Virus can be detected by culture from a number of different clinical samples, including respiratory secretions, stool, urine, and conjunctival swabs. Viral shedding can be found in the stool for weeks or longer after recovery from respiratory illness, raising questions about the diagnostic usefulness (specificity) of such specimens.

Other diagnostic methods have been used to ascertain adenovirus infection. Enteric adenoviruses can be identified by rapid antigen detection assays (latex agglutination or enzyme immunoassay) and by electron microscopy. Immunofluorescence can pinpoint viral antigen in respiratory samples. Polymerase chain reaction assays have been applied successfully to the detection of adenovirus DNA in many different clinical specimens, but this methodology is not widely available, is not standardized from one laboratory to another, and must be considered investigational at this time. Serologic methods, including complement fixation, neutralization, hemagglutination inhibition, and enzyme immunoassays, are less useful in clinical practice because of the requirement for acute-phase and convalescent-phase serum samples. These methods have been useful in epidemiologic studies.

OPTIMAL MANAGEMENT

No specific treatment of adenovirus infection is available at this time. Supportive care is targeted toward symptom management.

PREVENTION

A vaccine for the prevention of the acute respiratory disease seen in military recruits has been developed and is used to control disease in the military ([Table 310.2](#)). The vaccine contains serotypes 4 and 7 and is administered as an enteric-coated capsule. The nonattenuated vaccine viruses cause asymptomatic infection of the gastrointestinal tract and induce both systemic and mucosal immune responses. Adenoviruses also are being evaluated as vectors for the delivery of foreign genes.

Virus	Treatment	Prevention	Under Investigation
Adenovirus	None	Live, enteric adenovirus vaccines (types 4 and 7)—military only	None
Coronavirus influenza virus	None Amantadine, rimantadine	None Trivalent, inactivated vaccines	None Live, attenuated vaccines; neuraminidase inhibitors
Parainfluenza virus	None	None	Live, attenuated vaccines
Respiratory syncytial virus	Ribavirin	Respiratory syncytial virus immune globulin	Live, attenuated vaccines; subunit vaccines
Rhinovirus	None	None	Soluble receptor

TABLE 310.2. METHODS FOR SPECIFIC TREATMENT AND PREVENTION OF COMMON RESPIRATORY VIRAL INFECTIONS

CORONAVIRUSES

DEFINITION

Coronaviruses are pleomorphic, enveloped viruses ranging in size from 80 to 160 nm. The name of the virus is derived from the solar corona appearance produced by 20-nm-long, petal-shaped projections that extend from the viral envelope. The genome consists of single-stranded, positive-sense RNA, and it is surrounded by a viral nucleoprotein. Human coronaviruses are divided into two antigenic groups, represented by serotypes 229E and OC43. Two (229E) or three (OC43) envelope proteins are present on the viral surface. Other viral strains have been recognized, but difficulties in the cultivation of these viruses have made their characterization difficult. The cell receptor of the 229E virus is aminopeptidase N (CD13). The OC43 virus uses a different receptor that has not yet been identified.

INCIDENCE AND EPIDEMIOLOGY

Most of what is known about the epidemiologic characteristics of coronavirus infections is based on serologic studies. Infection is more common in the winter and spring, and cyclical epidemics of 229E and OC43 infections occur. There are few differences in infection rates in different age groups, and the annual incidence of infection ranges from 1% to more than 30% of the population, with a mean of 15% to 20%. Approximately 4% to 8% of respiratory illnesses are associated with coronavirus infection, and 15% to 20% of common colds are caused by these viruses. Spread of infection appears to be by the respiratory route; based on experimental human infection studies the incubation period is 1 to 5 days.

CLINICAL FEATURES

Coronaviruses provoke a common cold syndrome similar to that caused by rhinoviruses. Sore throat, malaise, headache, and cough are seen in approximately one-half of adults and low-grade fever in about 20%. Symptoms tend to be more severe in children, with low-grade fever occurring in up to 40%. Other respiratory illnesses associated with coronavirus infection include exacerbations of asthma and chronic obstructive lung disease and pneumonia. Coronavirus-like particles have been detected in the stools of persons with nonbacterial gastroenteritis, suggesting that viruses from this family also may cause diarrhea.

LABORATORY FINDINGS

Coronaviruses are difficult to grow in cell culture, and some strains have been isolated only in human embryonic tracheal organ cultures. Although serologic assays are the principal means of diagnosis, these assays are not readily available. Reverse transcription–polymerase chain reaction assays have been developed for virus detection and used successfully in epidemiologic studies, but the availability of these assays is limited to research laboratories.

OPTIMAL MANAGEMENT

No specific antiviral therapy is available, and treatment is targeted toward the relief of symptoms. The development of an effective vaccine is unlikely, owing to high reinfection rates, difficulties in propagating the virus *in vitro*, and the circulation of unidentified viral strains in humans.

INFLUENZA

DEFINITION

Influenza viruses are pleomorphic, enveloped viruses that form filamentous and spherical particles 80 to 120 nm in diameter. These viruses are members of the Orthomyxoviridae, and the genome is segmented and consists of single-stranded, negative-sense RNA. There are three types of influenza—A, B and C; influenza A and B viruses have eight gene segments, and influenza C viruses have only seven. Two glycoproteins, hemagglutinin and neuraminidase, extend as spikes from the surface of influenza A and B viruses, and variation in the antigenic composition of these proteins is responsible for recurring epidemics in humans. Influenza C viruses have a single surface glycoprotein (HE protein) that has both hemagglutination and esterase activity.

The replication cycle of influenza A and B viruses begins with the attachment of the viral hemagglutinin to sialic acid residues on the cell surface. The virus is taken into the cell by pinocytosis into endosomes. As the endosomes are acidified, protons pass through a transmembrane channel made of the viral M2 protein into the interior of the virus and trigger a conformational change in the hemagglutinin that results in the uncoating and release of the viral ribonucleoprotein complex into the cytoplasm. This complex is transported to the nucleus, where transcription and replication of viral RNA takes place. New virions are assembled at the surface of the infected cell and released by budding. The viral neuraminidase removes sialic acid residues on the cell surface to prevent aggregation of the virions being released

from the cell.

INCIDENCE AND EPIDEMIOLOGY

Influenza A and B viruses are significant causes of morbidity and mortality. Influenza C viruses are a minor cause of respiratory disease. Epidemics of influenza A or B virus infection take place annually in temperate climates. These epidemics occur during the cold weather months, but they may begin in different months from year to year. Minor antigenic changes (antigenic drift) in hemagglutinin or neuraminidase lead to decreased reactivity with antibody acquired from previous influenza virus infection and result in enhanced susceptibility to the variant virus. New variant viruses emerge every few years as the immunity of the population to past variants increases. Viral strains are designated by their type, location of isolation, an identifying number from that location, year of isolation, and, for influenza A viruses, subtype of hemagglutinin and neuraminidase.

Major antigenic changes (antigenic shift) in hemagglutinin and neuraminidase also can occur with influenza A viruses and are due to reassortment of human strains with animal (principally avian) strains. Because of the significant changes in these proteins, the entire population is susceptible to infection and, if the virus can spread efficiently from person to person, a pandemic may result. There have been four pandemics during the 1900s.

Influenza is spread by contact with virus-containing respiratory secretions. This happens primarily from contact with respiratory droplets, but it also may occur following direct contact with secretions. The incubation period ranges from 1 to 5 days. Influenza is transmitted rapidly and efficiently within closed populations (nursing homes, military barracks). School-aged children facilitate the spread of influenza within the community. The proportion of infection is highest in this age group at the beginning of an epidemic and declines over time, while the proportion of infection in other age groups increases. Thus, the arrival of influenza in a community is heralded by appreciable increases in school absenteeism and a rise in the number of ARIs that come to medical attention. Influenza also sparks an increase in mortality rates attributed to pneumonia or influenza compared with historical rates. This excess mortality rate lags behind peak influenza activity in the community by about 2 weeks, and the majority of deaths are among the elderly and those with underlying cardiac or pulmonary disorders. The rise in mortality rates detected each year in association with influenza epidemics demonstrates the significant impact of these viruses on the population.

CLINICAL FEATURES

Influenza illness is characterized by systemic symptoms, such as fever, headache, myalgias, and malaise in association with respiratory symptoms, including sore throat and dry cough. This constellation of symptoms is seen in approximately one-half of infected subjects when related viruses have been circulating within the population. Approximately 30% of infected subjects have upper respiratory symptoms without fever, and in another 20% the infection is inapparent. With febrile influenza, the systemic symptoms are often more prominent at the onset of illness, and respiratory symptoms begin to dominate as systemic signs diminish. Fever and systemic symptoms typically last 3 to 5 days; cough may continue for several weeks. Alterations in pulmonary function are seen with acute influenza and may persist for months.

Both pulmonary and nonpulmonary complications develop during or after influenza virus infection. The two principal pulmonary complications are primary viral pneumonia and secondary bacterial pneumonia. Primary viral pneumonia is characterized by progressive symptoms of dyspnea, tachypnea, cough, and cyanosis beginning within days of the onset of symptomatic influenza. Rales are heard over both right and left lung fields, and signs of consolidation are absent. Chest radiography usually shows bilateral interstitial infiltrates. If sputum is produced, sputum Gram's stain fails to show a predominant bacterial organism. Histologic findings include diffuse epithelial damage and hemorrhagic pneumonia with lymphocytic infiltrate. This frequently fatal complication is usually seen in association with influenza A virus infection and occurs most frequently in persons with underlying risk factors, including cardiovascular disease (especially rheumatic heart disease), pregnancy, organ transplants, and malignancy. There is also a milder and rarely fatal form of viral pneumonia, characterized by focal pulmonary features and the absence of progressive pulmonary symptoms.

Secondary bacterial pneumonia typically complicates influenza after a period of initial clinical improvement. Fever recurs, usually in association with increased cough and purulent sputum production; the symptoms and signs are the same as those seen with bacterial pneumonia in the absence of influenza. *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae* are the most common bacterial pathogens. Unlike primary viral pneumonia, secondary bacterial pneumonia responds to pathogen-specific antibiotic therapy. Other pulmonary complications of influenza include bronchitis, exacerbations of asthma and other chronic obstructive pulmonary diseases, and croup.

Nonpulmonary complications also develop in association with influenza virus infection. Otitis media and sinusitis are secondary bacterial infections of the respiratory tract and are caused by the same organisms that give rise to secondary bacterial pneumonia. A toxic shock syndrome has been seen in association with colonization or secondary bacterial infection by toxin-producing *S. aureus*. Myositis is characterized by severe pain and muscle tenderness and has been associated most frequently with influenza B virus infection. Elevated serum creatine kinase levels and myoglobinuria are found on laboratory examination. Myocarditis, pericarditis, and several neurologic diseases, including transverse myelitis and Guillain-Barré syndrome, are rare complications of influenza virus infection.

Reye syndrome is a severe complication seen in pediatric patients. After the symptoms of influenza have abated, the affected child experiences nausea and vomiting followed by neurologic manifestations that may include lethargy, seizures, delirium, and coma. Hepatomegaly is typical, and liver biopsy shows fatty infiltration. Laboratory findings include hyperammonemia, hypoglycemia, and elevated serum transaminase levels with normal protein levels and cell counts in the cerebrospinal fluid. Death is common and is related to the mental status at admission. Supportive care should be given, with special emphasis placed on the management of hypoglycemia and cerebral edema. Because the use of salicylates has been associated with the development of Reye syndrome, salicylate-containing compounds should not be used during the treatment of influenza illness.

LABORATORY FINDINGS

A presumptive diagnosis of influenza virus infection can be made in the context of typical clinical features of febrile influenza when influenza is documented in the community. The diagnosis is confirmed by detection of the virus or a serologic response to the virus. Several rapid virus detection tests are now commercially available, allowing the identification of viral antigen in respiratory secretions in less than 1 hour. Although these tests have good specificity (more than 90%), their sensitivity is poorer in samples collected from adults (less than 60%) than in those collected from children (70% to 90%). Influenza virus can be isolated from respiratory secretions after inoculation into the amniotic and allantoic cavities of fertile chicken eggs or onto cell culture monolayers. Virus isolation typically requires 3 to 7 days. Serologic assays necessitate the testing of acute-phase and convalescent-phase serum samples; the latter sample should be collected at least 2 weeks after the acute-phase sample.

OPTIMAL MANAGEMENT

Specific antiviral therapy is available for the treatment of influenza A virus infections. Amantadine and its a-methyl derivative, rimantadine, are effective in minimizing the duration of symptoms and viral shedding when administered within the first 48 hours of the onset of illness. These antivirals are not active against influenza B viruses. Resistance to these drugs develops frequently during the course of treatment, but in older children and adults such resistance has not been associated with diminished drug efficacy. Resistant virus can be transmitted, however, and causes a clinical syndrome indistinguishable from that caused by drug-sensitive virus. The major side effects stemming from the use of these antivirals are neurologic (insomnia, difficulty concentrating, lightheadedness, and irritability). These side effects are more common with amantadine and resolve after drug discontinuation. The daily dosage of amantadine must be adjusted in patients with renal insufficiency; both drugs are administered at lower dosages to patients over the age of 65 years.

Therapy also is directed toward the relief of symptoms. Antipyretics can be used for the reduction of fever, though salicylate-containing compounds should be avoided in children because of the risk of Reye syndrome. Newer antivirals that inhibit viral neuraminidase activity and that are active against both influenza A and B viruses are under development and may soon become available to the public.

PREVENTION

Inactivated influenza vaccines are the principal means used to minimize the impact of influenza virus infection. Vaccination in young, healthy adults is 70% to 90% effective in preventing clinical symptoms of influenza. Efficacy rates for disease prevention are lower in geriatric populations and in other risk groups, but the vaccine is still very successful in preventing hospitalization and death in these populations. The composition of the vaccine changes from year to year to reflect the antigenic changes seen in circulating influenza virus isolates. In recent years, the influenza vaccine has been trivalent, containing antigens from influenza A/H1N1, A/H3N2,

and B virus strains. The specifics of vaccine composition and recommendations for use are made annually by the Advisory Committee on Immunization Practices; the recommendations for vaccine usage for the 1998 to 1999 vaccine are shown in [Table 310.3](#).

TABLE 310.3. RECOMMENDATIONS FOR THE USE OF INFLUENZA VIRUS VACCINE (1998–1999)

The principal side effect of inactivated influenza virus vaccine is mild soreness at the injection site. Hypersensitivity reactions can occur and are usually due to allergy to residual egg protein contained in the vaccine; thus, persons with egg allergy should not be given inactivated vaccine. Guillain-Barré syndrome has been reported slightly more often in vaccinated individuals (one or two per million), but the influenza-related risks of hospitalization and death far outweigh the potential risk of Guillain-Barré syndrome.

Amantadine and rimantadine are approved for the prophylaxis of influenza A virus infections. These drugs are 70% to 90% effective in preventing disease due to influenza A viruses. [Table 310.4](#) outlines circumstances in which amantadine or rimantadine can be considered in place of or in addition to vaccine for influenza prophylaxis. A live, attenuated, influenza virus vaccine is in clinical trials and may soon be available for use in children and others.

Chemoprophylaxis is not a substitute for vaccination. In the context of a community outbreak, however, the use of rimantadine or amantadine prophylaxis should be considered for the following groups:

- Persons at high risk who are vaccinated after influenza A virus activity has begun (for up to 2 weeks after vaccination)
- Persons providing care to those at high risk (especially if unvaccinated)
- Persons who have immune deficiency (those unlikely to have an adequate immune response to vaccine)
- Persons for whom influenza vaccine is contraindicated
- Other persons who wish to avoid influenza A illness

All of these groups in situations in which the epidemic strain might not be controlled by the vaccine

TABLE 310.4. CHEMOPROPHYLAXIS FOR INFLUENZA A VIRUS INFECTION

PARAINFLUENZA VIRUS AND RESPIRATORY SYNCYTIAL VIRUS

DEFINITION

Parainfluenza virus and respiratory syncytial virus (RSV) are pleomorphic, enveloped viruses 150 to 300 nm in diameter. These viruses are members of the family Paramyxoviridae and contain a single-stranded, negative-sense RNA. Two spikelike proteins are found on the viral surface: F (fusion) and HN (hemagglutinin–neuraminidase) for the parainfluenza viruses and F and G (attachment) for RSV. These viruses replicate in the cytoplasm of epithelial cells. Four types of parainfluenza virus and two types of RSV are recognized to cause human infection.

INCIDENCE AND EPIDEMIOLOGY

Parainfluenza viruses cause both epidemic and endemic disease, and RSV produces annual epidemics. Parainfluenza types 1 and 2 virus infections occur during autumn months, whereas parainfluenza type 3 has been noted to occur sporadically throughout the year and in epidemics during the spring. The epidemiologic characteristics of parainfluenza type 4 are still being defined. RSV infections are usually first seen beginning in the autumn, and epidemic disease continues through the winter months and sometimes into early spring. Approximately two-thirds of children are infected with RSV and parainfluenza type 3 during the first year of life, and reinfections with these viruses throughout life is common. The greatest impact of these viruses is seen with primary infection. It is estimated that 0.5% to 1% of children require hospitalization for management of RSV infection in their first year of life. Parainfluenza viruses and RSV are spread by direct contact with respiratory secretions or fomites and by large-droplet aerosol. Thus, they can be a significant cause of nosocomial viral respiratory disease. The average incubation period for these viruses is 3 to 6 days.

PATHOGENESIS

Several clinical observations have led to intense interest in the pathogenesis of RSV infections. As noted, the most severe disease manifestations develop with primary infection in infants less than 1 year of age, and many of these infections occur during the first 6 months of life, a time when maternal antibody provides infants with partial protection from other viral infections. When a formalin-inactivated, parenterally administered vaccine was given to infants, it potentiated disease resulting from natural exposure to virus rather than providing protection. These observations led to the suggestion that immunopathologic mechanisms play a role in disease development. Several additional observations, however, suggest that serum antibody protects against disease and infection: (a) the risk of lower respiratory disease in infants is inversely related to RSV antibody levels measured in umbilical cord serum; (b) the administration of RSV immune globulin to high-risk infants protects them from the development of lower respiratory tract disease due to RSV; (c) lower respiratory tract disease occurs in the absence of measurable serum anti-RSV antibodies; and (d) serum antibody levels to the F and G viral proteins are inversely correlated with risk of RSV infection. The roles of direct cytotoxicity caused by RSV infection, inflammatory mediators induced by infection, and RSV-specific IgE are other areas under active investigation to determine the pathogenesis of RSV-induced disease.

CLINICAL FEATURES

The prototypic illnesses related to parainfluenza viruses and RSV manifest in children. Croup, or laryngotracheobronchitis, is seen most often in association with parainfluenza type 1, but parainfluenza type 2 also causes epidemic disease, and type 3 is associated with sporadic cases of croup. Fever, hoarseness, and a barking cough are the principal signs of croup. This disease must be distinguished from epiglottitis, which has become less common with the use of vaccines for *H. influenzae* type b. Bronchiolitis and pneumonia are the prototypical illnesses seen in the context of RSV. Wheezing, air trapping, and cough are common signs; rhinitis and fever also occur in the majority of patients. A small percentage of cases of bronchiolitis and viral pneumonia are provoked by parainfluenza types 3 and 4. Acute otitis media is a complication that has been associated with infection with each of these viruses.

In healthy adults, infection with parainfluenza viruses and RSV cause mild upper respiratory illnesses and are uncommon causes of lower respiratory illness. Recent studies suggest that approximately 3% of community-acquired cases of pneumonia in adults during the RSV season are associated with RSV infection. These viruses can lead to exacerbations of asthma and chronic obstructive pulmonary disease, but they do so less often than rhinoviruses and coronaviruses. In the geriatric

population, RSV is the root of outbreaks of respiratory disease in nursing homes, and its clinical features are often indistinguishable from those of influenza. Severe, frequently fatal lower respiratory infections are seen in immunocompromised patients, especially bone marrow transplant recipients.

LABORATORY FINDINGS

The diagnosis of parainfluenza virus or RSV infection is made by detection of the virus or a serologic response to the virus. Rapid virus detection tests are commercially available for parainfluenza type 3 and RSV. All of these viruses can be isolated from respiratory secretions after inoculation onto cell culture monolayers. The preferred clinical sample for these studies is a nasal wash or aspirate. RSV is particularly labile, and there is rapid loss of viability if the specimen is not handled properly. Virus isolation typically requires 3 to 5 days for RSV and 5 to 14 days for the parainfluenza viruses. Serologic assays require the testing of acute-phase and convalescent-phase serum samples, so the results of such assays are delayed until a convalescent-phase sample can be collected (2 weeks or longer after the collection of the acute-phase sample).

OPTIMAL MANAGEMENT

Specific antiviral therapy for the treatment of parainfluenza virus infections is not yet available. Care of the patient with croup is supportive, and mist therapy has been reported to be of value. A single dose of systemic corticosteroids is used by many physicians to treat airway obstruction in severe croup. Ribavirin is licensed for the treatment of moderate to severe cases of bronchiolitis caused by RSV. There is still much debate about the usefulness of this antiviral agent in this syndrome. The high cost of the medication has led to its use being restricted in many hospitals. No treatment of RSV disease in adults is available, though anecdotal reports have suggested that ribavirin in combination with high-titered RSV immunoglobulin lowers mortality rates among bone marrow transplant patients.

PREVENTION

High-titered RSV immunoglobulin and a humanized RSV-specific monoclonal antibody preparation are both available for the prevention of RSV infection and disease in certain high-risk children (those with chronic lung diseases or premature infants). RSV immunoglobulin has the advantage of providing protection against other respiratory viruses, but it must be administered intravenously. The monoclonal antibody preparation is given intramuscularly. The use of subunit or live attenuated vaccines is another approach under evaluation for the prevention of RSV and parainfluenza virus infection. RSV can be a major cause of nosocomial respiratory virus infection. Nosocomial transmission has been prevented effectively by the simple infection-control measures of hand washing and the use of gloves. Cohorting of staff caring for infected patients and isolation of such patients are additional measures that have been effective in preventing spread within the hospital. Such measures are less practical within the community.

RHINOVIRUSES

DEFINITION

Rhinoviruses are small, nonenveloped, single-stranded, positive-sense RNA viruses in the family Picornaviridae. They are approximately 30 nm in size and are differentiated from enteroviruses by their loss of infectivity after exposure to a low pH. More than 100 serotypes of rhinovirus are recognized, and the cell receptor for the majority is intercellular adhesion molecule 1 (ICAM-1). Most of the rest of the rhinoviruses use the low-density lipoprotein receptor for cell attachment.

INCIDENCE AND EPIDEMIOLOGY

Rhinoviruses cause illness throughout the year, with peak periods during the fall and spring. All age groups are affected. Illness rates are higher in infants and small children, who experience an average of one rhinovirus illness per year. Older children and adults average approximately one rhinovirus illness every 2 years. Several serotypes can be found circulating in a community at any given time, and these serotypes tend to change over time. Transmission of virus occurs via aerosols and after direct contact with respiratory secretions or fomites. The average incubation period is 2 to 3 days.

CLINICAL FEATURES

The common cold is the usual clinical manifestation of rhinovirus infection, and at least 50% of common colds are precipitated by rhinoviruses. The major symptoms include sneezing, nasal discharge and congestion, and sore throat. Cough, malaise, and headache also may be significant features. The main complications of rhinovirus infection are sinusitis and otitis media. Rhinovirus infection also is present frequently in both pediatric and adult patients who have symptoms of wheezing. Recent studies suggest that rhinoviruses have an etiologic role in triggering exacerbations of asthma and other reactive airway diseases.

LABORATORY FINDINGS

Rhinovirus infection can be suspected based on clinical manifestations in the patient with a common cold. The principal means of confirming the diagnosis is by cell culture. Antigen detection assays have not been useful because of the large number of serotypes and the lack of a common group antigen. For similar reasons, serologic assays are not useful for most patients. The polymerase chain reaction has been evaluated by many research laboratories and has proved to be much more sensitive than cell culture, but this assay is not readily available to most clinicians.

OPTIMAL MANAGEMENT

Treatment of patients with rhinovirus infections is directed at symptomatic relief. Topical or systemically administered sympathomimetics (pseudoephedrine, phenylpropanolamine) decrease nasal congestion and sneezing, whereas parasympatholytic agents (ipratropium bromide) diminish nasal mucus production. Acetaminophen, aspirin, and nonsteroidal anti-inflammatory agents provide relief from systemic symptoms without affecting local nasal symptoms. Dextromethorphan is a useful antitussive. The antihistamine chlorpheniramine also has been used to minimize sneezing and nasal mucous production. These medications often are used in combination to lessen local and systemic symptoms. There have been few studies of these medications in pediatric populations, and no studies have confirmed a clinical benefit of these medicines in the preschool child. The use of a decongestant plus an antihistamine has not limited the rate of development of secondary otitis media in preschool children.

Specific antiviral agents have not been effective in the treatment of rhinovirus-associated symptoms. Topical antiviral agents, including interferon- α and virus capsid binding agents have not shown consistent clinical benefits in the context of experimental human infection. Antibiotics have no role in the treatment of uncomplicated infection. Other treatments, such large doses of vitamin C, zinc lozenges, and warm humidified air, have failed to alter the clinical course of illness consistently.

PREVENTION

The large number of rhinovirus serotypes limits the likelihood of vaccine strategies for the prevention of rhinovirus infection. Interferon- α has been evaluated in studies of prophylaxis. When used topically in studies of natural transmission within the family, rhinovirus transmission was reduced by as much as 80%. The usefulness of this treatment strategy is limited by its lack of efficacy against other respiratory viruses, the unavailability of rapid diagnostic assays for rhinovirus infections, and the side effects associated with the use of topical interferon. Soluble ICAM-1 (the cellular receptor for the majority of human rhinoviruses) has been effective in the prevention of rhinovirus infections in a chimpanzee model; its efficacy in human beings remains to be determined. At present, the only available prevention strategies are nonspecific environmental controls, such as hand washing and measures to prevent autoinoculation.

CHAPTER 311: MEASLES, MUMPS, AND RUBELLA

WALTER A. ORENSTEIN AND MELINDA WHARTON

[Measles](#)
[Mumps](#)
[Rubella](#)

MEASLES

DESCRIPTION AND PATHOGENESIS

Measles is an acute illness characterized by rash and fever and caused by a paramyxovirus. The virus is inhaled into the nasopharynx and upper respiratory tract, penetrates the mucosa, and probably establishes primary viremia within 2 days and a more extensive form of secondary viremia beginning about 5 days after initial infection. The organism can be found in many different tissues of the body but has a predilection for the respiratory tract. Three viral proteins have major roles in pathogenesis and in some of the complications seen with measles. The hemagglutinin that projects from the surface allows attachment to cells. The F (fusion) protein plays a part in cell-to-cell spread through membrane fusion, and the M protein is important in packaging of the final virion. Acute infection results in solid immunity, which is typically lifelong. Although second clinical attacks of measles have been cited, they have not been well documented; if they occur, they are rare.

EPIDEMIOLOGY

The disease is usually spread by respiratory contact, with the victim inhaling virus contained in droplets expelled by a patient. Airborne spread over greater distances has been documented, however, and instances of infection have occurred when the victim did not enter a room until at least 1 hour after the original patient had left. Laboratory studies have documented viral survival in small droplets for at least 2 hours. After an incubation period of 7 to 10 days, the first symptoms of illness appear; the patient becomes infectious at that time. Although virus can be recovered from several body fluids, including urine, the most important means of transmission is through respiratory secretions. The period of infectivity lasts through the prodromal symptoms and for 3 or 4 days after appearance of the rash in the normal host.

Measles is one of the most highly contagious illnesses; 90% or more of susceptible household contacts become infected in a single generation of spread. Because of its infectiousness, it is essentially a universal disease, except in isolated populations. In the developing world, where measles vaccine has not been used widely, transmission often occurs in very young children, and 95% of people have had measles by 10 years of age. In the United States, before measles vaccine became available, 95% of people had measles before reaching 15 years of age. Primary transmission occurred in elementary schools and day care centers. Since introduction of measles vaccine in 1963 and its subsequent widespread use, the overall incidence has declined dramatically.

Indigenous measles transmission appears to have been interrupted in this country many times since 1993. Genomic analysis of measles virus isolates shows that current strains are different from those that circulated before 1993. During the late 1990s several genotypes were detected, usually linked directly to international importations or to genotypes known to circulate in other countries. Only 100 cases were reported in 1998, down from more than 27,000 cases in 1990, the peak of a 3-year resurgence of measles at the beginning of the decade. A target has been set to eliminate indigenous measles from the Western Hemisphere by the end of the year 2000, and other regional measles elimination goals have been established for the European and eastern Mediterranean regions of the World Health Organization.

Transmission of measles has been reported in three major patterns: preschool; school age, including college; and mixed. Preschool cases of measles have developed primarily in inner city populations and predominantly affect unvaccinated children. In contrast, school-age measles infects people in junior and senior high school and college and is characterized by a high number of cases (often most cases) among people with a history of having been given one dose of vaccine. These vaccine failures are mainly the result of initial failure to seroconvert rather than waning immunity; with increasing implementation of the two-dose measles vaccination schedule, such cases are being seen less often. Mixed patterns often involve young adults, who usually are not enrolled in institutions, and young preschool children. Outbreaks have also been reported among health care personnel.

CLINICAL FEATURES

The typical pattern of measles symptoms is a 2- to 4-day prodrome of fever, malaise, cough, coryza, conjunctivitis, and photophobia. Koplik's spots, which are faint, white, 1- to 2-mm elevated lesions on an erythematous base, may be present for 1 or 2 days before and after onset of rash and are pathognomonic of measles. The prodrome is followed by the appearance of a characteristic rash beginning on the head, neck, and trunk and spreading centrifugally over the course of 2 or 3 days. The rash lasts 5 to 7 days and may be followed by a period of desquamation lasting up to 1 week. The usual pattern of illness is similar in children and adults, but complications are most likely to develop in infants and more likely to occur in adults than in school-age children.

Measles is usually an uncomplicated disease, but because of its universality, the overall burden of complications can be high. Otitis media is seen in 7% to 9% of children with measles; pneumonia (either primary viral or secondary bacterial) occurs in 1% to 6%; diarrhea is reported in about 6% of cases. In the past, about 1% to 3% of children with measles in the United States were hospitalized. Hospitalization rates may be higher now. Encephalitis develops in about one in 1,000 cases and is a greater risk after measles in adults. The reported ratio of deaths to cases in the United States is about one to two deaths per 1,000 cases. Measles virus is also capable of establishing long-term infection in the central nervous system, causing subacute sclerosing panencephalitis, a fatal degenerative central nervous system condition, about once in every 100,000 infections. The incubation period for subacute sclerosing panencephalitis is typically 7 years. In infants, adults, and people with malnutrition or other debilitating or immunocompromising conditions, complications and death are more common. Abnormalities of cell-mediated immunity predispose to measles complications. People with agammaglobulinemia appear to recover from measles in a fashion similar to that of normal hosts. Overall, it is estimated that about one million people die each year as a result of measles or its complications. Most of these deaths take place in developing countries.

Clinical primary infections are the rule. Exposure to measles virus can result in subclinical boosts in antibody titer in immune hosts. Circulating, passively acquired antibody to measles can prevent or modify the infection and make it subclinical or much less severe. Such situations commonly arise in infants (because of maternally derived antibody) and those who have received immune globulin. In fact, immune globulin is used after exposure to abort or minimize illness.

DIAGNOSIS

Laboratory confirmation can be accomplished most readily by detecting IgM antibodies in a single specimen. Alternatively, a significant rise in antibodies to measles virus between acute-phase and convalescent-phase serum samples is also an acceptable indicator. Hemagglutination inhibition largely has been replaced by enzyme-linked immunosorbent assay (ELISA). IgM antibodies can be verified beginning almost simultaneously with rash onset, peak at about 10 days after rash onset, and may persist for 1 month or longer; tests performed within 72 hours of rash onset may show negative results. ELISA tests using a capture format for IgM are preferred. Measles IgG antibodies peak 2 to 4 weeks after onset of rash and fall off slightly thereafter. After measles, most patients maintain demonstrable antibodies for life. In the absence of reexposure, however, a few patients lose antibody, as measured by standard tests. Such individuals appear to be immune, however, because antibody is detectable in special sensitive assays and because these individuals give a prompt secondary antibody response on vaccination. Subclinical reinfections are also associated with boosts in antibody titer.

Measles virus can be isolated from urine, respiratory secretions, or blood. Sequencing of the H and N genes of viral isolates allows tracking of measles transmission within the United States and internationally. Other illnesses that might be confused with measles in adults are rubella (usually a milder illness and of shorter duration), Rocky Mountain spotted fever, secondary syphilis, parvovirus infection, and adenoviral or enteroviral illnesses with rash.

OPTIMAL MANAGEMENT

There is no specific treatment. Antibiotics are typically used to treat pneumonia associated with measles, because it is often bacterial, commonly caused by infection

with *Streptococcus pneumoniae* or *Staphylococcus aureus*.

PREVENTION AND CONTROL

In 1963, a killed virus vaccine and a live attenuated virus vaccine (Edmonston B strain) were introduced. The killed virus vaccine (which lacked the F protein) was soon shown to induce short-lived protection and to sensitize some recipients so that on subsequent exposure they contracted an unusual clinical illness with fever, atypical rash, and pneumonia (atypical measles syndrome). Consequently, this product was not distributed after 1967. The Edmonston B vaccine induced long-lasting immunity but also caused a mild measles-like illness in many recipients. As a result, it was usually given with immune globulin. In 1965, the further attenuated Schwarz strain vaccine, derived from Edmonston A virus, was introduced, followed in 1968 by the Moraten strain, which was similar to the Schwarz strain. These vaccines rapidly replaced the Edmonston B strain. The Moraten strain is the only vaccine strain used in the United States. Measles vaccine is available as a single antigen or combined with rubella (MR) or mumps and rubella (MMR).

More than 93% of susceptible people 12 to 15 months of age or older have antibodies after receipt of a single dose of the currently available measles vaccine. Seroconversion rates in infants are not as high because of interference from persisting maternally derived antibodies. Although antibody titers decline with time and may become undetectable (using standard tests), vaccine-induced immunity is long term, probably lifelong in almost all recipients. Although waning immunity has been reported, it appears to be rare. Measles transmission has been reported in highly vaccinated populations, primarily junior and senior high school and college students who received a single dose on or after their first birthday. These cases appear to represent mainly the 2% to 7% of vaccinees who initially fail to respond to vaccine.

To minimize measles vaccine failure, two doses of measles vaccine, given as MMR, began to be recommended for routine immunization starting in 1989. It is suggested that the first dose be administered at 12 to 15 months of age and the second dose at entry to school (kindergarten or first grade). A goal has been set to ensure that all children, in kindergarten through twelfth grade, receive a second dose of MMR by 2001. To prevent college outbreaks, all college entrants should have evidence of receipt of two doses of vaccine on or after the first birthday, previous physician-diagnosed measles, or laboratory evidence of immunity. All persons who work in health care facilities should be immune to measles as evidenced by the same criteria as for college students. Adults born before 1957 generally are considered to be immune as the result of early exposure to natural virus. Nonetheless, one dose of MMR should be considered for unvaccinated health care workers born before 1957, because cases of measles have been reported in this group.

During outbreaks, particularly in schools, all students and staff at risk should be vaccinated unless they have received two previous doses of vaccine on or after the first birthday, have evidence of previous physician-diagnosed measles, or have a positive serologic test for measles antibody. Reactions to measles vaccine are usually mild. Approximately 5% of recipients may have temperatures of 39.4°C (103°F) or more or rashes 5 to 12 days after vaccination. These features are usually mild and of short duration, though febrile convulsions have been reported. Encephalitis also has been reported within 30 days after vaccination at a rate of about one case per two million doses of vaccine distributed, but it is not clear that it is caused by the vaccine. Only nonimmune persons tend to have side effects attributable to vaccine virus complications, such as fever and rash. Reactions should be less common in people being revaccinated than in children receiving measles vaccine for the first time.

Measles vaccine virus is grown in chick embryo fibroblasts and may contain egg protein in picogram quantities. Most anaphylactic reactions are attributed to other vaccine components, however, and skin tests for egg hypersensitivity do not predict who will suffer anaphylactic reactions. Therefore, allergy to eggs, chickens, or feathers is not a contraindication to routine vaccination, though vaccination of those with anaphylactic hypersensitivity should be performed where epinephrine is available. Some cases of anaphylaxis may be related to sensitivity to gelatin. MMR also appears to cause thrombocytopenic purpura in one of 30,000 to 40,000 vaccinated children.

The only contraindications to receipt of measles vaccine are an immunocompromised state and, on theoretic grounds, pregnancy. Patients with human immunodeficiency virus (HIV) infection and no symptoms also should be vaccinated. Vaccine also should be considered for individuals with symptomatic HIV infection, but persons with HIV who are severely immunocompromised should not be vaccinated. In adults, this translates to CD4 counts of less than 200 per cubic millimeter or CD4 cells constituting less than 14% of total lymphocytes.

All people without contraindications who are not known to be immune to measles should be considered susceptible and should be vaccinated. Measles vaccine combined with other antigens should be used in anyone potentially susceptible to rubella or mumps. There is no harm in vaccinating someone who is already immune. People born before 1957 are likely to have been exposed to wild virus and can generally be considered immune. Women known to be pregnant should not be vaccinated. A practical way to deal with women of childbearing age is to ask them if they are pregnant or likely to become so in the next 3 months. If the answer is no, the potential risks are explained to them before they are vaccinated.

Immune globulin can be used to prevent or modify illness in people who have been exposed to measles. The usual dose is 0.25 mL per kilogram, up to a maximum of 15 mL. People with compromised immune systems should receive 0.5 mL per kilogram. Measles vaccine also can be used after exposure (≤72 hours) to prevent illness. The advantage of using vaccine is that if the exposure did not result in infection, the person is protected against subsequent exposure.

MUMPS

DESCRIPTION AND PATHOGENESIS

Mumps is an acute illness generally characterized by parotitis and caused by a paramyxovirus. The virus is typically inhaled, probably replicates in the respiratory epithelium or parotids, and disseminates through the bloodstream to localize in glandular or nervous tissue. Virus can be detected in saliva up to 7 days before onset and 7 days after clinical symptoms appear. Viruria can be confirmed up to 14 days after onset of illness. One infection confers long-lasting immunity; second attacks of clinical illness are rare.

EPIDEMIOLOGY

The incubation period typically is 16 to 18 days, with a range of 12 to 25 days. Infected people usually become contagious 1 or 2 days before symptom onset and can transmit virus for 5 to 9 days after parotid swelling. People with subclinical infection also can spread disease. Transmission is through inhalation of droplets of respiratory secretions containing virus and consequently involves face-to-face contact with an infected person. Mumps is highly infectious—more than 30% of susceptible household contacts are likely to be infected on exposure. Subclinical infection is common (20% to 40% of all infections) and also induces long-lasting immunity. Mumps traditionally has been a disease of school-age children, but cases have been documented in preschool children and adults. Widespread use of mumps vaccine has resulted in a dramatic decline in the incidence of mumps in the United States. Only 666 cases were reported in 1998, which represents less than 1% of prevaccine levels.

CLINICAL FEATURES

The illness typically begins with malaise and low fever. Within 1 or 2 days, parotitis (the most characteristic manifestation in 30% to 40% of cases) appears and lasts 4 to 6 days; it may be unilateral or bilateral. Fever usually persists 3 or 4 days. Recovery is complete and induces lifelong immunity. Complications are common, but they are generally mild. Aseptic meningitis develops in 4% to 6% of patients and, as a rule, it is mild, with no adverse effects. Mumps meningoencephalitis, a rare complication, can result in long-term side effects, including paralysis, cranial nerve palsies, and hydrocephalus. Many persons with mumps meningoencephalitis do not have parotitis. Orchitis is common in postpubertal men—it occurs in 20% to 40% of cases. Most cases are unilateral, and sterility is rare. Mastitis is seen frequently in postpubertal women. Other complications include oophoritis, thyroiditis, nephritis, arthritis, and myocarditis. Pancreatitis, usually mild, develops in about 4% of cases. In rare cases, diabetes has been associated temporally with mumps; however, the causal role of the virus, if any, has not been established clearly. The most common residual manifestation of mumps is nerve deafness, which seems to occur at a rate of about one case in 20,000 infections.

DIAGNOSIS

The diagnosis can be confirmed by a significant rise in mumps antibody levels using neutralization, complement fixation, ELISA, or hemagglutination inhibition tests. IgM ELISA antibody tests are highly sensitive and specific for mumps and allow diagnosis based on a single serum specimen. IgM antibodies usually are detectable during the first few days of illness and persist for weeks to several months. Immunity after infection appears to be lifelong, but antibody titers, particularly those

measured by complement fixation, decline with time and frequently become nondetectable (thus negating the usefulness of the complement fixation test in serologic screening for immunity). Mumps virus can be isolated from the nasopharynx, saliva, urine, and cerebrospinal fluid; however, isolation is used infrequently for diagnosis. The serum amylase value is elevated in most cases. No other agents are known to cause epidemic parotitis, but sporadic cases may stem from a variety of infectious and noninfectious sources. Other viral agents associated with parotitis include parainfluenza, influenza, cytomegalovirus, and coxsackievirus.

OPTIMAL MANAGEMENT

There is no specific therapy.

PREVENTION AND CONTROL

Live attenuated mumps virus vaccine (Jeryl Lynn strain) was introduced in the United States in 1967; since 1971, it has been available in combination with measles and rubella vaccines (MMR). The vaccine induces seroconversion in more than 90% of susceptible people who are at least 12 months of age. Vaccine-induced immunity appears to be lifelong. Although most cases of mumps develop among unvaccinated people, vaccine failure has been noted in some outbreaks. During field evaluations of vaccine efficacy, protection levels of 75% to 95% have been reported after a single dose of mumps vaccine.

Reactions to mumps vaccine are few. Mild parotitis or orchitis have been reported, but these reactions are rare. The only contraindications are an immunocompromised state and, on theoretic grounds, pregnancy. Mumps vaccine is prepared in chick embryo cell culture. While rare and serious allergic reactions have been reported in recipients with histories of anaphylactic reactions to eggs, skin testing for egg sensitivity is not predictive of anaphylaxis, and most cases of anaphylaxis do not appear to be related to egg sensitivity. Therefore, persons with anaphylaxis to eggs may be vaccinated. In about one per 30,000 to 40,000 immunizations, thrombocytopenic purpura can follow mumps vaccination when it is administered as MMR.

Since 1989 a routine two-dose vaccination schedule with MMR has been recommended, and most children vaccinated since then will have received two doses of mumps vaccine as MMR. It is suggested that the first dose be administered at 12 to 15 months of age and the second dose at entry to school (kindergarten or first grade). All children in school (kindergarten through twelfth grade) should receive a second dose of MMR by 2001 if they have not received it previously. A single dose of mumps vaccine is acceptable evidence of mumps immunity for people not in the age group for two doses. Other acceptable evidence of mumps immunity includes documentation of physician-diagnosed disease or laboratory evidence of immunity. From a practical point of view, people born before 1957 are likely to have been exposed to wild virus and generally can be considered to be immune. Women of childbearing age should be vaccinated according to the guidelines presented earlier for measles vaccine. Immune globulin is not reliably effective in preventing or modifying the effects of mumps after exposure. No clear evidence suggests that mumps vaccine given after exposure prevents disease. If exposure did not result in infection, however, such vaccination prevents disease on subsequent exposure.

RUBELLA

DESCRIPTION AND PATHOGENESIS

Rubella (sometimes called German measles) is an acute illness caused by a togavirus. The virus typically is inhaled, penetrates the upper respiratory tract mucosa, and establishes viremia, which may be present from about 1 week before rash onset. The virus freely infects and crosses the placenta and damages fetal tissues that are undergoing rapid division and maturation. Immunity is thought to be lifelong.

EPIDEMIOLOGY

Transmission is usually through respiratory secretions and typically involves face-to-face contact with an infected person. Airborne spread also has been postulated. People with subclinical infections can transmit virus. The period of infectivity typically begins a few days before rash onset and lasts up to 5 to 7 days after onset of rash. Before rubella vaccine was introduced, primary transmission of rubella occurred in school-age children; antibodies developed in 80% to 85% of people in the United States by 15 years of age. Because of the level of susceptibility in the young adult population, however, outbreaks of disease did develop among adults, with tragic outcomes. As a result of the nationwide epidemic in 1964 to 1965, an estimated 20,000 infants were born with congenital defects stemming from congenital rubella infection, and an additional 12,000 pregnancies ended in spontaneous or induced abortion.

Widespread use of rubella vaccine has resulted in marked declines in the incidence of both rubella and congenital rubella syndrome. In 1998, a total of 364 cases of rubella and seven cases of congenital rubella syndrome (two of which were imported) were reported in the United States. This number represents less than 1% of prevaccine era levels. A target has been set to eliminate indigenous rubella and congenital rubella syndrome in the United States by the year 2000. In the 1990s rubella emerged as a disease seen predominantly among Hispanic adults who were not born in the United States and who grew up in countries without programs for routine rubella vaccination of children. The recent epidemiologic characteristics of congenital rubella syndrome (most cases now arise among infants born to Hispanic women) reflect the current epidemiologic features of rubella.

CLINICAL FEATURES

Rubella is usually a mild illness and may pass unnoticed. Subclinical infections are common (25% to 50%). The typical illness begins 16 to 18 days (range, 2 to 3 weeks) after exposure, with slight malaise and low-grade fever, followed in 1 or 2 days by the appearance of a maculopapular rash that typically is not as widespread as in measles and lasts only 2 or 3 days. Occipital and postauricular lymphadenopathy are common and indicate the diagnosis. Arthralgia is common in adults (particularly in women) and may be found in half or more of cases. All manifestations typically subside within 2 to 5 days, and the patient subsequently has lifelong immunity.

Complications are rare and include thrombocytopenia and encephalitis, both of which usually resolve without residual effects. The major burden of rubella is related to infection in a woman in the early stages of pregnancy. Overall, more than 20% of women infected during the first trimester give birth to infected infants. The virus infects the placenta and the fetus and affects rapidly dividing and developing tissue. The incidence of defects is highest during the first month of gestation. By the fifth month, essentially there is no serious risk. Consequently, the major manifestations of congenital rubella infection depend on the stage of pregnancy in which infection occurs.

The most common manifestations of congenital rubella are fetal death, deafness, cataracts, congenital heart lesions, and mental retardation. Infection early in the first trimester is associated with major congenital anomalies, such as congenital heart disease, whereas infection in the fourth month is more likely to result in deafness alone. Because deafness may not be detected for some time after birth, babies with congenital rubella syndrome may appear normal in the neonatal period. Congenital infection can lead to chronic infection, and infants with congenital rubella syndrome may excrete virus (and infect others) for periods as long as a year after birth. Chronic infection also can lead to diabetes or progressive rubella panencephalopathy, which is a rare condition that is similar to subacute sclerosing panencephalitis.

DIAGNOSIS

Diagnosis based on clinical symptoms is unreliable. Laboratory confirmation involves detection of IgM antibodies in any blood specimen or evidence of a significant increase in antibody titer (using a variety of tests, including hemagglutination inhibition, complement fixation, ELISA, indirect fluorescent antibody, and hemolysis-in-gel tests) or virus isolation. ELISA is the most common test. Diagnosis in infants with suspected congenital rubella infection can be confirmed by detection of rubella-specific IgM, persistence of antibodies beyond the expected rate of decay from transplacental passage, virus isolation, or detection of rubella virus by the polymerase chain reaction.

OPTIMAL MANAGEMENT

There is no specific therapy.

PREVENTION AND CONTROL

The only effective preventive technique is the use of rubella vaccine. Live attenuated rubella virus vaccines were first introduced in 1969. Their widespread use in the United States has led to the virtual disappearance of rubella and congenital rubella syndrome. Vaccines have been prepared in a variety of different cell lines; currently available vaccine (RA 27/3) is prepared in human diploid cells (WI-38) and is commonly combined with measles and mumps vaccines as MMR. More than 95% of susceptible people at least 1 year of age have antibodies after administration of rubella vaccine. Levels of antibody are lower than those after natural infection and may decline to undetectable levels over time. Nonetheless, vaccine-induced immunity is long term, probably lifelong, in almost all vaccine recipients who seroconvert.

Less than 5% of recipients of vaccine experience mild fever or rash 10 to 15 days after vaccination. The most prominent adverse effect, arthralgia, is seen primarily in women and may develop in about 25% of susceptible vaccinees. It typically lasts 1 day to 3 weeks, is only rarely responsible for work loss, and does not recur. Frank arthritis occurs in approximately 10% of susceptible adult female vaccinees. Joint symptoms manifest only in susceptible vaccinees. Recurrence or persistence of arthralgia and frank arthritis has been reported, though the incidence rate is similar to incidence rates in unvaccinated populations, implying that rubella vaccine does not cause chronic arthropathy. Comparative studies show that chronic or recurrent joint symptoms after rubella disease are considerably more common than after rubella vaccines. In rare instances, thrombocytopenic purpura has followed rubella vaccine when administered as MMR.

Because rubella virus damages fetuses, there has been concern that the vaccine virus might have the same effect. Between 1971 and 1989, the Centers for Disease Control and Prevention maintained a registry of women who received vaccine when they were unknowingly pregnant. There were reports of 321 women, known to be susceptible to rubella, who had received RA 27/3 rubella vaccine within the 3 months before or after conception and who carried their pregnancies to term. None delivered a child with congenital deformities suggestive of congenital rubella syndrome. Although the measured risk is 0, the maximum theoretic risk is 1.6%, which is considerably lower than the measured risk of 20% or more with wild rubella virus in the first trimester. Although five of the infants had serologic evidence of in utero infection by the vaccine virus, no clinical abnormalities were verified.

Fetal tissues obtained at abortion have also yielded vaccine virus on occasion. Consequently, the potential for fetal infection exists even though experience indicates no cases of congenital rubella syndrome caused by vaccine virus. Because of this theoretic risk, rubella vaccination is contraindicated in pregnancy. A reasonable approach to vaccinating women of childbearing age is to ask if they are pregnant or likely to become pregnant within the next 3 months. If they say no, the possible risks should be explained, and they should be vaccinated. The possibility of risks to the fetus of rubella vaccine virus have been evaluated by the Advisory Committee on Immunization Practices, which concluded that the risk, if any, is negligible. Therefore, vaccination of a woman later found to be pregnant within 3 months of vaccination should not in itself be considered an indication for abortion. A final decision must rest with the woman and her physician.

Although one dose of rubella vaccine appears to be adequate, many people receive two doses as part of MMR. The first dose usually is administered at 12 to 15 months of age and the second dose at entry to school (kindergarten or first grade). By 2001, all students, kindergarten through twelfth grade, should receive a second dose of MMR if they have not been given a second dose previously. Because the clinical diagnosis of rubella is unreliable, people should be considered immune to rubella only if they have documentation of having received rubella vaccine on or after the first birthday or if they have laboratory evidence of immunity. Most persons born before 1957 can be considered immune from exposure to natural infection. Women of childbearing age who might become pregnant should be vaccinated if they lack evidence of vaccination or serologic evidence of immunity. The only contraindications for vaccination are pregnancy and an immunocompromised state. Immune globulin given after exposure can modify the clinical manifestations of rubella, but it does not reliably prevent fetal infection or fetal damage. Consequently, it should be used only for a pregnant woman exposed to rubella who would not consider abortion under any circumstance.

[Herpes Simplex Virus Latency and Reactivation](#)
[Immunity](#)
[Epidemiology](#)
[Clinical Manifestations](#)
[Diagnosis](#)
[Treatment](#)
[Prevention of Herpes Simplex Virus Infection](#)

Herpes simplex viruses (HSVs) are ubiquitous, remarkably host-adapted human pathogens. Initial (primary) HSV infection is usually asymptomatic or mild and self-limited, but instead of disappearing from the body during convalescence, the virus establishes a latent infection that persists for life. This latent infection is subject to intermittent reactivation, which results in recurrent disease or asymptomatic virus shedding and transforms each affected person into a lifelong reservoir of HSV infection. The prompt recognition of HSV infection is extremely important because of the potential for transmission and the availability of effective antiviral chemotherapy.

MICROBIOLOGY

There are two HSVs, type 1 (HSV-1) and type 2 (HSV-2), which are closely related but differ in their epidemiologic characteristics. They are classified as members of the herpesvirus family on the basis of virion architecture and genome structure. HSV-1 and HSV-2 are morphologically indistinguishable from each other and from other members of the herpesvirus family, including the six other human herpesviruses (HHV) discovered to date: varicella-zoster virus (HHV-3), Epstein–Barr virus (HHV-4), human cytomegalovirus (HHV-5), HHV-6 (the cause of roseola infantum), HHV-7, and HHV-8 (etiologically linked to Kaposi's sarcoma).

The HSV virion consists of a linear double-stranded DNA genome within an icosahedral protein shell, or capsid. This structure, the HSV nucleocapsid, is surrounded by a layer of viral protein (the tegument) and, finally, by a lipoprotein envelope containing viral glycoproteins that mediate virus attachment to and penetration into susceptible host cells. Because of the essential role of these envelope glycoproteins, only enveloped virions are infectious, and HSV infectivity is rapidly destroyed by organic solvents, detergents, proteolytic enzymes, heat, drying, and extremes of pH. The genomes of HSV-1 and HSV-2 share about 50% of their nucleotide sequences. Each encodes about 80 proteins, most of which are antigenically related and elicit cross-reactive immune responses. Replication of HSV is highly regulated. Viral genes are expressed in a sequentially ordered cascade controlled by viral regulatory proteins.

PATHOLOGY AND PATHOGENESIS

The pathologic changes that characterize HSV infections are the result of cytopathic effects induced by HSV in infected cells plus local inflammatory responses. Exogenous HSV infection is initiated when virus comes into contact with a mucosal surface (oropharynx, conjunctivae, vaginal mucosa, cervix) or penetrates the stratum corneum of the skin at a site where this barrier has been disrupted by small cracks, minor trauma, or disease. HSV replicates locally in cells of the stratum spinosum, producing papular lesions that rapidly evolve into intraepidermal vesicles. Inflammatory cells soon invade the vesicle, turning the fluid cloudy and transforming it into a pustule. The fluid is then absorbed, leaving a flat, adherent crust that is subsequently detached when subjacent epithelial cells grow back. The lesions heal without scars. Lesions in mucous membranes develop in the same way, but the thin roof of the vesicle quickly breaks down, leaving a shallow ulcer.

In most infected persons, even those who have a primary infection (the initial HSV infection of a host with no immunity to HSV-1 or HSV-2), virus replication and cell destruction are terminated quickly at the site of inoculation, and the infection remains asymptomatic or unrecognized. In some cases, however, virus replication and cell destruction are more extensive, resulting in clinically manifest disease at the portal of entry, spread of virus to regional lymph nodes, and some degree of viremia. In the normal host, nonspecific and specific defense mechanisms combine to localize infection, terminate virus replication, and eventually eliminate infectious virus from tissue at the portal of entry and at any sites of viremic spread.

HERPES SIMPLEX VIRUS LATENCY AND REACTIVATION

The most significant biologic property of the HSVs, which they share with other members of the herpesvirus family, is their ability to establish lifelong persistent infections that ensure their perpetuation in the human population. The key to this behavior is neuronal latency and reactivation. Early in the course of both symptomatic and asymptomatic infections, virus invades local sensory or autonomic nerve endings and is transported within axons to regional sensory or autonomic ganglia, where ongoing latent infections are established in neurons. Thereafter, despite the host's immunity, this latent virus is reactivated periodically, either spontaneously or by various stimuli, such as trauma to the ganglion or nerve root, fever, menstruation, ultraviolet light, sexual intercourse, or emotional stress. The reactivated virus travels within axons back to the periphery and reinfects epithelial cells in the skin or mucous membranes at or near the original portal of entry. There, virus replication and cell-to-cell spread may produce intraepidermal vesicles like those produced during primary infection. When reactivation of latent HSV results in clinically manifest disease, it is called a recurrence or an episode of recurrent HSV infection. In the normal host, immune mechanisms rapidly limit local virus replication and spread so that recurrent HSV infections are generally less severe, less extensive, and of shorter duration than primary infections. In fact, in the majority of instances, the local infection is so circumscribed that no recognizable lesions are produced and reactivation results only in asymptomatic virus shedding.

Several important questions about HSV latency with implications for prevention and treatment remain to be answered. The first is the mechanism by which HSV latency is established in sensory neurons. Studies with a variety of HSV mutants, as well as the use of antiviral agents that block HSV DNA synthesis, have shown that latency can be established and maintained in the absence of detectable HSV replication and even in the absence of significant HSV gene expression. Thus, the establishment of HSV latency appears to be a passive process governed by neuronal factors rather than by any specific viral gene products.

The absence of detectable HSV gene expression in latently infected neurons and the ability of replication-negative HSV mutants to establish and maintain latency in animal models indicate that HSV DNA replication, at least that catalyzed by HSV-encoded DNA polymerase, is not required for the maintenance of HSV latency in neurons. Consistent with this conclusion is the clinical observation that prolonged suppression of recurrent genital herpes with acyclovir, which blocks HSV DNA synthesis catalyzed by the viral DNA polymerase, fails to abolish latent HSV infection in the sacral ganglia.

IMMUNITY

In the normal host, an array of overlapping local and systemic defense mechanisms limit HSV replication and spread, destroy HSV-infected cells, and eventually eliminate infectious virus. These defenses fall into two categories, nonspecific and specific, that are most clearly differentiated during primary HSV infections. Only nonspecific defenses are operative during the first several days of primary infection, that is, until specific immune responses develop, yet these are sufficient to prevent the development of clinically manifest disease in the majority of infected individuals.

The normal cornified epithelium is an important nonspecific barrier—the first line of defense against the initiation and spread of HSV infection. When it is defective (as in patients with atopic eczema or burns), HSV infections are frequently severe, widespread, and occasionally disseminated. Once primary HSV infection is initiated in the skin or mucous membranes, a number of nonspecific defense mechanisms are mobilized, actuating a local inflammatory response. These include complement activation; production of interferons and other lymphokines; and the activity of neutrophils, monocytes, macrophages, and natural killer cells. Together, they slow HSV replication and limit its spread.

Antibodies to HSV are first detected several days after the onset of infection; they are elicited by epitopes on most of the HSV-encoded proteins, but those that are protective are directed primarily at the envelope glycoproteins that are exposed on the surface of virions and virus-infected cells. Later, during the second week of infection, HSV immune T lymphocytes can be detected. In addition to lysing cells that express HSV glycoproteins, these T lymphocytes lyse cells that express the immediate early (alpha) HSV proteins ICP4 and ICP27. Consequently, they are able to destroy HSV-infected cells early in the virus replication cycle, before any

progeny virus is produced.

Because of the multiplicity and overlap of these host defenses, it is difficult to determine the exact role and relative importance of each. Nevertheless, clinical and experimental observations indicate that the natural resistance of the normal epithelium and the virucidal and cytolytic capacities of macrophages and natural killer cells play a crucial role in localizing infection at the portal of entry and slowing virus replication during the first few days, before specific immune responses have developed. When these defenses are deficient, as they are in patients with eczema or extensive burns and in the newborn, there is risk of early virus dissemination and overwhelming systemic infection.

Antibody-dependent cellular cytotoxicity (ADCC), the appearance of which coincides with resolution of the systemic symptoms of primary HSV infections, also has an important role in limiting virus replication at the portal of entry and preventing visceral dissemination. Deficiencies in ADCC, due primarily to numerical or functional deficiencies in effector cells, are associated with a markedly increased risk of severe disseminated HSV infection in the newborn and in certain patients with leukemia; the presence of antibodies mediating ADCC is predictive of a better outcome in neonatal HSV infections. Finally, HSV-reactive T lymphocytes appear to be required for the eventual eradication of infectious virus from mucocutaneous sites of infection. Patients with deficient T-lymphocyte function, such as those infected with HIV, experience severe, persistent, locally progressive mucocutaneous HSV infections but rarely have hematogenous dissemination.

EPIDEMIOLOGY

The principal mode of transmission of HSV is close personal contact, which mediates the direct transfer of virus by infected secretions or from an infected mucocutaneous surface to the recipient's mucous membranes or skin. Because the intact stratum corneum is resistant to HSV infection, transmission to cutaneous sites generally requires some disruption of this barrier, either by trauma or disease. HSV is labile. Consequently, despite experimental evidence that it can survive for hours on a variety of contaminated surfaces, there is no documented transmission from inanimate objects (such as toilet seats) or from swimming pools or hot tubs, and there is no evidence of natural transmission by aerosols. There is no evidence of differing racial or sexual susceptibility to HSV or of significant seasonal or sexual variation in the incidence of overt disease. Genital herpes is transmitted more efficiently from men to women than from women to men, however, and the prevalence of antibody to HSV-2 is higher in women, even after controlling for other risk factors.

Epidemiologic studies have been complicated by two characteristics of HSV: the prevalence of occult infections and the nature of the immune response. More than two-thirds of initial HSV infections are asymptomatic or unrecognized, and reactivation of latent HSV results in asymptomatic virus shedding far more often than overt disease. Thus, at any point in time, persons shedding HSV asymptotically (many of whom are totally unaware of ever having been infected) far outnumber those with clinical disease. Consequently, clinical surveys greatly underestimate the incidence and prevalence of HSV infection. Furthermore, though the amount of virus in the lesions of overt disease is greater than that shed asymptotically, most new HSV infections result from contact with persons who are shedding HSV in the absence of recognized symptoms or lesions. In addition, the immune response to HSV is largely to type-common antigenic determinants. Thus, most serologic assays do not distinguish reliably between antibody responses to the two HSV serotypes.

The epidemiologic characteristics of HSV-1 and HSV-2 infections differ because of differences in their modes of transmission. HSV-1 is transmitted principally by contact with infected oral secretions or lesions, and consequently the incidence and prevalence of HSV-1 infection are influenced by factors that affect the degree of exposure to these sources of infection, such as crowding, poor hygiene, and age. Thus, the rate of acquisition of HSV-1 infection is inversely related to socioeconomic status. This was shown by early serologic studies that found that the age-specific prevalence of antibodies to HSV-1 was lower in upper-income groups than in lower-income groups. In children of low-income families in developing countries, seroconversion (primary HSV-1 infection) takes place early in life; the majority acquire antibodies to HSV-1 by 5 years of age, and 95% are seropositive by age 15 years. Similar results were obtained in low-income families in the United States and Western Europe during the 1950s.

Predictably, the age-specific prevalence of antibodies to HSV-1 has been declining during the past 40 years in Western industrialized countries, especially in middle-class populations, as the standard of living has improved. The prevalence of antibodies to HSV-1 in white adults in the United States has decreased to 40% to 60%. It is only 25% in white 14-year-olds and 25% to 30% in white college students; the figures are much higher for blacks (70% in 14-year-olds and 50% to 60% in college students), undoubtedly reflecting lower socioeconomic status and crowded living conditions during childhood. In a study of college students, most of whom were initially seronegative for HSV-1, primary infections occurred in nearly 10% per year. Thus, whereas primary HSV-1 infections are confined largely to early childhood in developing countries and even in poor urban populations in the United States, the majority of middle- and upper-income children in Western societies escape HSV-1 infections during childhood and are infected as adolescents or adults. Because the clinical manifestations of primary oropharyngeal HSV infection differ in young children (gingivostomatitis) and adults (pharyngotonsillitis and a mononucleosis-like syndrome), this epidemiologic change has resulted in the appearance of a previously unrecognized disease in young adults: acute herpetic pharyngotonsillitis.

Clinical surveys indicate that 20% to 25% of adults in the United States suffer herpes labialis; the majority experience no more than one episode per year, but approximately one-third have two to six episodes per year, and about 5% have recurrences as often as once per month. The frequency and severity of episodes tend to decline with age, and many persons infected with HSV-1 (i.e., with antibodies to HSV-1) do not appear to experience herpes labialis. Nevertheless, seropositive children and adults, including those with no history of symptomatic primary or recurrent infections, periodically shed HSV asymptotically in their saliva and are the major source of virus causing new HSV-1 infections. The proportion shedding virus at any given time appears to range from 1% to 10%, but it may be greater in children during the first year or two after primary infection and is markedly increased in immunosuppressed patients. Current data on seroprevalence indicate that approximately 130 million U.S. citizens of all ages (50%) are infected with HSV-1.

HSV-2, the predominant cause of genital herpes, is transmitted sexually by contact with infected genital secretions or mucocutaneous surfaces. Thus, HSV-2 infection is rare before puberty, and its acquisition thereafter is related to sexual activity. The highest rates of infection occur between ages 15 and 35 years: more than 80% of all primary HSV-2 infections develop in this age group. The prevalence of antibodies to HSV-2 varies from essentially zero in children younger than 14 years and celibate adults to more than 80% in prostitutes. Once an uncommon disease among members of the white middle class in Western industrialized countries, symptomatic genital herpes has increased dramatically in prevalence since the mid-1960s. Contributing factors include the increasing sexual activity of adolescents, the declining use of barrier contraceptives, and the lower proportion of white middle-class adolescents who have partial immunity to HSV induced by childhood HSV-1 infection.

HSV-2 antibody prevalence rates are 20% to 30% in middle-class women in the United States and more than 20% in the U.S. general population. Some 60% to 80% of these seropositive individuals have no history of symptomatic genital herpes. The incidence of initial HSV-2 infections is 1% to 2% per year in college students, 2% per year in middle-class women of childbearing age, 5% to 10% per year in multipartner heterosexual sexually transmitted disease (STD) clinic patients, and 5% per year in sexually active homosexual men. There are now 40 to 60 million people in the United States infected with HSV-2, an increase of more than 30% since the late 1970s, and more than a million new infections occur each year.

Risk factors for HSV-2 infection include several sexual partners, early age at first intercourse, years of sexual activity, history of other STDs, low family income, race, and gender; the age-specific prevalence of antibodies to HSV-2 is two to three times higher in black than in white persons and is consistently higher in women than in men. In heterosexual women in the United States, the probability of being infected with HSV-2 rises markedly with the number of sexual partners. It is less than 10% in women with one lifetime sexual partner, increasing to 40% with two to 10, 60% with 11 to 50, and more than 80% in women with more than 50 lifetime sexual partners. The corresponding probabilities of HSV-2 infection in heterosexual men are less than 1%, 20%, 35%, and 70%.

As in the case of HSV-1, latency and asymptomatic virus shedding play critical roles in maintaining HSV-2 in human populations. The majority of new HSV-2 infections are acquired from a sexual partner shedding virus in the absence of recognized signs or symptoms of disease. The decreasing prevalence of HSV-1 infections before puberty and the increasing popularity of orogenital sexual practices are changing the epidemiologic features of genital herpes. In the United States and Western Europe, 10% to 40% of initial episodes of genital herpes are now caused by HSV-1.

CLINICAL MANIFESTATIONS

The clinical manifestations of HSV infection are determined by the portal of entry of the virus; the previous experience of the host with HSV; the serotype and amount of virus initiating infection; and such host factors as age, immunocompetence, nutritional status, and the presence or absence of conditions like eczema or burns that compromise the normal resistance of the skin. Although HSV-1 is responsible for the majority of infections at anatomic sites above the waist and HSV-2 for the majority of infections at sites below the waist, both serotypes can cause infections at any site, and there is generally no discernible difference between the clinical presentation and course of a given syndrome caused by HSV-1 or by HSV-2. One exception appears to be the frequency of recurrences of oral-labial and genital

HSV infections caused by the two viruses. The recurrence rate of genital herpes is at least five times greater when it is caused by HSV-2 than by HSV-1, whereas the recurrence rate of oral–labial herpes is 10 to 100 times greater when it is caused by HSV-1 than by HSV-2. Because transmission of HSV and thus its survival in human populations depend chiefly on recurrent infections, the greater recurrence rate of HSV-1 than of HSV-2 in oral–labial infections and of HSV-2 than HSV-1 in genital infections may reflect the adaptation of the two serotypes to their respective anatomic niches. These differences help explain why HSV-1 is isolated from lesions of recurrent genital herpes so much less frequently than from lesions of primary genital herpes and why HSV-2 is almost never isolated from lesions of herpes labialis.

OROPHARYNGEAL HERPES SIMPLEX VIRUS INFECTIONS

Acute Herpetic Gingivostomatitis

Acute herpetic gingivostomatitis is a manifestation of primary oropharyngeal HSV-1 infection. It develops most often in children between 6 months and 5 years of age, but it is being reported with increasing frequency in older children and adults. The source of infection is usually an adult who has herpes labialis or who is shedding HSV-1 asymptotically in saliva, but it may be another infected child. The incubation period is usually 3 to 6 days (range, 2 days to 2 weeks). Onset is abrupt, with temperatures as high as 102°F to 104°F (38.9°C to 40.6°C), anorexia, and listlessness. The mouth becomes sore before oral lesions appear, and the child is restless, irritable, and unwilling to eat or drink. Gingivitis is the most striking manifestation of the disease. The gums are first hyperemic and then become markedly swollen, reddened, friable, and exquisitely tender. They bleed easily, and there is a bright red line along the dental margin. Vesicular lesions develop on the oral mucous membranes; they begin as tiny vesicles surrounded by narrow zones of erythema but quickly rupture, leaving tender, round, 1- to 3-mm, shallow, yellowish gray, indurated ulcers or plaques. These often coalesce and are surrounded by a thin red halo. They can manifest anywhere on the mucous membrane of the mouth or pharynx but are most common on the tongue, the inner surface of the lips, and the buccal and sublingual mucosa. Lesions develop less frequently on the soft palate and on the gums themselves, occasionally in the pharynx, and rarely in the larynx. Herpetic epiglottitis, esophagitis, and otitis media are unusual complications.

The submandibular and anterior cervical lymph nodes are enlarged and tender. Salivation and drooling are marked, and the breath is fetid owing to overgrowth of anaerobic oral bacteria. Herpetic lesions often develop in areas of skin contaminated with infected saliva, which contains large quantities of HSV. Thus, many children develop herpetic vesicles in the perioral skin, and herpetic whitlow is seen in finger suckers. Autoinoculation also can result in herpetic vulvovaginitis and HSV infections of the eye. The disease is self-limited and without adverse effects in normal children, but it varies considerably in severity and duration. Although viremia is rarely documented, it probably occurs in many cases of uncomplicated herpetic gingivostomatitis. Primary infection with HSV-1 causes acute herpetic gingivostomatitis in adults as well as in children, but the disease is generally less severe, and pharyngitis is much more prominent. Perioral skin lesions are uncommon, and lesions produced by autoinoculation are rare.

Acute Herpetic Pharyngotonsillitis

In adults, primary oropharyngeal HSV-1 infection causes pharyngitis and tonsillitis much more frequently than gingivostomatitis. The illness begins with fever, malaise, headache, and sore throat. Tiny vesicles appear on the tonsils and posterior pharynx, but they quickly break down to form shallow ulcers that run together. A grayish yellow exudate forms on the tonsils and posterior pharynx in more than half of patients, but lesions in the anterior mouth or lips are seen in fewer than 10%. In college and university students, about 70% of whom are HSV seronegative, HSV is a major cause of pharyngitis and tonsillitis. Although most cases appear to be caused by HSV-1, HSV-2 is being isolated with increasing frequency, especially when pharyngotonsillitis is associated with orogenital contact or occurs in the course of symptomatic genital herpes.

The disease is usually indistinguishable in clinical manifestations from pharyngotonsillitis caused by the group A β -hemolytic streptococcus, and it also may be confused with infectious mononucleosis caused by Epstein–Barr virus, primary HIV infection, herpangina, diphtheria, tularemia, and pharyngotonsillitis associated with adenovirus and enterovirus infections. Persons seropositive for HSV as a result of previous herpetic pharyngotonsillitis are latently infected. They experience periodic asymptomatic shedding of HSV in saliva and subsequently may show signs of herpes labialis. Recurrences of infection do not appear to result in recurrent pharyngotonsillitis.

Herpes Labialis

Herpes labialis (cold sore, fever blister) is the most common manifestation of recurrent HSV-1 infection. Most patients (50% to 80%) have a prodrome of pain, burning, tingling, or itching at the site of the subsequent eruption, which usually precedes its onset by 6 hours or fewer but occasionally last 24 to 48 hours. This is followed by the appearance of a small cluster of erythematous papules that rapidly develop into tiny, thin-walled, intraepidermal vesicles. These generally become pustular and then either burst, leaving shallow ulcers, or dry and form a scab. Left undisturbed, the scab is displaced by the regrowth of epithelium. The evolution of the lesions is generally rapid, the papular stage lasting only a few hours and the vesicles crusting within 2 days. Lesion area (usually less than 100 mm²) and pain are maximal during the vesicular stage and decline rapidly thereafter. Healing is completed, with loss of scabs and without scarring, in 6 to 10 days. Patients sometimes have local lymphadenopathy but no constitutional symptoms.

The most common site of herpes labialis is the vermilion border of the lip (95%), usually the outer third and more often the lower lip than the upper. Other sites include the nose, the chin, the cheek, and, rarely, the oral mucosa. Although HSV occasionally provokes recurrent lesions of the oral mucosa, it is not the cause of recurrent aphthous ulcers, which afflict many persons with no history of HSV infection and no antibodies to HSV. Herpes labialis afflicts 20% to 25% of the adult population, but this figure varies with the prevalence of latent HSV-1 infection (i.e., of antibody to HSV-1) in the population surveyed. Most people subject to herpes labialis suffer fewer than two episodes per year, but a small minority have recurrences at intervals of a month or less. In a given person, the lesions generally recur at the same site, and the provoking factor (exposure to sunlight, menses, fever, stress) is often stereotypic.

The quantity of HSV present is highest during the first 24 hours, when the lesions are vesicular, and it declines steadily thereafter; rarely is virus recovered after 5 days. HSV is usually present in the saliva during episodes of herpes labialis, and it also can be recovered from 1% to 10% of saliva samples obtained when persons are free of disease, though the concentration of virus is considerably lower. Intraoral lesions are rarely present, and HSV is not recovered from parotid gland secretions. Thus, the source of virus in the saliva remains a mystery. Because of the very low rate of reactivation following primary oral–labial infections caused by HSV-2, HSV-2 is almost never isolated from cases of herpes labialis.

OCULAR HERPES SIMPLEX VIRUS INFECTIONS

Primary HSV infections of the eye are found most commonly in children, often as a result of autoinoculation during acute herpetic gingivostomatitis or asymptomatic primary oropharyngeal HSV infection. The conjunctiva also may be the portal of entry of HSV and infection of the eye the sole manifestation of primary HSV infection. Most infections are asymptomatic or unrecognized, but even when ocular disease is obvious, the causal role of HSV often is unappreciated. Except in newborns, HSV infection of the eye almost always is caused by HSV-1. When it is symptomatic, primary ocular HSV infection usually manifests as unilateral follicular conjunctivitis often accompanied by blepharitis and preauricular lymphadenopathy. There may be herpetic vesicles on the lid margins and periorbital skin. Symptoms typically include photophobia, excessive lacrimation, chemosis, and edema of the eyelids. Some primary infections involve the cornea, producing acute herpetic keratoconjunctivitis accompanied by pain and a foreign body sensation.

Primary infection results in the establishment of HSV latency in the trigeminal ganglion and is followed by periodic reactivation. Most reactivations are asymptomatic, with shedding of HSV in tears, but some result in symptomatic recurrences characterized by keratitis, blepharitis, or keratoconjunctivitis. Recurrences develop in at least 25% of patients who have symptomatic primary infection and in many persons who are seropositive with no history of disease. Recurrent infections tend to involve the underlying stroma; with repeated recurrences, there may be progressive corneal scarring and neovascularization, with eventual loss of vision. HSV is the leading infectious cause of blindness in the United States and other developed countries. Corneal transplantation is frequently performed for end-stage corneal scarring caused by HSV. Unfortunately, some recipients experience recurrent HSV infection of the graft, which is easily confused with allograft rejection. Corticosteroids exacerbate ocular HSV infections, and they are contraindicated unless accompanied by effective antiviral therapy. Acute retinal necrosis is a rare, rapidly progressive form of HSV retinitis that occurs in immunocompetent as well as in immunocompromised persons. It also can be caused by varicella-zoster virus.

HERPES SIMPLEX VIRUS INFECTIONS OF THE SKIN

Because of the resistance of the intact cornified epithelium, isolated exogenous HSV infections of the skin are uncommon in normal adults. When they do arise, they usually are associated with cutaneous trauma. Most primary cutaneous HSV infections develop in the course of acute herpetic gingivostomatitis or primary genital

herpes. The skin lesions typically result from autoinoculation or zosteriform spread from an infected mucosal site in the same dermatome. Vesicles tend to be discrete, rather than grouped, and heal without scarring in 7 to 14 days. A normal person with acute herpetic gingivostomatitis or primary genital herpes occasionally experiences widespread cutaneous dissemination, resulting in a varicella-like rash. This rash is accompanied by malaise and fever, but rarely is there serious visceral infection.

Regardless of their location or pathogenesis, cutaneous HSV infections result in the establishment of latency in corresponding sensory ganglia, and the patient is subject to recurrences. Because the virus responsible for recurrent infections originates in sensory ganglia and is transported to the skin by sensory nerves, the lesions of recurrent cutaneous herpes appear as grouped vesicles rather than the discrete vesicles seen in primary infections, and they may assume a segmental or dermatomal distribution that resembles that of herpes zoster. In contrast to herpes zoster, recurrent zosteriform HSV infections recur repeatedly in the same dermatome.

A prodrome of pain, burning, itching, or tingling usually heralds the herpetic eruption, preceding it by 2 or 3 hours (occasionally by up to 2 or 3 days). Lesions begin as grouped, erythematous papules that progress to vesicles, pustules, and crusts and then heal without scarring in 6 to 10 days. There is often regional lymphadenopathy, but constitutional symptoms are rare. Recurrent cutaneous herpes sometimes is associated with severe local neuralgia. Recurrences on the extremities may be accompanied by local edema, erythema, lymphangitis, and tender axillary or inguinal lymphadenopathy. Thus, they may be misdiagnosed as streptococcal cellulitis.

Traumatic Herpes (Herpes Gladiatorum, Scrumpox)

Primary cutaneous HSV infections occasionally appear in normal persons in the absence of oropharyngeal or genital herpes. Such lesions generally result from direct exogenous infection of skin rendered susceptible by trauma. They may develop when an adult shedding HSV in saliva “kisses away” the pain of a child’s abrasion or tends an infant with diaper rash. Primary cutaneous herpes also is seen in wrestlers and rugby players (herpes gladiatorum, scrumpox); presumably, traumatized skin is infected by contact with an adversary’s cutaneous lesions or virus-bearing saliva. In addition to local vesicular lesions, which are generally confined to the area of traumatized skin (usually the head, trunk, or extremities), regional lymphadenopathy and often constitutional symptoms are present. Recurrences are common, often heralded by a prodrome of pain, burning, tingling, or itching. They frequently are accompanied by regional lymphadenopathy but almost never by symptoms of systemic illness. Herpes gladiatorum is endemic in many groups of high school and college wrestlers, with reported attack rates exceeding 50%. In this context, the primary mode of transmission appears to be direct skin-to-skin contact.

Herpetic Whitlow

Herpetic whitlow (herpetic paronychia) is a painful HSV infection of a terminal phalanx ([Fig. 312.1](#)). The thumb or index finger is most often affected, and the portal of entry is usually a damaged cuticle. Involvement of more than one finger is uncommon. In children, it is frequently caused by HSV-1 and occurs in the course of primary oropharyngeal infection as a result of finger sucking. The source of infection also may be an adult who kisses away the pain of an injured finger. In adults, herpetic whitlow is a preventable (by using gloves) occupational disease of medical and dental personnel exposed to oropharyngeal secretions containing HSV-1. The majority of adult cases are caused by HSV-2, acquired by autoinoculation during concurrent genital herpes. Although it can appear in persons with preexisting antibodies to HSV-1 or HSV-2, most initial episodes of herpetic whitlow are primary exogenous infections.

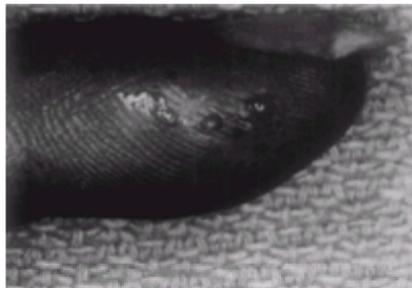

FIGURE 312.1. Herpetic whitlow. The terminal phalanx of the index finger of a respiratory therapist is exquisitely painful, swollen, and erythematous, with multiple deep and superficial vesicles. Herpes simplex virus type 1 was isolated from vesicle fluid. (From Oxman MN. Herpes stomatitis. In: Braude AI, Davis CE, Fierer J, eds. *Infectious diseases and medical microbiology*, second ed. Philadelphia: WB Saunders, 1986:752–772, with permission.)

The whitlow begins 2 to 7 days after exposure, with intense itching, pain, and erythema in the infected finger. Within a day, a deep vesicle appears, soon followed by others, which tend to coalesce. The process continues, destroying considerable tissue. In many cases, there appears to be pus under the cuticle, but incision discloses only a little clear fluid or, at a later stage, thick, yellow necrotic debris. Intense local pain is always present. Systemic symptoms and epitrochlear or axillary lymphadenopathy are common, and lymphangitis and neuralgia may occur. The lesions tend to progress for about 10 days, during which time pain persists unabated. There is then abrupt improvement, and the lesions begin to dry. Resolution is usually complete in 18 to 20 days. If the lesion is incised, the period of disability is prolonged, and there is risk of secondary bacterial infection.

Recurrences at the same site are typical; they are often as painful as the primary infection but are shorter in duration and rarely accompanied by constitutional symptoms. The recurrent whitlow is frequently heralded and accompanied by severe neuralgic pain in the hand and arm, and it is often associated with swelling and edema of the hand, lymphangitis, and regional lymphadenopathy. Herpetic whitlow is often confused with bacterial paronychia. When it is associated with lymphangitis and lymphadenopathy, it can be confused with streptococcal cellulitis. Prompt diagnosis is essential to avoid transmission (herpetic whitlow is an important source of nosocomial HSV infection) and inappropriate attempts at surgical drainage.

Herpes Simplex Virus Infections of Abnormal Skin

Cutaneous HSV is often severe and life threatening in patients with disorders of the skin, such as eczema, Darier disease, pemphigus, or burns, which permit more extensive local virus replication and spread and facilitate visceral dissemination. Infection may be acquired nosocomially or by autoinoculation from symptomatic oropharyngeal or genital lesions or asymptomatic virus shedding. Innumerable vesicular lesions can spread throughout the affected skin—a syndrome known as eczema herpeticum or Kaposi varicelliform eruption. The lesions may be ulcerative and nonspecific in appearance, though careful examination may uncover vesicles, especially in adjacent normal skin. Thus, diagnosis requires careful examination and clinical vigilance, with prompt biopsy and culture for virus. Patients are febrile and toxic and, without antiviral therapy, can die from widespread visceral dissemination. Enormous amounts of virus are present in the lesions, and such patients are often a source of nosocomial infections. Recurrences are common; while they may be extensive, they are usually less severe than the primary infection.

CENTRAL NERVOUS SYSTEM HERPES SIMPLEX VIRUS INFECTIONS

In children and adults, central nervous system infections with HSV are relatively uncommon complications of primary or recurrent HSV infections at peripheral sites. In contrast, central nervous system infection is a major component of neonatal HSV infection, occurring in at least 50% of affected newborns.

Herpes Simplex Encephalitis

Herpes simplex encephalitis is an acute necrotizing viral encephalitis that, beyond the neonatal period, nearly always is caused by HSV-1. It has a higher mortality rate than most other forms of viral encephalitis—greater than 70% in the absence of specific therapy. Although it is rare, this form of encephalitis is the most common cause of sporadic acute necrotizing encephalitis in the United States, with an annual incidence estimated to be two to three per million. In contrast to most other forms of viral encephalitis, there are no seasonal epidemics, and cases manifest throughout the year. Serologic data indicate that herpes simplex encephalitis takes the form

of a primary infection in about 30% of patients and a recurrent infection in the remainder, but there is no obvious difference between the two groups in initial symptoms, clinical course, or outcome.

The mode of manifestation, clinical features, and side effects are determined largely by the nature and distribution of the pathologic process—acute asymmetric necrotizing encephalitis that involves primarily the orbitofrontal and temporal cortex and the limbic system. Although the manifestations and rates of progression vary, most patients have two recognizable groups of findings: (a) nonspecific changes seen in most forms of encephalitis, which include fever (present in more than 90%), headache, signs of meningeal irritation, nausea, vomiting, global confusion, generalized seizures, and alteration of consciousness, and (b) changes referable to focal necrosis of the orbitofrontal and temporal cortex and the limbic system, which include anosmia, memory loss, peculiar behavior, defects of speech (especially expressive aphasia), hallucinations (particularly olfactory and gustatory hallucinations), and focal seizures. There is rapid progression in some cases, with the appearance of reflex asymmetry, focal paralysis, hemiparesis, and coma. Cerebral edema contributes to these manifestations and plays an important role in the outcome of the disease. Other patients have a more protracted course, with several days of mild, nonspecific illness punctuated by intermittent periods of bizarre behavior alternating with lethargy or sleep. These patients may present a picture of acute psychosis or delirium tremens and be admitted to the hospital for psychiatric care until the appearance of localizing neurologic signs, seizures, and coma alerts their physicians to the severe organic nature of their disease. Rarely, patients have initial symptoms of a brain stem encephalitis that bears little resemblance to the usual case of herpes simplex encephalitis.

Cerebrospinal fluid (CSF) examination usually shows mononuclear pleocytosis (50 to 500 cells per microliter); there are often 10% to 25% neutrophils, and neutrophils may predominate early in the disease. Red blood cells are present initially in 40% and at some time in more than 80% of cases. The protein concentration generally is elevated (50 to 200 mg per deciliter) and often increases markedly over time. Initially, the glucose concentration is often normal (5% of patients have hypoglycorrhachia), but it may be depressed later in the context of extensive cerebral necrosis. Some 5% to 10% of patients have normal CSF on first examination. Magnetic resonance imaging appears to be the most sensitive imaging procedure. The results of electroencephalography are almost always abnormal, and this method often localizes the area of maximum involvement; a pattern of periodic sharp wave or spike-and-wave complexes (periodic lateralized epileptiform discharges) on a background of arrhythmic slow wave activity is characteristic but not pathognomonic.

Detection of HSV DNA in CSF after polymerase chain reaction (PCR) amplification provides a rapid and definitive diagnosis. The sensitivity and specificity of this technique approach 100%, and it has replaced brain biopsy as the primary means of establishing the diagnosis of herpes simplex encephalitis. Antibodies to HSV generally appear in the CSF, but they are rarely detectable until 10 days or more after onset and are thus not helpful in establishing an early diagnosis. Mortality and morbidity rates can be minimized by early initiation of antiviral therapy, but 5% or more of patients suffer a clinical relapse after antiviral therapy has been discontinued. The efficacy of more prolonged antiviral therapy is under investigation. It has been proved on brain biopsy that more than half of patients thought to have herpes simplex encephalitis have another condition, including 9% with other treatable diseases. Thus, the diagnosis should be vigorously pursued, usually with brain biopsy, if PCR analysis of the CSF fails to identify HSV DNA.

Herpes Simplex Meningitis

Herpes simplex meningitis is an acute, generally benign lymphocytic meningitis that develops in otherwise normal adults, often in association with primary genital herpes. Most documented cases have been caused by HSV-2, which can often be isolated from the CSF. Symptoms, which include headache, fever, photophobia, nausea and vomiting, myalgia, and nuchal rigidity, usually resolve in about a week, but 15% to 25% of patients experience one or more recurrences, sometimes in association with an episode of recurrent genital herpes. Herpes simplex meningitis has been observed in children, from whose CSF HSV-1 has been isolated. The detection of HSV DNA in the CSF after PCR amplification has established HSV, predominantly HSV-2, as the principal cause of benign recurrent lymphocytic (Mollaret) meningitis.

Ganglionitis and Myelitis Associated with Herpes Simplex Virus Infections

Genital and anorectal HSV infections may be complicated by lumbosacral ganglionitis, radiculitis, and ascending myelitis. Clinical manifestations include urinary retention, obstipation, abdominal and lower extremity muscle weakness, paresthesia and anesthesia over sacral dermatomes, and severe sacral neuralgia. These symptoms usually resolve spontaneously after a week or two, but some, especially sacral neuralgia, recur in association with episodes of recurrent genital or anorectal herpes.

GENITAL HERPES SIMPLEX VIRUS INFECTIONS

Because of their extensive cross-reactivity, HSV-1 and HSV-2 both induce heterologous humoral and cell-mediated immune responses. Consequently, infection with one HSV serotype limits susceptibility to infection by the other and moderates the severity of those infections that do occur. The prevalence of antibodies to HSV-2 is lower in women with antibodies to HSV-1 than in HSV-1-seronegative women, indicating that HSV-1 infection, presumably acquired in childhood, provides partial protection against subsequent HSV-2 infection. Women with antibodies only to HSV-2 are more likely to have a history of symptomatic genital herpes than women with antibodies to both viruses, indicating that preexisting immunity to HSV-1 diminishes the severity of any HSV-2 infections, so that a higher proportion are subclinical. The protective effect of previous HSV-1 infection has been confirmed by prospective transmission studies in couples discordant for antibodies to HSV-2. The risk of acquiring HSV-2 infection is three to four times greater in women who lack antibodies to both HSV-1 and HSV-2 than in women with previously acquired antibodies to HSV-1.

Prospective clinical studies have shown that initial episodes of genital herpes caused by HSV-2 are less severe in patients with serologic evidence of previous HSV-1 infection than in those with no preexisting antibodies to HSV. In addition, initial episodes of genital herpes caused by HSV-1 are extremely rare in patients with preexisting antibodies to HSV-1, indicating that previous (presumably oropharyngeal) HSV-1 infection protects against genital herpes caused by the same HSV serotype. Finally, most initial HSV-2 infections are asymptomatic, but they still result in the establishment of latent infections that are subject to periodic reactivation. Consequently, many people experiencing their first recognized episode of symptomatic genital herpes are not, as they believe, experiencing an initial episode of exogenous infection. Instead, they are suffering their first symptomatic recurrence caused by reactivation of a latent infection established in the course of an earlier asymptomatic or unrecognized exogenous HSV infection. Such episodes frequently result in confusion and consternation, especially when they occur in one member of a monogamous couple, neither of whom has any history of recognized genital herpes. In this situation, imparting a clear understanding that the source of the virus responsible for the episode may be endogenous rather than exogenous is often more therapeutic than antiviral therapy.

These considerations, which are important in counseling patients and in evaluating any forms of treatment or prophylaxis, lead us to classify an initial episode of clinically manifest genital herpes as a primary infection if it arises in a person with no previous HSV infection at any site, as evidenced by the absence of antibodies to HSV-1 and HSV-2; as an initial nonprimary infection if it occurs in a person with preexisting antibodies to the heterologous HSV serotype (e.g., a first episode of symptomatic genital herpes caused by HSV-2 in a person with preexisting antibodies to HSV-1); and as a recurrent infection if it develops in a person with preexisting antibodies to the same HSV serotype. The average duration and severity of manifestations of clinical disease are greater in primary than in nonprimary first episodes of genital herpes, and episodes of recurrent genital herpes are usually the shortest and least severe. There is sufficient overlap, however, that distinctions are often difficult to make on clinical grounds in individual patients; even in referral clinics with experienced clinicians, almost 10% of persons judged to have a first episode of genital herpes prove to have a recurrent infection, and the proportion is substantially higher in pregnant women.

Acute Herpetic Vulvovaginitis in Infants and Children

In young infants and children, acute herpetic vulvovaginitis may result from autoinoculation during symptomatic or asymptomatic primary oropharyngeal HSV-1 infection or from contact with an adult shedding HSV (e.g., when diapers are changed). Because it also may result from sexual abuse (in which case, it may be caused by HSV-2), its occurrence warrants a thorough and sensitive appraisal of the child's social situation and possible contacts. Every attempt should be made to isolate and type the responsible virus, which then should be saved for comparison with isolates from suspected contacts. Symptoms include fever and malaise, and the perineal area is red, edematous, and studded with tiny vesicles that rapidly evolve into shallow, yellowish white ulcers 2 to 4 mm in diameter. The lesions are extremely painful and often coalesce to form large ulcers. HSV urethritis is generally present, and dysuria may lead to urinary retention. The inguinal lymph nodes are enlarged and tender. Fever and constitutional symptoms subside in a week, and healing is complete without scarring within 12 to 18 days.

Primary and Initial Nonprimary Genital Herpes

The incubation period after sexual contact is usually 3 to 7 days, with a range of 1 day to more than 2 weeks. Most infections in both sexes are asymptomatic, but symptomatic primary genital herpes is more severe in women than in men. Women have a larger total area of lesions, more intense and prolonged local symptoms,

more frequent constitutional symptoms, more numerous extragenital lesions, and more complications. They have a higher rate than men of dysuria (83% versus 44%), urethritis (85% versus 27%), meningitis (93% versus 13%), and pharyngitis (13% versus 7%). Primary genital herpes in women often begins with the appearance of herpetic vesicles, but this may be preceded by a short period of local burning, tenderness, and erythema of the labia minora and vaginal introitus. Typical herpetic vesicles first appear on the external genitalia, typically involving the labia majora, labia minora, vaginal vestibule, and introitus. New lesions continue to appear bilaterally in the same areas, and the eruption often extends to the mons pubis, clitoris, urethral orifice, perianal skin, buttocks, and thighs. In most areas within the labia minora, vesicles quickly rupture, leaving shallow, exquisitely tender ulcers covered with a yellowish gray exudate and surrounded by a red areola ([Fig. 312.2](#)). In drier areas, such as the outer surface of the labia majora and the adjacent skin, vesicles may remain intact, evolve into pustules, and then crust in several days.

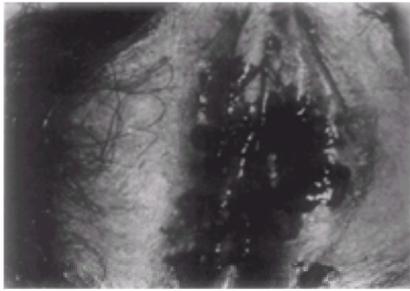

FIGURE 312.2. Primary genital herpes in a female patient. This young woman with primary herpetic vulvovaginitis has shallow, exquisitely tender ulcers on the inner surface of the labia majora, the labia minor, and the vaginal mucosa. The ulcers are covered with a yellowish gray exudate and surrounded by a narrow zone of erythema. Further examination shows herpetic cervicitis. (From Oxman MN. Genital herpes. In: Braude AI, Davis CE, Fierer J, eds. *Infectious diseases and medical microbiology*, second ed. Philadelphia: WB Saunders, 1986:1041–1054, with permission.)

New lesions continue to appear for a week or more. They are often extensive and may coalesce, forming bullae and large areas of ulceration that resemble a second-degree burn. The vaginal mucosa and vulva are inflamed and edematous. The cervix is almost always involved, and there is usually a profuse watery vaginal discharge. Examination typically reveals diffuse friability of the cervical epithelium; sometimes there is extensive ulceration and, occasionally, severe necrotic cervicitis. Herpetic cervicitis is sometimes the only clinical manifestation of primary genital herpes. Most patients have severe vulvar pain, exquisite tenderness of the affected tissues, and dysuria, which is sometimes severe enough to cause urinary retention. Dysuria nearly always is associated with urethritis and the presence of HSV in the urine. HSV appears to be present in the urine in a higher proportion of patients with primary genital herpes caused by HSV-1 than by HSV-2.

Most infected women have constitutional symptoms, including fever, headache, malaise, and myalgias, which usually peak during the first 3 to 4 days and disappear by the end of the first week. They also experience bilateral painful inguinal and pelvic lymphadenopathy. The local symptoms generally worsen during the first week, reach a peak between days 8 and 10, and gradually subside. Even when it is severe, primary genital herpes is normally self-limited. Virus replication is maximal during the first 3 to 4 days and declines thereafter; the mean duration of virus shedding is 11 to 12 days, though a few patients shed virus for several weeks. Pain usually remits in 10 to 14 days, and healing takes place without scarring in 2 to 4 weeks. Mucosal lesions heal without crusting. The cervix appears to be the source of virus that may be shed for weeks after visible lesions have healed and symptoms have disappeared.

In men, the lesions of primary genital herpes usually appear bilaterally on the glans penis, the prepuce, and the shaft of the penis and less often on the scrotum, thighs, and buttocks. Their evolution is similar to that in women. In dry skin (on the shaft of the penis), they progress from papule to vesicle to pustule to crust and then heal, as a rule by the middle of the third week. In moist areas (under the prepuce), the vesicles are quickly macerated and evolve into ulcers identical to those described in women. New lesions continue to appear for a week or more, and there is local pain, tenderness, inflammation, and edema. Dysuria, usually associated with herpetic urethritis and accompanied by a small amount of clear mucoid urethral discharge, develops in 30% to 40% of men with primary genital herpes. It is generally more painful than the dysuria of gonococcal or nongonococcal urethritis, and HSV typically can be isolated from urethral swabs. There is bilateral tender inguinal and pelvic lymphadenopathy, but it is less severe and of shorter duration than in women. Less than half of men with primary genital herpes have significant constitutional symptoms. Virus is present in large amounts during the first 3 to 5 days, and the mean duration of virus shedding is 10 to 11 days. Pain usually resolves during the second week, and healing ensues without scarring in 2 to 3 weeks.

The clinical manifestations and course of primary genital herpes caused by HSV-1 and HSV-2 are indistinguishable, but the rate of subsequent recurrences is lower after primary genital herpes caused by HSV-1. The clinical manifestations of initial nonprimary genital herpes are similar to those of primary genital herpes, but the disease is less severe and of shorter duration. There is a marked decline in the incidence of constitutional symptoms, extragenital lesions, and complications, and a smaller proportion of women shed HSV from the cervix.

Recurrent Genital Herpes

In all, 60% to 90% of individuals with symptomatic primary or initial nonprimary genital herpes experience one or more episodes of recurrent genital herpes during the subsequent year. The recurrence rate is lower for HSV-1 than for HSV-2. The mean monthly rate of recurrence for genital herpes caused by HSV-1 is 0.08, compared with 0.34 for genital herpes caused by HSV-2, and approximately 40% of HSV-2-infected patients will have six or more recurrences per year. This is probably why HSV-1 is isolated from 10% to 40% of patients with primary genital herpes but from only 1% to 5% of patients with recurrent disease. A study of patients with concurrent genital and oropharyngeal infections with the same HSV serotype showed that the oropharyngeal recurrence rate is higher for HSV-1 (0.12 per month) than for HSV-2 (0.001 per month). These differences in site-specific recurrence rates may reflect the adaptation of HSV-1 and HSV-2 to different anatomic niches. The rate of symptomatic recurrence is approximately 20% higher in men than in women.

Recurrent genital herpes is generally less severe and of shorter duration than either primary or initial nonprimary genital herpes. Although the same sites tend to be affected, there are fewer lesions, the area involved is more circumscribed, and the lesions often are unilateral. Most patients have a prodrome of tenderness, pain, burning, tingling, or itching at the site of the impending eruption, beginning from a few hours to 1 or 2 days before the appearance of lesions. Some have a prodrome of ipsilateral sacral neuralgia, with severe burning, aching, or lancinating pain in the leg, buttock, or genital area. The lesions of recurrent genital herpes begin as clusters of tiny erythematous papules, which quickly develop into clusters of tiny vesicles on an erythematous base. They sometimes coalesce, and they evolve in the same manner as in primary genital herpes but more rapidly. There is less pain, fewer days of new lesion formation, and a much smaller total area of lesions.

The clinical manifestations of recurrent genital herpes are more severe in women than in men. In women, the lesions are almost always painful. Most often they are located on the labia minora, labia majora, or perineum, but they may manifest on the mons pubis, perianal skin, or buttocks. Some women have linear ulcerations in the fourchette, which resemble inflamed excoriations and often are not recognized as herpetic by patients or their physicians. Lymphadenopathy may be present, but fever and constitutional symptoms are uncommon; only about one-fourth of women with recurrent genital herpes have dysuria. Virus is present in much smaller amounts in recurrent than in primary herpetic lesions (mean peak titers of 103 plaque-forming units or fewer per swab versus 105 plaque-forming units or more per swab); virus is shed for an average of 5 days, and its recovery after the seventh day is uncommon. Pain disappears during the first week, and the lesions generally heal within 8 to 10 days. The rate of positive results on cervical culture (5% to 10%) is much lower during recurrent than during primary episodes of genital herpes. Furthermore, there are no visible cervical lesions, and the amount of virus present is at least 1,000-fold less than the amount present during primary infections.

In men, recurrent genital herpes most often manifests in the form of one or more patches of grouped vesicles on the shaft of the penis, prepuce, or glans ([Fig. 312.3](#)). Lesions, which are usually unilateral, begin as papules and, on dry skin, evolve into vesicles, pustules, and crusts in the same manner as the lesions of herpes labialis. Under the prepuce, vesicles are quickly macerated, forming shallow, painful ulcers. There may be mild inguinal lymphadenopathy, but constitutional symptoms are rare, and urethritis is uncommon. Urethral cultures show positive results for HSV in less than 5% of men with recurrent genital herpes. The titer of virus is lower in recurrent than in primary lesions, and HSV rarely can be recovered after 4 to 5 days. Pain is present in about 60% of men with recurrent genital herpes. It is usually mild and disappears with the virus. Lesions heal in 7 to 10 days.

FIGURE 312.3. Recurrent genital herpes in a male patient. A typical patch of grouped vesicles on an erythematous base is seen on the shaft of the penis. (From Oxman MN. Genital herpes. In: Braude AI, Davis CE, Fierer J, eds. *Infectious diseases and medical microbiology*, second ed. Philadelphia: WB Saunders, 1986:1041–1054, with permission.)

In approximately 5% of patients, recurrent herpes genitalis may appear initially as a single, large, shallow, minimally tender ulcer, up to 1 cm in diameter, that has a clean, granular base and a sharply demarcated border. This lesion, which has been called a *herpetic chancre*, can be mistaken for a syphilitic chancre. Because herpes genitalis and syphilis can coexist in the same patient, diagnosis on the basis of laboratory tests is essential. Symptomatic genital HSV infections are only the tip of an iceberg. The majority of initial primary and nonprimary genital HSV infections are asymptomatic or unrecognized, and 70% to 80% of people with antibodies to HSV-2 have no history of symptomatic genital herpes. Nevertheless, these seropositive individuals are infected latently and experience periodic virus reactivation, as evidenced by virus shedding. The majority of these reactivations also are asymptomatic or unrecognized. Consequently, episodes of asymptomatic virus shedding are far more frequent than episodes of symptomatic recurrent genital herpes.

The rate of asymptomatic virus shedding is generally 1% to 2% in immunocompetent persons with antibody to HSV-2, but it is substantially higher (6% or more) in the first few months after initial HSV-2 infection, in the days immediately before and after a symptomatic recurrence, and in individuals with a high rate of symptomatic recurrence. HSV DNA can be detected by PCR at a rate approximately eight times higher than that reported for infectious virus, but the biologic significance of low levels of HSV DNA in the absence of infectious virus remains to be determined. Asymptomatic shedding appears to be at least as common from the usual lesion site on the vulva as from the cervix, and anal shedding is documented frequently.

The epidemiologic importance of asymptomatic genital HSV infection is underscored by the fact that most new cases of genital herpes are acquired from a partner shedding HSV asymptotically who has no history of recognized HSV infection. It is also evidenced by the observation that the majority of mothers of infants with neonatal herpes have had no signs or symptoms of genital herpes during pregnancy and no history of symptomatic genital herpes.

Complications of Genital Herpes

Although genital herpes is often physically and mentally distressing, in the normal host it is almost always self-limited and usually resolves spontaneously without major complications or adverse effects. Complications can be divided into three categories: bacterial or fungal superinfection, extragenital infection or aberrant behavior by the virus in an apparently normal person, and HSV infections in compromised hosts.

Bacterial and fungal superinfections are surprisingly uncommon. Rarely, balanoposthitis develops on the prepuce of an uncircumcised male due to bacterial superinfection of herpetic ulcers, and candidal balanitis is seen occasionally. Ulcerative lesions in moist skin areas may become superinfected. *Candida* vaginitis occurs in about 10% of women with primary genital herpes and is more common in patients with diabetes. These complications typically respond to local therapy and rarely require systemic antibiotics.

Most complications of genital herpes result from infection of extragenital sites. Virus may reach these sites by direct extension, autoinoculation, viremia, or neural (zosteriform) spread. Extragenital sites also may be infected exogenously at the time of genital infection, for example, concurrent oral and genital HSV-1 infection may result from exposure to infected saliva. These complications are much more common in primary than in initial nonprimary infections, and they are also more common and generally more severe in women than in men. Once established, these extragenital HSV infections may recur, but they rarely are initiated during episodes of recurrent genital herpes.

The cervix is infected in almost every woman with symptomatic primary genital herpes and in many asymptomatic cases as well. On occasion, the cervical infection may be extremely severe, producing necrotic cervicitis. Symptoms include profuse vaginal discharge; dysuria; abdominal, pelvic, or genital pain; and constitutional symptoms. The cervix is extremely tender, bleeds easily, and exhibits extensive superficial necrosis with sloughing of necrotic epithelium. Healing takes place spontaneously in 2 to 3 weeks. Herpetic cervicitis may be seen in the absence of other genital lesions. Now and then, extensive herpetic infection of the glans penis can produce necrotizing balanitis. Misdiagnosis and inappropriate therapy are typical.

Herpetic urethritis frequently accompanies primary genital herpes, arising in 20% to 40% of men and more than 80% of women. Typical herpetic lesions may be visible near the urethral meatus, or they may be intraurethral. There is usually severe burning pain on micturition but minimal discharge. Typical intranuclear inclusion bodies and multinucleated giant cells may be found in urethral smears. The urethritis may recur, with or without recurrent genital lesions, and herpetic urethritis may sometimes be the only clinical manifestation of primary genital herpes. Herpetic cystitis also has been observed in patients with primary genital herpes and may account for some instances of dysuria and urinary retention. Virus can reach the bladder by direct extension from the urethra or by neural transmission from infected sacral ganglia. The presence of cystitis caused by HSV-1 in adults with oropharyngeal HSV infection suggests that the bladder also may be infected as a result of viremia.

During an episode of primary genital herpes, cutaneous lesions frequently appear on the buttocks, thighs, or other areas of skin below the waist. They can result from contiguous spread, zosteriform neural transmission from newly infected sacral ganglia, or autoinoculation. When these lesions recur (typically in the absence of genital lesions), they can resemble herpes zoster and often are associated with a prodrome of deep neuralgic or sciatic pain. Frequent recurrence distinguishes this syndrome of "zosteriform herpes simplex" from true herpes zoster caused by varicella-zoster virus, which rarely recurs in the same dermatome. Many patients with zosteriform herpes simplex have never had a recognized episode of genital herpes. Nevertheless, they still have asymptomatic genital shedding of HSV and require counseling regarding transmission of infection to sexual partners.

From 10% to 30% of patients with primary genital herpes caused by HSV-1 or HSV-2 experience symptomatic herpetic pharyngotonsillitis, often as the first manifestation of HSV infection. In most cases, virus probably is introduced directly by oral–oral or oral–genital contact, but it may reach the pharynx by viremia. Clinical manifestations range from mild erythema to severe exudative pharyngotonsillitis, which may even result in pharyngeal obstruction. Most patients have constitutional symptoms and anterior cervical lymphadenopathy. Many are misdiagnosed as having streptococcal pharyngitis or infectious mononucleosis, especially if genital signs and symptoms are absent or ignored.

Autoinoculation of the finger during an episode of primary genital herpes may result in a herpetic whitlow that is indistinguishable from the forms of whitlow that develop in hospital personnel as a result of contact with HSV-1 in saliva and respiratory secretions. Most cases of herpetic whitlow in adults now are associated with primary genital herpes and are caused by HSV-2. These troublesome lesions are seen primarily in women and tend to recur. Autoinoculation occasionally results in skin lesions at other sites and appears to be responsible for herpetic keratoconjunctivitis, which may be seen in as many as 1% of patients with primary genital herpes.

Anorectal herpes and herpetic proctitis may be complications of genital herpes in women, the virus traveling from the vulva to the perineum, anus, and anal canal directly or by zosteriform spread from infected sacral ganglia. Most cases, however, result from anal intercourse, and the disease is seen most frequently in homosexual men. Typical herpetic lesions arise on the perianal skin and in the anal canal, where they frequently coalesce, producing an ulcerative cryptitis. Pain is severe, frequently radiating to the groin, buttocks, and thighs. There is often a serous rectal discharge and bilateral inguinal adenopathy, and constitutional symptoms are common. Pain in the anal canal usually results in reflex inhibition of defecation and sometimes tenesmus. In spite of its severity, the disease is self-limited;

symptoms resolve, and healing typically takes place without scarring in 2 to 4 weeks. Recurrent attacks of anorectal herpes are common after primary infections.

Primary genital or anal herpes sometimes is complicated by urinary retention, which may be accompanied by sacral neuralgia, impotence, and blunting of sensation over the sacral dermatomes. Patients with this syndrome have hypotonic bladders and CSF pleocytosis, indicating that urinary retention reflects acute herpetic ganglionitis or lumbosacral radiculomyelitis. This complication of genital herpes normally resolves spontaneously without residual effects in 7 to 10 days; the only report of prolonged dysfunction was in a patient treated with corticosteroids.

Recurrent genital herpes and recurrent zosteriform herpes simplex involving the skin below the waist may be associated with severe local neuralgia, usually in an L5-S1 dermatome distribution. When recurrent herpetic lesions and neuralgia affect the extremities, there may be local edema and lymphangitis, which can lead to a misdiagnosis of bacterial cellulitis. Neuralgia may precede the eruption by several days and usually resolves along with the cutaneous lesions. Although resolution is generally complete and multiple recurrences occur without permanent residual effects, repeated attacks over a period of years sometimes can result in chronic pain and permanent sensory and motor deficits. A similar syndrome occasionally is seen with recurrent herpetic whitlow.

Genital herpes sometimes disseminates in immunocompromised patients, producing widespread cutaneous lesions or fatal involvement of several visceral organs, especially the liver. This highly lethal complication of genital herpes, seen most often in organ allograft recipients in the first month after transplantation, is usually a consequence of reactivation of latent endogenous HSV infection, though it may result from exogenous infection introduced by the transplanted organ. It can be prevented by the use of acyclovir prophylaxis. Asymptomatic shedding of HSV-2 is markedly amplified in immunocompromised patients.

The diseases to be considered in the differential diagnosis of herpes genitalis and its complications include syphilis, chancroid, lymphogranuloma venereum, gonorrhea, nongonococcal urethritis, chlamydial urethritis, granuloma inguinale, herpes zoster, erythema multiforme, Behçet syndrome, mucocutaneous manifestations of inflammatory bowel disease, contact dermatitis, candidiasis, trichomoniasis, bacterial folliculitis, and impetigo. Multinucleated giant cells with eosinophilic intranuclear inclusion bodies indicate the presence of either HSV or varicella-zoster virus; direct detection and identification of HSV antigens or nucleic acids or virus isolation can give the specific diagnosis. PCR assays of the CSF can distinguish enteroviral from HSV aseptic meningitis. Because patients often have more than one STD, it is important to rule out other possibilities (e.g., syphilis) as well as HIV infection, even when an HSV infection is documented.

NEONATAL HERPES SIMPLEX VIRUS INFECTION

One of the most serious complications of genital herpes is the transmission of infection in a pregnant woman to her newborn infant. The infant usually is infected perinatally during passage through the birth canal of a mother with asymptomatic genital herpes. In some cases, ascending infection occurs shortly before birth, typically in a woman with prolonged rupture of membranes. Ascending infection can also be iatrogenic, introduced by a fetal monitor. The risk of neonatal infection is estimated to be 30% or more for infants born to mothers with an initial primary HSV infection acquired late in pregnancy who have not developed measurable levels of neutralizing antibody before the onset of labor, and the risk is greater from a primary than a nonprimary maternal infection. Conversely, the risk is much lower (probably less than 1%) when virus shedding at term results from recurrent infection or even from an initial primary or nonprimary HSV infection acquired early enough in gestation for complete seroconversion to take place before the onset of labor.

Congenital infection, a consequence of primary maternal HSV infection earlier in pregnancy, is responsible for 3% to 5% of cases among neonates. Some infants acquire infection postnatally from the mother, other family members, or nursery personnel with nongenital HSV infections or by nosocomial transmission from another infected infant. One-third of neonatal HSV infections are now caused by HSV-1. The overall rate of neonatal HSV infection in the United States is estimated to be 1 in 3,000 to 9,000 live births. Antiviral therapy has lowered the mortality rate and increased the proportion of survivors who function normally at 1 year of age. Early recognition of neonatal HSV infections is hampered by the absence of skin lesions in 30% or more of infected infants.

HERPES SIMPLEX VIRUS INFECTIONS AT OTHER SITES

Transient viremia is probably common during primary HSV infections in normal persons, but host defense mechanisms generally limit virus replication and spread so that foci of hematogenous infection in the skin and internal organs remain subclinical. These host defenses also limit the direct extension of HSV infection from the oropharynx to the trachea and esophagus. Nevertheless, clinically manifest disease due to hematogenous dissemination or direct extension of HSV infection does develop in normal hosts, though it is much more common in immunocompromised patients.

Disseminated Herpes Simplex Virus Infections

Primary oropharyngeal and genital HSV infections in apparently normal children and adults occasionally are complicated by clinically significant viremia, with cutaneous or visceral dissemination. This may even happen during otherwise asymptomatic primary infections, in the absence of signs or symptoms of disease at the portal of entry. In most cases, clinically significant dissemination is confined to the skin, producing an illness that is virtually indistinguishable from varicella (except when oropharyngeal or genital lesions are present). The illness is self-limited and resolves in 7 to 14 days, but skin lesions often recur.

Rarely, there is severe, often fatal visceral dissemination, which may or may not be accompanied by vesicular lesions in the skin. Several organs are involved, but fulminant HSV hepatitis is usually predominant, and it is generally accompanied by leukopenia, thrombocytopenia, and disseminated intravascular coagulation. This syndrome, fatal in the majority of untreated cases, occurs with greatest frequency in pregnant women, typically during the third trimester. Some cases have been associated with primary oropharyngeal HSV-1 infections, but most have accompanied primary genital herpes caused by either HSV serotype. The disease in these pregnant women resembles that observed in renal transplant recipients and other immunosuppressed patients and in the neonate. HSV-specific cellular immunity is depressed during the third trimester of pregnancy, which may explain the susceptibility of pregnant women to disseminated HSV infection. Disseminated HSV-1 and HSV-2 infections in apparently normal children and adults have been associated with herpetic esophagitis, adrenal necrosis, interstitial HSV pneumonitis, HSV cystitis, monarticular HSV arthritis, HSV meningitis, and, now and then, HSV encephalitis.

Respiratory Tract and Gastrointestinal Tract Infections Caused by Herpes Simplex Virus

Herpetic tracheobronchitis due to aspiration of oropharyngeal secretions containing HSV-1 may develop in apparently normal persons. This happens most often in the elderly and in association with endotracheal intubation. Clinical manifestations range from asymptomatic infection to severe tracheobronchitis with widespread mucosal ulceration. Focal or multifocal HSV pneumonitis can result from further aspiration or contiguous spread of infection, and these patients often have concurrent HSV esophagitis. Viremic infection of the lungs, more common in immunosuppressed patients, is rare in immunocompetent persons; it results in bilateral interstitial pneumonia. Diagnosis is complicated by contamination of specimens with HSV shed asymptotically in saliva.

HSV esophagitis, a commonplace manifestation of HSV infection in immunocompromised patients, also can develop in otherwise normal children and adults, especially in the presence of a nasogastric tube. Initial signs are fever, odynophagia, dysphagia, substernal pain, and, infrequently, hematemesis, but it is often asymptomatic. Endoscopy shows typical shallow herpetic ulcers of the esophageal mucosa. Herpetic esophagitis usually stems from direct extension of symptomatic oropharyngeal infection or from infection of traumatized esophageal mucosa by HSV shed in saliva, but it can be a recurrent infection resulting from reactivation of virus latent in the vagus ganglion. Symptoms usually resolve spontaneously within a day or two after removal of the nasogastric tube. HSV esophagitis may be difficult to distinguish from *Candida* esophagitis, and both organisms sometimes can participate in the pathogenetic process. HSV esophagitis usually responds to systemic antiviral chemotherapy.

HERPES SIMPLEX INFECTIONS IN IMMUNOCOMPROMISED HOSTS

The frequency and severity of HSV infections increase markedly in patients with hematologic and lymphoreticular malignancies, in patients with AIDS, and in organ and bone marrow allograft recipients, particularly during the first 4 to 6 weeks after transplantation, when immunosuppression is greatest. These infections develop mainly in patients with preexisting antibodies to HSV, reflecting reactivation of endogenous latent infection. Most seropositive transplant recipients shed HSV. Although these HSV infections are sometimes asymptomatic, they usually are associated with symptomatic mucocutaneous disease (herpes labialis, recurrent genital herpes). These recurrent infections often behave normally and resolve without complications. Sometimes, however, the local lesions do not resolve but slowly enlarge, ulcerate, become necrotic, and extend to deeper tissues.

Satellite lesions develop, and mucous membrane involvement is often extensive, with ulcerative, sometimes nodular, lesions on the lips, buccal mucosa, tongue, and palate. Pain and chronicity are hallmarks of the disease. These chronic, atypical mucocutaneous HSV infections, which involve the perioral or anogenital region, are a

major cause of morbidity in profoundly immunosuppressed patients. They are common in patients with AIDS. They often heal spontaneously when cellular immunity improves on induced remission of lymphoreticular malignant neoplasms, reduction in iatrogenic immunosuppression in organ allograft recipients, or effective chemotherapy of HIV infection.

Latent HSV is also reactivated during postchemotherapy mucositis; the majority of patients who suffer stomatitis after cancer chemotherapy shed HSV in saliva, and it is difficult to assess the relative contribution of chemotherapy and HSV to the mucosal disease. HSV dissemination is rarely associated with any of these chronic mucocutaneous HSV infections in seropositive patients, but local extension can be a major problem. Virus can spread from the oropharynx to the esophagus and trachea, where infection is facilitated by mucosal damage caused by radiation, chemotherapy, or intubation. Herpetic esophagitis is a common, but often unrecognized complication of oropharyngeal HSV infection in immunocompromised and debilitated patients, especially in the presence of a nasogastric tube. There are typical herpetic ulcers of the esophageal mucosa that may become confluent in the lower third. Herpetic esophagitis can lead to viremia, with infection of the liver and other organs, and the mucosal lesions are often superinfected with *Candida* species, which further obscures the diagnosis.

The lungs also can be infected by HSV, either by direct extension of infection from the oropharynx or as a consequence of viremia. Direct extension is facilitated by injury to the respiratory epithelium (by endotracheal intubation, chemotherapy, radiation, or burn injury). This probably explains the high incidence of herpetic tracheobronchitis in hospitalized burn victims and the frequency of local HSV infection in patients intubated for adult respiratory distress syndrome. In these contexts, most patients have focal or multifocal pneumonitis, and concurrent HSV esophagitis is common. There is usually evidence of active oropharyngeal infection long before the onset of pneumonia. Diffuse bilateral interstitial pneumonia, a consequence of hematogenous HSV dissemination, is rare except in profoundly immunosuppressed patients and is much more likely to occur in the course of a primary rather than a recurrent HSV infection.

HERPES SIMPLEX VIRUS INFECTION AS A CAUSE OF ERYTHEMA MULTIFORME

Recurrent HSV infections may be associated with allergic cutaneous and mucocutaneous disorders, especially erythema multiforme. In 15% to 70% of patients with erythema multiforme, especially those with recurrent erythema multiforme, the onset of disease is regularly preceded by a symptomatic attack of recurrent HSV infection (Fig. 312.4). Furthermore, the disease has been induced by the intradermal inoculation of inactivated HSV antigens in patients who suffer erythema multiforme but not in persons who have a history of uncomplicated recurrent herpes simplex. Erythema multiforme usually begins 3 to 10 days after the appearance of the herpetic lesions. It can range in severity from mild disease with typical target (iris) lesions on the extremities (erythema multiforme minor) to severe and extensive disease with lesions over the entire body, including the palms and soles, and painful bullous, erosive lesions on the mucous membranes of the eyes, nose, oropharynx, genitalia, and anus (erythema multiforme major or Stevens–Johnson syndrome).

FIGURE 312.4. Recurrent erythema multiforme associated with recurrent cutaneous herpes simplex. Erythema multiforme regularly develops in a young man with recurrent herpes simplex involving a small area of skin over his left scapula (herpes gladiatorum), 3 to 5 days after the onset of each herpetic recurrence. The rash consists of characteristic target (iris) lesions primarily affecting the skin of the trunk and extremities, including the palms and soles, and there is oropharyngeal mucositis. Herpes simplex virus type 1 is isolated from the herpetic lesions over the scapula, but not from the target lesions or oral mucosa, and no multinucleated giant cells or intranuclear inclusion bodies have been detected in biopsy specimens of the erythema multiforme lesions. Suppression of the patient's recurrent bouts of cutaneous herpes simplex with acyclovir, 400 mg orally twice daily, has eliminated recurrences of erythema multiforme. (From Oxman MN. Herpes stomatitis. In: Braude AI, Davis CE, Fierer J, eds. *Infectious diseases and medical microbiology*, second ed. Philadelphia: WB Saunders, 1986:752–772, with permission.)

Although the mucosal lesions can be confused with lesions caused directly by HSV infection, their histopathologic appearance is different. The lesions of erythema multiforme result from vasculitis, and vesicles, when present, are subepidermal. They do not result from virus replication in the skin, and thus they do not contain inclusion bodies or multinucleated giant cells, and they almost never yield HSV on culture. Their formation represents an allergic response, presumably to circulating HSV antigens or antigen–antibody complexes, and these complexes, as well as HSV DNA, have been detected in the skin lesions. Suppression of HSV recurrences with oral acyclovir can prevent the occurrence of erythema multiforme in the majority of patients.

HERPES SIMPLEX VIRUS AND IDIOPATHIC NEUROLOGIC SYNDROMES

The intimate association of HSV with neurons has aroused suspicion that the virus plays a part in the pathogenesis of a variety of neurologic syndromes of unknown cause, including trigeminal neuralgia (tic douloureux), atypical pain syndromes, idiopathic facial paralysis (Bell's palsy), temporal lobe epilepsy, recurrent psychosis, and multiple sclerosis. The ubiquity of HSV, its lifelong latent residence in seropositive persons, and its frequent reactivation in response to a variety of stimuli, however, minimize the etiologic significance of any temporal association between the occurrence or recurrence of HSV infection and the onset of another disease. Nevertheless, the association of HSV with atypical pain syndromes, including trigeminal neuralgia, enjoys a measure of clinical and serologic support. Recurrent cutaneous HSV infections sometimes are associated with a prodrome of severe neuralgic pain, and repeated attacks over a period of years occasionally have resulted in the development of chronic pain and permanent sensory loss.

HSV appears to be the principal cause of idiopathic facial palsy (Bell's palsy). Previously based primarily upon serologic data, this association has been strengthened greatly by the finding of latent HSV in the geniculate ganglion and by the detection of HSV DNA after PCR amplification in endoneurial fluid from 11 of 14 patients with acute Bell's palsy but from none of eight control patients with Ramsay Hunt's syndrome. Varicella-zoster virus DNA was detected in all eight of the Ramsay Hunt patients, but in none of the Bell's palsy patients. The association of recurrent HSV with trigeminal neuralgia, which, like herpes labialis, almost always affects the second and third divisions of the trigeminal nerve, is supported by serologic data and by the association of some cases with recurrent cutaneous herpes in the same area. These associations do not prove causality, however, and the absence of antibodies to HSV in some patients with trigeminal neuralgia indicates that even if HSV does cause the syndrome, it is not the only cause.

GENITAL HERPES AS A RISK FACTOR FOR HUMAN IMMUNODEFICIENCY VIRUS INFECTION

It has long been recognized that genital ulcer disease enhances the transmission of HIV infection among sexually active persons. HIV transmission is facilitated by disruption of the epithelial barrier and the presence of HIV-infected T lymphocytes and macrophages in the ulcer base. In North America and Europe, where HSV infection is the most common cause of genital ulcer disease, epidemiologic evidence indicates that orogenital HSV infection is an important risk factor for HIV infection. Thus, controlling symptomatic HSV infections with effective antiviral chemotherapy may contribute to AIDS prevention.

HERPES SIMPLEX VIRUS INFECTION AND CANCER

The capacity of HSV to induce cell transformation in vitro and the observation made in many (but not all) seroepidemiologic studies that the prevalence of antibodies to HSV-2 is higher in women with carcinoma of the cervix than in matched control subjects led to the suggestion that HSV-2 might play a causal role in cervical carcinoma. The epidemiologic studies indicate only that HSV-2 infection and cervical carcinoma are covariable: both are linked to sexual promiscuity and early age at first coitus. Convincing evidence of any more direct linkage is lacking. Furthermore, compelling data now indicate that human papillomavirus infections are responsible for most cases of cervical carcinoma.

DIAGNOSIS

The potential for transmission and the availability of specific antiviral agents now place a high premium on early and reliable diagnosis. A presumptive diagnosis of HSV infection often can be made on clinical and epidemiologic grounds (in patients with typical herpes labialis or recurrent genital herpes). Many other diseases can be confused with HSV infections, however, and lesions caused by HSV are often atypical, especially in immunocompromised patients. Even among very experienced physicians, the specificity of a clinical diagnosis of HSV infection is less than 80%. Thus, diagnosis based on laboratory testing is often required, and it is always desirable. There is, however, an important caveat. The high prevalence of unrecognized HSV infections and the frequency of asymptomatic virus shedding—which is markedly higher in the context of immunosuppression and the stress and fever of most illnesses—limit the etiologic significance of the presence of HSV in many clinical specimens (e.g., a specimen of lung obtained by transbronchial biopsy, which may be contaminated with saliva). In such situations, diagnosis requires histopathologic evidence of the direct involvement of HSV in the pathologic process.

VIRUS ISOLATION

Virus isolation in cell culture has been the gold standard for the diagnosis of HSV infections. It offers high sensitivity and unsurpassed specificity when specimens are obtained early in the course of HSV infection (at the vesicular stage) and handled properly to avoid loss of infectivity. It also yields virus for subsequent studies, such as measurement of sensitivity to antiviral drugs and restriction endonuclease fingerprinting, and it may detect pathogens other than HSV. HSV grows readily in a variety of human and nonhuman cells, and characteristic cytopathic effects typically are apparent in 1 to 3 days. Even with culture enhancement techniques (including early immunostaining for HSV antigens), however, results are generally not available for 24 hours or longer. Because many therapeutic decisions require diagnostic information in minutes to hours, much effort has been devoted to developing methods for rapid diagnosis.

RAPID DIAGNOSIS—HISTOPATHOLOGY

The histologic appearance of lesions caused by HSV provides a rapid and practical means of diagnosis. Multinucleated giant cells containing eosinophilic intranuclear inclusion bodies distinguish the lesions of HSV from those produced by almost all other pathogens. Other than HSV, only measles and varicella-zoster virus produce multinucleated giant cells with eosinophilic intranuclear inclusion bodies. Measles does not resemble HSV infection in clinical features or epidemiologic characteristics, the rash is normally not vesicular, and the skin lesions are distinct in histologic appearance from those caused by HSV. The characteristic cytologic changes induced by HSV can be seen easily in Tzanck smears prepared at the bedside. Cells are scraped from the base of an early vesicle, spread gently on a glass microscope slide, and stained with hematoxylin-eosin, Giemsa, Papanicolaou, or Paragon multiple stain. A punch biopsy taken at the edge of a lesion provides better tissue for cytologic and immunologic diagnosis, especially in atypical ulcerative lesions, such as those found in immunocompromised patients. Biopsy also facilitates diagnosis in the prevesicular stage. Specimens also can be examined for virus particles by electron microscopy. While these cytologic techniques are useful in rapidly differentiating HSV infection from most other vesicular diseases (contact dermatitis, hand-foot-and-mouth disease), they are relatively insensitive (50% to 80%), and they do not distinguish between HSV and VZV infections.

RAPID DIAGNOSIS—DIRECT DETECTION OF HERPES SIMPLEX VIRUS ANTIGENS OR NUCLEIC ACIDS IN CLINICAL SPECIMENS

Rapid direct detection and identification of HSV antigens and nucleic acids in clinical specimens are now a reality. Although they are often less sensitive than virus isolation, these techniques can detect viral proteins and nucleic acids late in the course of disease, when infectious virus may not be recovered. Immunofluorescent or immunoenzyme staining with monoclonal antibodies to HSV-1, HSV-2, and varicella-zoster virus can strengthen sensitivity and provide a specific diagnosis, distinguishing HSV from varicella-zoster virus and HSV-1 from HSV-2.

IDENTIFICATION OF HERPES SIMPLEX VIRUS DNA BY POLYMERASE CHAIN REACTION ASSAYS

The development of PCR assays for the detection of viral DNA and RNA has vastly improved the laboratory diagnosis of virus infections. The use of primers from DNA sequences that are common to HSV-1 and HSV-2 (e.g., DNA polymerase) permits detection of either HSV serotype, whereas primers from type-specific DNA sequences can be used to identify the HSV serotype. Because of their extraordinary sensitivity (substantially greater than virus isolation or direct detection of HSV antigens or nucleic acids), assays employing PCR amplification have revolutionized the diagnosis of HSV infections. In herpes simplex encephalitis, detection of HSV DNA in CSF now provides a noninvasive diagnostic technique that is at least as sensitive as brain biopsy. PCR assays also have established that HSV (usually HSV-2) is the principal cause of benign recurrent lymphocytic (Mollaret) meningitis and confirmed a strong association between HSV-1 infection and Bell's palsy. PCR assays are substantially more sensitive than virus isolation for detecting symptomatic and asymptomatic virus shedding in patients with genital herpes. Their use has led to a three- to eightfold increase in the estimated rate of HSV shedding by HSV-2 seropositive women. The clinical significance of small quantities of HSV DNA detected by PCR in the absence of infectious virus remains to be determined.

SEROLOGIC DIAGNOSIS

The usefulness of serologic assays for the diagnosis of HSV infections has been limited by the need to obtain a sample of convalescent-phase serum to establish seroconversion; by the fact that recurrent infections, which account for much of the morbidity of HSV, generally do not stimulate a significant increase in antibody titers; and by the antigenic cross-reactivity of HSV-1 and HSV-2. Commercially available enzyme immunoassays do not discriminate reliably between HSV-1 and HSV-2 infections despite claims to the contrary. These assays are useful only for confirming a diagnosis of primary HSV infection by documenting HSV seroconversion and for identifying persons not infected with either HSV serotype (who are HSV seronegative).

Type-specific serologic assays are now available in which serum samples are reacted with HSV proteins that have predominantly type-specific epitopes (e.g., gG1 from HSV-1 and gG2 from HSV-2) in solid-phase enzyme immunoassays or with electrophoretically separated HSV-1 and HSV-2 proteins in Western blot assays. The enzyme immunoassays are accurate and simple to perform on large numbers of serum samples, but antibodies to gG2 may not develop until 6 to 8 weeks after initial HSV-2 infections and may remain undetectable in some patients, especially immunosuppressed patients, with culture-proven recurrent HSV-2 infections. Western blot assays are more cumbersome, but they can ascertain early seroconversion, identify HSV-2 infections when antibodies to gG2 are not detectable, and detect seroconversion to HSV-2 in patients with previous HSV-1 infections despite their early anamnestic response to type-common epitopes. Type-specific assays can distinguish between initial primary and nonprimary HSV infections and identify persons previously infected with HSV-1, HSV-2, or both (e.g., when screening organ donors and recipients, pregnant women and their sexual partners, and potential vaccine recipients). The clinical application of these type-specific assays has revolutionized the serologic diagnosis of genital herpes and led to a clear delineation of the epidemiologic characteristics of HSV-1 and HSV-2 infections.

TREATMENT

No treatment is presently available that can eradicate latent HSV infections or prevent the establishment of HSV latency. Nevertheless, antiviral chemotherapy can limit the morbidity and mortality of HSV infections, and suppressive therapy can markedly lessen the rate of symptomatic recurrences and of asymptomatic virus shedding. Nine compounds that interfere with HSV DNA replication—idoxuridine, trifluorothymidine, vidarabine, acyclovir, penciclovir, foscarnet, cidofovir, famciclovir, and valacyclovir—have been proved effective and are licensed for use in the United States. Idoxuridine and trifluorothymidine are effective for topical treatment of HSV keratitis but are too toxic for systemic use. Vidarabine, acyclovir, penciclovir, foscarnet, and cidofovir are licensed for both topical and systemic use.

Acyclovir, the first truly selective inhibitor of HSV replication to be evaluated in clinical practice, is phosphorylated actively by HSV-encoded thymidine kinase (TK) but is a poor substrate for cellular TKs. Thus, it is concentrated in HSV-infected cells. Cellular enzymes then convert acyclovir monophosphate to acyclovir triphosphate, which is a selective inhibitor of HSV-encoded DNA polymerase. In addition, any acyclovir triphosphate that is incorporated into DNA causes chain termination. As a consequence of these properties, acyclovir is a highly effective and nontoxic inhibitor of HSV replication. It is available in intravenous, oral, and topical formulations, though topical acyclovir is rarely indicated.

Penciclovir is similar to acyclovir in mechanism of action and anti-HSV activity but differs in its pharmacologic properties (e.g., penciclovir triphosphate has a much longer intracellular half-life than acyclovir triphosphate). Penciclovir is available in intravenous and topical formulations. Two licensed prodrugs, famciclovir (prodrug of penciclovir) and valacyclovir (prodrug of acyclovir), provide much greater oral bioavailability than acyclovir, which permits less frequent dosing and results in blood levels of antiviral activity heretofore achievable only with intravenous acyclovir. Foscarnet and cidofovir are more toxic than acyclovir and penciclovir, and their use is limited to the treatment of acyclovir-resistant HSV infections. Additional compounds that target HSV-encoded DNA polymerase are being evaluated, and viral protease

inhibitors offer another promising avenue for selective inhibition of HSV replication.

In normal persons infected with HSV, virus replication is terminated effectively by host defense mechanisms, and clinical manifestations, when present, resolve quickly without medical intervention. This is especially true of such recurrent HSV infections as herpes labialis. Consequently, antiviral therapy may have little clinical impact. In contrast, when HSV replication is prolonged, as it is in symptomatic primary infections and in immunocompromised patients, antiviral therapy can limit morbidity and mortality markedly.

TREATMENT OF PRIMARY AND INITIAL NONPRIMARY HERPES SIMPLEX VIRUS INFECTIONS

Symptomatic treatment should be directed toward prevention of autoinoculation and bacterial superinfection and minimization of local discomfort. Lesions should be kept clean and dry and nonspecific creams and ointments avoided. Burrow solution compresses or sitz baths are often helpful. Painful urination in women with genital herpes may be relieved by urinating in a sitz bath or bathtub. HSV infections of the eye respond to topical antiviral therapy—trifluridine appears to be the drug of choice. Systemic therapy with oral acyclovir, famciclovir, or valacyclovir should be added if deeper tissues are affected. Eye infections should always be managed in collaboration with an experienced ophthalmologist.

In double-blind, placebo-controlled studies, both acyclovir and vidarabine have been shown to reduce the mortality and morbidity rates of neonatal HSV infections and herpes simplex encephalitis. Because of its lower toxicity, greater ease of administration, and superior efficacy in HSV encephalitis, intravenous acyclovir has replaced vidarabine for the treatment of these and other serious HSV infection. Suppression with oral acyclovir or valacyclovir after initial therapy with intravenous acyclovir is being evaluated for prevention of relapses of herpes simplex encephalitis and cutaneous recurrences in neonatal HSV infections.

Acyclovir is the drug of choice for the treatment of primary and nonprimary first episodes of genital herpes. Oral and intravenous therapy substantially shortens the duration of local symptoms and virus shedding; accelerates healing; and diminishes new lesion formation, dysuria, vaginal discharge, and extragenital manifestations. Oral acyclovir generally is recommended (Table 312.1). Intravenous therapy is reserved for disease severe enough to require hospitalization, especially if there are such extragenital manifestations as urinary retention or HSV meningitis. Topical acyclovir has no role in the therapy of initial genital HSV infections. Famciclovir and valacyclovir produce higher blood levels of antiviral activity and offer the possibility of less frequent administration. Their clinical efficacy does not appear to be superior to that of oral acyclovir, however, and they are generally more expensive. Unfortunately, no form of therapy appears to lessen the frequency or severity of subsequent recurrences.

TABLE 312.1. ANTIVIRAL THERAPY OF HSV INFECTIONS^{a,b}

Oral acyclovir is indicated for immunocompetent persons who have severe herpetic gingivostomatitis or pharyngotonsillitis; initial episodes of herpetic whitlow; HSV proctitis; primary herpetic infections of the skin, such as herpes gladiatorum. Higher daily doses of oral acyclovir appear to be required for HSV infections at these sites. Intravenous therapy is suggested for patients hospitalized with severe infections or with visceral or neurologic complications. Famciclovir or valacyclovir may be preferable to oral acyclovir, but studies establishing their superiority are not available at present.

TREATMENT OF RECURRENT HERPES SIMPLEX VIRUS INFECTIONS

Recurrent HSV infections typically are limited in duration and extent and resolve spontaneously without complications. Nevertheless, they cause sufficient physical and emotional distress to prompt most afflicted persons to seek some form of relief. Oral acyclovir, even when administered during the prodrome, has only a modest effect on the course of herpes labialis and recurrent genital herpes, and it does not seem to alter the frequency or severity of subsequent recurrences. Oral acyclovir does provide meaningful relief to patients whose episodes are more extensive and prolonged and to most patients with recurrent herpetic whitlow. Topical acyclovir is ineffective for recurrent HSV infections in normal hosts, but topical penciclovir shows modest clinical efficacy in patients with herpes labialis. Because treatment of herpes labialis and recurrent herpetic whitlow require higher doses of acyclovir than treatment of recurrent genital herpes, famciclovir or valacyclovir may be preferred.

PROPHYLAXIS (SUPPRESSION) OF FREQUENTLY RECURRING HERPES SIMPLEX VIRUS INFECTIONS

Long-term prophylaxis with oral acyclovir markedly reduces the incidence and severity of repeated episodes of genital herpes in persons with frequent recurrences. Suppressing therapy can be continued safely for 10 years or longer, but even such prolonged suppression does not eliminate HSV shedding or abolish latency; recurrences resume when suppressive therapy is stopped. Although suppression with acyclovir does not eliminate asymptomatic shedding, it limits it markedly, and the effect of this reduction on HSV transmission is under investigation. Until these results are available, it seems reasonable to prescribe suppressive therapy for sexually active patients with recurrent genital herpes but to advise them that they still may be capable of transmitting the infection when they are asymptomatic. Famciclovir and valacyclovir administered twice daily are comparable in efficacy to acyclovir, but these prodrugs are generally more expensive.

Suppression with oral acyclovir is also effective for recurrent herpetic whitlow, HSV proctitis, and cutaneous HSV infections. Suppression with oral acyclovir is especially beneficial for patients whose recurrences are associated with severe complications, such as recurrent meningitis, erythema multiforme, or neuralgia, and for patients with recurrent ocular HSV infections associated with stromal keratitis or iritis. Placebo-controlled studies of natural sunlight-induced and experimental ultraviolet light-induced herpes labialis have shown that prophylaxis with oral acyclovir lessens the incidence of lesion formation and the severity of the lesions that do occur. Suppression of herpes labialis requires higher doses of acyclovir than suppression of recurrent genital herpes, however, and, in any case, is less effective (50% to 78% vs. 80% to 90%). Perhaps famciclovir or valacyclovir would be more effective, but results of comparative studies are not available.

TREATMENT AND PROPHYLAXIS OF HERPES SIMPLEX VIRUS INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Symptomatic initial and recurrent mucocutaneous HSV infections in immunocompromised patients respond to intravenous or oral acyclovir (Table 312.1). The addition of topical acyclovir or penciclovir may speed resolution of external lesions. Recurrent HSV infections are a major cause of illness in patients undergoing organ or bone marrow transplantation or remission-induction chemotherapy for acute leukemia; mucocutaneous HSV infections develop in 60% to 90% of seropositive patients during the early posttransplantation period, when immunosuppression is greatest. A number of placebo-controlled studies have shown that intravenous and oral acyclovir provide effective prophylaxis, lowering the rate of recurrences by 90% or more. Long-term suppression with oral acyclovir is often indicated, but immunocompromised patients require high doses of acyclovir, and famciclovir is a useful alternative.

DEVELOPMENT OF RESISTANCE TO ANTIVIRAL DRUGS

Because the selective antiviral activity of acyclovir involves two HSV-encoded enzymes, TK and DNA polymerase, mutations altering either one can lead to resistance. Resistant mutants, most of which are TK deficient, are readily selected in the laboratory and have been isolated sporadically from immunocompetent patients before, during, and after acyclovir therapy. These acyclovir-resistant isolates have been associated only in rare instances with treatment failure. Clinically significant acyclovir resistance is being encountered with increasing frequency, however, in severely immunocompromised patients, especially HIV-infected patients

and bone marrow transplant recipients receiving acyclovir for persistent mucocutaneous HSV infection. Many of these viruses have caused locally invasive disease and even disseminated infections that were unresponsive to acyclovir. Most are TK deficient and thus also resistant to penciclovir and ganciclovir.

Although these mutants are susceptible to both foscarnet and vidarabine in vitro, only foscarnet is effective in vivo. Occasionally, acyclovir resistance is due to a mutant TK with altered substrate specificity; though resistant to acyclovir, such viruses may still be sensitive to penciclovir. DNA polymerase mutants resistant to both acyclovir and foscarnet have been isolated from immunocompromised patients with lesions unresponsive to these drugs. These mutants have been found to be sensitive to cidofovir and trifluridine. The emergence and potential spread of such drug-resistant mutants place at risk our recently acquired capacity to treat HSV infections.

PREVENTION OF HERPES SIMPLEX VIRUS INFECTION

PREVENTION OF EXPOSURE

At present, avoidance of exposure is the only proven means of preventing HSV infection. Consistent condom use appears to be an effective means of curbing genital HSV transmission. The high incidence of asymptomatic virus shedding, however—usually by persons who have no history of symptomatic infection to alert them to their potential infectiousness—makes avoiding exposure impractical except in special circumstances. For example, health care workers who have herpetic whitlow should not engage in direct care of patients. Hospitalized patients with extensive HSV infections, such as eczema herpeticum, should be isolated. Persons with herpes labialis and recurrent genital herpes should avoid sexual contact when active lesions are present, and all sexually active persons should be aware that infection frequently is transmitted during episodes of asymptomatic virus shedding. Pregnant women who have active genital herpes at term should be delivered by caesarean section before membranes rupture, to lower the risk of neonatal HSV infections. Susceptible pregnant women with seropositive sexual partners should practice abstinence, including abstinence from oral–genital contact, during the 6 weeks before delivery, to avoid acquiring primary infection near term.

PREEXPOSURE PROPHYLAXIS

No means of prophylaxis has been proved to be effective in humans. In addition, the high proportion of HSV infections that follow unrecognized exposures suggests that even if effective, short-lived forms of prophylaxis, such as the administration of acyclovir or antibodies to HSV, would have little practical application. On the other hand, effective preexposure immunization could provide an ideal means of prophylaxis. Several experimental vaccines have entered clinical trials, but results obtained to date have been disappointing. Therapeutic immunization to reduce the rate of recurrent HSV infections has a long and colorful history. Placebo-controlled trials of vaccines containing recombinant HSV-2 glycoproteins D and B have shown only very modest clinical activity. Trials of additional vaccines are likely to follow.

POSTEXPOSURE PROPHYLAXIS

The short incubation period of symptomatic HSV infection, the early establishment of latency, and the ability of replication-negative HSV mutants to become latent all suggest that postexposure prophylaxis will be ineffective in preventing HSV infection or the establishment of latency. However, studies in animal models indicate that postexposure prophylaxis with antibodies to HSV, with antiviral agents, or with combinations of the two may lower the incidence and severity of disease in some circumstances. This approach is being evaluated in clinical trials of acyclovir prophylaxis in newborns exposed to HSV at delivery, in the hope of improving the results achieved with antiviral therapy initiated after the onset of the symptoms and signs of neonatal HSV infection.

CHAPTER 313: CYTOMEGALOVIRUS

SARAH H. CHEESEMAN

[Definition](#)
[Incidence and Epidemiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)

DEFINITION

Cytomegalovirus (CMV), a member of the herpesvirus family, derives its name from the characteristic enlargement of infected cells, or cytomegaly. The first human disease linked to this virus was a devastating congenital infection syndrome, called cytomegalic inclusion disease. CMV is a major cause of heterophile-negative infectious mononucleosis as well as significant disease in transplant recipients and patients with AIDS.

INCIDENCE AND EPIDEMIOLOGY

Most infection with CMV is asymptomatic, and seroprevalence studies show early acquisition, almost universal by age 2, in countries with poor socioeconomic conditions. In the United States, 0.4% to 2.5% of newborns excrete the virus at birth, and about 3,000 cases of cytomegalic inclusion disease are expected each year. A large number of children become infected in the first 2 months of life from exposure to maternal genital secretions at delivery and through subsequent breast-feeding. Despite the similarities to the epidemiologic characteristics of perinatal HIV or hepatitis B virus, CMV acquired postnatally by these routes is a benign infection without clinical manifestations or long-term effects. Infants and toddlers in close contact transmit infection to each other and to their caretakers, at home or day care, via excretion of virus in urine and saliva. Later in life, sexual transmission predominates, but acquisition by other routes also takes place, with a seroconversion rate of 1% to 2% per year for the general population, leading to seroprevalence rates in excess of 60% by age 60. Infection by CMV is lifelong, and fluctuations of serum antibody titer as well as culture evidence of shedding indicate that silent reactivation of the infection occurs. It is not surprising, therefore, that blood products and solid organ transplants can transmit CMV to their recipients.

In normal hosts, most symptomatic CMV disease is the result of primary acquisition, though even in adults, primary acquisition is often asymptomatic. In this respect, the pattern of CMV closely resembles that of Epstein–Barr virus (EBV), though the seroprevalence rate at any given age is lower. Most persons with AIDS who acquired their infections by routes other than transfusion of blood or clotting factors also have CMV, so the late-stage syndromes are assumed to be due to reactivation. In the context of solid organ transplantation, disease may result either from reactivation of the recipient's own previous CMV infection, reinfection with a different strain derived from the donor, or primary infection derived from the donor. Disease manifestations follow a gradient, with the most severe syndromes occurring in seronegative recipients of an organ from a seropositive donor [D(donor)+, R(recipient)-], followed by seropositive recipients of a seropositive organ (D+R+) and seropositive recipients of organs from seronegative donors (D+R-). The least severe disease manifests in seronegative recipients of seronegative organs, whose infections may come from blood products. By contrast, in allogeneic bone marrow transplantation, the recipient with pretransplant antibody to CMV is at highest risk of CMV disease after transplant, though the risk in autologous marrow transplantation is quite low.

The most feared consequence of CMV infection may well be the congenital infection syndrome. Overt symptomatic CMV disease at birth is the result of maternal primary infection during pregnancy, with only two or three well-documented exceptions; most cases derive from infection in early gestation. For a pregnant woman diagnosed with primary CMV infection, the risk that the baby will be infected congenitally is 40%. Among babies with congenital infection due to primary maternal infection during pregnancy, 18% have symptomatic CMV infection (fatal in 4% to 12% and leaving 90% of the survivors with neurologic impairment) and 25% have some adverse consequence (15% having sensorineural hearing loss). A woman with primary CMV infection in early pregnancy faces a 10% risk that her baby will have neurologic impairment as a result of this infection. Only 1% of infants born to mothers thought to have had primary CMV infection before pregnancy are congenitally infected, of whom 5% to 8% have any neurologic consequences.

PATHOGENESIS

Remarkably little is known about the pathogenesis of CMV infection beyond that which can be inferred from its epidemiologic characteristics. Although antibody is a useful marker of infection, the concentration of disease in patients with severe deficiency of cell-mediated immunity points to the importance of this mechanism of protection, as does protection of CMV-seropositive allogeneic bone marrow transplant recipients by infusion of donor-derived CMV-specific cytotoxic lymphocytes. Active CMV infection produces immunosuppression, measurable in both the normal host and in solid organ transplant recipients; in the latter group, an increased rate of other opportunistic infections, especially fungal infections, accompanies CMV disease. CMV can transactivate HIV *in vitro*; studies in hemophiliacs suggest that co-infection hastens the progression of immunodeficiency. Overt CMV disease does not develop in HIV-infected persons until there has been profound depletion of CD4 cells (median CD4 count of 25/ μ L).

CMV can be isolated from circulating leukocytes, principally neutrophils, in normal hosts with CMV mononucleosis, and detection of viremia by a variety of means accompanies and may precede clinical manifestations of CMV disease in immunosuppressed hosts. CMV disease has been reported in almost every organ, but the site of true viral persistence remains a mystery. Attempts to link various chronic diseases with CMV, based on seroprevalence studies or detection of viral antigens or polymerase chain reaction (PCR) fragments in tissues, have not yet defined any causal associations, but one has been disproved: Kaposi's sarcoma is now thought to be related to human herpesvirus 8.

CLINICAL FEATURES

Symptomatic primary infection, or CMV mononucleosis, is a febrile illness sharing many features with the classic infectious mononucleosis syndrome produced by EBV: malaise, fatigue, and atypical lymphocytes (generally not as numerous in CMV disease as in EBV). Pharyngitis and lymphadenopathy are not as common as in EBV; they are found in about one-third of patients with primary CMV. Elevated liver enzymes are present in at least 90%. Either leukocytosis or leukopenia may be present, and relative or absolute neutropenia is a useful clue. The illness may last for several weeks. Particularly in young people, this diagnosis should be sought before embarking on a costly workup for fever of unknown origin. Pope John Paul II contracted CMV mononucleosis as a consequence of blood transfusions after his attempted assassination. When acquired in this manner, CMV takes the form of a late postoperative fever, with an incubation period of 3 to 6 weeks. Specific organ involvement is rare in normal hosts, but case reports have described most of the syndromes seen in immunocompromised hosts in normal individuals as well. Slow but spontaneous resolution is the rule.

CMV disease is becoming less frequent in immunocompromised hosts, thanks to gentler immunosuppression and screening of blood products for transplant recipients and to the impact of more effective antiretroviral therapy in AIDS. Before the introduction of protease inhibitors, CMV retinitis afflicted more than a third of AIDS patients before they died; now it is unusual even among those with an inadequate response of HIV infection to protease inhibitor-containing regimens. Recent reports, however, suggest that protection may wane as the CD4 count drops below 50/ μ L.

Patients with CMV retinitis report spots or floaters before their eyes, a curtain or veil over a portion of the visual field, or blurred vision—not eye pain or conjunctival injection. Funduscopic examination shows exudates, often tracking along blood vessels and with hemorrhage, described as “cottage cheese and ketchup” or “cheese pizza”; these exudates represent retinal necrosis. Undilated funduscopy permits examination of only 25% of the retina, and many examiners see much less. Examination of visual fields by confrontation may define a more peripheral area of visual loss, but the patient with suggestive symptoms should be referred to an ophthalmologist. Untreated CMV retinitis progresses over a few weeks and eventually results in blindness. Very rapid progression may occur when the patient with undiagnosed and untreated CMV retinitis begins highly active antiretroviral therapy. A new syndrome of vitritis in patients on these therapies whose CMV retinitis is in control is presumed to result from immune recovery and response to CMV antigens; the clinical symptoms are floaters and impaired visual acuity. Sudden visual loss in a patient treated for CMV retinitis most often indicates retinal detachment.

CMV can produce a form of necrotizing encephalitis difficult to distinguish from that due to HIV but frequently associated with preexisting CMV retinitis. It can also cause a distinctive syndrome characterized by periventricular enhancement on neuroimaging studies and neutrophilic pleocytosis and a low glucose level in the

cerebrospinal fluid (CSF). The same CSF abnormalities occur in CMV polyradiculopathy or cauda equina syndrome, with initial signs of urinary retention and lower-extremity weakness often accompanied by pain. The other major target for CMV in AIDS is the gastrointestinal tract. CMV colitis results in abdominal pain and diarrhea, which is often bloody. CMV esophagitis causes odynophagia in bone marrow transplant recipients as well as AIDS patients. It is the third most frequent cause of esophagitis in HIV-infected persons, after candida and aphthous ulceration.

By far the most dreaded complication of CMV in transplant recipients is pneumonia. The highest fatality rates are seen among bone marrow transplant recipients with graft-versus-host disease and solid-organ recipients with accompanying neutropenia and liver enzyme abnormalities. Chest radiography shows an interstitial infiltrate early in the course of infection, but it may progress to confluent opacification ("white-out") with respiratory failure.

CMV also causes a febrile illness without specific organ manifestations in transplant recipients, characterized by leukopenia, elevated liver enzymes, and atypical lymphocytes (in small numbers, since the immunosuppressive medications tend to produce lymphopenia); this condition is often termed the "CMV syndrome." Another curious feature of CMV is its association with rejection and other disease of the transplanted organ: re-stenosis of coronary arteries in heart transplants, hepatitis in liver transplants, and glomerulonephritis in transplanted kidneys.

LABORATORY FINDINGS

Primary CMV infection can be diagnosed with assurance when a specimen of blood obtained early in the illness tests negative for CMV antibody and antibody is detected in specimens obtained 2 to 3 weeks later. More often, however, low levels of antibody are present by the time someone considers the diagnosis. Evidence of a fourfold rise in titer between acute and convalescent specimens tested in the same assay, along with the presence of IgM antibody to CMV, constitutes strong evidence of primary CMV infection. Unfortunately, IgM antibody testing for CMV is not as reliable as one would like for the most critical situations (such as pregnancy)—27% false-negatives and 11% false-positives were found in a careful evaluation of one commercial assay. IgM testing is also not useful in immunosuppressed hosts, who may not make IgM even when they sustain primary infection, or in patients whose CMV disease is a result of reactivation.

With new methods of inoculation and detection of CMV early antigens by fluorescent antibody staining, isolation of CMV in cell culture has become a semirapid test, yielding results within 24 hours. A positive culture result is proof of infection, but it may not always establish that CMV is the cause of clinical symptoms: 7% of asymptomatic seropositive normal persons shed CMV in the urine, and the rate is much higher among immunocompromised patients. Isolation of virus from a person lacking serum antibody, however, can confirm primary infection, and isolation of virus from a newborn infant proves congenital infection.

Isolation of CMV from blood is strongly suggestive of the role of CMV in the clinical syndrome under investigation, but it is neither 100% specific nor 100% sensitive and may not be sufficiently rapid. The overnight method is not as successful with buffy coat as with urine. Detection of virus in blood by PCR or by examination of leukocytes for viral matrix antigen (leukocyte antigen detection) has become the mainstay of diagnosis in transplant patients, permitting early initiation of therapy, even before (and with the hope of forestalling) clinical symptoms. PCR of CSF can be helpful in the diagnosis of central nervous system disease due to CMV.

The gold standard for establishing infection of a target organ is histopathologic diagnosis of CMV by identification of the typical enlarged cell with a basophilic intranuclear inclusion with surrounding halo that resembles an owl's eye. This finding is particularly important in distinguishing CMV pneumonia or upper gastrointestinal tract disease from clinically insignificant viral shedding detected by culture of secretions—even those obtained at bronchoscopy or endoscopy, since both may be contaminated by saliva. To avoid false-negative histopathologic results, biopsy samples should be taken at ulcer edges and at several lesion sites and even apparently uninvolved areas in the colon. CMV retinitis diagnosed by an experienced ophthalmologist requires no laboratory test for confirmation.

OPTIMAL MANAGEMENT

Reassurance and counseling are all that are needed for the normal host. A diagnosis of primary CMV infection may be a welcome finding in a workup that included the possibility of newly acquired HIV infection and a useful opening to discuss prevention of other sexually transmitted diseases; care should be taken to recognize that CMV may have been acquired by other routes. Since the highest risk of symptomatic congenital CMV infection is associated with acquisition near the time of conception, attempts at pregnancy should be postponed.

Specific antiviral therapy is indicated for transplant recipients with evidence of CMV disease. The addition of immune globulin to antiviral therapy is lifesaving in bone marrow transplant recipients with CMV pneumonia. Many centers monitor patients prospectively for viremia and initiate preemptive antiviral therapy as soon as it is detected as well as at the first sign of any potential symptoms. Ganciclovir and foscarnet, administered by the intravenous route, are the two drugs currently approved for systemic therapy. Patients with AIDS and CMV retinitis can be treated systemically with these drugs or cidofovir or with an intravitreal implant that releases ganciclovir locally. In the absence of potent antiretroviral therapy, the risk of contralateral or disseminated CMV disease was very high for patients treated only with implants, and those on maintenance systemic therapy could expect periodic activation of retinitis. Patients whose CD4 counts rise substantially as a result of antiretroviral therapy seem to be at very low risk of progression even if they stop maintenance therapy once retinitis has healed (though recurrences are now being reported among patients whose CD4 counts drop below 50/ μ L). All patients requiring treatment for CMV infection should be referred to an expert.

CHAPTER 314: EPSTEIN–BARR VIRUS AND THE INFECTIOUS MONONUCLEOSIS SYNDROME

JOSEPH S. PAGANO

[Virology](#)
[Epidemiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Optimal Management](#)

Best known in North America as the causative agent of infectious mononucleosis (IM), Epstein–Barr virus (EBV) infection is also associated with malignancy, especially Burkitt's lymphoma (BL) in Africa and nasopharyngeal carcinoma (NPC) in China. The question of how a single virus can play a part in these disparate diseases, one benign and two malignant, is long-standing and now complicated by more associations. In terms of the prevalence of EBV diseases, IM and NPC head the list, followed by lymphoproliferative disorders in immunodeficient states; other lymphomas, including Hodgkin's disease (HD); hairy leukoplakia of the tongue; and gastric carcinoma. These diseases have some common features at the molecular pathobiologic level.

The herpesvirus group, of which EBV is a member, has three hallmark phases of infection: primary, latent, and reactivated. The symptoms of primary and reactivated EBV infection differ strikingly; in general, the malignancies are associated with viral reactivation. EBV has many claims as a human tumor virus, but it acts as contributor rather than as sole cause, which is in agreement with the idea of the genesis of malignancy as a multifactorial, stepwise molecular process. Its disease associations are still emerging, influenced by such therapies as organ transplantation, the onslaught of acquired immunodeficiency syndrome (AIDS), and new molecular diagnostic techniques.

VIROLOGY

EBV, one of two human members of the Gammaherpesvirinae, looks like other herpesviruses. It is enveloped and has an icosahedral nucleocapsid containing a double-stranded piece of DNA consisting of about 172,000 nucleotide base pairs. This linear genome is replicated by virally encoded DNA polymerase, the target for most antiviral drugs. The genome itself is characterized by distinctive sequence reiterations. At the termini are ten to 20 copies of a 500-base-pair repeated sequence that is complementary and therefore permits circularization of the linear genome to form the EBV episome. The fused termini of episomes are useful for determining clonality of EBV conditions.

The EBV episome is the molecular basis for latent infection. It is a circular intracellular form of the genome not found in virus; instead it maintains a persistent relationship within the cell, like an autonomous piece of DNA situated in the chromatin. The episome is replicated by host DNA polymerase and thus is not susceptible to antiviral drugs specific to viral enzymes. Each copy of the EBV episome is replicated only once during the cell cycle, so that constant numbers are maintained from one cell generation to the next, which is part of the mechanism of persistence of the EBV genome in latency.

The EBV genome encodes about 100 genes, but only a few are expressed during latent infection and in tumor cells. These genes are keys to latency, and some are involved in immortalizing cells. Proteins encoded by these genes are found either in the nucleus or in the plasma membrane. One of the nuclear antigens, Epstein–Barr nuclear antigen 1 (EBNA-1), is the universal EBV protein needed to replicate and maintain the latent EBV episome in cells; EBNA-1 binds to the origin of replication, *ori-P*, used by episomes. Another nuclear protein, EBNA-2, is a transcription factor necessary for cell immortalization; it activates cellular proliferation genes as well as the other EBV latency and immortalization genes. Lymphocyte membrane-associated protein 1 (LMP-1), is the EBV oncoprotein. LMP-1 affects cellular processes that promote proliferation; it also counters apoptosis by inducing bcl-2, and it activates the epithelial growth factor receptor. LMP-1 uses the tumor necrosis factor receptor intracellular signaling pathway by engaging tumor necrosis factor receptor–associated factors, which are involved in cell transformation.

There are at least three forms of EBV latency, classified according to the pattern of viral protein expression. Type 1, in which chiefly EBNA-1 is expressed, is exemplified by BL. Type 2 latency, typified by NPC and HD, expresses EBNA-1 and the three latent membrane proteins, LMP-1, LMP-2a, and LMP-2b. In type 3 latency, represented by EBV lymphoproliferative diseases, the full range of latency antigens is expressed—all six nuclear antigens and the three membrane proteins. In all latently infected and immortalized cells, certain small nuclear RNAs called EBERS are also expressed. Although the function of these non–protein-coding RNAs is unknown, their abundance in EBV-immortalized cells makes them sensitive detectors of latent infection and EBV malignant cells. In most tumors, 100% of cells are latently infected. The fact that BL does not express either of the two principal EBV transforming proteins, LMP-1 or EBNA-2, underscores that the virus is not the etiologic agent for BL, as is discussed later. Finally, LMP-1 not only is itself an oncoprotein, it also can induce a cellular enzyme that is important for tumor invasion and metastasis, matrix metalloproteinase 9. LMP-1 is expressed in EBV-associated tumors with a proclivity for invasiveness, such as NPC and lymphoproliferative neoplasias. Thus, latency type also relates to disease phenotype.

In contrast, in productive infection, virtually all the EBV genes are expressed, starting with the immediate-early genes (R and Z), which encode transcriptional transactivator proteins that trigger the viral replicative cycle by inducing expression of early viral genes needed for viral replication. The early viral genes encode enzymes involved in viral replication, including early antigen-diffuse (EA-D), a DNA processivity factor required for DNA replication, and the virally encoded DNA polymerase, which is the target for most current antiherpetic drugs. Different origins of replication, *ori-lyt*, are used for replication of linear genomes. EA-D, which has served for years as a diagnostic antigen, is now a target for a new antiviral drug. The rest of the cytolytic cycle genes encode proteins that make up the virion structure. For the most part, none is activated in tumor cells, though antibodies to Z protein, the key activator of the cytolytic cycle, attain high titers during viral reactivation and are detected early in the genesis of NPC. The Z protein can dampen the growth-suppressor protein p53, while its immediate-early partner, the R protein, interacts with Rb; both may act in tandem to stimulate transiently the cell cycle and synthesis of cellular macromolecules needed for viral DNA replication.

EPIDEMIOLOGY

EBV is found worldwide, and infection is virtually universal. In underdeveloped countries, most infants are infected asymptotically within the first year of life, but not in utero or in the first few months after birth, because maternal EBV antibodies are protective. In upper-socioeconomic classes, most people are infected within the first three decades of life; the infection is often asymptomatic or undiagnosed. Typically, IM occurs in adolescence and the early third decade of life and rarely in older people. The virus spreads from person to person by close contact and exchange of oral secretions. Although there are no epidemics of IM, the incidence is higher in college students in early fall and winter, when semesters begin, presumably because of new opportunities for virus exposure. The incubation period, variable and difficult to estimate because of the insidious onset, is about 4 to 6 weeks. Asymptomatic cervical infection with EBV has been detected in up to 20% of sexually active women, but its significance is unknown. Two types and many strains of EBV can be distinguished by polymorphisms in the *EBNA2* gene. Although these viral differences do not account for the different EBV diseases, there are patterns of geographic distribution of some of the intratypic variants, especially in NPC. The rich and often puzzling epidemiologic features of EBV-associated malignancies are presented with the specific diseases.

PATHOGENESIS

The virus infects the oropharynx, where it replicates in epithelial cells, the seat of productive infection. Virus replicates in pharyngeal lining cells, parotid ductal cells, and perhaps on the tongue, accompanied early by infection of B lymphocytes, where the virus becomes latent. The principal features, then, are superficial infection of epithelium and infection of lymphocytes. In lymphocytes (CD21 cells), attachment of virus is accomplished by means of a normal cellular complement receptor (C2R). In epithelial cells, replication of linear EBV genomes dominates, in a complete cycle leading to virus production and cytolysis. In contrast, in B lymphocytes there is production of EBV episomes with expression of latent EBV gene functions and cell proliferation. These infection events are often subclinical. The dual cell-stimulatory aspects of the primary infection, both of B lymphocytes and reactive T cells, are self-limiting except in rare people with specific inborn genetic defects or acquired defects that produce severe deficiency in cell-mediated immune systems. In such people, B-cell proliferation escapes, and lymphomas result.

The pharyngitis of IM arises from cytolysis of epithelial cells caused by virus replication, which diminishes to the point of being asymptomatic, though small amounts of virus are shed into the saliva for months or years. Most of the other manifestations of IM are caused by cytotoxic T-cell and natural killer cell responses to the EBV-infected B lymphocytes, which present new virally encoded antigens on their plasma membranes. The atypical lymphocytosis in the peripheral blood (up to 40%) that is so characteristic of EBV-caused IM represents a cytotoxic T-cell response in which both CD4 and CD8 lymphocytes participate. When infection is at its height,

up to 10% of circulating B cells are latently infected. Rather than being lysed, these cells are stimulated to proliferate polyclonally, and, indeed, B cells explanted from the peripheral blood are immortalized and will form EBV-infected cell lines in vitro. The numbers of EBV-infected B lymphocytes subside gradually, but a low level persists in the circulation many years after infection. These cells contain EBV episomes.

The molecular and immunologic bases for IM thus fall into a still hypothetical but rational scheme that suggests the genesis of EBV-infected lymphomas in immunodeficient states. The role of EBV in BL and NPC follows different pathways, however, because clinical immune dysfunction precedes neither BL nor NPC and patients appear normal after treatment. From a molecular pathogenetic standpoint, NPC stands apart because it is an epithelial malignancy that must represent the exception to the cytolysis usually produced by EBV in epithelial cells, perhaps through a variance in viral gene expression.

CLINICAL FEATURES

INFECTIOUS MONONUCLEOSIS

While IM formerly was considered a constellation of symptoms of unknown origin, after the studies of Werner and Gertrude Henle in 1968, EBV now can be deemed the sole source of 90% of cases. The onset is insidious. Most symptoms are caused not by direct viral invasion but by secondary immunopathic responses that affect the brain, liver, and bone marrow; the virus does not infect the dominant cell types in these organs. IM is the result of primary, not reactivated infection. Acute pharyngitis often brings the patient to the physician. The classic features are fever lasting up to 3 weeks or more, lymphadenopathy, splenomegaly, and florid, atypical lymphocytosis along with malaise that may be slow to resolve, consistent with the subacute nature of the illness. Coupled with a positive heterophil antibody reaction or "monospot test," these features are enough for diagnosis in most cases. Heterophil antibodies are nonspecific IgM antibodies that react with surface antigens of sheep and horse but not guinea pig red blood cells. The diagnosis is verified by the presence of EBV antibodies. The symptom complex characterizing IM develops in postpubescent people in the second or early third decade of life. Infections earlier in life produce nondescript symptoms, such as fever and malaise alone.

IM can be complicated by neurologic syndromes, such as encephalitis, neuritis, transverse myelitis, and Guillain-Barre(c) syndrome, and by hematologic abnormalities, such as agranulocytosis, aplastic anemia, and thrombocytopenia. Acute hepatitis is the most common complication, but it is usually short-lived and mild. Because the virus is not directly cytolytic in these organ tissues, the often alarming complications of IM tend to resolve without treatment. A rare complication is splenic rupture. Some patients with prominent lymphadenopathy, splenomegaly, and fever have a fluctuating course that mimics lymphoma. Sometimes acute IM seems to lapse into a chronic phase lasting a year or more, marked by persistent fatigue, low-grade fevers, malaise, and a labile emotional state.

Protracted virus excretion has raised the possibility that a subset of the so-called *chronic fatigue syndrome* (CFS) may be caused by EBV infection. CFS, which is ill defined, certainly has a variety of causes. CFS attributable to EBV begins with acute IM proven by EBV serologic testing and lasting a year beyond a subacute phase. Persistently high EA-D antibody levels, formerly thought to point to CFS, are not a reliable indicator, in that normal people may have such titers several years after primary infection. CFS is rarely caused by EBV. Mononucleosis caused by cytomegalovirus infection mimics EBV mononucleosis, though sore throat and atypical lymphocytosis may not be prominent features and the heterophil reaction is usually negative. Toxoplasmosis can be confused with IM because a rash may develop in IM, especially if ampicillin is given. When complications of IM dominate, the differential diagnosis is extended and complex.

BURKITT'S LYMPHOMA

In the 1950s, an Irish surgeon, Dennis Burkitt, working in Uganda wondered whether a common childhood malignancy that appeared in the form of a tumor of the jaw might be caused by a transmissible agent because of its pattern of incidence ([Table 314.1](#)). The tumor, BL, is endemic at lower elevations in a belt sweeping from east to west across equatorial Africa. It is a rapidly growing, multifocal B-cell lymphoma whose initial symptom is a tumor of the jaw that can impinge on the ocular orbit; it is usually multifocal, affecting parenchymatous organs, the ovaries, and the testes. Bone marrow involvement is rare, in contrast to the sporadic American form of the disease. The virus now called EBV was first isolated from explanted specimens of the tumor. Patients with BL in Africa often had high titers of EBV antibodies. A firm link of virus to disease was established only by molecular hybridization analyses, which showed that cryptic viral genome, but not virus itself, was present in African BL tissue, first linking a human malignancy with a virus. More than 98% of cases of African BL contain EBV DNA, present as the EBV episome, in contrast to about 15% of the American form of BL. EBV infection precedes by years the development of lymphoma. The role of EBV in the genesis of BL appears to be as contributory cofactor.

Tissues Affected and Diseases	Role of Epstein-Barr Virus
Lymphoid	
Burkitt's lymphoma	Cofactor, nonessential; clonal
B-cell immunoblastic lymphomas	Causal
T-cell lymphomas	Clonal association
Hodgkin's disease	Clonal association, Reed-Sternberg cells infected
Chronic interstitial lymphocytic pneumonitis	Causal
Epithelial	
Nasopharyngeal carcinoma	Essential factor
Parotid carcinoma	Clonal association
Gastric carcinoma	Clonal association
Hairy leukoplakia of the tongue	Causal
Lymphoid and epithelial	
Infectious mononucleosis	Causal
Other	
Leiomyosarcoma	Clonal association in AIDS

TABLE 314.1. DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS INFECTION

In the endemic regions, the incidence of BL is estimated to be about ten per 100,000, with evidence of a downward trend. The sporadic form of BL that occurs in North America and western Europe is a much rarer disease. Although EBV is no longer thought to cause BL, it takes prime place because the virus was discovered in this neoplasm. The mean age for occurrence of BL in Africa is approximately 7 years. Because most children there are infected in the first few months of life, this figure establishes the average latency period of EBV infection in the development of BL. In the endemic areas, BL is more likely to develop in children with higher than average titers of EBV antibodies followed prospectively. Cofactors are postulated to explain the high incidence in the endemic regions. One is holoendemic malaria, the geographic distribution of which is similar to that of endemic BL. In recent years the incidence of authentic BL has risen in nonendemic regions because of AIDS, and in the United States it now exceeds the incidence in Africa.

Translocations involving the immunoglobulin loci on chromosomes 14, 22, and 2 and the *c-myc* locus on chromosome 8 are found in all cases of BL regardless of geographic origin or whether they are coincident with EBV infection, with the result that expression of the *c-myc* proto-oncogene is turned on by the immunoglobulin regulatory sequences. The role of EBV as a cofactor for BL arises from its stimulation of B lymphocytes to proliferate, which increases the likelihood of selection of cells with such a mutation, because overexpression of *c-myc* results in enhanced growth properties. This molecular lesion also accounts for the monoclonality of BL. BL cells are not recognized by the immune system, even though they express EBNA-1, an antigen. The EBNA-1 protein contains a distinctive Gly-Gly-Ala polymer, which inhibits its presentation as an antigen by major histocompatibility complex class I molecules and therefore protects BL cells from destruction by cytotoxic T lymphocytes.

B-CELL LYMPHOMAS

In contrast to BL, which arises in immunocompetent hosts (as well as in patients with AIDS), EBV lymphoproliferative syndromes (also called immunoblastic sarcomas) are complications of organ transplantation and AIDS. At first, lymphoproliferation (diffuse or localized) is polyclonal; monoclonal lymphomas are likely to evolve. None of these B-cell lymphomas has the chromosomal changes of BL, but the lymphomas are consistently infected with EBV, at least in transplant recipients. The virus is believed to be directly responsible for neoplastic growth, just as it can drive polyclonal growth of B cells in culture. Solitary lymphomas of the brain are striking examples—all are latently infected with EBV. Masses in the retroperitoneum are also common. These neoplasias almost certainly are triggered by EBV alone, without the necessity for cofactors. The tumors exhibit the type 3 latency phenotype, which is characterized by expression of all the EBV latency genes. In its early phases, lymphoproliferation in transplant recipients can be reversed by reduction of immunosuppression. With conversion to monoclonality, the proliferation is not reversible and is notoriously difficult to treat. Even with successful anti-HIV therapy, such tumors may still progress, depending on stage.

HD was associated inconclusively with EBV in the past because of high EBV antibody titers in some patients and a somewhat higher incidence of HD after IM detected in epidemiologic surveys. Stronger direct evidence of a link with the virus emerged during the early 1990s. The EBV genome is detected in up to 70% of HD tissues, in some cases as monoclonal episomes in Reed–Sternberg cells. The profile of EBV gene expression includes EBNA-1, LMP-1, LMP-2, and EBER RNA, similar to the pattern in NPC. EBV infection may contribute to the genesis of HD. EBV is more likely to be expressed in the mixed cellularity form than in the nodular sclerosing form of the disease; expression of EBV in lymphocyte-depleted HD is inconsistent and probably rare. EBV-associated HD is more common in pediatric and middle age or older patients.

There is also developing evidence of EBV infection in T-cell lymphomas, which comes as a surprise because EBV is predominantly B-lymphotropic. The tumors appear as solitary or several neoplasms or sometimes as a diffuse T-cell proliferation; they also can be sited in the nasopharynx, sometimes as a midline lesion. All are reported as negative for human T-cell leukemia virus 1 infection. They are rare conditions (up to now found in Japan, Taiwan, and the United States), but they are significant because of the monoclonality of the EBV episomes found in them and the possible new perspective on the genesis of lymphomas. Finally, the human herpesvirus 8–associated primary effusion lymphomas of B cells in patients with AIDS are sometimes co-infected with EBV, raising the possibility of an interaction between these viruses, which contain several genes in common. Lesions of Kaposi's sarcoma are not infected with EBV.

NASOPHARYNGEAL CARCINOMA

An epithelial malignancy that arises in the posterior nasopharynx in the fossa of Rosenmüller in Waldeyer's ring, NPC is a fascinating malignancy in terms of etiologic and epidemiologic characteristics, early detection, and the prospects for novel therapeutic approaches. The most common histologic type (World Health Organization [WHO] type 1) is the anaplastic form. Often infiltrated with T lymphocytes (NPC is described as a lymphoepithelioma), the EBV episomes nonetheless are found in the transformed epithelial cells, not the lymphocytes, which are normal and may be a response to a lymphokine secreted by the carcinomatous cells. NPC exhibits type 2 latency with expression of EBNA-1 and the EBV oncoproteins LMP-1 and LMP-2. The association of EBV with this malignancy is consistent worldwide, regardless of whether the disease appears in regions of sporadic or endemic incidence. EBV genomes or gene products can be detected uniformly, though with more difficulty in the rarer differentiated form (WHO type 3), where genome copy numbers are low. EBV genomes are detected even in tissues with the earliest changes leading to NPC, namely, hyperplasia. Since hyperplastic and dysplastic lesions rarely are detected, even in the endemic regions where prophylactic instrumentation and biopsy are routine in high-risk persons and full-blown NPC is common, progression of this malignancy is probably rapid.

Although it is one of the major malignancies in the world, NPC is a sporadic disease in North America and western Europe. The incidence of NPC in southern China is about 100 times higher than in the United States. Cofactors proposed to explain this high incidence are diet (ingestion of salted fish in infancy); exposure to medicinal herbs containing phorbol esters, which can induce reactivation of EBV replication from the latent state; and genetic predisposition. Other regions of high incidence include Taiwan, Singapore, Hong Kong, Malaysia, and, to a lesser extent, the west coast of North America, where southern Chinese immigrate. The incidence is also high among the Inuits of North America. NPC has a moderately high incidence in whites in North Africa, where the disease affects younger persons as well as the characteristic middle age group. North African expatriates in France have a high incidence of NPC for at least a generation, much like the Chinese immigrants. Explanations for these extraordinary epidemiologic patterns are largely speculative.

The pathogenesis of NPC in the endemic region of southern China can be outlined tentatively. EBV infection occurs early in life in the whole population. A long period of latent infection, typical of EBV, ensues until middle age (40 to 60 years). There then appear circulating IgA antibodies to EBV replicative cycle antigens, which signal viral reactivation, presumably in the nasopharynx. The trigger of this viral replication is unknown, but activation may take place when the target epithelial cells are infected. The early neoplastic changes of NPC after viral infection probably develop in selected persons with somatic mutations acquired during the latency period from the suspected environmental or nutritional carcinogens or through genetic predisposition. Monoclonal episomes in the carcinomatous cells indicate that virus infection comes before cellular proliferation leading to malignancy. The p53 gene is not mutated in NPC, except occasionally late in the course of disease, as a secondary event. Thus, in this scheme, infection is not dormant in nasopharyngeal epithelial cells. Instead, the target cells for NPC in the fossa of Rosenmüller are newly infected, perhaps mediated by IgA antibodies as a consequence of viral reactivation elsewhere. In any case, the appearance of EBV IgA antibodies is a harbinger of NPC, either already present or in incipient stages; carcinoma is detected within 12 to 18 months.

Carcinomas of other portions of the upper aerodigestive tract, including supraglottal and laryngeal carcinomas, thymomas of epithelial origin, and some parotid carcinomas, also are suspected of having a link to EBV infection. The parotid gland is a site of EBV replication, and all these tissues have a common origin in the primitive oropharynx. Infection of the aerodigestive tract extends, unexpectedly, to the stomach. Some gastric carcinomas contain clonal EBV genomes and express an EBV latency gene (*EBNA2*) not detected in the other epithelial malignancies.

A distinctive EBV-associated disease is hairy leukoplakia of the tongue, which usually produces lesions on one side of the tongue; on histologic examination there is epithelial proliferation, followed by shedding of cells, which lyse. The disease was recognized first as a lesion in patients with AIDS, but it also occurs in some allograft recipients. The most remarkable feature is the enormous number of herpesvirus particles in the lesion, identified as EBV by molecular hybridization analyses; there is florid virus replication, often with several EBV strains, leading to viral recombination. Hairy leukoplakia responds promptly to treatment with acyclovir, though it may recur.

LABORATORY FINDINGS

The EBV-associated diseases are distinctive in their clinical features, but in each case diagnosis should be established by specific tests. For IM, evidence of antibodies to the EBV viral capsid antigen (VCA), both IgG and IgM in primary infection, and, ideally, EA-D antibodies but not EBNA antibodies confirms the diagnosis. Antibodies to EA-D are transient and indicate recent infection or reactivated infection; however, EA antibody titers may persist for several years, probably because of sporadic asymptomatic virus reactivation. Antibodies to EBNA-1 often are not detectable in primary infection, appearing up to 6 months later. The characteristic pattern of past infection would be a moderate titer of IgG VCA antibodies and a low titer of EBNA antibodies, both persisting for life.

Virus is detected in saliva by exposure of cord-blood lymphocytes to filtered throat washings, which results in proliferation of the cells within 4 to 6 weeks after infection. The cell lines that emerge are immortalized and bear EBNA-1 antigen and EBV episomes in low copy numbers. The usefulness of this test is limited by its difficulty and because of protracted virus shedding in saliva. Past infection is also confirmed by cultivation of peripheral blood lymphocytes; the EBV-infected fraction in 50% or more of infected people proliferates spontaneously, and the resulting polyclonal B-cell lines bear EBV antigens and genomes.

In BL, diagnosis is based on distinctive histopathologic characteristics and cytogenetic analysis for the characteristic chromosomal translocations. In the African endemic regions, all patients with BL have VCA, EA-R, and EBNA-1 antibodies, often in high titers. Molecular hybridization analyses of tumor tissue show EBV episomes and EBER RNA. In the sporadic form, EBV serologic and viral hybridization analyses are of little value.

EBV-induced lymphoproliferative syndromes result from primary or reactivated infection and arise in the context of immunodeficiency states, most usually acquired, as in allograft recipients (up to 10% of graft recipients, depending on the intensity of immunosuppressive therapy). Primary immunodeficiency states, though rare, are associated with a very high incidence of EBV-induced lymphomas; they include X-linked lymphoproliferative syndrome (Duncan's syndrome), Wiskott–Aldrich syndrome, ataxia–telangiectasia, and combined immunodeficiency disease. The proliferations, initially polyclonal, express B-cell surface markers and do not have distinctive chromosomal abnormalities. The tumor cells evidence EBNA-1 on touch preparations, EBV episomes by Southern blot hybridization, and EBER RNA by in situ cytohybridization. Except for the absence of EBNA-1 antibodies in some EBV-infected patients with primary immunodeficiency, the serologic pattern is not distinctive; both VCA and EA antibodies are present or elevated.

Patients with NPC have a highly distinctive EBV serologic profile marked by IgA antibodies to VCA and EA antigens as well as high titers of the usual IgG antibodies to these same antigens (VCA and EA-R or EA-D). The titers of IgG antibodies to viral products, such as DNase and BZLF1 (Z), are useful as indexes of response to therapy and recurrence. The EBV IgA antibodies appear in the earliest stages of disease, including the period when premalignant hyperplastic changes are found in biopsy samples of the fossa of Rosenmüller. Evidence of EBV IgA antibodies therefore may be uniquely valuable for early detection of disease or even to predict onset in high-risk groups. In addition to EBER RNA, NPC tissues invariably contain EBV episomes, though the number of copies is low or not detectable in the differentiated WHO type 3 form. Hairy leukoplakia of the tongue is diagnosed by EBV replicative antigens and linear forms of the genome in tissue biopsy samples, which also show evidence of abundant virions on electron microscopy.

OPTIMAL MANAGEMENT

In EBV-infected cell cultures, replication of virus can be checked entirely by exposure to any of a number of nucleoside analogs and other antiviral drugs used experimentally. Latently infected cells in the cultures are unaffected. Controlled trials of acyclovir for treatment of IM have shown marginal benefit, in part because many of the symptoms of IM are caused by secondary immunopathologic processes unaffected by antiviral treatment. In theory, a nontoxic, nonmutagenic, orally administered drug that produces high blood and salivary levels plus an immunomodulator, such as a corticosteroid—coupled with early diagnosis—might be effective for the treatment of IM. An ideal antiviral pro-drug for such a regimen is valcyclovir. Another highly effective drug for use in vitro, an L-benzimidazole riboside that is thought to inhibit an EBV protein kinase, with the unique result of disabling a necessary replication cofactor—the EBV DNA processivity factor—is in development. Certain rare forms of chronic EBV infection of the lung in infants, called chronic interstitial lymphocytic pneumonitis, appear to respond transiently to acyclovir. There is no evidence that so-called chronic mononucleosis responds to antiviral drugs; the single placebo-controlled trial of acyclovir for CFS showed no benefit. The cases were heterogeneous, however, and the time after primary EBV infection uncertain.

Polyclonal B-cell lymphoproliferation may be reversed in its early phases by reducing the immunosuppressive regimen. Acyclovir may add some benefit by preventing infection of additional B lymphocytes. Other approaches are still theoretical. The concept of curing latent infection by disrupting episomal replication with the use of antisense deoxyribonucleotide oligomers to EBNA-1 in mRNA or analogous ribozymes is attractive but limited by difficulties in delivery. Such antisense oligomers should stop not only replication of EBV episomes but also proliferation of the EBV-immortalized lymphocytes. Their proliferation is also retarded by interferon- α .

Gene therapy of solitary brain lymphomas poses an interesting challenge. Approaches would be by direct inoculation of viral vectors with several objectives. One proposal is delivery of a vector carrying the herpes simplex virus thymidine kinase (tk) gene or other viral kinase, which will locally activate a systemically administered cytotoxic drug, such as ganciclovir. Similarly, the cytosine deaminase (CD) gene has been delivered to EBV lymphomas grown in SCID mice. When the pro-drug 5-fluorocytosine is given to the mice, it becomes activated by CD in the tumors, which regress. Another hypothetical approach would be to deliver by direct inoculation a viral vector containing the EBV activator gene Z. Expression of the Z protein will specifically convert latent EBV infection to active viral replication that is cytolytic. Moreover, expression of viral cytolytic cycle enzymes can activate cytotoxic pro-drugs. The difficulty is penetration into all the tumor cells; however, a bystander effect may expand cytotoxicity. Finally, systemic administration of a drug, such as a butyrate compound, might induce EBV reactivation in tumor cells (as well as in other latently EBV-infected cells), which in turn, would provide virally encoded enzymes that could activate a cytotoxic drug in the tumor cells. This strategy avoids direct inoculation but requires an effective, relatively nontoxic inducing agent.

Cell-mediated immunotherapy is no longer hypothetical for systemic treatment of EBV lymphomas. EBV-specific autologous T cells are selected and clonally expanded in vitro. Infusion of these cells has produced dramatic long-term remissions without graft-versus-host disease. The target cells in EBV lymphoproliferative disease have the type 3 latency phenotype, which responds best because all the latency proteins are expressed and only some are good antigens. A similar strategy for treatment of HD and NPC may not be as effective, because of the more restricted viral latency protein profile in these diseases. African BL, even in advanced stages, responds well to chemotherapy with cyclophosphamide. Protocols also include vincristine, methotrexate, and prednisolone. Complete, long-term remissions are expected in the EBV-associated form of the disease. The American form of BL, with dissemination to bone marrow, responds less well.

NPC is best approached in its earliest or incipient stages, which are heralded in endemic regions by the distinctive EBV IgA responses to replicative antigens. In theory, antiviral therapy with an acyclovir pro-drug might be beneficial if started early enough. Retinoids prevent second primary head and neck tumors (EBV negative) by favoring epithelial differentiation. In vitro retinoids interfere with the triggering effect of the EBV BZLF-1 (Z) protein in viral reactivation. Combination of a retinoid with a viral inhibitor at the earliest stages of pathogenesis of NPC might therefore be of benefit, but it has not been tested. Genetically engineered EBV vaccines, mainly using the GP350 membrane protein as antigen in several viral vectors, have been tested in animal models. The purified protein is not expected to prevent primary infection, but it may prevent disease.

CHAPTER 315: VARICELLA-ZOSTER VIRUS INFECTION

ANNE A. GERSHON

[Definition](#)
[Epidemiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Diagnosis](#)
[Optimal Management](#)
[Prevention and Control](#)

Varicella and zoster are two diseases that are caused by the varicella-zoster virus (VZV). Varicella (chickenpox), the primary infection, is mainly a disease of young children, but about 5% of adults in the United States remain susceptible; varicella tends to have more severe effects in adults than in children. Zoster, the secondary infection, is caused by reactivation of latent VZV that was acquired during infection with varicella. Zoster is mainly a disease of adults; after the age of 50 years, the incidence begins to climb steeply. Zoster is also more common in immunocompromised people than in normal people of similar ages. It results when cell-mediated immunity to VZV wanes either with time or because of underlying illness.

DEFINITION

VZV is a member of the herpesvirus family, closely related to herpes simplex virus (HSV) types 1 and 2, cytomegalovirus, and Epstein–Barr virus. These agents are composed of a DNA core surrounded by a protein capsid, a tegument, and an outer envelope consisting of lipids and glycoproteins. Their diameter is about 200 nm. Herpesviruses become latent after primary infection and may later reemerge and provoke a second clinical illness. VZV causes latent infection in dorsal root ganglia; its DNA and RNA have been identified there in autopsy specimens.

EPIDEMIOLOGY

In temperate climates, varicella is largely a disease of children; most cases develop before the age of 10 years. In these areas, about 95% of adults are immune to chickenpox. Most adults who recall having had clinical symptoms of varicella are immune, but only about 25% with no recollection of varicella are actually susceptible. In countries with tropical climates, there is often less spread of VZV among children and consequently a greater percentage of adults who are susceptible. The basis of this phenomenon is unknown, but it may be related to lack of urbanization, a warm ambient temperature, or both. Varicella in temperate climates is mainly seen in cold weather seasons.

After varicella infection, specific antibodies and cell-mediated immune responses develop and persist for many years. They probably play a major role in prevention of second cases of varicella, which are unusual. Varicella is a highly contagious disease; in families, about 90% of susceptible people in the household become infected. Immune people who are reexposed to the virus often experience a boost in VZV antibody and cell-mediated immunity without symptoms. In contrast to varicella, zoster occurs with equal frequency throughout the year. It is unusual in young adults, including those frequently exposed to VZV. Zoster is rare in childhood, but its occurrence increases with age, especially during the fifth decade; its rate approaches 20% in the ninth decade. Immunocompromised patients are also at higher risk of zoster; the risk is proportional to the degree of compromise in immunity. For example, zoster has been reported in as many as half of patients with advanced Hodgkin's disease. Zoster usually develops despite residual humoral immunity to VZV; most people who have it have depressed cell-mediated immunity to VZV. Cell-mediated immunity to VZV decreases with advancing age, beginning at about 50 years of age.

PATHOGENESIS

Varicella is an exogenous, primary infection ([Table 315.1](#)). External sources of VZV are vesicular skin lesions and the respiratory tract. VZV, which is spread by the airborne route, presumably reaches the respiratory tract of a susceptible person and begins to multiply, invading the local lymph nodes and eventually causing primary viremia. The virus then reaches the viscera and multiplies further, causing secondary viremia that delivers VZV to the skin.

Characteristics	Varicella	Zoster
Type of infection	Primary	Secondary
Distribution of rash	Generalized, especially trunk and face	Localized to one to three dermatomes, unilateral
Usual age at onset	Childhood	After age 50 years
Specific antibody at onset	Absent	Present
Cellular immunity to virus at onset	Absent	Low
Complications	Progressive, potentially fatal in untreated immunocompromised patients, including human immunodeficiency virus-positive patients bacterial encephalitis, superinfection	Generalized rash with viremia in immunocompromised patients May be first sign of acquired immunodeficiency syndrome Postherpetic pain in the elderly after healing of acute illness

TABLE 315.1. CHARACTERISTICS OF DISEASES CAUSED BY VARICELLA-ZOSTER VIRUS

Zoster is caused by reactivation of latent VZV in sensory ganglia, with transport of the virus down the sensory nerve to the skin. Development of zoster has not been recognized as a sign of underlying malignancy. It has been noted, however, as an early clinical sign of acquired immunodeficiency syndrome (AIDS) in people at high risk for human immunodeficiency virus infection.

CLINICAL FEATURES

Varicella takes the form of a generalized rash, after an incubation period ranging from 10 to 21 days (mean, 14 days; [Fig. 315.1](#)). The rash, which usually is accompanied by fever, is most concentrated on the trunk and head, and it consists progressively of maculopapules, vesicles, pustules, and crusts. There often are several crops of lesions, so that all forms of the rash may be seen in any one area of skin. The rash is intensely pruritic, and skin vesicles are full of infectious virions. In healthy children, the disease is usually mild. A second case in a family is often more severe than the first case. All vesicles usually crust within 5 to 7 days, and the patient is no longer infectious to others. Complications in otherwise healthy children are unusual.

FIGURE 315.1. Skin eruption of chickenpox in an adult patient.

Varicella in pregnant women may be severe; they should be observed closely in case antiviral therapy is required. A rare constellation of congenital anomalies has been reported in roughly 2% of infants born to women who contract varicella during the first or second trimester of pregnancy. These anomalies include skin scarring; a hypoplastic limb; eye abnormalities, such as chorioretinitis; low birth weight; and mental retardation. There is no recognized means of prenatal diagnosis. Ultrasonography may be helpful in assessing limb formation in case abortion is being considered.

Varicella in immunocompromised patients, including patients being treated for underlying malignancy, those with immunodeficiency diseases, and patients treated with high doses of corticosteroids (more than the equivalent of 1 mg per kilogram per day of prednisone), may be severe or fatal. Patients with underlying leukemia or lymphoma are at greatest risk; untreated, their mortality rate approaches 10%. Severe varicella may be either fulminant—with hemorrhagic skin lesions, disseminated intravascular coagulation, and death—or more indolently fatal. In the latter case, the disease seems to progress normally for the first week. Fever continues, however, and many new, often large vesicles appear during the second week, when pneumonia often develops, which is usually the fatal event. According to the Centers for Disease Control and Prevention, estimated fatalities due to varicella are two per 100,000 in otherwise healthy children, 50 per 100,000 in adults, and 7,000 per 100,000 in children with an underlying malignancy. Newborns whose mothers have varicella at term are also at increased risk for severe chickenpox, which resembles varicella in immunocompromised patients and has a mortality rate of about 20%.

Adults may have extensive skin lesions, and they have a high incidence of varicella pneumonia. Pulmonary involvement occurs 1 to 6 days after the onset of rash. In studies of military recruits, the incidence of pulmonary disease (cough and shortness of breath) is 4% of adult cases, with abnormal chest radiographic features in 16%. The typical radiologic finding in varicella pneumonia is diffuse nodular infiltration. In contrast to children, adults tend to have a prodromal period before onset of rash, and their convalescent period may last several weeks. The severity of pneumonia appears to reflect directly the degree of cutaneous involvement. Adults with varicella should be observed closely so that antiviral therapy can be administered if necessary. It should be given, for example, to adults in the early stages of varicella pneumonia.

Zoster appears as a unilateral rash in a dermatomal distribution; from one to three dermatomes are usually involved. Fever may be present. Zoster is seen most commonly in the thoracic region, followed by the facial–cervical area, trunk, and extremities. Pain is associated with the acute phase of zoster, and older patients may experience postherpetic neuralgia that may last for many months after the rash has healed. The incidence of postherpetic pain begins to increase sharply at about the age of 50 years. Zoster actually represents a spectrum of disease—some patients experience only dermatomal pain without rash, some have only a few vesicular lesions, and some show extensive dermatomal involvement. It is not uncommon for 10 to 15 scattered vesicular lesions to develop outside the dermatomal area.

Zoster of the face often involves the ophthalmic division of the trigeminal nerve; this is commonly associated with central nervous system symptoms, such as headache, aphasia, and seizures. Granulomatous angiitis, appearing as contralateral paralysis days to weeks after the onset of trigeminal zoster, may be caused by VZV infection of the cerebral blood vessels; it is seen most often in elderly patients. The time course of zoster varies and is often longer in immunocompromised people. Patients are no longer infectious to others after all lesions are dried. The mortality rate from disseminated zoster in immunocompromised patients is 1% to 2%.

DIAGNOSIS

Infections caused by VZV are usually distinctive in clinical features, and for this reason, laboratory confirmation often is not required ([Table 315.2](#)). The concentration of lesions on the face and trunk as well as the vesicular and pruritic character of the rash in varicella are most helpful diagnostically. Epidemiologic clues, such as exposure to VZV and the season of the year, also may be helpful. Zoster is less likely to be confused with other diseases, with the exception of HSV infection. About 10% of cases diagnosed as zoster actually are caused by HSV. Recurrent dermatomal rashes are almost always attributable to HSV rather than VZV. A specific diagnosis of VZV infection is best made by examination of skin scrapings of vesicular lesions. A fourfold or greater rise in VZV antibody is considered diagnostic of varicella. It is usually indicative of zoster as well, but patients with HSV who have had varicella at one time may also have a concomitant rise in VZV antibody titer. Therefore, zoster is best diagnosed by analysis of vesicular fluid. In VZV encephalitis, it is rare to isolate the virus from cerebrospinal fluid. High VZV antibody titers in cerebrospinal fluid may suggest this complication. Polymerase chain reaction assays for VZV DNA in cerebrospinal fluid may show positive results.

Differential for varicella
Contact dermatitis, coxsackievirus infection, generalized herpes simplex virus infection, impetigo, insect bites, rickettsialpox, scabies, Stevens–Johnson syndrome
Laboratory testing
Examine skin lesions for evidence of VZV
Detect viral antigen by immunofluorescence (using commercial tagged monoclonal antibodies); detect viral DNA by polymerase chain reaction
Culture moist lesions for virus (can take a week or longer)
Tzanck smear (not specific for VZV)
Detect fourfold or greater increase in specific antibody titer in acute- and convalescent-phase serum specimens (takes at least 10 days to collect specimens)
Assays: immunofluorescence, enzyme-linked immunosorbent assay, radioimmunoassay, latex agglutination, complement fixation

VZV, varicella-zoster virus.

TABLE 315.2. DIAGNOSIS OF VARICELLA. ZOSTER VIRUS INFECTION

OPTIMAL MANAGEMENT

Local treatment measures, such as calamine lotion for varicella and Burow's solution for zoster, are often used. Aspirin should not be given to children and adolescents with varicella, because of the risk of Reye's syndrome; acetaminophen may be taken to control fever. Antihistamines may control itching. Acyclovir (ACV), a selective inhibitor of VZV DNA synthesis, is useful for therapy of VZV infections. Patients with severe or potentially severe infections should be treated with the intravenous formulation at a dose of 30 mg per kilogram per day for adults and adolescents and 1,500 mg per square meter per day for children (in both instances given in three divided doses), because only about 20% of the oral formulation is absorbed from the gastrointestinal tract. ACV is excreted by the kidneys; for this reason, patients with creatinine clearances of less than 50 mL/min/1.73 m² should receive one-half to one-third the normal dosage. ACV should be infused over at least 1 hour, with maintenance fluids given both before and during the infusion. Precipitation of the drug in the renal tubules, with reversible increases in serum creatinine levels, has been associated with bolus administration. Other side effects of ACV include phlebitis, rash, nausea, and neurologic manifestations, such as headache and tremor; however, the drug is remarkably well tolerated, in part because an enzyme induced by VZV is required for the antiviral effect of ACV.

Because ACV has little toxicity and therapy within 3 days of onset has been associated with the best outcomes, it is recommended that early treatment be instituted for patients at high risk of severe VZV infections, to prevent dissemination of the virus. This therapy should not be considered merely potentially lifesaving; in many cases, considerable morbidity can be prevented by antiviral treatment in immunosuppressed patients. In zoster patients, intravenous ACV is associated with more rapid healing of skin lesions and resolution of acute pain than if no specific treatment is given.

There has been considerable interest in the question of whether orally administered ACV is useful for treatment of varicella and zoster in patients who are not immunocompromised. Dosages used are 4 g per day (in five divided doses) for adults and 80 mg per kilogram per day (in four divided doses) for children. Therapy with oral ACV begun within 24 hours of rash onset shortens the course of varicella by about 1 day but does not prevent complications or spread of VZV. For zoster, drug efficacy has been established even if 3 days have elapsed since onset, but the earlier ACV is begun, the greater the effect is likely to be. Although it has not been verified conclusively, there is some indication that therapy minimizes the pain associated with zoster. It has therefore become customary to treat elderly patients with early zoster, because the older the patient with this disease, the more likely it is that pain (especially postherpetic neuralgia) will be a problem. A study conducted by Wood and colleagues found no difference in outcome in older patients with zoster whether they were treated with ACV for 7 days or 21 days. Moreover, healing was no more rapid, and postherpetic neuralgia was no less likely to occur, if a 3-week course of tapering prednisolone (beginning at 40 mg per day) was given in

addition to ACV.

One concern about widespread use of ACV is that drug resistance may develop. Resistance is less of a problem with VZV than for HSV. In the case of HSV, VZV resistant to ACV has been reported, most often in patients with underlying AIDS. The antiviral drug foscarnet, which is more toxic than ACV and can be administered only intravenously, has proved useful for therapy of ACV-resistant VZV. The antiviral drug famciclovir has been approved by the Food and Drug Administration for oral therapy of zoster. This antiviral is the prodrug of the active compound penciclovir, to which it is rapidly converted in the body. Like ACV, penciclovir has no antiviral activity until it is phosphorylated by viral enzymes. Its main advantage over ACV is that it can be administered three times a day (1,500 mg per day) rather than five times daily, which may lead to better compliance. There are no data concerning whether varicella can be treated successfully with famciclovir, nor are there any published data on the use of famciclovir in immunocompromised patients. A drug analogous to famciclovir, valcyclovir, has also been approved for treatment of zoster.

PREVENTION AND CONTROL

Passive immunization against varicella may be achieved with varicella-zoster immune globulin (VZIG). VZIG is available through local blood centers and the American Red Cross. It is indicated for prevention or modification of severe varicella in high-risk people, including those with an underlying malignancy or immunodeficiency disease, patients receiving high doses of corticosteroids for any reason, and newborns whose mothers have had onset of varicella 5 days or less before or within 2 days after delivery. Recipients should also have had intimate exposure to varicella within the preceding 5 days, but preferably within 3 days. Intimate exposure is usually defined as that occurring in a household, as the result of indoor play in a closed area for more than 1 hour, or through having adjacent hospital beds. Exposure to either varicella or zoster is considered significant.

Immunocompromised adults as well as immunocompromised children with no history of varicella also should be passively immunized after an exposure. It is helpful to determine the immune status of such immunocompromised adults in advance. Because 95% of people older than the age of 30 years are immune to varicella, adults with detectable VZV antibodies measured by a reliable method do not require passive immunization should an exposure occur.

VZIG should not be used to try to control nosocomial varicella because it may not necessarily prevent clinical symptoms of chickenpox but rather modify them. In addition, it increases the possible time of risk, because the incubation period of varicella may be increased. VZIG should be given to otherwise healthy adults only if they have been proved by serologic testing to be susceptible to chickenpox. It should not be given to healthy children for modification of benign disease. Overuse of VZIG in populations not at high risk of severe varicella is unnecessarily expensive. VZIG has not been found to be useful for treatment of VZV infections or for prevention of zoster in high-risk patients. High-risk patients who have received VZIG may still experience a mild form of varicella. They need to be observed carefully, but only rarely do they require any specific antiviral chemotherapy. Nosocomial varicella typically can be controlled by a combination of testing of employees (in advance) for susceptibility to varicella, obtaining accurate histories for varicella in all patients admitted to the hospital, furloughing susceptible personnel during potential incubation periods, cohorting exposed susceptible children and those with active varicella, and discharging exposed susceptible patients early.

A live attenuated varicella vaccine was developed in Japan in the early 1970s. It is extremely effective in preventing severe varicella. Mild breakthrough cases of varicella have been noted in a few vaccinees. Thus far, these cases have required no specific therapy, even in highly immunocompromised children. Immunization has been associated with a decline in the incidence of zoster in leukemic children. In 1995, this vaccine was approved for routine use in healthy persons susceptible to the disease who are more than 1 year of age. Adults should be given two doses 1 month apart for optimal protection.

CHAPTER 316: ENTEROVIRUS INFECTIONS

ROSS E. MCKINNEY, JR.

[Definition](#)
[Epidemiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Management](#)

DEFINITION

The enteroviruses are small, nonenveloped, single-stranded RNA viruses. They are members of the family Picornaviridae (*pico* meaning “small”—hence, “small RNA viruses”) and consist of a single RNA strand and a capsid made up of four virus-encoded proteins. The enteroviruses are divided into subtypes, shown in [Table 316.1](#). The missing serotypes (for example, echovirus 10) are due to reclassification of early serotypes as further information became available. Hepatitis A previously was classified as one of the enteroviruses but was reclassified as a separate genus in 1991 (Hepatovirus). The classification of a given virus as an echovirus, coxsackievirus, or poliovirus is determined by the virus receptor (the cell protein to which the virus attaches before entry).

Poliovirus	Types 1-3
Coxsackievirus, group A	Types 1-22, 24
Coxsackievirus, group B	Types 1-6
Echovirus	Types 1-9, 11-27, 29-33
Enterovirus	Types 68-71

TABLE 316.1. MEMBERS OF THE GENUS *ENTEROVIRUS*

EPIDEMIOLOGY

The enteroviruses spread from person to person through the fecal–oral route. As nonenveloped viruses, they are physico-chemically very stable and persist in the environment for long periods of time. The lack of an envelope and their dense protein capsid make the enteroviruses relatively resistant to inactivating agents, such as soaps and detergents. They are shed in the feces of infected people and may be excreted for as long as months. Sewage frequently contains enteroviruses and may be a source of contamination of water supplies. Young children, with their feces contained in diapers, are another important source of enteroviral exposures. Children also have the highest attack rates of enteroviral infection and disease. The enteroviruses are distributed worldwide and are affected by the seasons in temperate climates, occurring more frequently during the summer and early fall. In the tropics, they have a year-round incidence.

Poliovirus eradication has been an important international objective since the development of polio vaccines in the 1950s. While the Western Hemisphere has been free of wild-type poliomyelitis since the mid-1990s, the disease continues to be endemic in Africa and southern Asia. Because human beings are the only animal host for polio, there is still hope that with complete vaccination, wild-type polio eventually will be eliminated.

PATHOGENESIS

The enteroviruses are cytolytic. Once they infect a cell, they monopolize the cellular protein synthesis system so that the cell produces almost only viral proteins. These proteins are assembled into viral particles, and the cell ruptures. Virus particles are released into the extracellular milieu, and eventually the viruses attach to the receptor on another susceptible cell. The requirement for an extracellular step in the life cycle makes the enteroviruses vulnerable to neutralizing antibodies as a host defense.

The enteroviruses invade their human hosts through mucosal surfaces. Initial penetration and replication take place either in the oral mucosa and tonsillar tissues or in the lower gastrointestinal tract. The viruses are stable in an acid environment and thus are able to pass through the stomach into the intestines. The virus traverses the intestinal wall, and replication occurs in submucosal lymphatic tissue, particularly Peyer’s patches. From the intestinal tract, some virus enters the circulation. This period is usually asymptomatic but can result in mild symptoms, primarily fever; this is referred to as the “minor viremia.” During this phase the virus spreads to more distal lymphatic tissue. In some cases, the minor viremia produces a sufficient antigenic stimulus to trigger an immune response, and the virus is controlled, predominantly through the production of neutralizing antibodies (rather than cytolytic T cells). Tropism of the virus determines the sites where the virus is able to replicate as it is carried through the circulation. For example, poliovirus has tropism for the central nervous system, particularly the anterior horn cells of the spinal cord, and thus produces central nervous system disease.

CLINICAL FEATURES

The most common clinical result of an enterovirus infection is asymptomatic viremia and gastrointestinal shedding or a mild febrile illness of a few days’ duration. Nonetheless, there are several important clinical syndromes associated with enteroviral infection.

POLIOMYELITIS

More than 90% of poliovirus infections are asymptomatic. Only one in 1,000 infected people show signs of paralytic disease. Symptomatic poliomyelitis is often biphasic. The first phase, or “minor illness,” develops in roughly 10% of poliovirus disease. It begins with fever and nonspecific symptoms, such as myalgias, headache, and sore throat. This phase resolves within 1 or 2 days. The major illness with polio infection is marked by the abrupt onset of aseptic meningitis. The symptoms include fever, headache, nuchal rigidity, and vomiting. The cerebrospinal fluid evidences pleocytosis, mildly elevated protein levels, and a normal glucose level. At this stage, aseptic meningitis cannot be distinguished from any other enteroviral meningitis.

The characteristic motor disease of poliomyelitis begins with severe myalgias. The pain is alleviated by exercise, such that patients may pace or perform other maneuvers in the early stages of disease to minimize myalgia. The pain and subsequent weakness are characteristically asymmetrical. Flaccid paralysis begins 1 to 2 days into the major phase of illness. Any combination of limbs can be afflicted, but the muscle groups are generally proximal more often than distal. The lower limbs tend to be affected more frequently than the upper limbs. Painful spasms can arise in nonparalyzed muscles. Deep tendon reflexes diminish or disappear, and sensory function remains normal. Bowel and bladder dysfunction can be an early symptom.

In general, paralysis peaks within 5 days, and recovery is slow; most recovery occurs within 6 months. Sixty percent of patients are left with residual weakness. Less than 10% of patients die; those that do commonly succumb to respiratory failure. Cranial nerve involvement (bulbar poliomyelitis) is noted in 5% to 35% of paralytic disease. It can strike any cranial nerve, but the ninth and tenth are the most often affected. The major concern with bulbar poliomyelitis is the effect on respiration. Other diseases can mimic polio. Several enteroviruses can produce a poliomyelitis syndrome, particularly coxsackie A7 and enterovirus 71. Guillain-Barré syndrome and neonatal botulism can mimic polio, but symptoms of these diseases are symmetrical, in contrast to polio. Moreover, Guillain-Barré syndrome often has sensory

manifestations.

ASEPTIC MENINGITIS

Most of the enteroviruses can cause aseptic meningitis. The typical pattern is fever, malaise, headache, nuchal rigidity, and sometimes a petechial rash. The onset is typically acute, most often in the summer or early fall. Cerebrospinal fluid shows moderate pleocytosis with neutrophils predominating in the early stage; over the course of 24 hours this changes to lymphocyte predominance. The total leukocyte count is generally in the range of 30 to 400, the protein level is mildly elevated, and the glucose level is normal. The usual course of illness is 2 to 5 days. The disease can be more serious in young infants, though there are generally no significant residual effects at any age. A small number of infants experience disease-associated seizures, but these are usually easily controlled.

ENCEPHALITIS

Most cases of enteroviral encephalitis are truly a form of meningoencephalitis, involving both brain matter and the meninges. In the immunologically normal host, symptoms initially are those of aseptic meningitis. Progression to confusion, lethargy, and irritability occurs over days. Seizures, coma, or death are possible outcomes. At times, the syndrome can mimic the symptoms of herpes encephalitis. Children and adults with X-linked agammaglobulinemia are susceptible to an unusual chronic form of enteroviral meningoencephalitis. The disease takes the form of slowly diminishing cognitive function and cortical atrophy on computed tomographic or magnetic resonance imaging. Hypogammaglobulinemic children not treated prophylactically with intravenous immune globulin may show signs of a dermatomyositis-like syndrome.

MYOCARDITIS

The enteroviruses, particularly coxsackie B viruses, are the most common cause of acute viral myocarditis, producing 25% to 35% of the cases for which a source can be determined. Neonates are particularly susceptible, though the disease can affect persons of any age. Symptoms include signs of congestive heart failure, palpitations, and chest pain. The pain can mimic that of a myocardial infarction. Arrhythmias as a result of myocardial inflammation can be life threatening. Blood levels of cardiac isoenzymes may be elevated. The pericardium is often involved; at times there may be significant pericardial fluid and tamponade. A small proportion of patients progress to chronic congestive heart failure, endocardial fibroelastosis, or dilated cardiomyopathy. In most patients (80% or more) the disease resolves completely.

PLEURODYNIA

Pleurodynia, also known as the Devil's gripe and Bornholm disease, is an inflammation of costal and abdominal muscles. It is produced most often by the coxsackie B viruses and is marked by sharp pain on cough or deep breathing. The illness begins with typical enteroviral symptoms of fever and malaise, before the onset of thoracic symptoms. The illness lasts 7 to 10 days, though the symptoms may recur for a period of weeks. Treatment is symptomatic.

PANCREATITIS AND DIABETES MELLITUS

Enteroviruses are one of the most common causes of acute viral pancreatitis, though the disease itself is relatively uncommon. There is also a long-standing suspicion that the enteroviruses, especially coxsackie B viruses, contribute to the pathogenesis of diabetes mellitus, perhaps through triggering an autoimmune process in a genetically susceptible host.

HAND, FOOT, AND MOUTH DISEASE

Outbreaks of hand, foot, and mouth disease often occur in the summer months. The most common source is coxsackie A16 virus, but enterovirus 71 and other coxsackie A serotypes also can induce the disease. Typically, the patient has fever, headache, a maculopapular rash on the palms and soles, and small oral ulcers. Both the palm/sole exanthem and the oral enanthem can be painful. The oral rash frequently involves the palate and posterior pharynx, making it distinct from the more anterior lesions of herpes simplex stomatitis. Occasionally, hand, foot, and mouth disease can be severe. During a 1998 outbreak in Taiwan, 90,000 cases of the disease were reported; 320 patients required hospitalization, and 55 died. The cause of death was most often shock beginning 2 to 7 days after a nonspecific febrile prodrome. Most of the victims were children less than 3 years old.

ACUTE HEMORRHAGIC CONJUNCTIVITIS

Acute hemorrhagic conjunctivitis is characterized by swelling of the eyelids, acute eye pain, photophobia, headache, and subconjunctival hemorrhages. Most hemorrhagic conjunctivitis is caused either by enterovirus type 70 or by a coxsackievirus A24 variant. The virus is spread primarily in tears, an unusual pattern for the enteroviruses. Paralytic disease similar to poliomyelitis has been reported in some enterovirus type 70 outbreaks.

OTHER

The enteroviruses are one of the most common causes of parotitis (inflammation of the parotid glands) and are part of the differential diagnosis of possible mumps infection. Herpangina, which is distinct from hand, foot, and mouth disease, appears as multiple papulovesicular lesions on the posterior palate and tonsils. The gums are rarely afflicted. Coxsackie A viruses are most often implicated, and treatment is symptomatic.

LABORATORY FINDINGS

The enteroviruses can be detected by either culture or polymerase chain reaction testing. Detection by tissue culture is relatively quick—typically less than a week—and is marked by a characteristic cytopathic effect. Nonetheless, not all enterovirus types grow well in tissue culture. Most coxsackie A viruses, for example, are cultured more effectively in the brains of suckling mice than in vitro. The echoviruses, polioviruses, and coxsackie B viruses can be detected fairly reliably in tissue culture. Culture also can be used to determine the serotype of a given enterovirus through the use of overlapping pools of neutralizing antibodies.

Virus detection by polymerase chain reaction is faster and more sensitive than culture, though it is not yet widely available. The method detects a conserved noncoding region of the virus and is able to recognize enteroviruses regardless of serotype. It is particularly useful in detecting low levels of virus in such conditions as chronic enteroviral meningoencephalitis in agammaglobulinemic patients. Antibody tests are of little general diagnostic benefit. If the serotype of virus is known, a rise in antibody titer can be used to confirm infection. In most cases, however, the specific serotype is uncertain, and screening batteries of antibodies are often inaccurate, because of both false-positives and false-negatives.

MANAGEMENT

The primary management strategy for poliovirus has been prevention through vaccination. The approach recommended at present is inactivated polio vaccine (Salk). This strategy limits the exposure of immunocompromised children to live virus like the Sabin attenuated poliovirus vaccine at a time when their immune problem may not be diagnosed. The major treatment for enteroviral infections is symptomatic care. Intravenous immunoglobulin is useful to prevent enteroviral disease in hypogammaglobulinemic patients and can be administered to treat chronic meningoencephalitis in agammaglobulinemic individuals. Pleconaril is an experimental antiviral that has shown early promise in the treatment of serious enteroviral disease. It acts at the level of virus uncoating and blocks the release of viral RNA once the virus has entered a cell. Its use in human disease is still at an early stage.

CHAPTER 317: VIRAL GASTROENTERITIS

ROGER I. GLASS

[Epidemiology](#)
[Microbiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Diagnosis](#)
[Treatment](#)

In the past, diarrhea often was attributed to viruses when a bacterium or parasite could not be pinpointed as the causative agent. In 1972, the Norwalk agent was the first virus to be identified as a source of diarrhea in humans; since then, rotaviruses, enteric adenoviruses, astroviruses, and other human caliciviruses, including both Sapporo-like viruses and Norwalk-like viruses, have been recognized to cause diarrhea in humans. Other viruses—among them, torovirus, picobirnavirus, coronavirus, enterovirus 22, pestivirus, and parvovirus—have been found in fecal specimens of patients with diarrhea but have not yet been proved to be causative agents of human disease. Viral gastroenteritis is generally mild and self-limited, but in some patients, particularly small infants, the elderly, and the immunocompromised, illness can be severe, leading to extreme dehydration and occasionally death. Viral gastroenteritis induces either diarrhea or vomiting, or both. Viruses are the recognized source of a syndrome previously described as *winter vomiting disease*.

EPIDEMIOLOGY

Viral diarrheas take two distinct forms—common childhood diarrheas that develop in all children during their first 5 years of life and epidemic disease that afflicts both children and adults in sporadic outbreaks. Childhood diarrhea is associated with rotavirus (group A), enteric adenovirus, astrovirus, and human caliciviruses, including both Sapporo-like viruses and Norwalk-like viruses. These viruses infect most children in their first few years of life. First infections usually are associated with disease, and their modes of transmission are generally unknown but may be by direct contact or through airborne droplets. For those agents whose epidemiologic characteristics have been better studied, the declining incidence of disease with increasing age and the low rate of subsequent infections suggest that immunity develops after early infections. In the United States, as well as in other developed countries, a majority of all diarrheal illness in children is provoked by viruses, whereas in developing countries, these agents also are present but complemented by many other bacterial and parasitic pathogens. In temperate climates, rotavirus, astrovirus, and Norwalk-like viruses have a distinct seasonality from late fall to early spring, whereas in tropical settings disease occurs year-round.

Epidemics are typically caused by the Norwalk-like viruses, whose many representatives (Snow Mountain, Hawaii, and Taunton agents) share a characteristic small, round-structured appearance seen on electron microscopy (EM); nonetheless, they are antigenically distinct. Epidemics associated with the Norwalk-like viruses are the most commonly identified and affect groups of all ages. Transmission often can be traced to fecally contaminated water or foods, especially oysters, and dissemination by direct contact, vomitus, or air-borne droplets has been suggested when no other route of transmission has been identified. Epidemics often can be aborted by distinguishing the mode of transmission—particularly contaminated food or water or an ill food handler—and implementing specific public health controls. Rotaviruses of group B have triggered epidemics of cholera-like diarrhea throughout China since 1982 and also have been identified in India. Rotaviruses of group C have been implicated in epidemics worldwide, mostly in infants and small children, but the epidemiologic features of disease caused by this virus are poorly understood, because detection methods are not commonly available. The observation that endemic childhood diarrhea (rotavirus, astrovirus) has been identified less frequently in outbreaks also suggests that their mode of transmission in these settings may be different. For example, rotavirus can cause outbreaks among children in day care centers or in hospital wards, where patients may have direct contact with contaminated food or other vehicles of transmission (toys, surfaces).

The disease burden of viral diarrheas is enormous. Globally, rotavirus alone accounts for an estimated 600,000 deaths per year in children under age 5 and about one-third of all hospitalizations for childhood diarrhea, making it the most severe cause of childhood diarrhea. In the United States, approximately 10% to 12% of all hospitalizations among children less than 5 years old are for diarrhea—160,000 hospitalizations per year, with a mean duration of 3.5 days. The majority of these illnesses are associated with viral agents. Among adults, 1.5% to 2% of all hospitalizations are for diarrhea, and a bacterial pathogen can rarely (less than 10%) be identified, suggesting that many of these episodes are due to viruses.

MICROBIOLOGY

All enteric viruses can be seen by EM and confirmed in reference or research laboratories, but in clinical settings simple diagnostics using commercially available assays are available only for rotavirus and adenovirus. The difficulty in detecting gastrointestinal viruses has precluded in-depth investigation of the epidemiologic characteristics of disease caused by these agents, particularly for sporadic cases requiring hospitalization. It also has made clinicians underestimate their importance.

Rotavirus (group A), a member of the family Reoviridae and the most important source of severe diarrhea in children worldwide, is a 70-nm triple-shelled virus that contains 11 segments of double-stranded RNA and can be cultivated. Two outer capsid proteins are involved in neutralization activity and specify the four main serotypes commonly found in humans. The immune response to infection can be measured by antibodies in serum, though the mechanism of protection, believed to be mediated by local immunity, is not well understood. Rotaviruses with other group antigens—groups B and C—that cause epidemic diarrhea in humans are indistinguishable by EM from the more common group A strains of rotavirus. Diagnosis rests on their distinct profile on polyacrylamide gel electrophoresis (PAGE), their failure to be detected with common immunoassays to group A strains, and detection of their unique antigens by enzyme immunoassay and their distinct genetic sequences by reverse transcription–polymerase chain reaction (RT-PCR).

Norwalk-like viruses and Sapporo-like viruses are genetically distinct groups in the family Caliciviridae. They are 27 to 35 nm in size; contain positive-sense, single-stranded RNA; and cannot be grown in tissue culture or propagated in animal models. Sapporo-like viruses were previously called *classic human caliciviruses* because of the large calicis at their rim surrounding a distinct Star of David structure at the core. Until recently, the virus could be detected routinely only by EM, which is quite insensitive. Immunoassays for the Norwalk-like viruses in fecal specimens and antibodies in serum samples required non-replenishable virus and paired samples obtained from human volunteers. The recent cloning of these viruses has led to new molecular methods to detect virus (RT-PCR, Southern blot hybridization) and characterize strains by sequence analysis, but these techniques are not yet suitable for routine use. Expression of the capsid protein of Norwalk virus in baculovirus has yielded viruslike particles that have been useful in immunoassays to detect seroconversion. Further advances in our understanding of the epidemiologic features and clinical importance of these agents will require improved diagnostic assays and further advances from research laboratories.

Enteric adenoviruses, particularly of serotypes 40, 41, and 31, are 80-nm icosahedral viruses with double-stranded DNA that grow fastidiously in cell culture. They can be detected by commercially available immunoassays to the adenovirus hexon and then serotyped using monoclonal antibodies to serotypes 40 and 41, the strains that most often provoke diarrhea. Astroviruses are rarely seen by EM and were thought to be an uncommon cause of diarrhea in children. The recent development and application of simple immunoassays to detect virus in fecal specimens and to confirm and serotype positive strains by culture and molecular methods have led to the recognition that this virus is a common pathogen in children. By EM, the 30-nm virus is often visible in large sheets and has a smooth outer surface that occasionally surrounds a star-shaped structure that gives it its name. The core contains single-stranded RNA, which has an unusual replication strategy and has been classified in its own family, Astroviridae. Simple diagnostic methods for astrovirus may be commercially available soon. Other viruses have been found by EM or PAGE in fecal specimens from patients with diarrhea, but their role as etiologic agents has not been established. They include the toroviruses, picobirnavirus, coronavirus, reovirus, pestivirus, and parvovirus.

PATHOGENESIS

Whereas the pathogenetic conduits of most viral agents of gastroenteritis have been well studied in animals, our understanding of their pathogenicity in humans is quite limited. Generally, infection occurs in the proximal portion of the small intestine and the pathologic agents, like the disease, are transitory. Rotavirus infects and damages the villous tips of mature epithelial cells, causing sluffing of the mucosa and secretory diarrhea. Norwalk infects epithelial cells as well, producing blunting of the villous tips, hypertrophy of crypt cells, and accumulation of inflammatory cells in the lamina propria. Infections with these viruses are localized to the intestine; extra-intestinal manifestations have been documented but are rare. For example, rotavirus has been found in the liver of patients who have died of severe combined immunodeficiency syndrome, and rotaviral RNA has been found by RT-PCR in cerebrospinal fluid of children with rotavirus diarrhea and seizures.

CLINICAL FEATURES

The clinical features of viral gastroenteritis can range from asymptomatic infection to overwhelming, dehydrating diarrheal illness. Vomiting is often prominent and precedes the onset of diarrhea. Rotavirus is associated with low-grade fever and dehydration that can last 3 to 7 days. In the United States, a majority of children less than 2 to 3 years of age who are hospitalized in the winter season have rotavirus. Rotavirus diarrhea is uncommon in the first 3 months of life, and the incidence declines rapidly after 2 years of age. Rotavirus also can develop in adults as a form of traveler's diarrhea, among parents and caretakers of infants with rotavirus, and among immunocompromised patients who experience prolonged shedding. Childhood diarrhea associated with other viruses is indistinguishable from that of rotavirus diarrhea.

Viral gastroenteritis in adults typically is provoked by Norwalk-like viruses and has symptoms of vomiting and diarrhea. Older patients suffer from low-grade fever, abdominal cramps, myalgias, malaise, and headaches. The incubation period is 18 to 36 hours, and the illness lasts for 18 to 48 hours and is self-limited. Fecal leukocytes and elevated white blood counts are absent. Viral agents have not been associated with dysentery, and chronic diarrhea in the context of infection with these viruses has been documented only in immunocompromised patients.

DIAGNOSIS

EM is the only method to detect the variety of agents causing diarrhea, and most diagnoses require help from a reference laboratory. Commercial assays for rotavirus and adenovirus are based on the detection of antigen in fecal specimens using enzyme-linked immunosorbent assays, latex agglutination, and PAGE. Molecular methods, including RT-PCR, are available in research laboratories to detect the caliciviruses (Norwalk-like viruses) and characterize Sapporo-like virus as well as astrovirus. Proper collection and handling of specimens are key to establishing a viral origin. Fecal specimens collected in large volume and maintained at 4°C are best suited for electron microscopy and can be used for both immune and molecular diagnostic assays. Paired acute- (0 to 5 days) and convalescent-phase (14 to 28 days) serum samples are useful to document an immune response to the virus and help establish that the virus was the causative agent of the disease and not a mere traveler in the intestinal tract.

TREATMENT

Treatment of viral diarrhea rests on the replacement of fluid and electrolyte losses with oral rehydration therapy in patients who are alert and on intravenous rehydration in patients with severe dehydration (more than 10%), recurrent vomiting, or inability to take an adequate volume of oral rehydration solution. Since most diarrheas in children are of viral origin, antibiotics are specifically contraindicated, and antimotility drugs have no established role. In immunocompromised patients, immune globulin has been suggested to treat gastroenteritis stemming from rotavirus infection; it may minimize symptoms of diarrhea caused by other viral agents.

PREVENTION AND CONTROL

At present, no specific measures are available for the control of the common childhood diarrheas caused by viral agents, except for rotavirus. Rotavirus vaccine (Tetravalent Rhesus Rotavirus—RotaShieldR) has been licensed and recommended for the routine immunization of American children. Three oral doses of this vaccine provide more than 80% efficacy against severe rotavirus disease. This vaccine and others under development hold the prospect of preventing this specific cause of childhood diarrhea. In outbreaks, identification of the mode of transmission (water, food, shellfish, or an infected food handler) can lead to specific public health interventions. In the absence of specific control measures, nonspecific enteric precautions are recommended, particularly for outbreaks in day care centers, retirement homes, or hospital settings. These precautions include hand washing; the hygienic disposal of diapers, feces, and vomitus; and provision of clean food and water.

CHAPTER 318: RABIES

CHARLES E. RUPPRECHT

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Optimal Management](#)
[Prognosis](#)

DEFINITION

Rabies is an acute, fatal encephalomyelitis due to infection with rabies and related lyssaviruses. It is widespread among mammals worldwide, with the exception of areas that have prevented its establishment (Oceania) or achieved secondary elimination (Great Britain). Humans almost always become infected from the bite of a rabid animal by way of virus-laden saliva. Human infection is also known as hydrophobia; unlike more recently recognized emerging conditions, such as acquired immunodeficiency syndrome and hantavirus pulmonary syndrome, rabies is one of the oldest known viral diseases.

INCIDENCE AND EPIDEMIOLOGY

Rabies is a zoonosis with diverse natural reservoirs; hence, its incidence is poorly quantified because of the variables related to the wild populations at risk. Predominant hosts are bats and mammalian carnivores. These animals include canids, such as the domestic dog as the principal global reservoir; foxes in the Arctic, eastern Canada, portions of New England, Central and Western Europe, the Middle East, and scattered foci throughout the western United States; coyotes in the western United States and Latin America; skunks, primarily in the central and western United States, Canada, and portions of Latin America; raccoons, in the eastern United States; and several species of viverrids, such as the mongoose in Asia, Africa, and several Caribbean islands. "Bat" rabies per se is a New World phenomenon, described primarily among the insectivorous species in the Western Hemisphere and the hematophagous vampires in Latin America. Related lyssaviruses have been diagnosed in African, European, and Australian bat species. Although the disease is naturally maintained by relatively few taxa, rabies can affect any mammal, such as ungulates, and result in a largely "dead-end" infection. Contrary to popular belief, cases of rabies in rodents (mice, rats), lagomorphs (rabbits, hares), and other small mammals are uniformly rare.

Rather than a global rabies pandemic, single or multispecies assemblages are apparent when disease surveillance is practiced systematically. Combined with historical temporal and geographic data, antigenic characterization and nucleotide sequence analysis can be used to understand and compartmentalize rabies virus with different reservoirs responsible for their perpetuation and thus attribute relative risks of human disease from differential animal exposure. For example, during 1997, only four human fatalities but 8,509 animal rabies cases (an increase of 19% over 1996) were reported in the United States (including the District of Columbia and Puerto Rico). In contrast to fulminant canine rabies before World War II, more than 90% of current animal rabies cases are in wildlife. Most of these cases resulted from continued spread of a predominant raccoon rabies virus variant, because of unrestricted progression of an outbreak initiated during the late 1970s by animal translocation to the Virginias from an infected nidus in the southeastern United States. By 1997, New York State (including New York City) alone reported 1,266 rabies cases (versus only 54 in 1989), primarily as a consequence of the raccoon outbreak; in contrast, Hawaii remains unique in never reporting a case of indigenously acquired rabies, the result, in part, of its isolation.

Rabies cases in other important wildlife were also reported, primarily skunks (2,040 cases) and foxes (448 cases), in the Midwest, Alaska, and the eastern and western United States, respectively, and 958 bat rabies cases were widely distributed over 46 states and the District of Columbia. Alarming, new wildlife rabies outbreaks continue to emerge: 83 cases of rabies in coyotes were diagnosed in 1995 (80 from southern Texas). By comparison, only seven rabid coyotes had been reported from that state during 1997, which put in place a large-scale oral vaccination program. Domestic animals most at risk include those with a lower probability of induced immunity from vaccination but higher potential for rabies exposure if poorly supervised, such as cats. Consequently, the 300 cases of rabies reported in cats during 1997, almost entirely from states also reporting raccoon rabies, constituted a 13% increase over 1996; rabies cases in cats often surpass its canine counterpart, owing in part to the increased popularity of cats as pets but also to lower rates of vaccination. By temporal comparison, 126 cases of rabies in dogs were reported in the United States during 1997, an increase of 14% from 1996.

Human rabies is rare in developed countries. Before the 1940s, human rabies cases numbered in the hundreds, but between 1981 and 1998, only 37 human deaths were reported in the United States, 12 of which were likely acquired abroad. Of the remaining cases suspected to have resulted from infection while in the United States, 22 were associated with bat rabies virus variants. Before 1960, most U.S. human rabies cases originated from the bite of rabid dogs and, more rarely, cats, whereas a definitive history of animal exposure often is difficult to elicit in the case of most of the current human fatalities. In contrast to North America and Europe, where wildlife rabies predominates, in Southeast Asia, Latin America, and Africa, dogs continue to be the principal causative vectors of rabies to humans, with a consequent high case load (estimated at more than 25,000 annual human fatalities in India alone).

ETIOLOGY

Rabies belongs to the RNA virus family Rhabdoviridae, genus *Lyssavirus*. On electron microscopy, rabies virus has a characteristic bullet-shaped morphologic picture (~75 × 180 nm), a nucleocapsid core composed of ribonucleoprotein, and a lipid envelope through which spikes of glycoprotein project. Lyssaviruses are inactivated readily by heat, ultraviolet radiation, and most detergents. Two antigens of rabies virus have diagnostic and clinical importance: antibodies to the nucleocapsid can identify intracytoplasmic viral inclusions (Negri bodies) in neurons, and the surface glycoprotein stimulates virus-neutralizing antibodies.

Viruses isolated from rabid animals previously were thought to be indistinguishable, regardless of species or geographic origin. Variants of rabies virus and other lyssaviruses now can be differentiated by monoclonal antibody typing and genetic sequencing. Although true rabies viruses are global in distribution, related lyssaviruses potentially capable of zoonotic transmission are restricted to the Old World (Duvenhage, Mokola, and Lagos bat; European bat; and Australian bat viruses).

PATHOGENESIS

Much of what is known concerning the dynamic events after rabies virus infection is based on experimental animal inoculation. Transmission in nature usually originates from the bite of an infected animal, with the introduction of virus-laden saliva deep into the wound. Virus gains direct access to the central nervous system (CNS) from severed or intact unmyelinated peripheral nerves, in the vicinity of motor end plates or a neuromuscular spindle apparatus. Virus may attach at acetylcholine-related receptors or a separate series of unrelated receptors. Rabies virus travels centripetally at approximately 2 to 3 mm per hour by retrograde axoplasmic flow to the CNS, where replication and assembly of mature virions ensue. Movement across neuronal synapses may involve budding from intracytoplasmic and plasma membranes, or spread may result from direct cell-to-cell passage by fusion mechanisms. Viremia has not been implicated to any significant extent. Successive cycles of replication and passive transport result in widespread dissemination throughout the brain, particularly the brain stem, hippocampus, subcortical nuclei, limbic cortex, and Purkinje cells in the cerebellum. Infection progresses from the CNS with the centrifugal migration of virus through the nerve terminals of a variety of organs, most notably the salivary glands, by way of neural innervation of secretory cells. At this portal of exit, additional viral replication may take place.

Variations on the generalized neurotropic pathogenesis scheme may include localization of virus in striated muscle at or near the bite site for long periods before neural transit and replication in dorsal root ganglia; direct infection of sensory neurons or olfactory neuroepithelia by aerosol transmission of virus under unique environmental conditions; viral entry through the gastrointestinal route; sequestration of virus in additional non-nervous tissue; and, very rarely, transplacental transmission. Traditionally, the bite route is regarded as the primary means of rabies virus transmission, but less is known about other lyssaviruses.

The final outcome of rabies virus-induced encephalitis usually is death from neurologic dysfunction of vital brain regions. Gross findings are lacking in most cases. The histopathologic lesions are nonspecific and include neuronal degeneration, neuronophagia, and monocytic cellular infiltration with perivascular cuffing, as

expected from viral inflammation of the CNS. Cytoplasmic inclusion bodies of viral nucleocapsid aggregates, or Negri bodies, in CNS neurons formed the basis of postmortem laboratory examination in concert with the intracerebral inoculation of laboratory animals with suspect brain material, until replacement by the more sensitive fluorescent antibody technique as the preferred method of rabies diagnosis.

Rabies virus infection per se is not synonymous with death. Patients' outcomes can be predicated in part on the dose of virus, the route of infection, the particular virus variant, the biting animal species in question, as well as the age and physiologic status of the host. The incubation period is usually 1 to 3 months, but it is highly variable and ranges from days to years. The particular role played by humoral and cell-mediated immunity in the pathogenesis of rabies and viral evasion of host-derived responses until late in the course of infection are poorly understood.

CLINICAL FEATURES

Exposure to rabies is defined by transdermal or mucosal contact with potentially infectious virus-laden material, such as saliva or CNS tissue. The primary route of transmission is the bite of a rabid animal. Very rarely, rabies develops as the result of a few other nonbite conduits; four patients are believed to have acquired infection by the aerosol route (two from laboratory accidents and two from prolonged exposure to the highly humid air from caves inhabited by millions of bats). Human-to-human transmission is possible in theory, but it has not been readily documented, with the exception of eight cases resulting from corneal transplant; both the donors and the recipients succumbed to rabies.

The symptomless period between exposure and first sign of disease is usually 1 to 3 months, rarely less than 10 days or more than a year. During a prodromal phase of 4 to 7 days, the symptoms are initially nonspecific, with complaints including moderate fever, headache, chills, cough, sore throat, dyspnea, lack of appetite, weakness, nausea, vomiting, or general malaise. Thereafter, in the acute neurologic phase, there may be an array of signs and symptoms, including intermittent anxiety, confusion, excitation, agitation, insomnia, hallucinations, percussion myoedema, cranial nerve deficits, chorea, dysphagia, anorexia, hypersalivation, piloerection, priapism, paresis, paralysis, and sometimes maniacal behavior, interspersed with periods of calm. Classic symptoms include paresthesia at or near the site of bite exposure and hydrophobia (a synonymous term for the human disease) or aerophobia, manifesting as phobic pharyngeal or inspirational musculature spasms after provocative stimuli, such as anticipation of swallowing or air currents. One type of the disease, "dumb rabies," may spare central consciousness but take the form of ascending paralysis and progressive unresponsiveness as primary features of the clinical spectrum, gradually progressing to coma. Once the neurologic phase nears its termination in 2 to 10 days, the remaining clinical course is rapid and downhill, with death ensuing within days and usually attributable to respiratory or cardiac failure. Because human rabies is rare in developed countries and disease onset is nonspecific, diagnosis may be delayed until late in the course of disease or at postmortem examination.

LABORATORY FINDINGS

Rabies should be suspected in any case of unexplained viral encephalomyelitis, especially if there is a history of animal bite within the past 3 months. It is important to include arbovirus, enterovirus, and herpesvirus encephalitides in the differential diagnosis. In suspect animals, diagnosis is confirmed only at euthanasia by the fluorescent antibody test on brain tissue. In human cases, routine laboratory tests are nonspecific. Antemortem diagnosis can be confirmed by the finding of rabies antigen with fluorescent antibody testing of a brain biopsy specimen or in highly innervated areas, such as a full-thickness nuchal skin biopsy sample. Virus may be isolated from saliva in cell culture or by animal inoculation. Rabies virus RNA can be detected by the reverse transcription–polymerase chain reaction technique from saliva or sometimes from other tissues. Evidence of rabies-specific antibodies in the serum of an unvaccinated person or at anytime in the cerebrospinal fluid of a suspect patient also confirms the diagnosis.

OPTIMAL MANAGEMENT

Rabies remains a significant global viral disease that almost inevitably results in death, without spontaneous recovery. With the institution of prompt and proper prophylaxis, its prevention is virtually ensured. In excess of 1,000,000 humans annually undergo antirabies postexposure prophylaxis, and an estimated 50,000 others or more succumb, primarily from the bite of an infected dog and inappropriate or no prophylaxis. Contact between humans and animals is frequent, but exposure to a rabid animal is a relatively rare event in most developed countries. Application of regional epidemiologic surveillance and knowledge of rabies pathogenesis can significantly minimize human morbidity and mortality through the identification of likely reservoirs, development of vaccination consideration charts, and estimation of occupational risk groups ([Table 318.1](#), [Table 318.2](#), and [Table 318.3](#)). After a bite from an infected mammal, postexposure treatment of rabies in humans, as recommended by the United States Advisory Committee on Immunization Practices, includes proper wound care and the simultaneous administration of multiple doses of an efficacious rabies vaccine together with antirabies immune globulin of human origin (HRIG).

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10-day observation	Should not begin prophylaxis unless signs of rabies develop in the animal ^a
	Rabid or suspected rabid (unknown exposure)	Immediate vaccination
	Regarded as rabid unless laboratory tests show negative result ^b	Consult public health officials
Skunk, raccoon, fox, and most other carnivores		Immediate vaccination
Bats		Immediate vaccination
Carnivores, rodents, lagomorphs	Consider individually	Consult public health officials
Sabals and felines, and other mammals		Bites of squirrels, humans, guinea pigs, ferrets, chipmunks, rats, mice, other small rodents, rabbits, and birds should never require antirabies prophylaxis

^aDuring the 10-day holding period, begin prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten anyone. The suspect animal should be euthanized immediately and tested.
^bThe animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Definitive source of immunofluorescence test results are negative.
 (From Centers for Disease Control and Prevention. Human rabies prevention—United States, 1989. *MMWR* 1989;38(26):1-11, with permission.)

TABLE 318.1. RABIES POSTEXPOSURE PROPHYLAXIS GUIDE, UNITED STATES

Vaccination Status	Treatment	Regimen ^a
Not previously vaccinated	Wound cleaning	All postexposure prophylaxis should begin with immediate, thorough cleaning of all wounds with soap and water. If available, a virucidal agent such as a povidone iodine solution, should be used to irrigate the wounds.
	HRIG	Administer 20 U/kg body weight. If anatomically feasible, the HRIG dose should be infiltrated around the wounds, and the rest should be administered in an anatomical site distant from wounds. HRIG should not be administered in the same syringe as vaccine. Because HRIG may partially suppress active production of antibody, no more than the recommended dose should be given.
	Vaccine	HRIG, RIG, or POC, 1.0 mL (in 0.5-mL dose), one each on days 0, 1, 3, 7, and 14 ^b
Previously vaccinated ^c	Wound cleaning	All postexposure prophylaxis should begin with immediate, thorough cleaning of all wounds with soap and water. If available, a virucidal agent such as povidone iodine solution should be used to irrigate the wounds.
	HRIG	HRIG should not be administered.
	Vaccine	HRIG, RIG, or POC, 1.0 mL (in 0.5-mL dose), one each on days 0 and 7 ^d

^aHRIG, human antirabies immune globulin (in, intramuscular); HRIG, human diploid cell vaccine; RIG, rabies vaccine; absorbed; POC, purified chick embryo cell vaccine.
^bThese regimens are applicable for all age groups, including children.
^cThe initial dose is the only appropriate site of injection for adults and older children. The scapular (between the outer aspect of the thigh) may be used. Vaccine should never be administered in the gluteal area.
^dAny person with a history of postexposure vaccination or previous antirabies prophylaxis with HRIG, RIG, or POC in previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the previous vaccination.
 (From Centers for Disease Control and Prevention. Human rabies prevention—United States, 1989. *MMWR* 1989;38(26):1-11, with permission.)

TABLE 318.2. RABIES POSTEXPOSURE PROPHYLAXIS SCHEDULE, UNITED STATES

Risk Category	Nature of Risk	Typical Populations	Preexposure Recommendations
Continuous	Very present continuously, often in high concentrations; specific exposure likely to go unrecognized; little, multiple, or annual exposures	Rabies research laboratory workers; rabies biologic production workers*	Primary course, serologic testing every 6 months; booster vaccination if antibody level is below acceptable level**
Frequent	Frequent weekly contacts, with some recognized, but exposure may also be unrecognized; little, multiple, or annual exposures	Rabies research laboratory workers, spelunkers, veterinarians and staff, and animal control and wildlife workers in rabies enzootic areas†	Primary course, serologic testing every 7 years; booster vaccination if antibody level is below acceptable level**
Infrequent	Frequent weekly animal contacts with some recognized bite or scratch exposure	Veterinarians and animal control and wildlife workers in areas with low rabies rates; veterinary students, residents serving areas where rabies is enzootic and immediate access to appropriate medical care—including serologic testing—available	Primary course; no serologic testing or booster vaccination
Rare (exposure at large)	Exposure always episodic with some recognized, bite or scratch exposure	U.S. population at large, including persons in rabies enzootic areas	No vaccination necessary

*Judgment of relative risk and need for monitoring of vaccination status of laboratory workers is the responsibility of the laboratory supervisor.
 **Minimum acceptable antibody level is complete virus neutralization at a 1:10 serum dilution by the rapid fluorescent focus inhibition test. A booster dose should be administered if the titer is below this level.
 †From Centers for Disease Control and Prevention. Human rabies prevention—United States, 1999. *MMWR* 1999;48(RR-13):1, with permission.

TABLE 318.3. RABIES PREEXPOSURE PROPHYLAXIS GUIDE, UNITED STATES

Modern inactivated rabies vaccines produced in cell culture are used throughout the developed world and are major improvements over the Pasteurian neural attenuated products of animal origin from the past century. The human diploid cell vaccine was the first of this new generation of biologics, one of only three vaccines now licensed in the United States. The other two are rabies vaccine, adsorbed, which is produced in fetal rhesus lung culture, and a purified chick embryo cell vaccine, grown in primary chicken fibroblast culture; both are used for either preexposure or postexposure treatment ([Table 318.2](#) and [Table 318.4](#)). Although the concept of potent cell culture vaccines and HRIG inclusion is not new, it is little practiced; the majority of prophylactic treatment in Africa, Asia, and Latin America is with nerve tissue vaccines only, because of the associated high cost of production of alternative products. It is unclear whether the lack of an even greater burden of human death due to rabies can be attributed to relative human insusceptibility, differences in regional genetics, variation in local virus virulence, wound severity factors, degree of surveillance, or other phenomena.

Type of Vaccination	Route	Regimen
Primary	i.m.	HDCV, RVA, or PCEC, 1.0 mL (Jeltoid area), one each on days 0, 7, and 21 or 28
	i.d.	HDCV, 0.1 mL, one each on days 0, 7, and 21 or 28
Booster*	i.m.	HDCV, RVA, or PCEC, 1.0 mL (Jeltoid area), day 0 only
	i.d.	HDCV, 0.1 mL, day 0 only

i.m., intramuscular; i.d., intradermal; HDCV, human diploid cell vaccine; RVA, rabies vaccine, adsorbed; PCEC, purified chick embryo cell vaccine.
 * Administration of routine booster dose of vaccine depends on exposure risk category.
 (From the Centers for Disease Control and Prevention. Human rabies prevention—United States, 1999. *MMWR* 1999;48(RR-13):1, with permission.)

TABLE 318.4. RABIES PREEXPOSURE PROPHYLAXIS SCHEDULE, UNITED STATES

Preexposure rabies vaccination may be offered to certain risk groups whose activities often bring them into contact with rabies virus or rabid animals. Such immunization simplifies postexposure prophylaxis; benefits those exposed whose postexposure prophylaxis might be delayed, such as travelers to regions of enzootic dog rabies; and may protect people at risk of inapparent exposure. Although preexposure vaccination does not eliminate the need for local wound care and proper boosters, it does simplify such therapy by removal of the need for HRIG administration and minimization of the number of vaccine doses required.

PROGNOSIS

Once symptoms manifest in the naive patient, rabies is invariably fatal; recovery has been well documented in only four patients, two with serious neurologic adverse effects. Cardiac dysrhythmias, respiratory failure, and systemic nosocomial infections may all occur. Specific antiviral treatment is currently unavailable. Despite the experimental use of parenteral or intrathecal application of rabies immunoglobulin, F(ab')₂ rabies immunoglobulin fragments, cytosine or adenine arabinoside, interferon, acyclovir, antithymocyte globulin, steroids, vidarabine, tribavirin, inosine pranobex, or ribavirin, no treatment of clinical human rabies has shown any proven benefit. The most effective means to protect humans against this zoonosis are preventive measures designed to lessen the opportunity of contact with the virus, including compulsory companion animal vaccination and reduction of the risk of wildlife exposure through targeted public education and sound animal control policies, and postexposure prophylaxis when these measures fail.

[Etiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

Human papillomaviruses (HPVs) form a large, ubiquitous collection of more than 100 distinct DNA viruses that latently or actively infect the tegumental and mucosal epithelia. Active infections manifest in the form of tumors that range from benign (such as warts) to malignant (such as squamous cell carcinomas). HPVs can be divided into three broad groups according to the tissues they infect and their biologic characteristics ([Table 319.1](#)). The first group is represented by the cutaneous HPVs, which are distributed over the distal extremities of the body, where they occasion deep plantar warts, common warts, and flat warts. The anogenital HPVs constitute the second group. They are found not only over the external genitalia, vagina, cervix, anus, and anal canal but also in the upper respiratory mucosal surfaces. They produce such conditions as nasal or laryngeal papillomas but mostly anogenital warts, intraepithelial neoplasias, and cancers. HPVs of the third group are dispersed over the trunk, proximal extremities, and face. They cause the rare disease epidermodysplasia verruciformis as well as skin lesions in allograft transplant recipients.

Diseases	HPV Types
Deep plantar warts	1, 2
Common warts	2, 1
Flat warts	3, 10
Anogenital warts (condylomata acuminata)	6, 11
Intraepithelial neoplasia	
Low grade	6, 11
High grade	16, 18 ^b
Cervical carcinoma	16, 18 ^b
Recurrent respiratory papillomatosis	6, 11
Epidermodysplasia verruciformis	2, 3, 10, 5, 8, 9, 12, 14, 15, 17 ^b

^a HPV, human papillomavirus. Further information on HPV types can be found at <http://hpvweb.lanl.gov>.

^b HPV types with high malignant potential are indicated in bold.

TABLE 319.1. MAIN DISEASES AND HPV TYPES ASSOCIATIONS^a

INCIDENCE AND EPIDEMIOLOGY

Cutaneous warts are most common in children and affect up to 20% of the population. More than two-thirds of affected patients have common warts, while one-third, usually older patients, have plantar warts. Flat warts make up less than 5% of cutaneous warts. The mode of acquisition is not well understood, but microtrauma and humidity can play a role.

It is estimated that in the United States 500,000 subjects acquire anogenital warts each year and 1% of the sexually active population is affected. The incidence seems to have risen over the past 30 years. In a study done in the United States, 8% of college women had cytologic evidence of HPV infection by Papanicolaou (Pap) smear of the uterine cervix. When the presence of cervical HPV infection was determined by using an HPV DNA polymerase chain reaction assay, the prevalence increased to 46%. Many cervical HPV infections are in fact transient, and it appears that the development of cytologic lesions is associated with persistence and high levels of HPV DNA.

Anogenital HPV infections are mostly sexually transmitted, as evidenced by their association with the onset of sexual activity and the number of sexual partners. In the case of rare recurrent respiratory papillomatosis, risk factors in the juvenile-onset form of the disease include the presence in the mother of genital warts at the time of delivery and oral sex in the adult-onset form. The smoke plume generated during wart ablation by laser or electrosurgery may be infectious, but the role of fomites in disease transmission remains to be established.

There is now very strong evidence that some of the HPV types associated with anogenital infection cause cancer of the uterine cervix. The DNA of these so-called high-risk types (e.g., HPV-16 and HPV-18) was found in 93% of cervical squamous cell carcinomas worldwide. In addition, the presence of high-risk HPV types in the cervix of women with normal cytologic features is a very strong predictor of the development of high-grade cervical intraepithelial neoplasia, the lesion precursor to cancer. Seroepidemiologic studies also have confirmed these relationships. Although HPV infection is a necessary factor for the vast majority of cervical cancers, it is not sufficient. The other co-factors are not well characterized but may include immunosuppression.

A strong epidemiologic association has been established between anal cancer and anal HPV infection or, to a lesser degree, anogenital warts. Co-infection with the human immunodeficiency virus (HIV) is an additional risk factor for anal cancer. Weaker links exist between HPV infection and cancers of the vulva, vagina, and penis. Lesions of epidermodysplasia verruciformis can degenerate into squamous cell carcinomas, and the role of HPV in nonmelanoma skin cancers is being investigated.

ETIOLOGY

HPVs belong to the *Papillomavirus* genus of the family Papovaviridae and are made of a naked, icosahedral, 55-nm capsid that encloses a circular, double-stranded, super-coiled DNA approximately 7,900 base pairs in length. These small viruses have the same genetic organization, which consists of three different functional regions. A noncoding stretch, called the upstream regulatory region, possesses numerous binding sites for cellular and viral proteins that are the main biologic switches for the virus. A second region is made up of several genes (E1, E2, E4, E5, E6, and E7) that code for nonstructural proteins. Among them, E1 and E2 are necessary for viral replication, whereas E6 and E7 are essential to the oncogenic properties of HPV by interfering with at least two key cellular tumor-suppressor proteins. The E6 protein binds to the p53 tumor-suppressor protein and leads to its accelerated degradation, while E7 binds to and inactivates the retinoblastoma protein, Rb. E7 is the major oncogene. Introduced alone or in concert with E6, it causes cell immortalization and malignant transformation in cell lines, and in transgenic mice it leads to the formation of skin squamous cell carcinomas. The third genomic region comprises the two structural genes L1 and L2 that encode the major and minor capsid proteins, respectively.

Because of the inability to propagate HPVs in vitro and, under most circumstances, to purify virions, the rich diversity of these viruses was recognized only in the past three decades using genetic methods rather than the more traditional serotyping. HPV genotypes differ from one another by more than 10% in DNA homology of the L1 gene. At least 75 distinct HPVs have been characterized fully, and more have been identified. HPV virions appear to be relatively resistant to physico-chemical factors and thus may persist in the environment.

PATHOGENESIS

HPVs infect the keratinized and nonkeratinized stratified epithelia only of human beings, but each HPV type has particular anatomic predilections that result in different diseases ([Table 319.1](#)). The typical incubation period of HPVs causing cutaneous and genital warts is 3 to 4 months. Incubation durations ranging from 6

weeks to as long as 2 years have been observed in experimental inoculation experiments. Susceptibility to infection appears to vary among individuals, and in the case of genital warts, only two-thirds of the asymptomatic sexual partners of patients show signs of warts within 2 years of follow-up.

The virus is presumed to infect the keratinocytes in the basal, dividing layer of the epithelium. As the keratinocytes differentiate while moving toward the epithelial surface, the different phases of the HPV life cycle are activated sequentially, resulting in the formation of viral particles that eventually are released with the desquamating epithelial cells. In benign infections, this process is associated with the proliferation of all the epithelial layers, except the basal layer, hence causing papillomatosis, acanthosis, parakeratosis, and hyperkeratosis. Another characteristic feature of the infection, seen often with some HPV types, is the development in the upper stratum spinosum of a large cell with a distinctive perinuclear vacuole, the koilocyte (from the Greek *koilos*, meaning “cavity”).

Only a subset of HPV types also causes malignant lesions, typically squamous cell carcinomas ([Table 319.1](#)). In the anogenital epithelia, intraepithelial neoplasias (also improperly called dysplasias) are transitional lesions that may regress eventually or progress to invasive carcinoma. Intraepithelial neoplasia is characterized by a proliferation of basal cells and an abundance of abnormal mitoses (dyskaryosis). While HPV DNA remains episomal in benign lesions, in the highest grades of intraepithelial neoplasias (carcinoma in situ) copies of the viral genome become integrated into the host genome. This integration typically disrupts the E2 gene, which loses its negative regulatory properties on the expression of E6 and E7 oncogenes. The vast majority of HPV infections are neither active nor oncogenic, but latent. The factors that maintain latency are not known.

Immunosuppression and immunodeficiency are risk factors for more frequent and florid disease manifestations, a persistent course, and, when oncogenic HPVs are involved, malignant evolution. Genetic factors control the development of epidermodysplasia verruciformis. HPV infection elicits an inconsistent humoral response. The significance of neutralizing antibodies in human beings is unclear at present, but in animal papillomavirus infection-neutralizing antibodies are protective.

CLINICAL FEATURES

CUTANEOUS WARTS

The three main types of cutaneous warts are deep plantar warts, common warts, and plane or flat warts. Deep plantar warts (or myrmecia, from the Greek for “anthill”) are typically few in number and range in size from 2 to 10 mm. Each lesion looks like a deep-seated, soft, multistranded bundle of keratin fibers, transected as it protrudes from the skin. Deep plantar warts are often present on pressure points, which makes them painful and sometimes confused with corns and calluses. Shaving of the wart surface, however, reveals the punctation of bleeding blood vessels, a distinctive sign. Myrmecia can be present on the palms as well.

Common warts are well-demarcated, hemispheric papules with a rough, hyperkeratotic surface. They can be found anywhere on the hand, but also on the soles of the feet, where they may coalesce and flatten to form mosaic warts. Occasionally, they can be found in the oral cavity. Plane warts are characteristically small, flat, slightly irregular papules found on the face, neck, and hands of children. Most cutaneous warts spontaneously disappear. In one study of children, the rates of resolution at 1 and 5 years follow-up were 50% and 90%, respectively. Malignant degeneration is extremely rare.

ANOGENITAL WARTS AND RELATED DISEASES

Anogenital or venereal warts (also called condylomata acuminata) take the form of flesh-colored or more pigmented papules that are sessile or attached by a broad and short peduncle. They offer great variation in size, but usually their diameters range from 2 to 8 mm. Their surface contour may look like a mulberry or a cauliflower, but they can be jagged or acuminate. In men, warts are mostly distributed over the penile shaft and in the preputial cavity of the uncircumcised penis. In women, the vulva, particularly the introitus, can be affected. Perianal lesions are more common in women than in men, but their prevalence is increased substantially by anal intercourse, which also is associated with extension of the disease to the anal canal. In a minority of women, vaginal and cervical involvement can occur in the form of condylomas.

HPV papillomas tend to turn white when exposed to acetic acid. Thus, previous soaking of the genitalia with 3% to 5% acetic acid (or white vinegar) for 1 to 3 minutes and examination with magnifying optics, like a loupe or a colposcope, facilitate the detection and identification of lesions, particularly on the cervix. The presence of acetowhite macules on the vulva alone is not diagnostic of HPV infection. Symptoms are absent in about three-fourths of patients with anogenital warts; when present, they typically consist of itching, burning, or tenderness. The greatest impact of the disease is psychosexual. Our knowledge of the natural history is very limited, but 10% to 20% of patients experience complete spontaneous resolution over a 3- to 4-month period.

Exophytic anogenital warts rarely transform into carcinomas, but large, bleeding, or darkly pigmented lesions merit expert attention and biopsy, because they may be intraepithelial neoplasias or early carcinomas. Intraepithelial neoplasias (IN) can involve the penis (PIN), vulva (VIN), vagina (VAIN), anus (AIN), and cervix (CIN). They all carry a risk of progression to cancer that has been defined best for CIN and increases from grade 1 through grade 3. For example, CIN-3, the highest grade, is associated with a 12% chance of progression to cancer. The presence of perianal warts and a history of passive anal intercourse should prompt an anoscopy exam, particularly in a patient infected with HIV, because of the increased risk of AIN and anal carcinoma.

Recurrent respiratory papillomatosis is uncommon and typically develops either in early childhood or young adulthood. It is heralded by voice hoarseness, stridor, or dyspnea, which reflect the proliferation of papillomas in the larynx. The course of the disease can be relentless, with obstruction of the airways, local extension, and, occasionally, malignant transformation after irradiation. Nasal papillomatosis is another rare condition, which, like recurrent respiratory papillomatosis, is caused by an infection with anogenital HPVs. Anogenital HPVs can produce oral condylomas (the mouth should be examined) and conjunctival papillomas.

EPIDERMODYSPLASIA VERRUCIFORMIS AND RELATED CONDITIONS

Epidermodysplasia verruciformis (EV) is a very rare condition characterized by flat papules or red macules distributed over the face, torso, and upper extremities, which transform into squamous cell carcinomas at high rates in sun-exposed areas. EV-associated viruses have been recovered in squamous cell carcinomas, EV-like lesions, and the healthy skin of immunosuppressed solid-organ-transplant recipients. HPV-5 has been implicated in the etiologic course of psoriasis.

LABORATORY FINDINGS

HISTOLOGY AND CYTOLOGY

Histologic examination is the gold standard used for the diagnosis of HPV disease. Biopsy is indicated when the clinical diagnosis is in question or when there is a risk of malignancy. Screening for cervical malignancy is done by cytology (Pap smear). Cytologic findings are usually reported according to the Bethesda classification, which distinguishes four types of squamous cell abnormalities: (a) atypical squamous cell of unknown significance (ASCUS), the single largest category of diagnoses; (b) low-grade squamous intraepithelial lesion (LSIL), which corresponds to CIN-1 by histology; (c) high-grade squamous intraepithelial lesion (HSIL), the correlate of CIN-2 and -3; and (d) squamous cell carcinoma. As a detection tool of cervical carcinoma in the general population, the Pap smear is 80% sensitive and more than 99% specific.

SEROLOGY

The best serologic assays of HPV infection use HPV viruslike particles (VLP), but they are not commercially available. VLPs are produced by expression in eukaryotic cells via the appropriate vector (baculovirus, vaccinia virus, and so on) of the gene (L1) that encodes the major capsid protein. The protein self-assembles into a capsid-like structure that bears the same antigenic properties as the virion. The antigenicity seems genotype-specific. Unfortunately, only half to two-thirds of infected patients have detectable antibodies, which limits the assays' usefulness for clinical diagnosis.

MOLECULAR DIAGNOSIS

The diagnosis of HPV infection, particularly in the absence of disease, rests on the detection of viral nucleic acids. The Hybrid Capture assay (Digene Diagnostics) is the only HPV detection kit approved by the Food and Drug Administration and currently on the market. In that assay, HPV DNA is extracted from the target tissue or cells and bound in liquid phase to an HPV type-specific RNA probe. The DNA–RNA complex is captured by an antibody coating the test tube and detected quantitatively by another antibody conjugated to alkaline phosphatase. The assay uses two pools of probes—one that detects anogenital HPVs with a low oncogenic

risk and another that recognizes anogenital HPVs with a high oncogenic risk. A more sensitive hybrid capture that detects additional high-risk HPVs is likely to become commercially available. The Hybrid Capture assay appears to be helpful in the management of Pap smear with ASCUS, in the proper triage strategy to colposcopy, and in the screening of postmenopausal women. Polymerase chain reaction assays are the most sensitive tools for the detection and typing of HPV DNA, but they are reserved for research only. Consensus and degenerate primers have been designed to amplify known and new HPV types.

OPTIMAL MANAGEMENT

Three principles govern the management of HPVs. First, current treatments are directed at the diseases rather than at the infections caused by HPVs. Second, the often self-limited nature of benign HPV diseases should be kept in mind when considering the costs and limitations of the available treatment methods. Third, screening and detection of premalignant and malignant anogenital lesions is part of the optimal management of HPV diseases.

CUTANEOUS WARTS

Most cutaneous warts will spontaneously disappear; if treatment is desired for cosmetic reasons or to alleviate symptoms, it is important to consider carefully the risk of scarring and mutilation. Hand warts are best treated with a salicylic and lactic acid (SAL) paint (salicylic acid, lactic acid, collodion, 1:1:4). Numerous over-the-counter medications are available (Duofilm, Occlusal, Paplex, among others), and about two-thirds of patients respond to daily self-application for up to 12 weeks. Cryotherapy administered every 3 weeks gives the same response rate. This is the favored mode of treatment for eyelid, nasal, and periungual warts. Mosaic warts respond to topical SAL paint, 10% glutaraldehyde, or 5-fluorouracil. Deep plantar warts respond even better to treatment with SAL paint or 25% podophyllum resin, but preliminary paring may be necessary. Flat warts usually do not require treatment.

The cited treatment methods generally are well tolerated. Curettage to partially remove a deep plantar wart may be appropriate, but more extensive surgery is not needed as a rule. Electrosurgical techniques tend to cause scarring and are better reserved for small and well-localized lesions. Myriad other treatments, including suggestion, have been proposed for the treatment of cutaneous warts without being submitted to a rigorous evaluation.

ANOGENITAL WARTS

It is unclear whether the treatment of anogenital warts has any effect on the eradication of HPV, the risk of HPV transmission, or the extremely rare malignant transformation of the lesions. Consequently, the indications for therapy are the alleviation of physical and psychological symptoms and cosmesis. Because none of the treatment options are completely satisfactory, it is important to discuss with the patient the goals of therapy, the costs, the possible adverse reactions, and the alternatives, including the fact that spontaneous resolution is not uncommon. A great variety of therapies have been promoted for the treatment of anogenital warts. We focus on the most common and best studied and make comments regarding their application to related conditions. As with cutaneous warts, most of the treatments aim at the destruction of wart tissues by physico-chemical means.

PHYSICAL TREATMENTS

Cryotherapy usually is delivered weekly either with a cryoprobe or a liquid nitrogen spray. Severe pain is transient and, as with all the physical methods, can be controlled by the previous application of EMLA (lidocaine and prilocaine) cream. Reported complete response rates vary between 50% and 100%, and response may take six or more treatments. Long-term scarring is unusual.

Electrosurgical techniques (electrocautery, electrodesiccation, fulguration, electrocoagulation) can be quite efficacious, possibly more so than cryotherapy, but they require some expertise. Scarring may occur. The loop electrosurgical excision procedure is the most common tool for the treatment of HPV cervical diseases.

Cold-blade excision, which is done under local anesthesia with curved (iridectomy) scissors, is a prompt and very effective way of treating anogenital warts that are few in number. Hemostasis is achieved by the application of a chemical cauterizing agent (trichloroacetic acid), and long-term scarring is rare.

Laser surgery is very costly and demands expert handling. The surgery also requires local or general anesthesia. The effectiveness of laser surgery is not necessarily superior to that of the other physical methods, but laser surgery is a useful tool for the treatment of cervical lesions and is ideally suited for the management of laryngeal papillomas.

CHEMICAL TREATMENTS

Podophyllin, a resin extract from the rhizome of *Podophyllum peltatum* (podophyllum resin, USP), has long been used, usually as a 25% solution in benzoin. It is a cytotoxic agent that acts on the microtubules. Because it causes skin necrosis, it should not be applied to healthy skin. Podophyllin ingestion or extensive application can lead to serious, sometimes fatal hematologic, neurologic, pulmonary, or renal complications. The product is cheap, but the efficacy is poor, ranging from 20% to 40%. Moreover, it needs to be applied by a health practitioner. Podofilox (podophyllotoxin) is the most active compound in podophyllin. It is a standardized product that is also less toxic and, for that reason, can be self-administered. Complete response rates typically vary from 45% to 60%, but recurrences are common. Podophyllin and podofilox are contraindicated during pregnancy.

Trichloroacetic and bichloroacetic acids in a 10% to 90% solution are favored by gynecologists. Topical application is painful and causes temporary ulcerations. Pregnancy is not a contraindication. This common and cheap treatment has not been well evaluated, but it may be as effective as cryotherapy. Interferons have been well studied for the treatment of genital warts, but the results have been disappointing in general. Intralesional, as opposed to systemic or topical, administration is the most effective route. The 35% to 60% response rates that are reported apply only to the usually few lesions that are injected. Systemic interferon administration is used to some advantage for the treatment of recurrent respiratory papillomatosis. Imiquimod, the newest addition to the therapeutic armamentarium against anogenital warts, is an inducer of interferon- α and other cytokines. In one pivotal study, the topical application by the patient of a 5% cream formulation for up to 16 weeks was associated with a 50% complete response rate, compared with 14% in the placebo group. Only about 10% of patients experienced recurrence in the 12-week follow-up period. The treatment was more effective in women than men, 72% versus 33%. Side effects were local and well tolerated. They included itching, burning, erythema, erosions, and swelling.

[Table 319.2](#) and [Table 319.3](#) summarize how the different treatment methods can be used to the benefit of patients. Self-applied treatments are usually preferred by patients and can be delivered easily by primary caregivers. Nonetheless, patients should be instructed in the proper use of the medication and show that they can apply it properly (women may find the use of a mirror helpful).

Priority ^a	Provider	Therapy ^b
First line	Patient	Imiquimod Podofilox
First line	Practitioner	Cryotherapy Trichloroacetic acid Podophyllin Cold-blade excision
Second line	Practitioner	Electrosurgery Laser surgery Intralesional interferon

^a If the patient fails a given first-line treatment, it is not necessarily an indication for trying a second-line treatment. A different first-line treatment, or even the same one, may still prove effective.
^b The determination of the cost/benefit ratios of the different treatments should include not only the cost of the medication but also that of the visits to the practitioner. Consequently, there will be substantial geographic variation in these ratios. Nevertheless, second-line therapies are markedly more expensive than any of the first-line choices.

TABLE 319.2. MANAGEMENT STRATEGIES FOR ANOGENITAL WARTS

Drug	Commercial Name and Presentation	Dosing Regimen
Imiquimod	Aldara 5% cream, box of 12 single-use, 250-mg packets	Thrice-weekly, every-other-day applications, ≤16 weeks
Podofilox	Condylox 0.5% solution, 3.5-ml bottle with cotton-tipped applicators	Every-other-day applications for 3 consecutive days per week, ≤4 cycles
Podophyllin	Podophyllum USP, Podoxon 25-, 15-ml bottle; Podofin 15-ml bottle	Once-weekly application, ≤6 applications
Bi- or trichloroacetic acid	Bichloroacetic acid 80%, 10-ml bottle; Trichloro 80%, 15-ml bottle	Once-weekly application, ≤6 applications

TABLE 319.3. GENERAL DOSING INFORMATION FOR ANOGENITAL WART MEDICAL THERAPIES

FOLLOW-UP AND REFERRAL

There are no guidelines for the follow-up of patients with anogenital warts, but periodic evaluations should be arranged at least for those patients with persistent or recalcitrant disease. Histologic verification of the clinical diagnosis is appropriate in instances of long duration, progressive growth, or pigmentation or if the patient is immunosuppressed or immunodeficient. Referral to an expert is recommended.

CERVICAL CANCER SCREENING

Cervical cancer screening should not be overlooked in women ([Table 319.4](#)). The Pap smear collection gives the opportunity to examine the vagina and cervix. Cytology reports of HSIL and squamous cell carcinoma are mandates for colposcopic examination and directed biopsies of the cervix. Different management strategies have been proposed for the more common diagnoses of ASCUS and LSIL. Compliance on the part of the patient and the pathologist's impression are important. Under the most favorable circumstances, the patient can be followed with repeated Pap smears every 4 to 6 months for 2 years until three consecutive Pap smears have shown negative results. The management of internal HPV disease is best left to the specialist.

1. Obtain the first Papanicolaou (Pap) smear when the patient becomes sexually active or reaches her eighteenth birthday. Follow-up with at least two other annual Pap smears.
2. The Pap smear should be obtained every 6 months in the year that follows the diagnosis of HIV infection and annually thereafter.
3. In the absence of HIV infection or other sexually transmitted diseases (including anogenital warts) in the previous year, Pap smears can be obtained every 3 to 5 years if three previous annual Pap smears have all shown negative results and if the patient is compliant with follow-up. Otherwise, Pap smears should be obtained annually.

TABLE 319.4. CERVICAL CANCER SCREENING GUIDELINES

RECURRENCE AND PREVENTION

HPV disease recurrence is caused mostly by relapse rather than reinfection; thus, barrier methods of contraception would be chiefly of benefit to the asymptomatic sexual partner. Unfortunately, the evidence of their effectiveness is sparse and equivocal. Investigations of animal papillomaviruses have shown that HPV VLPs (see Laboratory Findings and Serology) can be used as effective vaccines. Anogenital HPV VLP-based vaccines are under development and hold great promise.

CHAPTER 320: HUMAN HERPESVIRUS 6

THOMAS H. BELHORN

[Definition](#)
[Incidence and Epidemiologic Factors](#)
[Etiologic Factors](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

Human herpesvirus 6 (HHV-6), a herpesvirus first reported in 1986, not only is a common pathogen in young children but is capable of causing significant morbidity and mortality in immunocompromised patients. In addition, because HHV-6 and HIV can coinfect T lymphocytes, much speculation exists concerning the consequences of interactions between these two viruses.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Serologic studies have demonstrated that HHV-6 is a ubiquitous pathogen. The peak age of acquisition is from 6 months to 2 years, with more than 90% of children having evidence of prior infection by age 2 to 3 years. Although the precise mechanism of infection is not documented, it is assumed that infection occurs by way of infected secretions, as saliva has been shown to contain HHV-6.

ETIOLOGIC FACTORS

Human herpesvirus 6 exhibits the general characteristics of a herpesvirus, including an enveloped icosahedral structure, a double-stranded DNA genome with a large coding capacity, and the apparent ability to establish a latent infection with reactivation after the initial primary infection in the human host. Unlike previously discovered herpesviruses, HHV-6 preferentially replicates in T lymphocytes. The genome of HHV-6 is most homologous with that of HHV-7 and human cytomegalovirus; cross-reacting monoclonal antibodies to these viruses have been documented. Restriction endonuclease profiles, nucleotide sequence comparisons, monoclonal antibody reactivity, and growth properties can be used to distinguish two distinct variants of HHV-6, termed variant A and variant B. HHV-6 variant B is isolated from children with acute febrile illness or roseola, whereas either variant may be isolated from immunocompromised patients.

CLINICAL FINDINGS

Primary infection with HHV-6 in young children can be asymptomatic, manifest as roseola, or present as an acute febrile illness without rash. Roseola (also called exanthem subitum or sixth disease), a disease presenting in late infancy or early childhood, has long been defined clinically by several days of high fever with few or no localized findings of infection, followed by defervescence concurrent with onset of a rose-colored rash. Both roseola and the acute febrile illness without the rash associated with HHV-6 primary infection may be associated with a febrile seizure. The rare primary infection occurring in an older child or adult may manifest as adenopathy or an acute mononucleosis-like illness. Kikuchi's disease, a necrotizing adenitis with a characteristic histologic pattern, may also be associated with HHV-6.

Human herpesvirus 6 persists after the primary infection and is capable of reactivation from a latent state. Although such reactivation is thought to be asymptomatic in most adults, the clinical consequence of HHV-6 reactivation in an immunocompromised host is variable. HHV-6 reactivation has been associated with fever, leukopenia, rash, encephalitis, pneumonitis, and graft rejection. In transplant recipients, HHV-6 may induce bone marrow suppression. The virus is clearly neurotropic, and the association between HHV-6 infection and multiple sclerosis as well as white matter demyelination in AIDS dementia complex is under investigation. The association of HHV-6 with specific malignancies, specifically Hodgkin's disease and non-Hodgkin's lymphoma, has been reported but not proven. Ongoing research will hopefully elucidate the precise role HHV-6 plays in such disease processes in immunocompromised populations.

LABORATORY FINDINGS

The diagnosis of roseola has historically been made clinically, and laboratory findings are nonspecific. Serologic studies are available to aid in the confirmation of a primary HHV-6 infection by documenting seroconversion. Serologic testing is of little use in documenting reactivation disease. Virus can be isolated from blood, saliva, and, occasionally, tissue in primary infection as well as in reactivation disease; specimens are usually cultured in cord blood lymphocytes, which may not be available in many laboratories. Polymerase chain reaction and hybridization techniques are valuable for HHV-6 detection and are being used more frequently to document the presence of HHV-6 in immunocompromised patients.

OPTIMAL MANAGEMENT

Primary infection in children is a self-limiting disease that requires no specific antimicrobial therapy. The prognosis for primary disease with the usual manifestations of roseola or an acute febrile illness is excellent, with no long-term sequelae. Severe disease associated with HHV-6 infection or reactivation in an immunosuppressed host should be treated with an appropriate antiviral regimen and supportive measures. In vitro data support the efficacy of either foscarnet or ganciclovir in the therapy of HHV-6 infections, although the usefulness of these agents has not been well documented in vivo. No effective means of prophylaxis for HHV-6 infection or reactivation exists, and no vaccine is available.

CHAPTER 321: INTESTINAL PROTOZOA

PABLO C. OKHUYSEN AND CYNTHIA L. CHAPPELL

[Cryptosporidiosis](#)
[Isosporiasis](#)
[Cyclosporiasis](#)
[Microsporidiosis](#)
[Amebiasis](#)
[Giardiasis](#)

CRYPTOSPORIDIOSIS

Cryptosporidium parvum inhabits the mucosal epithelium of the small bowel. The oocyst (3 to 5 μm ; [Fig. 321.1](#)) sporulates within the parasitophorous vacuole prior to release into the intestinal lumen and when shed in feces are directly infectious to others. The incubation period ranges from 4 to 24 days post exposure.

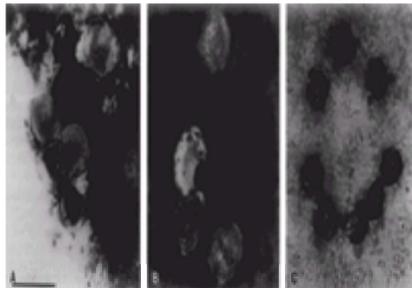

FIGURE 321.1. **A:** *Cyclospora*; **B:** *Cryptosporidium muris*; **C:** *Cryptosporidium parvum*. Bar represents 10 μm . (From Ortega Y, et al. *Cyclospora* species: a new protozoan pathogen of humans. *N Engl J Med* 1993;328:1308, with permission.)

C. parvum is a ubiquitous organism that can infect humans and is a common pathogen of many mammals. Two distinct transmission cycles occur in nature and are related to specific genotypes. Infections with genotype H demonstrate preference for causing infection in humans, whereas genotype C favors a zoonotic transmission. Oocysts are resistant to water chlorination and hospital disinfectant solutions. In the height of the AIDS epidemic in the United States, cryptosporidiosis was the AIDS-defining infection in 4% of patients reported to the U.S. Centers for Disease Control and Prevention, and prior to the advent of highly active antiretroviral therapy, up to 50% of HIV-infected patients experienced *Cryptosporidium* infection at some point of their disease. The incidence of AIDS-associated cryptosporidiosis has decreased significantly in recent years due to effective antiretroviral therapy and the prophylactic use of macrolides. Transmission via the fecal–oral route may occur by contact with an infected person, farm animals, or pets, or by drinking contaminated water. Those at increased risk of acquiring disease include travelers to developing countries, children in day care centers, immunosuppressed persons, the elderly, veterinarians, and dairy farmers. As few as ten oocysts can cause infection in healthy volunteers and presumably even fewer in immunocompromised individuals. Immunocompetent individuals may experience a self-limited illness that rarely lasts more than 14 days. Symptoms of cryptosporidial infection include watery stools, fatigue, abdominal pain, general malaise, and in 20% nausea and vomiting. Low-grade fever can also occur. In HIV-infected individuals, when CD4 counts are higher than 200 per cubic milliliter, *C. parvum* infection may resolve spontaneously; however, in the later stages of HIV disease (CD4 counts under 100), chronic infection can lead to dehydration, malnutrition, and wasting, frequently culminating in death. In profoundly immunosuppressed hosts, extraintestinal infections have been described. The invasion of the biliary tract may manifest as cholestasis, acalculous cholecystitis, or cholangitis with right upper quadrant pain, marked elevation of serum alkaline phosphatase, and slight or no elevation of serum bilirubin. Associated strictures may respond to ampullary dilatation with endoscopic retrograde cholangiopancreatography (ERCP). A diarrheagenic toxin has been suggested, but evidence to date is incomplete. Experimental data suggest that interferon- γ , intestinal intraepithelial lymphocytes, and CD4 and CD8 T-cell lymphocytes are important in clearing cryptosporidiosis.

Diagnosis is made by identifying oocysts with a modified acid-fast stain of a fresh fecal specimen. Leukocytes are usually absent. Recently, more sensitive, monoclonal-based, direct immunofluorescence assay and enzyme-linked immunosorbent assay (ELISA) have been introduced. Since oocyst excretion is variable, the analysis of several specimens may be necessary to confirm the diagnosis.

The treatment of cryptosporidiosis in an otherwise healthy individual is supportive. In AIDS-associated cryptosporidiosis, the combination of paromomycin and azithromycin improves symptoms and decreased parasitic burden. Uncontrolled studies using hyperimmune bovine colostrum have shown some benefit in HIV-infected patients, and controlled, clinical trials have shown little effect.

ISOSPORIASIS

Isospora belli produces large (12 \times 30 μm), oval-shaped oocysts that sporulate outside the body. This process takes 2 to 3 days before the oocysts become infectious. Isosporiasis was rarely diagnosed prior to the HIV epidemic, although healthy individuals can also become infected. The organism is endemic in tropical and subtropical environments, is associated with outbreaks of diarrheal disease, and has been implicated in traveler's diarrhea. *I. belli* infection is confined to humans and, perhaps, to dogs. No other animal reservoir has been identified. Transmission is associated with contaminated water, although that route is not proven.

Biopsies of severe cases reveal flattened villi and crypt hyperplasia of the small bowel with a cellular infiltrate of lymphocytes and eosinophils. The watery diarrhea caused by this organism suggests an enterotoxin, but no evidence for this molecule yet exists. The clinical features of *I. belli* infection in immunocompetent hosts are abdominal pain, cramping, nausea, and watery diarrhea, occasionally with eosinophilia. In immunodeficient hosts, prolonged diarrhea with malnutrition may occur. Several case reports have documented dissemination to the mesenteric lymph nodes or acalculous cholecystitis in advanced HIV infection.

Oocysts can be visualized with an acid-fast stain. Symptomatic infection responds to treatment with trimethoprim–sulfamethoxazole (TMP-SMX; [Table 321.1](#)). In AIDS patients with recurrent disease, secondary prophylaxis with TMP-SMX and pyrimethamine sulfadoxine prevents relapses. Nitazoxanide, a thiazolide compound, and its desacetyl derivative, tizoxanide, have antimicrobial properties against anaerobic bacteria, as well as against helminths and protozoa. Therefore, it is a promising agent in the treatment of this and other parasitoses.

Organism	Size	Shape	Stain	Location	Transmission	Diagnosis	Treatment
<i>Cyclospora</i>	8–12 \times 12–18 μm	Oval	Modified acid-fast	Small intestine	Contaminated water	Modified acid-fast stain	Trimethoprim-sulfamethoxazole
<i>Cryptosporidium</i>	3–5 μm	Oval	Modified acid-fast	Small intestine	Contaminated water, farm animals, pets	Modified acid-fast stain	Paromomycin, azithromycin
<i>Isospora belli</i>	12 \times 30 μm	Oval	Modified acid-fast	Small intestine	Contaminated water	Modified acid-fast stain	Trimethoprim-sulfamethoxazole

TABLE 321.1. RECOMMENDED TREATMENTS FOR THE MAJOR HUMAN INTESTINAL PROTOZOAN PARASITES

CYCLOSPOROSIS

Cyclospora cayentanensis is excreted as an unsporulated oocyst. It has been found in developing countries and in the United States during outbreaks in children, travelers to developing nations, and AIDS patients. An initial study has found a prevalence rate of 10.9% in Peruvian children. Data regarding pathologic factors are absent, but the organism is suspected of infecting the proximal jejunum. After an incubation period of approximately 17 days, an explosive diarrhea occurs accompanied by cramping, abdominal pain, nausea, vomiting, fatigue, and, occasionally, fever. In one study, the median duration of diarrhea was 43 days, at which point symptoms resolved spontaneously in immunocompetent hosts. However, the immunocompromised may experience an unusually prolonged course.

Cyclospora and *Cryptosporidium* show staining similarity, but *Cyclospora* oocysts are slightly larger (8 to 10 μm) ([Fig. 321.1](#)). *Cyclospora* oocysts can also be identified in fecal samples by auto-fluorescence at 330 to 380 nm. Small-bowel biopsies reveal local erythema and villous atrophy. Open-label studies of TMP-SMX have demonstrated rapid improvement in the clinical symptoms and clearing of *Cyclospora* after 10 days ([Table 321.1](#)) and may thus be of use in the treatment and prevention of relapses.

MICROSPORIDIOSIS

Microsporidia are small, obligate, intracellular parasites that infect vertebrate and invertebrate hosts. Only a few of the more than 1,000 species known to belong in this phylum have been identified as pathogenic agents for humans. Two species are associated with enteric infection: *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* (formerly known as *Septata intestinalis*); the former is the more common. Microsporidia share several common characteristics, including specialized polar tubes that transfer the parasite to the host cell. Intracellular asexual reproduction leads to formation of small (0.5 to 0.9 \times 1.5 μm), thick-walled spores that can survive for months in the environment. *E. bieneusi* and *E. intestinalis* can be distinguished morphologically by electron microscopy of small-bowel biopsies.

To date, *E. bieneusi* has only been reported in humans, but it is apparently found worldwide. The prevalence in selected groups of HIV-infected patients in different countries has indicated a range of 1.7% to 30%.

Both *E. bieneusi* and *E. intestinalis* infections are identified with diarrhea in individuals with CD4 counts lower than 100 and frequently also in asymptomatic carriers. *E. bieneusi* infects the enterocytes of the proximal jejunum and occasionally spreads to the biliary tract. In comparison, *E. intestinalis* is found in enterocytes, macrophages, and fibroblasts. In both infections, changes in the local cellular architecture may vary from a mild inflammatory, lymphocytic infiltrate to severe epithelial deterioration with decreased brush-border enzymes. *E. intestinalis* infects the intestinal tract but may also disseminate to the mesenteric nodes and kidney.

Free and intracytoplasmic spores can be stained with Giemsa or fluorochrome stains (Calcofluor, Uvitex 2B) that have affinity for chitin, but identification of the specific species requires electron microscopy. Preliminary data suggest that albendazole may be of use in the treatment of *E. intestinalis* ([Table 321.1](#)) and in *Encephalitozoon* infections.

AMEBIASIS

Entamoeba histolytica infection of the colonic mucosa is initiated by the ingestion of cysts (8.5 to 19.0 μm). After excystation, asexual division results in the formation of trophozoites (12 to 60 μm diameter), which bind to mucous secretions and intestinal cells via a galactose-specific lectin. A portion of the trophozoites develop into cysts and are excreted.

E. histolytica infection is especially prevalent in Mexico, India, Africa, and Central and South America. Major routes of transmission are through contaminated water and food or by direct fecal–oral contact. Individuals at highest risk for infection include travelers to developing nations, immigrants or migrant workers, immunocompromised individuals, and individuals housed in psychiatric facilities.

Both pathogenic and nonpathogenic strains of *E. histolytica* occur in humans. The strains are morphologically indistinguishable but can be differentiated by zymodeme patterns, monoclonal antibodies, and DNA probes. Nonpathogenic strains are associated with asymptomatic infection and do not usually elicit a serologic response. In contrast, 10% of infections are with pathogenic strains, resulting in symptomatic illness (80% to 98%) or invasive disease (2% to 20%) and the production of serum antibodies. After invasive disease, there is development of immunity to subsequent invasion but not to colonization; immunity is thought to be mediated by cellular mechanisms. Pathogenic amebae release a pore-forming protein, soluble toxic molecules, and increased concentrations of a cysteine proteinase, which can degrade matrix proteins. Host leukocytes, neutrophils, and macrophages also play a role in cell damage when they are lysed and release their toxic products. Ulcerative lesions in the intestinal mucosa and liver abscesses are characterized by a moderate inflammatory response. Advanced lesions have necrotic centers with amebae concentrated at the outer zone of normal tissue.

Entamoeba histolytica can cause intestinal syndromes, including the following: (a) a dysenteric syndrome with production of small volumes of bloody, mucoid stools without fecal leukocytes; (b) colitis characterized by ulcerations of the colonic mucosa with typical flask-shaped abscesses; or (c) the formation of a fibrotic mass in the intestinal wall (ameboma). Chronic amebic colitis is clinically indistinguishable from inflammatory bowel disease, and those receiving corticosteroids are at risk for toxic megacolon and perforation. Infective trophozoites can migrate hematogenously to the right lobe of the liver, causing abscess formation, abdominal pain, jaundice, and fever. Adjacent anatomic structures, such as the pulmonary parenchyma, peritoneum, and pericardium, can become involved. Amebae can also disseminate to the brain. Immunosuppressed or malnourished individuals, those at the extremes of age, patients with malignancy, and women during pregnancy and postpartum stages are especially at risk for invasive amebiasis. Indications for surgical drainage of an amoebic abscess include large dimensions, impending rupture, left lobe location, or lack of therapeutic response.

Identification of *E. histolytica* cysts and trophozoites requires examination of a fresh stool and a trichrome stain. New fecal antigen detection methods (ELISA) may also prove useful. Periodic acid–Schiff-stained tissue obtained by colonoscopy may be required to confirm the diagnosis. An episode of dysentery may not necessarily precede abscess formation. In areas of low endemicity, a positive serologic response correlates with severe colitis or invasive disease. However, titers persist for prolonged periods of time and are of no use in determining acute versus remote infection in areas of high endemicity. The identification of cysts in an asymptomatic host should prompt treatment with diloxanide or paromomycin ([Table 321.1](#)). Invasive disease, such as severe colitis or parenchymal abscess, should be treated with metronidazole followed by a luminal agent to prevent future invasion with any remaining cysts.

GIARDIASIS

Giardia lamblia can produce infection in humans and is also a zoonosis. *G. lamblia* cysts are ingested with contaminated water or food. In the environment this protozoan parasite is found in a cystic stage that is resistant to conventional concentrations of chlorine used to treat drinking water. Giardiasis is a common problem in day care centers and has also been associated with water-borne outbreaks. Brief exposure to temperatures higher than 50°C results in inactivation. Once cysts are ingested, trophozoites (10 to 20 μm) emerge in the duodenum and adhere to the upper small-bowel microvillar surface, crypts, and occasionally to the common bile duct epithelium. A ventral suction cup is thought to mediate the attachment. After an incubation period of 7 to 9 days, infectious cysts (8 \times 12 μm) are excreted intermittently.

The clinical manifestations are variable and range from completely asymptomatic infections to watery diarrhea with abdominal cramping and distention. Urticaria and eosinophilia are rarely associated with giardiasis. During heavy infestations, microvillar blunting and malabsorption can ensue. Infection may resolve spontaneously or result in chronic diseases with steatorrhea, malabsorption, and weight loss. Chronic or recurrent giardiasis should prompt an evaluation for IgA deficiency because of its association with giardiasis.

Giardia can be visualized in trichrome iodine stains of fecal smears. Infection can be identified by sensitive ELISA. A direct immunofluorescence assay that can detect *Cryptosporidium* and *Giardia* simultaneously is available commercially. Staining a sampling of duodenal bile obtained by the Enterotest capsule method may improve

the diagnostic yield. Treatment of asymptomatic cyst passers remains controversial since most individuals clear the infection spontaneously. However, for those in whom the likelihood of reinfection is low (e.g., an asymptomatic traveler returning to a developed nation who is found to pass cysts), eradication of *G. lamblia* may be indicated. For individuals with symptomatic disease the antiparasitic agent of choice is metronidazole administered as outlined in [Table 321.1](#).

CHAPTER 322: MALARIA

DONALD J. KROGSTAD

[Definition](#)
[Epidemiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)
[Prevention and Control](#)

DEFINITION

Four species of plasmodia infect humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. Humans acquire malaria from the bite of infected female *Anopheles* mosquitoes (Fig. 322.1). After their injection under the skin by a mosquito, sporozoites travel through the circulation to enter the liver cell (hepatocyte). Within the hepatocyte, the parasite matures to a tissue schizont containing large numbers of infectious merozoites (2,000 to 30,000). The merozoites then invade red blood cells (RBCs) and mature through a series of asexual erythrocytic stages: ring, trophozoite, and schizont. After either 48 or 72 hours, the schizont stage of the parasite lyses its host RBC, freeing 6 to 32 merozoites, which then invade other RBCs and repeat the asexual erythrocytic cycle.

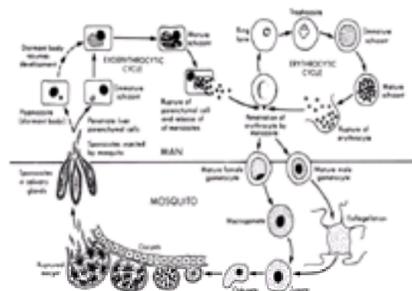

FIGURE 322.1. Malaria life cycle. Red cell infection (the asexual erythrocytic form of the parasite) is responsible for the morbidity and mortality associated with malaria. The hypnozoite is responsible for relapse in *Plasmodium vivax* and *Plasmodium ovale* infection. (From Remington, Swartz. *Curr Clin Top Infect Dis* 1982;3:56, with permission.)

Some intraerythrocytic parasites develop into the sexual forms (male or female gametocytes) necessary to complete the life cycle. In the mosquito, the gametocytes (which are haploid, like the asexual erythrocytic stages) transform to gametes and fuse to form a diploid oocyst. The oocyst then undergoes a reduction division (meiosis) to produce haploid sporozoites that migrate to the salivary gland, where they are infectious for humans.

Two malaria species (*P. vivax* and *P. ovale*) have persistent liver stages (hypnozoites) that may remain dormant in the liver for 6 to 11 months or more. When hypnozoites finally mature to tissue schizonts and release merozoites, they produce either a delayed primary attack (if the patient was taking antimalarial chemoprophylaxis and did not develop symptomatic parasitemia within 2 to 4 weeks of the initial infection) or a relapse (if symptomatic parasitemia developed at the time of initial infection).

Malaria may also be transmitted by the parenteral inoculation of infected blood (inadvertent transfusion of parasitized RBCs, sharing of needles among drug addicts). Because induced malaria is acquired from parasitized RBCs (rather than sporozoites), no hypnozoites form in the liver and relapses do not occur, even with *P. vivax* or *P. ovale* infection.

EPIDEMIOLOGIC FACTORS

Malaria is endemic in most of the developing tropical world. Because malaria transmission depends on the *Anopheles* mosquito, it usually does not occur at altitudes above 1,500 m. Because of their importance for both chemoprophylaxis and treatment, the areas where chloroquine-resistant *P. falciparum* is present are outlined in Table 322.1. Note that this list is continually in flux as new data become available. In countries such as the United States, the lack of transmission results primarily from the lack of infected people. This is because competent mosquito vectors are present in many regions of the United States (*A. albimanus*, *A. quadrimaculatus*, and *A. freeborni*). Therefore, malaria transmission can (and does) occur in the United States when significant numbers of infected people are exposed to (and reinfect) the domestic anopheline mosquito pool. For this reason, malaria introductions occurred in the United States after World War II, after the Korean and Vietnam Wars, and after the entry of large numbers of refugees from Southeast Asia.

TABLE 322.1. COUNTRIES WITH CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM* MALARIA^a

PATHOGENESIS

The morbidity and mortality of *P. falciparum* malaria are related in large measure to the cytoadherence of RBCs containing mature parasites to the microvascular endothelium. RBCs containing mature parasites cytoadhere because their surfaces contain parasite proteins that mediate adherence to ligands on endothelial cells such as CD36 and intercellular adhesion molecule 1. The clinical consequences of this microvascular disease may include ischemia (hypoxia), hypoglycemia, and acidosis in the affected tissues. Thus unresponsive coma or seizures (cerebral malaria) may be produced by metabolic factors, such as hypoglycemia, or physical factors, such as the presence of cytoadherent parasitized RBCs on the microvascular endothelium of the brain. Pulmonary edema in malaria is associated with a capillary leak syndrome, not with congestive heart failure, and may result from parasite-stimulated release of tumor necrosis factor- α (TNF- α), as it does in gram-negative bacterial septicemia. Acute renal failure may result from hemolysis and the microvascular disease associated with *P. falciparum* infection, particularly in

the renal cortex.

The morbidity and mortality of malaria are also related to the magnitude of the parasitemia. Thus, *P. falciparum*, which is able to invade RBCs of any age, may produce parasitemias greater than 10^6 per microliter. In contrast, *P. vivax* and *P. ovale*, which are able to invade only younger RBCs such as reticulocytes, and *P. malariae*, which is restricted to older RBCs, produce more limited parasitemias ($\leq 25,000$ per microliter and $\leq 10,000$ per microliter, respectively), and therefore pose a lower risk of complications and death.

Complications observed with malaria caused by plasmodial species other than *P. falciparum* include an immune complex nephrotic syndrome associated with *P. malariae* infection. These immune complexes contain parasite antigens, complement, and host antibodies to parasite antigens, consistent with an immune complex glomerulonephritis.

CLINICAL FINDINGS

The cardinal clinical features of malaria are recurring fevers and chills (associated with the lysis of RBCs containing mature schizonts) in the absence of localizing signs. The periodicity of the fevers and chills is typically 48 hours with *P. vivax* or *P. ovale*, and 72 hours with *P. malariae*. In contrast, irregular, hectic fevers and chills are usually observed with *P. falciparum* infection, especially in nonimmune patients (those who have never been exposed to plasmodia), who are at the greatest risk of complications and death.

In severe *P. falciparum* infection ($\geq 10^6$ parasites per microliter of blood), acute complications include coma (due to hypoglycemia, the microvascular disease produced by the parasite, or TNF- α), pulmonary edema, acute renal failure, thrombocytopenia, and gastroenteritis (predominantly diarrhea). Chronic *P. falciparum* infection may produce splenomegaly, which typically resolves after suppressive treatment with prophylactic doses of antimalarials for 6 to 12 months.

P. malariae infection is associated with an immune complex nephrotic syndrome (see previous discussion). *P. vivax* infection predisposes to late splenic rupture with trauma (1 to 3 months after the initial, or primary, infection).

LABORATORY FINDINGS

Malaria is diagnosed by the identification of parasites on a Giemsa-stained blood film. Wright's stain is less sensitive than Giemsa, especially for inexperienced observers. Correct identification of the infecting species is essential for treatment because many *P. falciparum* strains are resistant to chloroquine, pyrimethamine-sulfadoxine (Fansidar), and other antimalarials. In contrast, all *P. ovale* and *P. malariae* organisms are susceptible to chloroquine. Although most *P. vivax* organisms are susceptible to chloroquine, chloroquine-resistant *P. vivax* organisms have been reported.

With Giemsa stain, the parasite cytoplasm and nucleus are light and dark blue, respectively. In *P. falciparum* infections, the diagnostic crescent-shaped gametocytes may appear only after an additional 7 to 10 days. In addition, only ring-stage asexual parasites are visible initially on the peripheral smear. This is because *P. falciparum*-parasitized RBCs containing the more mature trophozoite- and schizont-infected RBCs are sequestered in the peripheral microvasculature and therefore do not circulate in the bloodstream. In contrast, in *P. vivax*, *P. ovale*, and *P. malariae* infections, all asexual erythrocytic stages circulate in the bloodstream and are therefore seen on the blood smear because they do not cytoadhere.

In acutely ill patients, the differential diagnosis can usually be simplified to *P. falciparum* versus *P. vivax*. This is because *P. ovale* is virtually identical to *P. vivax* (morphologically and clinically) and because *P. malariae* typically produces a more chronic infection. On a thin blood film (in which the morphologic characteristics of the RBCs are preserved), *P. vivax*-parasitized RBCs characteristically demonstrate both Schüffner's dots in the RBC cytoplasm (eosinophilic dots 0.2 μm in diameter) and RBC enlargement with parasite maturation. In contrast, neither Schüffner's dots nor RBC enlargement occur with *P. falciparum* infection. Potentially confusing factors include Maurer's dots in the cytoplasm of *P. falciparum*-parasitized RBCs and infections with more than one parasite species (in 5% to 7% of patients with malaria).

Thick blood films (in which the RBCs have been lysed) permit the examination of approximately ten times as much blood per unit time as thin films and are therefore often diagnostic in patients with low parasitemias. However, inexperienced observers are frequently confused by thick films because RBC lysis makes it impossible to determine the effect of parasite maturation on RBC size.

Although serologic (antibody) testing ultimately demonstrates increases in species-specific antibody titers in most patients with malaria, it is not useful for the management of acutely ill patients because 3 to 4 weeks or more is typically required to produce a diagnostic rise in antibody titer. Conversely, antigen detection (e.g., based on parasite lactate dehydrogenase) may be useful and is now available in kit form.

DNA probes have been developed for several plasmodia, especially *P. falciparum*. In combination with amplification using the polymerase chain reaction and nonradioactive probes, they provide sensitivities and specificities similar to those of the thick smear. Despite this progress, DNA probes are not used routinely because neither the necessary reagents nor the expertise to use them are readily available in most malaria-endemic areas.

OPTIMAL MANAGEMENT

CHOICE OF ANTIMALARIALS

Infection of the nonimmune patient with *P. falciparum* is considered a medical emergency, and treatment is based accordingly (Table 322.2). Chloroquine should be used if the patient has come from an area where there is no evidence of chloroquine resistance, such as Haiti. In contrast, nonimmune patients who have taken chloroquine chemoprophylaxis in areas with chloroquine resistance should be treated initially with other agents. Semi-immune persons exposed to chloroquine-resistant *P. falciparum*, who have not taken chemoprophylaxis, are not critically ill and have no more than 10^4 parasites per microliter, may be treated initially with chloroquine if they can be observed carefully. However, other antimalarials known to be effective against chloroquine-resistant *P. falciparum* should be given at the first sign of clinical deterioration or if the parasitemia rises above 10^4 per microliter.

TABLE 322.2. TREATMENT OF MALARIA

The choice of antimalarials for persons who may be infected with chloroquine-resistant *P. falciparum* is controversial and difficult. Oral mefloquine is available in the United States and is effective in most chloroquine-resistant *P. falciparum* cases. However, persons who have been on mefloquine prophylaxis should not be treated with halofantrine because many mefloquine-resistant *P. falciparum* organisms are also halofantrine-resistant. Pyrimethamine-sulfadoxine (Fansidar) may be effective but should not be used for critically ill, nonimmune patients because resistance to the drug has occurred in many areas with chloroquine-resistant *P. falciparum*. Quinine and quinidine are usually effective and may be given orally or parenterally, although they have substantial toxicity (see following discussion), especially when

begun with an intravenous loading dose in elderly patients. Qinghao and other artemisinin derivatives (artemether, arteether, artesunate) are used with increasing frequency in Southeast Asia and Africa because they are active in most cases involving chloroquine-resistant *P. falciparum* and typically produce rapid parasite clearance. Unresolved questions about these compounds that have impeded their acceptance in the United States include evidence for neurotoxicity in animal models, a question of cerebellar toxicity in humans, and uncertainty about their safety in pregnancy. Atovaquone plus proguanil is a recently available option for chloroquine-resistant *P. falciparum* infections. In summary, potentially chloroquine-resistant *P. falciparum* infections are usually treated with mefloquine or quinidine in countries such as the United States.

Chloroquine is the treatment of choice for *P. vivax*, *P. ovale*, and *P. malariae* infections. However, there are reports of resistance to chloroquine among *P. vivax* organisms from Indonesia, Papua New Guinea, and elsewhere. Thus far, these infections have responded to treatment with quinine (plus doxycycline or pyrimethamine–sulfadoxine) or single-dose mefloquine (1,250-mg salt; [Table 322.2](#)). The addition of primaquine is recommended for patients with *P. vivax* or *P. ovale* infections acquired by mosquito-borne transmission to prevent late relapse from persistent hypnozoites in the liver. Primaquine is usually given after the initial treatment with chloroquine has cleared the patient's parasitemia. This permits time for glucose-6-phosphate dehydrogenase (G6PD) testing of the patient's RBCs to avoid the hemolysis that may occur in patients with G6PD deficiency and obviates potential confusion between the side effects of primaquine and the patient's illness.

MODE OF ADMINISTRATION AND TOXICITY

Because of its cardiotoxicity (arrhythmogenic potential), chloroquine should not be given by rapid intravenous infusion. It may be given intramuscularly or by slow (carefully controlled) intravenous infusion ([Table 322.2](#)).

Quinine is often given intravenously for the treatment of chloroquine-resistant *P. falciparum* infection but may produce cinchonism (vertigo, nausea, tinnitus) at excessive serum concentrations ($35 \mu\text{g}$ per milliliter). Hypoglycemia is an important side effect of both quinine and quinidine because they stimulate the release of insulin directly from the pancreatic β cell, regardless of the plasma glucose concentration. For this reason, and because hypoglycemia may also result from the parasite's consumption of glucose and there is decreased oral intake during the patient's illness, comatose patients infected with *P. falciparum* should be treated empirically with intravenous glucose if blood glucose measurements are not available on an emergency basis. Patients who are comatose because of hypoglycemia typically respond to treatment with one or two ampules of 50% dextrose intravenously. In countries such as the United States, intravenous quinidine is now preferred because it is two to three times more active than quinine against the parasite because quinidine (but not quinine) drug levels can be measured in many hospitals (to identify dose level–related side effects) and because intravenous quinine is now available only through the U.S. Centers for Disease Control and Prevention.

For patients with *P. falciparum* infections that may be partially resistant to quinine, a quinine loading dose (16.7-mg base per kilogram intravenously over 4 hours) has been recommended to produce therapeutic serum levels more rapidly than maintenance doses alone (8.3-mg base per kilogram intravenously every 8 hours) because it clears the parasitemia more rapidly. Corticosteroids are not recommended for the treatment of coma in cerebral malaria because controlled studies have shown that patients who receive steroids take longer to recover from coma and clear their parasitemias more slowly than control patients who did not receive steroids.

PREVENTION AND CONTROL

DEVELOPMENT OF A MALARIA VACCINE

Most investigators believe that an effective malaria vaccine will need at least three antigens—specifically, sporozoite, merozoite (asexual), and gametocyte (sexual) stage antigens—to simultaneously reduce infection of the liver by sporozoites, replication of asexual forms in the bloodstream, and infectivity for the anopheline mosquito vector. Although the genes responsible for the immunodominant epitopes on the sporozoite, merozoite, and gamete have been cloned and are now being used to produce candidate vaccines, it is not yet clear as to whether those candidate vaccines will be successful or when a safe and effective malaria vaccine will be available.

CHEMOPROPHYLAXIS

For the immediate future, chemoprophylaxis is the most important preventive measure for nonimmune travelers to malaria endemic areas ([Table 322.3](#)). Chloroquine remains the chemoprophylactic agent of choice for areas without chloroquine resistance because of its safety (even during pregnancy) and the lack of visual side effects (at doses used for malaria chemoprophylaxis). Alternative chemoprophylactic agents for areas with chloroquine resistance include mefloquine (which is probably safe during pregnancy) and doxycycline (which is not safe during pregnancy or for young children, and produces yeast vaginitis frequently and a photosensitive dermatitis infrequently).

Drug	Dosage
All species except chloroquine-resistant <i>Plasmodium falciparum</i>	
Chloroquine phosphate (Aralin)	300 mg base (500 mg chloroquine phosphate) weekly, beginning 1 wk before exposure, and continuing for 4 wk after exposure
Chloroquine-resistant <i>P. falciparum</i>	
Mefloquine (Lariam)	250 mg mefloquine (225-mg base) weekly during exposure and continuing for 4 wk after exposure
Doxycycline (Mibramycin)	100 mg/d beginning 1 d before exposure, continuing during the period of exposure, and for 4 wk thereafter
Proguanil (Paludrine)*	200 mg/d in combination with weekly chloroquine during the period of exposure and for 4 wk thereafter
Prevention of late relapse due to <i>Plasmodium vivax</i> or <i>Plasmodium ovale</i>	
Primaquine phosphate	15-mg primaquine base (26.3 mg primaquine phosphate) per day \times 14 d after leaving the endemic area

*Not available in the United States.

TABLE 322.3. CHEMOPROPHYLAXIS OF MALARIA

ANCILLARY MEASURES

Especially in areas with chloroquine resistance, it is important to reduce vector exposure as much as possible with conventional measures such as mosquito netting and mosquito repellents (*N,N*-diethyl-*m*-toluamide, or DEET). Bed nets or curtains impregnated with pyrethroid insecticides (permethrin, deltamethrin) have been shown to reduce the frequency of biting by anophelines and the prevalence of infection. However, the impact of this strategy on the incidence of severe and complicated malaria is not yet clear.

accompanied by the suppression of the cellular immune response to the parasite with negative skin tests and suppression of the T-helper type 1 cytokines (interleukin-2 and interferon- γ). In contrast, there is augmented production of T-helper type 2 cytokines, particularly interleukin-10. In mucosal disease, the parasites metastasize from the site of infection in the skin to mucosa of the nose and mouth. An intense granulomatous infiltrate, with a mixed T-helper types 1 and 2 cytokine profile, is present in the mucosa. Few parasites can be detected, and it is thought that the tissue destruction is mediated by the intense host inflammatory response.

CLINICAL FEATURES AND MANAGEMENT OF VISCERAL LEISHMANIASIS (KALA AZAR)

Most infections with *L. donovani* complex parasites are either asymptomatic or oligosymptomatic. Only a minority of infections progress to classic visceral leishmaniasis. Oligosymptomatic infection may be characterized by intermittent fever, malaise, diarrhea, and cough. Nearly all patients will have hepatomegaly, but splenomegaly is less common. Most cases will resolve spontaneously over 3 years, but a minority will progress to classic visceral leishmaniasis.

The incubation period for classic visceral leishmaniasis (kala azar) is usually 2 to 8 months. Most patients will note gradual onset of fever. Rarely, there is an abrupt onset of high fever and chills. Other common symptoms include abdominal distention or pain (due to hepatosplenomegaly), weight loss, and lethargy. Complaints of pallor, cough, diarrhea, bleeding, and amenorrhea are less common. On examination, splenomegaly, which may be massive, is nearly always observed. Most patients will have abdominal distention, hepatomegaly, pallor, and wasting. Laboratory evaluation reveals normocytic anemia. Most patients also have leukopenia, thrombocytopenia, and elevated γ -globulins. Mild elevations of transaminases, prolonged prothrombin time, and depressed albumin are also common. Secondary bacterial infections are common in patients with visceral leishmaniasis, especially skin and respiratory tract infections. The primary cause of death is superinfection, including bacterial sepsis, pneumonia, tuberculosis, and dysentery.

Visceral leishmaniasis can present as an opportunistic infection in immunosuppressed patients (e.g., patients with AIDS or with solid organ transplants). In contrast to normal hosts, immunosuppressed patients are less likely to have splenomegaly, and fever is less prominent. Involvement of the lungs, pleura, gastrointestinal mucosa, and skin has also been reported. There are also reports of visceral infection due to parasites of other complexes, including visceral *L. tropica* infection in U.S. troops who served in Operation Desert Storm. The symptoms resembled those seen in visceral leishmaniasis (chronic low-grade fever, malaise, fatigue, and diarrhea) but tended to be milder.

Post-kala azar dermal leishmaniasis is seen in a minority of patients. The lesions vary from hyperpigmented macular to nodular skin lesions primarily on the face and trunk that usually develop months to years after an apparently successful treatment of visceral leishmaniasis. In contrast to cutaneous disease, these lesions will persist unless treated.

CUTANEOUS LEISHMANIASIS (OLD WORLD)

Cutaneous leishmaniasis in the eastern hemisphere is caused predominantly by *L. major*, *L. tropica*, or *L. aethiopica*. After a typical incubation period of several weeks to several months, an erythematous nodule develops at the site of the insect bite (usually in exposed areas). The center of the nodule begins to crust and then develops an ulcer with raised, inflamed borders containing amastigotes and granulomatous inflammation. The central ulcer gradually crusts. Ulcers will usually heal spontaneously, but healing may require months to years and may leave extensive scarring. *L. major* more frequently causes multiple lesions, is more likely to cause necrosis and ulceration (wet-type lesions), and always heals spontaneously (usually within a few months). *L. tropica* more frequently causes single lesions, often forms a crust rather than ulceration (dry-type lesions), and may heal slowly or not at all. *L. tropica* is associated with leishmaniasis recidivans, in which nodular granulomatous papules recur near the edge of a scar, resembling lupus vulgaris. In addition to localized cutaneous leishmaniasis, *L. aethiopica* is associated with disseminated cutaneous leishmaniasis, with chronic nodular skin lesions disseminated throughout the skin.

CUTANEOUS LEISHMANIASIS (NEW WORLD)

In the western hemisphere, cutaneous leishmaniasis can be caused by parasites of the *L. mexicana* and *L. braziliensis* (subgenus *Viannia*) complexes. The clinical presentation of cutaneous leishmaniasis is similar in eastern and western hemispheres, with papular lesions developing at the site of sandfly bites, followed by ulceration and eventual healing. In one study from Guatemala, lesions caused by *L. braziliensis* were likely to be more numerous, larger, and less likely to heal spontaneously than lesions caused by *L. mexicana* (Figure 323.1). Biopsy specimens also showed fewer parasites in the lesions caused by *L. braziliensis*. Nodular or ulcerative lesions developing along the lymphatics, termed sporotrichoid leishmaniasis, have been associated with *L. braziliensis* complex parasites. *L. mexicana* complex parasites may result in disseminated cutaneous leishmaniasis. Disseminated cutaneous and visceral infections due to *L. braziliensis* have been reported in patients with AIDS. The diagnostic methods are the same for all cases of cutaneous leishmaniasis.

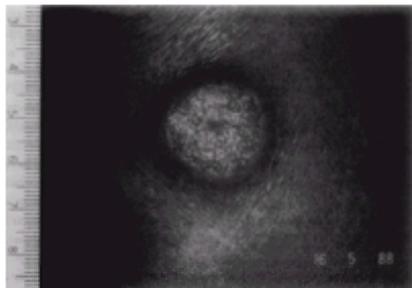

FIGURE 323.1. Typical lesion of cutaneous leishmaniasis showing a cutaneous ulcer with an indurated erythematous border. This patient was infected in Guatemala. (Photograph courtesy of Dr. Thomas R. Navin. From Herwaldt BL et al. American cutaneous leishmaniasis in U.S. travelers. *Ann Intern Med* 1993;118:779.)

MUCOSAL LEISHMANIASIS

Mucosal leishmaniasis results from the spread of amastigotes from a cutaneous lesion to the mucosa of the nose, mouth, throat, and upper respiratory tract. Mucosal lesions may develop concurrently with a cutaneous lesion, but more commonly the primary lesion has healed before (in some cases decades before) the onset of mucosal disease. Patients initially develop epistaxis or nasal congestion. Untreated disease may progress to involve the nasal septum, palate, lips, oropharyngeal mucosa, larynx, and epiglottis. The appearance of the lesions may range from erythema, edema, or infiltration to frank ulceration. Severe disease may result in destruction of the nasal architecture. Aspiration pneumonia is a common complication of advanced disease and can be fatal.

DIAGNOSIS

The clinical presentation of visceral leishmaniasis is often indistinguishable from other coendemic diseases including malaria, typhoid fever, typhus, acute Chagas' disease, amebic liver abscess, brucellosis, schistosomiasis, lymphoma, or lymphocytic leukemias. Definitive diagnosis depends on demonstration of amastigotes in tissues or of promastigotes in cultures. Bone marrow aspirates are the most common source of diagnostic material. Giemsa- or Wright-stained smears are positive in two-thirds of cases. Splenic aspiration is more sensitive but is avoided because of the risk of potentially life-threatening bleeding. In patients with lymphadenopathy, it is often possible to demonstrate organisms in lymph node aspirates. Cultures of bone marrow or splenic aspirates are positive in 70% to 96% of cases. Serologic tests (indirect immunofluorescence antibody assay, ELISA, direct agglutination assay) show high titers of antileishmania antibodies in patients with active visceral leishmaniasis, providing presumptive evidence of infection. In some regions, cross-reactivity to other infectious agents (most notably *Trypanosoma cruzi*) may diminish the specificity. Recently, a serologic test using a recombinant *Leishmania* antigen (rK39) was shown to be highly sensitive and specific. The sensitivity of serologic tests in patients with AIDS is poor. Other techniques have been used to identify parasites, including immunofluorescence with monoclonal antibodies and polymerase chain reaction.

Diagnosis of cutaneous leishmaniasis is made by identifying organisms on biopsy specimens or on aspirates taken from the dermis of the nonulcerated edge of the

lesion. Touch preparations are thought to be more sensitive than biopsies. The diagnostic yield can be improved by culturing the aspirate or ground biopsy material. Serologic tests have limited value in the diagnosis of cutaneous leishmaniasis. Montenegro skin tests are usually positive in localized cutaneous disease and mucocutaneous disease, but are negative in disseminated cutaneous and visceral leishmaniasis. A presumptive diagnosis of mucosal disease can be made in patients with typical lesions and exposure history. Biopsy specimens show granulomatous inflammation but few parasites. Cultures may also be negative.

To culture for *Leishmania* promastigotes, aspirates or tissue homogenates should be inoculated onto a biphasic medium consisting of blood agar [Nicolle–Novy–MacNeal (NNN) medium] overlaid with tissue culture medium (available from the Division of Parasitic Diseases, U.S. Centers for Disease Control and Prevention, Atlanta, GA). When cultured at 24°C to 26°C, the tissue amastigotes transform into motile, flagellated promastigotes that are visible within a few days to several weeks. The isolation of promastigotes enables species identification by a reference lab.

MANAGEMENT

The treatment of choice for visceral leishmaniasis is pentavalent antimony. Sodium stibogluconate (Pentostam, Burroughs Wellcome, London; available in the United States only through the Drug Service of the U.S. Centers for Disease Control and Prevention), containing 100 mg per milliliter of antimony, or meglumine antimonate (Glucantime, Rhône-Poulenc, Paris), containing 85 mg per milliliter, are given by either intramuscular or intravenous routes. Optimal response requires a dose of 20 mg per kilogram per day of antimony. In visceral disease, therapy should be continued for 28 days. Response rates are generally over 90%. Lower rates are seen in patients previously treated with antimonials, during epidemic transmission, and in immunosuppressed hosts. Common side effects include myalgias, arthralgias, mild elevation of liver enzymes, elevation of pancreatic enzymes, and nonspecific electrocardiographic changes. These necessitated interruption of treatment in 28% of cases in one large study, but there were no lasting sequelae. Severe side effects are rare but include cardiac arrhythmias, hematologic abnormalities, and pancreatitis. In patients who fail normal doses of antimonials, prolonging the duration of antimony therapy (e.g., 20 mg per kilogram per day for 40 days) appears to increase response rates. Amphotericin B is also highly effective, but complications are common. Recent studies using lipid formulations of amphotericin B (liposomal amphotericin, AmBisome, Vestar, San Dimas, CA; amphotericin lipid complex, Abelcet, Liposome Technology, Menlo Park, CA; or amphotericin cholesteryl sulfate complex, Amphotec, Sequus, Menlo Park, CA) demonstrated high response rates with few side effects. Pentamidine has been used as an alternative but is associated with higher failure rates as well as toxicity. Parenteral paromomycin (aminosidine) has been shown to be highly effective in Indian kala azar for which antimony treatment has a high failure rate. Aminosidine, interferon-g, and allopurinol have all been reported to improve response rates when used in combination with pentavalent antimonials.

In immunosuppressed patients (e.g., AIDS patients), there is a poor initial response to antimonials and a high relapse rate. Better initial response rates have been reported using liposomal amphotericin or pentavalent antimonials combined with allopurinol or interferon-g. Secondary prophylaxis to prevent relapses may be needed, but the optimal regimen has not been defined.

Specific antileishmanial therapy is not routinely indicated for uncomplicated cutaneous leishmaniasis caused by strains that usually self-heal (*L. major*, *L. mexicana*). Lesions that are extensive, located where a scar would result in disability or cosmetic disfigurement, or do not begin healing within 3 to 4 months should be treated. Cutaneous lesions suspected or known to be caused by members of the *Viannia* subgenus (New World) should be treated because of the low rate of spontaneous healing and the potential risk of developing into mucosal disease. All patients with mucosal disease should receive therapy.

Pentavalent antimonials are also the primary therapy for Old World cutaneous leishmaniasis and should be given at a dose of 20 mg per kilogram per day for 20 days. Topical treatment with heat, paromomycin, or intralesional antimony has been reported to be effective in some cases. Uncontrolled trials have described cures with oral allopurinol or ketoconazole.

The treatment of American cutaneous leishmaniasis has only recently been studied in carefully controlled trials. Pentavalent antimonials are the standard treatment and should be given at a dose of 20 mg per kilogram per day of antimony. The recommended duration of therapy is 20 days, but excellent response rates have been reported with 10 days of treatment. Oral allopurinol was superior to pentavalent antimony in a trial from Colombia for leishmaniasis due to antimony-resistant *L. panamensis* but was not effective in trials from Ecuador and Panama. Ketoconazole has some efficacy, but trials of itraconazole have been disappointing. Ketoconazole at 600 mg per day was superior to antimonials for *L. mexicana* in a trial from Guatemala. One study noted excellent response rates to pentamidine. Reports also exist of successful immunotherapy using a vaccine composed of bacille Calmette-Guérin and killed *Leishmania* promastigotes.

Mucocutaneous disease responds poorly to antiparasitic agents. The recommended therapy is pentavalent antimonials at 20 mg per kilogram per day for 28 days. Cure rates with isolated nasal disease approach 75%. With involvement of the oropharynx, cure rates range from 10% to 63%. Failures include patients who do not respond and others relapsing after initial improvement. Prolonging therapy does not improve the response rate. Amphotericin B or lipid preparations of amphotericin have most often been used in patients failing antimonials.

Cure of disseminated cutaneous leishmaniasis is difficult and relapses are the norm. Some efficacy has been reported with a combination of pentavalent antimony and interferon-g. Disseminated cutaneous disease in the Old World responds poorly to antimonials but may respond to pentamidine.

CHAPTER 324: AFRICAN AND AMERICAN TRYPANOSOMIASSES

MARIO PAREDES-ESPINOZA AND PATRICIA PAREDES-CASILLAS

[Definition](#)
[Etiologic Factors](#)
[African Trypanosomiasis](#)
[American Trypanosomiasis](#)

DEFINITION

African and American trypanosomiasis, also called sleeping sickness and Chagas' disease, respectively, are caused by protozoan parasites that belong to the genus *Trypanosoma*. The subspecies *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* cause West African and East African trypanosomiasis, respectively, and are transmitted by blood-sucking tsetse flies. *T. b. brucei* is a third African trypanosome subspecies that causes a usually fatal disease of cattle called nagana, which means "in low spirits" in Zulu. Chagas' disease is caused by the species *Trypanosoma cruzi*, which is transmitted by numerous species of hematophagous triatomine insects, also called kissing bugs.

ETIOLOGIC FACTORS

These organisms are fusiform hemoflagellate protozoans belonging to the family Trypanosomatidae, order Kinetoplastida. Their single mitochondrion contains a unique structure called the kinetoplast, which contains many thousands of interlocking circular DNAs. Most morphologic stages of these trypanosomes have a flagellum anchored by an undulating membrane that produces forward motion of the parasite resembling that of an auger (*trupanon* in Greek). The nucleus is large and oval with a central karyosome. Trypanosomes have complex life cycles involving mammals as well as insect vectors, and in passing from one group of hosts to the other undergo major morphologic and metabolic changes. In the case of *T. b. brucei*, discovered by David Bruce in Zululand in 1894, some of the longitudinally dividing slender bloodstream trypanosomes in mammals differentiate into relatively stumpy forms that are preadapted for infecting tsetse flies ([Fig. 324.1](#)). Carlos Chagas discovered *T. cruzi* in 1907. Infected triatomine insects transmit the disease while painlessly sucking blood for 20 or more minutes from mammals. Rising intra-abdominal pressure causes the bug, in many instances, to deposit parasite-containing feces on the skin at or near the puncture site. These organisms can enter the mammalian host through breaks in the skin, including the puncture site, as well as through normal mucosae or conjunctivae ([Fig. 324.2](#)).

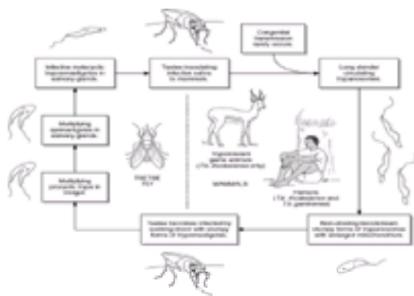

FIGURE 324.1. *T. b. brucei*. Differentiation in mammals of the longitudinally dividing slender bloodstream trypanosomes, preadapted for infecting tsetse flies.

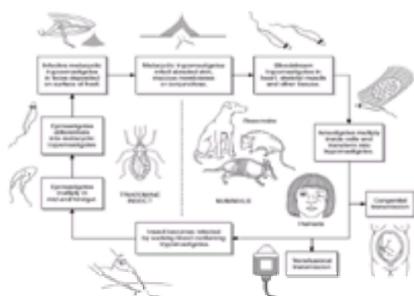

FIGURE 324.2. *T. cruzi* transmission. Infected triatomine insects transmit the disease while sucking blood. The bug deposits parasite-containing feces on the skin at or near the puncture site. These organisms enter the host through breaks in the skin, mucosae, or conjunctivae.

AFRICAN TRYPANOSOMIASIS

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The complex epidemiology of African (or Rhodesian) trypanosomiasis involves tsetse flies ("flies that destroy cattle" in Zulu), trypanosomes, humans, game animals, and the ecological circumstances within which they all coexist. The bite of riverine tsetse *Glossina palpalis* and open-savannah *Glossina morsitans* transmit the disease in sub-Saharan West, Central, and East Africa in an area approximately equal to the size of the United States.

Approximately 50 million people live in areas endemic for sleeping sickness, and 20,000 to 30,000 cases of acute and chronic sleeping sickness are reported annually. The actual number of cases probably is many times this figure, and as many as 55,000 persons may die annually due to sleeping sickness. In Angola, the Democratic Republic of Congo, the Sudan, and Uganda, the disease is considered epidemic, with a prevalence greater than 50% in many villages, a high transmission rate, and total deaths equal to or greater than those due to AIDS. Little is known about the epidemiology of sleeping sickness in countries such as Ethiopia, Liberia, or Senegal. Infected tsetse can transmit the disease to young babies who are being carried on their mothers' backs. Game wardens, hunters, poachers, honey gatherers, firewood collectors, and others who venture into areas populated by wild animal reservoirs are at risk for acquiring Rhodesian trypanosomiasis in East Africa.

PATHOGENESIS

Once inoculated into a mammalian host with tsetse saliva, trypanosomes multiply locally and often invade the lymphatics. Parasitemia appears within a week or two but is initially controlled by antibody-mediated mechanisms of destruction. Symptomatic, periodic parasitemia occurs throughout the life of the host due to sequential antigenic variations of the surface glycoprotein of the parasite. No long-standing immunity develops. Direct parasite-macrophage interactions initiate a cascade of immunomodulatory mechanisms that eventually lead to profound immunosuppression. A diffusible *T. b. rhodesiense* immunosuppressive factor has been shown to block interleukin-2R (IL-2R) expression by activated human lymphocytes in vitro. There is initial polyclonal activation of CD5⁺ B-cell proliferation with consequent exhaustion of antigen B lymphocytes and arrest of T-cell proliferation.

CLINICAL FINDINGS

A trypanosomal chancre appears within days at the site of the infected tsetse bite. This is generally a tender and indurated inflammatory lesion several centimeters in diameter. Weeks or months later the hemolymphatic stage of the disease develops, which is notable for cyclic episodes of high fever, severe headaches, and malaise alternating with progressively shorter asymptomatic periods.

Areas of pruritic annular skin rash up to 10 cm in diameter (trypanids) may appear on the trunk and shoulders. Kerandel sign is an uncommon but nearly pathognomonic form of hyperesthesia that causes patients to become obsessed with a fear of hurting themselves. Hepatosplenomegaly and diarrhea (more marked in children), initial polyphagia, severe hemolytic anemia, wasting, recurrent pneumonia, spontaneous abortion, amenorrhea, impotence, and high abortion rate occur. Progressive myocarditis with heart failure and disseminated intravascular coagulation with or without severe central nervous system (CNS) involvement may cause death within weeks to a few months in the East African form of the disease, whereas the course of West African trypanosomiasis is usually less aggressive.

Particularly in the case of infections with *T. b. gambiense*, months after the beginning of the hemolymphatic stage chronic progressive meningoencephalitis may develop, with profound somnolence and apathy. Prominent adenopathy in the posterior cervical triangle (Winterbottom's sign) may represent lymphatic drainage of trypanosomes from the ventricles and the base of the brain. Extraparasympathetic and cerebellar damage, emotional lability, slurred speech, sad expression, facial edema, cachexia, and death occur over a course of 2 to 3 years. Sleeping sickness in children usually follows a rapid course. Reactivation of chronic gambiense infection has not been observed in HIV-infected patients.

LABORATORY FINDINGS

The diagnosis of sleeping sickness must be made by parasitologic methods. Therapy should never be started until parasites have been visualized because of the potential toxicity of the drugs used for treatment. Microscopic examination of wet preparations and Giemsa-stained thin and thick smears of peripheral blood or buffy coat is a sensitive method for detecting African trypanosomes. Fluid aspirated from a swollen lymph node or the bone marrow, as well as cerebrospinal fluid, can be examined similarly (Fig. 324.3). Implementation of even these simple approaches is limited in many endemic regions because of a lack of human and material resources.

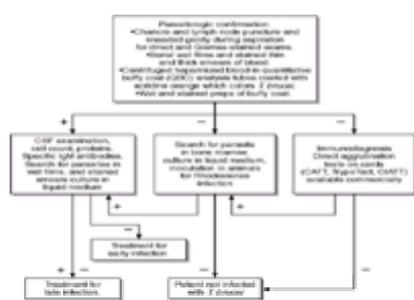

FIGURE 324.3. Lymph fluid, as well as cerebrospinal fluid, can be examined for a diagnosis of sleeping sickness.

OPTIMAL MANAGEMENT

Suramin, arsenicals, and eflornithine [2-(difluoromethyl)-DL-ornithine; DFMO] achieve a parasitologic cure in over 90% of cases of early and late stage sleeping sickness (Fig. 324.4). Drug toxicity is high, especially with arsenicals, and related mortality may exceed 5%. Untreated sleeping sickness is usually fatal. Corticosteroids can be used as adjunctive treatment of late-stage sleeping sickness with CNS involvement or to prevent reactive encephalopathy induced by arsenicals, which occurs in about 10% of patients and has a mortality of 50%. The signs and symptoms of reactive arsenical encephalopathy can include headache, fever, psychosis, seizures, and coma.

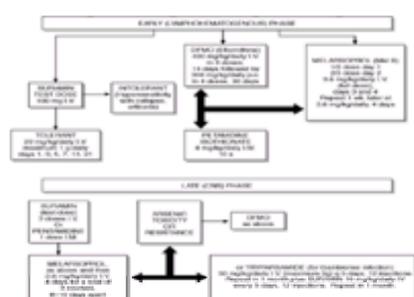

FIGURE 324.4. Effectiveness of treatment with Suramin, arsenicals, and eflornithine in cases of early and late stage sleeping sickness.

AMERICAN TRYPANOSOMIASIS

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Insect-borne acquisition of *T. cruzi* by humans, which is the most common mode of transmission, depends on the interaction of a number of complex factors relating to vector density and feeding habits, biological characteristics of the parasites, host immune status, and a conducive physical environment (Table 324.1). Some 50 triatomine species are known to transmit *T. cruzi*, and over 100 species of mammals are reservoirs of the parasite. The wild mammals most commonly infected with *T. cruzi* are armadillos, raccoons, and opossums. *Triatoma infestans*, *Panstrongylus megistus*, *Rhodnius prolixus*, *T. dimidiata*, and *T. barben* are vector species that are well adapted to living in rural dwellings in endemic regions. *T. cruzi* also can be transmitted by transfusion of contaminated blood, and many thousands of transfusion recipients become infected by this route each year in areas where effective donor-screening programs have not been implemented. Prevalence of *T. cruzi* among blood donors in many endemic regions is higher than that of HIV and hepatitis B and C viruses. Congenital *T. cruzi* infection is present in a small portion of babies born to infected mothers, but precise incidence data are not available.

Contact with triatomine feces
 Blood transfusions
 Congenital transmission
 Laboratory accidents

TABLE 324.1. TRANSMISSION OF *TRYPANOSOMA CRUZI* TO HUMANS

Over 100 million Latin Americans are at risk of acquiring *T. cruzi* infection, and 16 to 18 million chronically harbor the parasite. Roughly 5 million persons have symptomatic disease and 45,000 die of the illness each year. One hundred eight acute cases of Chagas' disease have been reported on the west coast of Mexico. The annual economic loss resulting from disability and early mortality due to Chagas' disease, which frequently occurs in economically productive young adults, currently is estimated to be more than U.S. \$8 billion.

It is estimated that 50,000 to 100,000 Latin American immigrants currently living in the United States are chronically infected with *T. cruzi*. No assay for detecting *T. cruzi* infection in donated blood has been cleared by the U.S. Food and Drug Administration. Currently, a questionnaire is being used in an effort to identify high-risk donors. Transfusions of *T. cruzi*-infected blood are particularly hazardous in immunosuppressed patients.

PATHOGENESIS

After contacting susceptible tissues of a mammalian host, infective forms of *T. cruzi* enter macrophages and other cells where they transform into amastigotes. The amastigotes then multiply and eventually differentiate into flagellated trypomastigotes. The latter are released when infected cells rupture and then spread via the lymphatics and the bloodstream to invade other cells, mainly in the heart, skeletal and smooth muscle, CNS, parasympathetic neurons, and reticuloendothelial system.

Most circulating parasites are destroyed by specific antibodies plus complement or in combination with Fc receptor-bearing leukocytes. In turn, trypanosomal immunosuppressor factor (TIF) inhibits the production of IL-2 and down-regulates the expression of IL-2R. Polyclonal activation is observed during *T. cruzi* infection, which triggers uncontrolled proliferation of autoreactive clones of B cells, leading to possible autoimmune reactions. The persistent presence of *T. cruzi* in the heart has been demonstrated with sensitive techniques such as immunohistochemistry and polymerase chain reaction (PCR)-based assays. *T. cruzi* is the first microorganism described to suppress the expression of T-cell receptor molecules, which is required for antigen recognition. Parasympathetic cardiac denervation occurs. Destruction of cells of the myenteric plexus can cause megaesophagus and megacolon.

CLINICAL FINDINGS

When the skin is the portal of entry of *T. cruzi*, an indurated, erythematous, and painless primary chagoma with regional adenopathy may develop. When the conjunctiva is the site of entry, unilateral, palpebral swelling, called the Romaña sign, can arise. After multiplication at the site of entry, spread of the organisms results in acute Chagas' disease. This may be asymptomatic, manifested by mild symptoms, or may cause life-threatening disease (Table 324.2). Congenital Chagas' disease is a form of acute Chagas' disease. Its manifestations can also be mild to severe, and occasionally may involve megaviscera, which is not seen acutely in patients infected by other mechanisms. Acute Chagas' disease resolves spontaneously in 4 to 8 weeks in almost all patients, who then enter the indeterminate form of the illness characterized by lifelong, subpatent parasitemias and easily detectable levels of specific anti-*T. cruzi* antibodies.

- Portal of Entry:
 - Primary chagoma or Romaña sign
- Systemic Manifestations:
 - Fever
 - Malaise
 - Adenopathy
 - Edema
 - Hepatosplenomegaly
 - Myocarditis
 - Meningoencephalitis
- Skin Manifestations
 - Schizotrypanids (skin rash)
 - Secondary chagomas

TABLE 324.2. MANIFESTATIONS OF ACUTE CHAGAS' DISEASE

Years or even decades after resolution of the acute infection, up to a third of chronically infected patients develop symptomatic cardiac and/or gastrointestinal disease. Chagas' cardiopathy typically involves rhythm disturbances and progressive cardiomyopathy causing congestive heart failure (Table 324.3). Megadisease is usually manifested as megaesophagus and/or megacolon. Immunosuppressed patients, including persons with AIDS, who are chronically infected with *T. cruzi* are at risk for developing reactivated acute Chagas' disease that may be manifested in its typical form or atypically as ulcerating skin lesions or brain abscesses.

- Ventricular extrasystoles
- Atrioventricular block
- Brady and tachyarrhythmias
- Right bundle-branch block, left anterior hemiblock
- Ventricular tachycardia
- Ischemic chest pain
- Dilated cardiomyopathy, ventricular aneurysms
- Congestive heart failure, clot formation, embolization
- Sudden death

TABLE 324.3. MANIFESTATIONS OF CHRONIC CHAGAS' CARDIOPATHY

LABORATORY FINDINGS

The diagnosis of acute Chagas' disease must be made by parasitologic methods. Parasites sometimes can be seen in wet preparations of anticoagulated blood or buffy coat, or in Giemsa-stained smears of these same specimens. Bone marrow aspirates may be examined similarly. Hemocultures in a specialized media have a

sensitivity of about 80% but have the disadvantage of taking several weeks before parasites are evident. Sensitive and specific PCR assays that amplify highly repetitive nuclear or kinetoplast DNA sequences of *T. cruzi* have been described, but their accuracy still needs further definition and they are not available commercially.

The diagnosis of chronic *T. cruzi* infection is made by serologic methods, and parasitologic approaches play a secondary role. The sensitivities of conventional serologic methods, such as indirect immunofluorescence assay, complement fixation test, and enzyme-linked immunosorbent assay, are high, but a lack of specificity has been a persistent problem historically. False-positive reactions typically occur with specimens from patients with other parasitic and infectious diseases, as well as with collagen vascular diseases, and because of this it is generally recommended that two or three tests be employed before a specimen is accepted as positive. Alternatively, confirmatory testing can be carried out using a radioimmune precipitation assay that has been shown to be highly sensitive and specific (L. V. Kirchhoff, University of Iowa). A role for PCR assays in chronic Chagas' disease has not been defined.

OPTIMAL MANAGEMENT

A panel of experts that recently convened under the sponsorship of World Health Organization recommended that all patients infected with *T. cruzi* be treated with one of the two currently available drugs. This recommendation was based on recent laboratory and clinical data indicating that the progression of lesions is less in animals and humans who have been cured parasitologically. However, the two drugs used to treat *T. cruzi*, nifurtimox and benznidazole, lack efficacy, and the probability of parasitologic cure is approximately 70% in patients with acute Chagas' disease and 20% in persons with longstanding chronic infections. Benznidazole is the drug of choice for treatment of *T. cruzi*, and the recommended course is 5 mg per kilogram per day in two divided doses for 60 days. Leukopenia and skin eruptions are the most common side effects of benznidazole. The recommended dose of nifurtimox is 8 to 10 mg per kilogram per day for adults, 12.5 to 15 mg per kilogram per day for adolescents, and 15 to 20 mg per kilogram per day in children 10 years of age or less. In all patients the daily dose should be given orally in four divided doses and continued for 90 to 120 days. The most common side effects of nifurtimox are anorexia, nausea, and vomiting, and they are generally more bothersome than those of benznidazole.

Chagas' disease is an illness that primarily affects poor people living in rural settings. A major effort for eliminating vectorial and transfusional transmission of *T. cruzi* in the Southern Cone nations of South America was launched in 1992, and major successes have been achieved in several regions. Uruguay was certified as transmission-free in 1997, and the spread of the parasite in Chile is expected to be stopped by the end of this year. Brazil and Argentina are expected to follow this pattern within the next few years. The success of the Southern Cone initiative and the implementation of similar programs in the northern part of South America and Central America provide a basis for optimism regarding the eventual elimination of transmission ([Table 324.4](#)).

CHAPTER 325: BABESIOSIS

MURRAY WITTNER

[Definition](#)
[Epidemiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)
[Prevention](#)

DEFINITION

Babesiosis is a worldwide tick-borne hemolytic disease of wild and domestic animals that is caused by intraerythrocytic protozoan parasites of the genus *Babesia*. Human infection with several diverse species of *Babesia* may cause a broad spectrum of clinical features, from severe and occasionally fatal hemolytic anemia, with fever, jaundice, and splenomegaly, to a condition that is entirely asymptomatic.

EPIDEMIOLOGIC FACTORS

Since 1957, when the first human case of babesiosis was described in a Yugoslavian farmer who died of severe hemolytic anemia, sporadic cases have been reported with increasing frequency, especially along the northeastern coast of the United States. In the United States, infections have been reported from California, Missouri, Minnesota, Washington State, and Georgia; the most endemic areas, however, are the islands off the coast of Massachusetts, including Nantucket and Martha's Vineyard, and eastern and south central Long Island, including Shelter Island and Fire Island in New York. Foci in Connecticut that overlap with Lyme disease, as well as in Wisconsin and Indiana, have been recorded. Sporadic cases have also been reported from France, Great Britain, Ireland, the Soviet Union, and Mexico. In the United States, with one possible exception, the murine species *Babesia microti* has been implicated. However, in the western United States those cases of babesiosis reported from California have been caused by a non-*B. microti* species, whereas those cases reported from Washington State, although morphologically indistinguishable from *B. microti*, were shown to be antigenically and genotypically distinct from *B. microti*. Most European and African cases have been caused by bovine and other nonmurine species of *Babesia*.

Recent reports have suggested an increased prevalence of babesiosis in such areas of New England as Connecticut, possibly because of the marked increase in the population of white-tailed deer, which are essential to the life cycle of the northern deer tick. In this regard, in a recent study of 1,000 *Borrelia burgdorferi*-seropositive patients from Connecticut, 10% were also seropositive for *B. microti*.

Babesia microti is transmitted through the bite of the northern deer tick, *Ixodes dammini* (= *scapularis*). Dissemination of *B. microti* to humans appears to be the result of indiscriminate feeding by infected larval and especially nymphal stages of *I. dammini* on a variety of hosts, including humans. Epidemiologic studies on Nantucket have shown that about 60% of the trapped white-footed or deer mice (*Peromyscus leucopus*) are infected with *B. microti*. Throughout its larval, nymphal, and adult stages, *I. dammini* feeds on three hosts, dropping off between each blood meal. In the larval and nymphal stages, it usually feeds on white-footed mice; the adults usually feed and mate on deer, who are naturally immune. Human infection usually occurs from late spring to early fall, when many nymphs are questing and when humans enter the tick-infested habitat. Evidence of transovarial transmission in *B. microti*, as there is in other species of *Babesia*, has been reported occasionally.

Seroepidemiologic studies carried out on residents of Nantucket and Shelter Islands have shown a 4% to 7% seroconversion. Similar results were obtained in studies on residents of a rural area along the Gulf Coast of Mexico that was a known focus of babesiosis of domestic animals. These studies imply that asymptomatic human infection seems to be common. In some of these symptom-free individuals, low numbers of circulating parasites have been found and have been a source of transfusion babesiosis. Despite the widespread prevalence of putative asymptomatic infection, clinical disease has not been reported from people immunodepressed during a course of corticosteroid or cyclophosphamide therapy. However, patients with AIDS are apparently unable to control their infection naturally or after usual treatment, and must be maintained on antibiotic therapy indefinitely.

The risk for transmission of *B. microti* infection via contaminated blood products has been recognized since the late 1970s. However, direct measures of risk are not available, and estimates of the likelihood of acquiring *Babesia* from a unit of blood are based on reported cases or seroepidemiologic studies. Although *B. microti* is the second most commonly reported cause of transfusion-transmitted parasitic infection, testing of all blood donors for evidence of *B. microti* infection has not been considered cost-effective. Despite the low overall incidence of transfusion-transmitted babesiosis, it is likely that the risk of transmission of babesiosis by blood products depends on where the blood is collected. For example, a seroepidemiologic study from Connecticut estimated the risk to be 0.17% per unit of packed cells. Furthermore, since in the vast majority of immunocompetent individuals infection with *B. microti* is subclinical and therefore undiagnosed, the standard question "Have you ever had babesiosis?" is unlikely to be useful in excluding infected donors. Given the lack of effective screening strategies, the widening geographic range of *B. microti*, and the concomitant increase in human infections with this parasite, one may expect the incidence of transfusion-associated babesiosis to increase.

PATHOGENESIS

After an infectious tick bite, the organisms invade red blood cells and a trophozoite differentiates, replicating asexually by budding with the formation of two to four merozoites. A second type of undifferentiated trophozoite is also formed that does not replicate but rather enlarges and differentiates into gametocyte-like forms similar to that seen in *Plasmodium* species. Merozoites eventually disrupt infected erythrocytes and reinvade other red blood cells. These events cause a hemolytic anemia that, when severe, can bring about hemoglobinuria, renal insufficiency, or renal failure.

Although symptomatic infection with *B. microti* is seen regularly in otherwise immunocompetent people, the most severe cases have been recorded from patients splenectomized for a variety of reasons, including trauma.

Splenectomized animals have more severe infections than those with intact spleens, and they often die with an extraordinarily high parasitemia. In animal experiments, after recovery from a *B. microti* infection, splenectomy often provokes a severe and fatal relapse.

If untreated, clinically symptomatic *B. microti* infections in immunocompetent patients are usually self-limited; it has been shown that both humoral and cell-mediated immune mechanisms influence the outcome of the infection. Experimental studies have demonstrated that without T-helper cells specific humoral immunity cannot be established and the animals die. Similarly, athymic nude mice have been shown to have severe and fatal infections. Several studies have documented that in patients with acute babesiosis, in vitro lymphocyte mitogenic responses were profoundly depressed; on recovery, these T-cell changes returned to normal. It is not clear as to whether the age of the host influences the severity of a *Babesia* infection, except at the extremes of life, when these patients are probably immunocompromised.

CLINICAL FINDINGS

After a recognized tick bite, the incubation period varies from 5 to 33 days, whereas after an infected blood transfusion, the clinical incubation period has been 6 to 9 weeks. In a recent cluster of transfusion-derived babesiosis the clinical incubation period was 43 days. Frequently, however, infected people are unaware of being bitten because (a) *I. dammini* is 1 to 2 mm in overall diameter, (b) feeding is painless, and (c) soon after feeding the organisms drop off the host. In persons with intact spleens, the clinical onset can be gradual, beginning with a general feeling of malaise and myalgias, followed by fatigue, weakness, and chilliness, to frank shaking chills with fever and diaphoresis. This presentation is often mistaken for malaria, and the symptoms continue for weeks if untreated. Some patients have severe arthralgias. Occasionally, nausea and vomiting and severe headache, as well as mood and personality changes, are noted. As frequently found in malaria, splenomegaly is often evident but lymphadenopathy is not. A mild to severe hemolytic anemia and a normal to slightly depressed leukocyte count are usually found. In most patients, the serum bilirubin, aspartate aminotransferase, and alkaline phosphatase values are mildly elevated, and the parasitemia can range from below 1% to more than 50%. Splenectomized patients usually have greater levels of parasitemia and more severe hemolytic anemia. Unless other clinical problems intervene, patients with *B. microti* infections usually recover. In patients with underlying heart disease, babesiosis may precipitate cardiac failure; elderly patients in particular

have died after acute myocardial infarction.

Because *I. dammini* is also the vector of *B. burgdorferi* (the etiologic agent of Lyme disease) and *Ehrlichia chafeensis*, and because babesiosis, Lyme disease, and ehrlichiosis coexist in a number of localities in the northeastern United States, it is important to be alert for the coexistence of these diseases. This has been reported, and the spirochete has been demonstrated in the myocardium.

In Europe, human babesiosis with bovine species of *Babesia* is seen exclusively in splenectomized patients in whom the disease is fulminant and characterized by chills, fever, nausea, vomiting, and severe hemolytic anemia. These patients were often icteric, had acute renal insufficiency or failure, and died.

LABORATORY FINDINGS

The diagnosis of babesiosis should be entertained in anyone with a febrile hemolytic disorder, regardless of a history of tick bite, who has been to an endemic area or who has received a blood transfusion. The diagnosis can be firmly established with the finding of characteristic intraerythrocytic parasites on thick or thin blood smears stained with Giemsa or Wright's stain. *B. microti* is frequently mistaken for ring forms of *Plasmodium falciparum*, especially when multiple rings are present in a single erythrocyte. *Babesia* species do not produce residual hemozoin pigment, a by-product of hemoglobin digestion, as is usual with late-stage malarial schizonts. In some instances, cruciate, Maltese cross, or tetrad forms lacking pigment can be seen in a blood smear. These are characteristic and diagnostic ([Fig. 325.1](#)). It may be necessary to examine blood smears made at frequent intervals with low-level parasitemia. An indirect immunofluorescence test performed by the U.S. Centers for Disease Control and Prevention can be helpful, but low-titer cross-reactions between *Babesia* and P 1024 are present during acute disease and decline over the ensuing year to a ratio of 1:256 to 1:32 or less. If 1 mL of the patient's blood is inoculated intraperitoneally into a golden hamster or gerbil, a parasitemia becomes evident. High *Babesia* antibody titers (1:12 to 14 days) should help to confirm the diagnosis. The use of polymerase chain reaction (PCR) is especially useful to assess whether infection has been eliminated. Recent studies suggest that this procedure is more sensitive than microscopic examination of thin blood smears. This has also been reported for other infectious agents including *P. vivax* and *B. burgdorferi*.

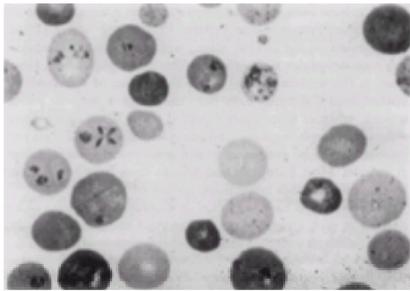

FIGURE 325.1. Blood smear showing intraerythrocytic parasites of *Babesia microti*. Many ring forms that resemble those of *Plasmodium falciparum* are evident, but the pathognomonic “tetrad” or “Maltese cross” form is also present. (Original magnification $\times 1,250$.)

Babesiosis can be mistaken for rickettsial disease, especially when there is a history of tick bite, fever, myalgias, headache, hemolytic anemia, and thrombocytopenia. A blood smear should quickly eliminate this diagnosis. In case of *B. microti* infection, concurrent Lyme disease should also be considered, especially when arthralgias, rash, and cardiac symptoms are evident. The diagnosis of coexisting Lyme disease or ehrlichiosis can be made serologically. PCR for these conditions is also available.

OPTIMAL MANAGEMENT

In patients who are otherwise immunocompetent and who have normal, intact spleens, spontaneous recovery from *B. microti* infection seems to be the rule, although lingering symptoms with low-grade parasitemia can be evident for months.

In asplenic patients and those infected with *Babesia bovis* or *Babesia divergens*, symptoms are often too severe to temporize. Bovine babesiosis usually is severe with a fulminant downhill course and must be treated aggressively if the patient is to survive. Several patients who were placed on renal dialysis and transfused have survived. Diminazene aceturate (Berenil), an aromatic diamidine that is an effective babesiacide in animals, was unsuccessful in a fatal case of *B. divergens* infection. More recently, however, a human case of *B. divergens* infection was treated successfully with trimethoprim–sulfamethoxazole and pentamidine.

Treatment for human *B. microti* infection has been more successful. Initially, most patients received chloroquine, primarily because of the morphologic similarities of *B. microti* to *P. falciparum* in human blood smears. However, there is little evidence of its efficacy. Experimental babesiosis in hamsters was shown to be unaffected by chloroquine, as well as by sulfadiazine, primaquine, or metronidazole in combination with pyrimethamine. Minocycline and tetracycline, when used at high and toxic doses, had some effect in reducing parasitemia; at usual therapeutic levels, however, tetracycline had no effect. Pentamidine isethionate (Pentam 300), 4 mg per kilogram per day for 14 days by deep-muscle injection, has had limited success when used to treat human *B. microti* infection, lowering but not eliminating the parasitemia. Recrudescence occurred after completion of therapy. Significant side effects included the development of renal insufficiency, severe pain at the injection site, and formation of large sterile abscesses. Red blood cell or whole-blood exchange transfusion has been used with apparent success in several ill patients who had high parasitemias (40% to 60%).

Since the mid-1980s, clindamycin plus quinine has been regarded as the standard therapy for this infection on the basis of numerous clinical observations and experimental hamster studies. Clindamycin, 1,200 mg intravenously every 12 hours for 7 days, combined with quinine, 650 mg orally every 8 hours for 7 days, has been used successfully to treat in adults. The pediatric dose is clindamycin, 20 to 40 mg per kilogram per day in three doses for 7 days, and quinine, 2.5 mg per kilogram per day in three doses for 7 days. However, there have been several reports and unpublished observations that, in some immunocompromised and HIV-infected patients, babesiosis has been difficult to treat successfully with the standard therapy and as a result other modalities, such as exchange transfusion, have been required. In these patients, it was unclear as to whether this was because of relapse, persistence, or emergence of resistance. AIDS patients initially respond to quinine–clindamycin therapy but usually experience relapse after it is discontinued. They often become refractory to further repeated treatment with this regimen. Experimental animal studies have suggested that azithromycin and quinine may be an effective alternative for *B. microti* infections. Animal and human studies have suggested that the combination of atovaquone and azithromycin is effective in immunocompromised patients who have become resistant to the quinine–clindamycin regimen.

The use of atovaquone, an agent with antimalarial, anti-*Pneumocystis*, and anti-*Toxoplasma* activity, was prompted by two recent studies demonstrating the efficacy of atovaquone in the hamster model of *B. microti* infection. When used as monotherapy, atovaquone was reported to be effective for both treatment and prophylaxis. However, other studies have shown that with monotherapy, recrudescence and development of high-grade resistance appeared that was not encountered with the atovaquone–azithromycin combination. Rapid emergence of resistance with atovaquone monotherapy also has been reported in malaria chemotherapy.

In malaria, the combination therapy of atovaquone plus proguanil has been used successfully in a fixed combination. Studies in several species of *Plasmodium* have indicated that the site of action of atovaquone is at the mitochondrial cytochrome bc1 (complex III). This agent inhibited electron transport at the bc1 complex by collapsing the mitochondrial membrane potential. However, the role of proguanil is not clear since it did not appear to function as a dihydrofolic acid reductase inhibitor.

PREVENTION

Specific chemoprophylaxis is not available. Those who are immunocompromised, especially postsplenectomized patients, should avoid tick-infested areas. Because normal, immunocompetent people may acquire symptomatic and sometimes severe disease, they also should be wary when entering these areas. Because *I. dammini* is small and often feeds undetected for long periods (48 hours), patients should inspect themselves and their pets daily and remove ticks completely. Gentle traction

with a forceps applied close to the capitulum (head) usually suffices to remove the entire tick. If the tick is deeply entrenched in the skin, mineral oil or even a hot needle can be applied and usually causes the tick to relax its hold. In tick-infested areas, repellents should be used on clothes, especially on the lower parts of trousers. It is advisable to wear long-sleeved garments, and shirts should be tucked under the belt. One of the most effective tick repellents is *N,N*-diethyl-*m*-toluamide, or DEET. It is commercially available in concentrations up to 100%. Care should be taken in its use because 10% to 15% of each application can be recovered in urine. Serious toxic and allergic reactions have been reported in those individuals who have used it frequently or in high concentrations. In young children, toxic encephalopathy has occurred. Use of nonabsorbable, long-acting formulations such as Ultrathon or DEET-Plus should obviate many of these adverse reactions. In any event, DEET products containing more than 38% DEET should be avoided.

CHAPTER 326: TOXOPLASMOSIS

BENJAMIN J. LUFT

[Pathogenesis](#)
[Epidemiologic Factors](#)
[Clinical Manifestations](#)
[Diagnosis](#)
[Treatment](#)
[Prevention](#)

Toxoplasmosis, the disease caused by the obligate intracellular protozoan *Toxoplasma gondii*, is a ubiquitous zoonosis that is responsible for significant morbidity and mortality in both animals and humans throughout the world. Long recognized as a cause of serious disease in congenitally infected neonates and immunocompromised hosts, it is only with the advent of AIDS that toxoplasmosis has occurred in epidemic proportions. It is one of the most common causes of focal central nervous system (CNS) infection in patients with AIDS.

PATHOGENESIS

Toxoplasma gondii is a coccidian, classified among the Sporozoa in the suborder Eimeria. It exists in three life forms: oocysts, tachyzoites (trophozoites), and tissue cysts. The complete life cycle takes place only in felines. Humans become infected most commonly by ingesting raw or undercooked meat containing tissue cysts, or foods or beverages contaminated with oocysts, and by ingesting oocysts following exposure to excrement from an infected cat. After replicating in the intestinal mucosa, tachyzoites invade the lymphatics and blood and disseminate widely, infecting all organs and tissues. The intracellular proliferation of tachyzoites usually causes host cell death. Cell death may result in acute disease or asymptomatic infection, depending on the host's immune response. Both humoral and cell-mediated immunity are important, but cell-mediated immunity is of particular consequence. In the immunodeficient host, the acute infection may continue unabated and cause potentially fatal local or diffuse disease such as encephalitis, myocarditis, or pneumonitis. With the development of an adequate immune response, tachyzoites disappear and tissue cysts form.

Generally, infected individuals will remain seropositive for anti-*T. gondii* antibodies, and viable tissue cysts will remain in various organs for the remainder of the host's life. For AIDS patients, the predominant pathogenetic mechanism is recrudescence of a chronic, latent infection arising from tissue cysts. The spontaneous and simultaneous development of multifocal areas of encephalitis in these previously seropositive patients strongly supports this assumption. In contrast, there is often epidemiologic evidence that the toxoplasmosis was newly acquired in other immunocompromised patients.

EPIDEMIOLOGIC FACTORS

In humans, serologic surveys report an increasing prevalence of antibodies to *T. gondii* with increasing age, with no significant difference between the sexes. Lower prevalence is noted at higher altitudes, in cold regions, and in hot arid climates. In the United States, serologic evidence of prior infection has been demonstrated in 6% to 21% of children and in 10% to 67% of adults over the age of 50. The seroprevalence rate is much higher in other countries, particularly France, Central Africa, and El Salvador, often reaching 90% in the population 40 years of age or older. A number of factors affect the incidence of toxoplasmosis among different populations, including climactic conditions, cat population, methods of farming and animal husbandry, and hygienic and cultural habits with regard to food preparation and consumption. The two major routes of transmission in humans are oral and congenital. Other modes of transmission include blood or leukocyte transfusion as a result of persistent parasitemia in a normal asymptomatic donor, accidental self-inoculation of tachyzoites in laboratory workers, and organ transplantation.

Transplacental transmission deserves particular mention. In the immunocompetent host, the fetus is at risk of infection only when the mother is acutely infected for the first time during gestation. The incidence and severity of fetal infection are related to the trimester during which maternal infection takes place. If maternal infection during the first trimester is untreated, then transplacental infection occurs in about 25% of infants and the disease may be severe. Transplacental infection during the second and third trimesters occurs in 54% and 65% of infants, respectively, but disease tends to be less severe or asymptomatic during the neonatal period. In rare cases, maternofetal transmission has been reported in women of childbearing age who contract acute toxoplasmosis 6 to 8 weeks prior to conception. It is recommended that pregnancy be avoided for at least 6 months in these cases.

For women infected with HIV, the primary mode of transmission in congenital toxoplasmosis is from reactivation of chronic infection. This is a risk only for immunocompromised patients and has been reported for pregnant women with Hodgkin's disease, with systemic lupus erythematosus for which corticosteroids are being given, and with AIDS. Of the 29 cases of toxoplasmosis in HIV-infected children reported to date, 15 (51%) of infections were acquired in utero. Most of these infections occurred during reactivation of chronic maternal toxoplasmosis, which was either symptomatic and manifested as toxoplasmic encephalitis (TE), or asymptomatic. At the time of fetal infection, maternal CD4 lymphocytes counts have been as high as 459 per cubic millimeter. The initial manifestations of infection are similar to those observed in non-HIV-infected infants, but the disease seems to follow a more progressive course. The frequency of vertical transmission of *T. gondii* in chronically infected women with AIDS is under study.

CLINICAL MANIFESTATIONS

Clinical manifestations of toxoplasmosis vary with the timing of infection (acute, newly acquired, or reactivation of chronic latent disease), the particular type of host (immunocompetent versus immunocompromised), and the organs involved. In the immunocompetent host, it is convenient to consider toxoplasmosis as congenital, acquired, or ocular (either congenital or acquired), and in the immunocompromised host as acquired or reactivation of chronic infection.

CONGENITAL TOXOPLASMOSIS

The fetus is at risk of infection regardless of the severity of disease during pregnancy. Acute infection in the mother is most frequently asymptomatic; symptomatic disease (usually lymphadenopathy) is seen in only 10% to 20% of cases. No correlation exists between the severity of disease in the infant and that of the mother. Eighty percent of infected newborns are asymptomatic at birth. The incidence of chorioretinitis in untreated infants with subclinical infection has been found to be greater than 85% on follow-up in one series (Koppe et al.). Infants with clinically apparent disease at birth may have any combination of the following: a mild nonspecific illness, failure to thrive, fever or hypothermia, lymphadenopathy, hepatosplenomegaly, pneumonitis, myocarditis, CNS involvement, or ocular disease. Clinically apparent disease in the neonate is usually associated with severe sequelae, whereas asymptomatic disease at birth may be followed by either mild or severe sequelae, particularly retinochoroiditis, hydrocephalus, mental retardation, sensorineural hearing loss, blindness, and delayed psychomotor development. Congenital toxoplasmosis as a result of reactivation of latent infection in HIV-infected women has been described. The initial clinical manifestations are similar to those of non-HIV-infected infants at birth but may progress more rapidly.

ACQUIRED TOXOPLASMOSIS

The spectrum of disease in acquired toxoplasmosis in the immunocompetent host ranges from subclinical lymphadenopathy to fatal fulminant infection. The most common manifestation is asymptomatic lymphadenopathy, which may be generalized or localized to a single node or area. The cervical nodes are most frequently enlarged. Nodes are usually discrete and vary in firmness and tenderness; suppuration is not seen. Associated signs and symptoms include fever, headache, fatigue, and malaise. A few patients may have a *mononucleosis-like* syndrome consisting of fever, maculopapular rash, sore throat, myalgia, headache, hepatosplenomegaly, and atypical lymphocytosis. The lymphadenopathic form is usually self-limited; symptoms resolve within several weeks but may recur for months. Routine laboratory studies are unremarkable other than a slight lymphocytosis, an increased sedimentation rate, and mildly elevated hepatic transaminases. The differential diagnosis usually includes lymphoma, infectious mononucleosis, and cytomegalovirus infection. Rarely, severe disease occurs with signs and symptoms referable to the specific organ involved: myocarditis, pneumonitis, hepatitis, polymyositis, or encephalitis. Fever of unknown origin has also been described. Prolonged parasitemia in asymptomatic, acquired toxoplasmosis has been observed and associated with transfusion-related infection (particularly whole blood). *T. gondii* was shown to survive in whole citrated blood stored at 4°C for up to 50 days.

OCULAR TOXOPLASMOSIS

Ocular toxoplasmosis is most frequently a late manifestation of congenital infection but is also seen in acute acquired disease (about 1% of cases) and in patients with AIDS. It is estimated that toxoplasmosis accounts for 35% of all cases of retinochoroiditis. Clinical manifestations include decreased visual acuity, scotomas, eye pain, photophobia, epiphora, loss of central vision (with macular involvement), nystagmus, and strabismus if the extraocular muscles are affected. Signs of systemic infection are uncommon except in AIDS patients in whom ocular toxoplasmosis is frequently associated with CNS disease. Ophthalmologic examination reveals single or, more frequently, multiple yellow–white patches with elevated indistinct margins surrounded by an area of hyperemia usually involving the posterior pole of the retina. If inflammation of the vitreous is present, the fundus may be obscured. Older lesions are atrophic, whitish gray plaques with distinct borders and black spots of retinal pigment. Lesions of varying age may be seen, indicating episodic flare-ups of activity. Multiple recurrences that progressively destroy the retina can lead to glaucoma. In patients with AIDS, toxoplasmic retinochoroiditis can be identified by the following: absence of hemorrhage, location at the posterior pole, presence of inflammation of the vitreous and anterior chamber, and fluorescein angiography. In addition, cytomegalovirus retinitis is virtually seen only when absolute CD4 counts are fewer than 50 per cubic millimeter.

INFECTION IN THE IMMUNOCOMPROMISED HOST

Severe infections with *T. gondii* are seen in epidemic proportions in patients with AIDS and are one of the most common causes of focal CNS infection in these patients. Other immunodeficient states associated with toxoplasmosis are malignancies of the reticuloendothelial system, especially Hodgkin's disease, leukemia, collagen vascular diseases, solid organ transplantation, and chronic corticosteroid use. The pathogenesis is usually reactivation of latent infection particularly in the overwhelming majority of cases of AIDS-associated toxoplasmosis. Signs and symptoms may include those noted in the immunocompetent host with acquired toxoplasmosis. However, the most common clinical manifestations reflect involvement of the CNS and, less frequently, the lungs, eyes, and heart.

Patients at risk for developing toxoplasmosis from reactivation of latent infection can easily be identified by measuring serum anti-*T. gondii* antibody titers. In this setting, toxoplasmosis is most frequently manifested by encephalitis, usually alone or, less frequently, as part of a multiorgan infection. Isolated organ involvement without CNS disease is uncommon. Toxoplasmosis becomes clinically apparent when CD4 counts fall below 200 per cubic millimeter with over 80% of cases occurring in patients with less than 100 per cubic millimeter. The clinical characteristics are protean and depend on the number, size, and location of the lesions. Signs and symptoms of focal or generalized neurologic dysfunction or, more frequently, a mixture of both are seen. Cerebral edema and, on occasion, frank hemorrhage, which can occur concomitantly with active infection, also contribute to the disease process. Fifty percent to 89% of patients have a subacute onset with focal neurologic deficits, with or without evidence of generalized cerebral dysfunction. Seizures may be the initial manifestation of TE in 15% to 25% of cases. Occasionally, generalized cerebral dysfunction is the predominant initial manifestation; focal neurologic deficits develop as the infection progresses. The most common focal neurologic deficits are hemiparesis and speech disorders. Headache, when present, can be focal, generalized, and unremitting. Fever is not invariably present. TE is predominantly intra-axial, so that meningeal involvement is rare; thus, signs and symptoms of meningeal irritation are unusual.

A form of TE that appears to be unique to AIDS patients is a *diffuse encephalitis* manifested by rapidly progressive, fatal, generalized cerebral dysfunction without focal neurologic deficits or focal lesions on neuroradiographic study. Myelitis without TE can occur. *T. gondii* pneumonitis with or without associated TE is clinically indistinguishable from *Pneumocystis carinii* pneumonia. The diagnosis requires a high index of clinical suspicion and the demonstration of *T. gondii* in specimens obtained via bronchoalveolar lavage (BAL) or lung biopsy. Cardiac involvement may be asymptomatic or manifest with cardiac tamponade or biventricular failure. Clinical manifestations attributable to infection of other organs (testis, gut, liver, pancreas, kidney, bladder, adrenals, and skeletal muscle) occur infrequently.

DIAGNOSIS

The diagnosis of toxoplasmosis can be made by several means: isolation of *T. gondii* from blood or other body fluids; demonstration of tachyzoites or *T. gondii* antigens in tissue sections, smears, or body fluids; use of serologic tests; or detection of *T. gondii* DNA by polymerase chain reaction (PCR) in tissue or body fluids.

TOXOPLASMOSIS IN THE IMMUNOCOMPROMISED HOST

Clinically, serologic tests for the diagnosis of toxoplasmosis in AIDS patients are useful only to identify HIV-infected individuals at risk for developing TE and to support the diagnosis of TE in AIDS patients with focal brain lesions. Many serologic tests are available that can detect different classes of antibodies. It is important to be aware that the results from these tests vary considerably in different laboratories.

The Sabin–Feldman dye test is the accepted standard for measurement of IgG antibodies, which have been shown to be higher in AIDS patients with TE than in those without TE. IgG titers usually appear 1 to 2 weeks after infection, reach levels of 1:1,000 by 6 to 8 weeks, then gradually decline over months and years. Low titers (1:65) may persist throughout life. The indirect fluorescence assay is used more commonly and measures the same IgG antibodies as the dye test. Commercially available kits are poorly standardized, and the results must be used within the context of the clinical setting. Almost 100% of AIDS patients with TE will have detectable IgG by dye test or indirect fluorescence assay. The level of the titer can be variable, however, and is unimportant in diagnosis. Variable IgG levels also occur in patients with toxoplasmosis infections other than TE. Patients with TE rarely show a significant rise in antibody titer over time. Simply the presence of antibodies in the serum of an HIV-infected individual identifies a patient at risk for development of TE. The absence of these antibodies strongly suggests an alternative cause for a patient presenting with neurologic signs and symptoms.

The current standard of care allows the treatment of TE to be initiated on presumptive diagnosis in the presence of a characteristic neuroradiographic abnormality (e.g., multiple contrast enhancing mass lesions) on computed tomography (CT) or magnetic resonance imaging (MRI) and clinical manifestations that include signs and symptoms of focal or generalized neurologic dysfunction. MRI is a more sensitive neuroradiographic imaging study than CT for the demonstration of focal CNS lesions. If CT scanning is unremarkable in a clinical setting consistent with TE, multiple lesions may be detected on MRI. The presence of multiple lesions on CT or MRI greatly increases the probability of TE versus other causes of focal CNS disease. The probability of a CNS lymphoma is higher than or equal to that of TE in the presence of a solitary lesion on MRI. However, the clinical manifestations and radiographic findings are not specific for toxoplasmosis. The differential diagnosis includes other infections that cause space-occupying CNS lesions such as tuberculoma, cryptococcoma, and, most frequently in the United States, CNS lymphoma. A definitive diagnosis requires a brain biopsy, which should be reserved for the following settings: (a) patients whose baseline abnormalities (except headaches and seizures) do not improve within the first 10 to 14 days of therapy or whose condition deteriorates early in the course of therapy; (b) patients with solitary CNS lesions on CT or MRI; and (c) patients receiving trimethoprim–sulfamethoxazole (TMP-SMX) for *P. carinii* prophylaxis. The absence of a response to therapy does not always exclude TE because concurrent disease processes (e.g., other infections or lymphoma) may be present.

A presumptive diagnosis of TE may be confirmed by inoculation of tissue specimens into mice or tissue cultures. In addition, using histopathologic methods, definitive diagnosis is made possible by demonstration of the protozoa, usually the tachyzoite form, in tissue sections or smears (e.g., brain biopsy, bone marrow aspirate) or body fluids (e.g., cerebrospinal fluid and amniotic fluid). Direct or indirect fluorescent antibody methods and peroxidase–antiperoxidase methods have been used with success to identify the organism by Wright, Giemsa, immunoperoxidase, or eosin–methylene blue II staining. Since meningeal involvement is not prominent, examination of the CSF was usually unrewarding and was only used in excluding other diseases. However, detection of *T. gondii* DNA by polymerase chain reaction (PCR) in CSF has proven a rapid and sensitive test that is especially useful in the diagnosis of TE in AIDS patients, avoiding the more invasive brain biopsy. However, variations in technique can affect results. Diagnostic sensitivity decreases when patients are receiving antiparasitic therapy.

TOXOPLASMOSIS IN THE PREGNANT WOMAN AND FETUS

Women who acquire toxoplasmosis during pregnancy expose their fetuses to the risk of infection. Infection of the fetus may result in stillbirth, spontaneous abortion, or birth of a symptomatic or an asymptomatic infant.

In 1994, Wong and Remington recommended a systematic, standardized screening program for all pregnant women. Accordingly, all pregnant women should be tested as early as possible for antibodies to *T. gondii* by dye test or an equivalent battery of serologic assays. Ideally, women should be tested no later than at 10 to 12 weeks of gestation. If results are seronegative, the pregnant woman should be tested again at 20 to 22 weeks. If seroconversion is substantiated, prenatal diagnostic testing should be performed, if feasible. For non-HIV-infected women, a definitive prenatal diagnosis of congenital infection may be accomplished by several methods: isolation of *T. gondii* from fetal blood (mouse inoculation) or amniotic fluid (mouse inoculation, cell culture), or detection of IgM *Toxoplasma* antibodies in fetal blood. The IgM enzyme-linked immunosorbent assay (ELISA) is based on the earlier appearance and disappearance of IgM antibodies. The presence of IgM antibodies in the fetus and neonate represents synthesis in utero because, unlike the IgG antibodies, IgM antibodies do not cross the placental

barrier. If diagnostic tests are used in combination, a correct diagnosis could be achieved for the vast majority (more than 90%) of cases. The results of inoculation studies may not be available for 3 to 6 weeks, however, and this delay is of particular concern when pregnancy termination is being considered. The use of PCR assay for the detection of *T. gondii* DNA in amniotic samples has been shown to be of value in early diagnosis. It is a rapid (1 to 2 days) and highly sensitive (70% to 100%) diagnostic tool. Amniocentesis followed by both PCR and mouse inoculation may prevent the risk of fetal loss as a result of fetal blood sampling. It has been hypothesized that transmission of HIV may be more likely during fetal blood sampling as compared with amniocentesis, but no published studies support or refute this theory.

TREATMENT

Most episodes of toxoplasmosis in immunocompetent hosts are asymptomatic and do not require therapy. However, specific instances do occur when treatment is necessary based on the location of infection, its severity, mode of transmission (e.g., congenital disease), and host immune status. Therapeutic regimens are based on data from in vitro and in vivo experimental animal models (mostly murine) of infection, as well as a few large, well-controlled clinical trials, and the practice of physicians experienced in the treatment of toxoplasmosis. The ideal dosage, combination of drugs, and length of therapy are still under study.

TOXOPLASMOSIS IN THE IMMUNOCOMPETENT HOST

The majority of infections in this setting are asymptomatic and do not require therapy. Lymphadenopathy, the most common manifestation, is self-limited and usually resolves within 1 to 3 weeks. Treatment in this setting should only be considered if systemic symptoms are severe or prolonged, or in the rare event that visceral involvement (encephalitis, pneumonitis, myocarditis) is present. Acute infection as a result of laboratory accident or transfusion may be severe and should be treated. The treatment regimen consists of a combination of pyrimethamine (Daraprim) and sulfadiazine or trisulfapyrimidine (a mixture of equal parts of sulfamethazine, sulfamerazine, and sulfadiazine) given for 2 to 4 weeks with folic acid (leucovorin) (Table 326.1). Oral pyrimethamine is administered at a loading dose of 2 mg per kilogram per day, up to a maximum of 100 to 200 mg for 2 days, followed by 25 to 50 mg per day, along with 10 mg of folic acid. Sulfadiazine or trisulfapyrimidine is administered orally at 100 mg per kilogram per day (maximum daily dose of 4 to 8 g) in four equally divided doses. In the event of pyrimethamine-induced hematologic toxicity (cytopenia), the dose of folic acid may be increased. For patients allergic to sulfa, clindamycin (300 mg orally every 6 hours) in combination with pyrimethamine and folic acid is successful.

Antibiotic	Adverse Effects	Recommended Dose (Immunocompetent)	Recommended Dose (Immunocompromised)
Pyrimethamine (Daraprim)	Cytopenia, rash, GI intolerance	Loading dose = 2 mg/kg (max 100-200 mg) for 2 d then 25-50 mg/d, 1-4 wk, with folic acid 10-20 mg/d	Acute loading dose = 100-200 mg 10-75 mg/d, 1-4 wk, with oral folic acid (leucovorin), 10-20 mg/d
Oral			Maintenance 25-50 mg/d with folic acid 10-20 mg/d
Sulfadiazine or Trisulfapyrimidine*	GI intolerance, rash, Stevens-Johnson syndrome, cytopenia, nephrotoxicity, crystalluria, interstitial nephritis, myalgia/arthralgia	100 mg/kg (max 4 g) in 4 equally divided doses, 1-4 wk	Acute 4-8 g/d, 1-4 wk
Oral			Maintenance 1-4 g/d in 4 equally divided doses
Clindamycin*	GI intolerance, rash, pseudomembranous colitis	300 mg every 6 h, 1-4 wk, repeat as needed	600 mg every 6 h, 1-4 wk
Oral & IV			Maintenance same

* Used in combination with pyrimethamine.

TABLE 326.1. OVERVIEW OF DRUGS CURRENTLY USED IN TREATMENT OF TOXOPLASMOSIS

OCULAR TOXOPLASMOSIS

Toxoplasmic retinochoroiditis is usually a manifestation of congenital infection but is also seen occasionally in acute acquired disease and in patients with AIDS. Signs of systemic involvement are uncommon except in patients with AIDS, in whom ocular disease can be a harbinger of CNS infection. Diagnosis is based on the ophthalmologic examination combined with serologic evidence of toxoplasmosis. Treatment is required to prevent relapse with the risk of progressive visual loss and other complications such as glaucoma. The drugs of choice are oral pyrimethamine and sulfadiazine or trisulfapyrimidine with folic acid in the same dosages as described for the immunocompetent host. Therapy is given for 4 weeks and repeated as needed. Adjunctive therapy with systemic corticosteroids (prednisone, 80 to 120 mg per day, or an equivalent) is indicated if the macula, optic nerve or papillomacular bundle is involved. In particular cases, photocoagulation and vitrectomy may be necessary.

TOXOPLASMOSIS IN THE IMMUNOCOMPROMISED HOST

Therapy for TE in HIV-positive patients is generally started empirically based on the clinical and neuroradiographic evidence in a patient with CD4 lymphocyte counts lower than 200 per cubic millimeter and seropositive for anti-*T. gondii* antibodies. The combination of pyrimethamine, an initial 100- to 200-mg loading dose in two divided doses followed by 50 to 75 mg per day orally, and sulfadiazine, 4 to 6 g per day orally in four divided doses, remains the mainstay of treatment. Oral folic acid, 10 to 20 mg per day, is added to preclude the hematologic toxicities associated with antifolate agents. Acute therapy is given for at least 3 weeks; 6 weeks or more is indicated in severely ill patients and when a complete clinical and radiographic response has not been achieved. Patients with sulfa allergy can be given clindamycin, 600 mg orally or intravenously every 6 hours, in combination with pyrimethamine as described. Seventy percent of patients with TE have a quantifiable clinical improvement by day 7 of therapy. Conversely, patients not responding to empirical therapy usually have evidence of progressive disease within the first 10 days. Ninety percent of patients have improvement on neuroradiographic studies within 6 weeks of starting therapy.

Chronic suppressive therapy is indicated in all immunocompromised patients until an adequate cell-mediated immune response is restored. Pyrimethamine, 25 to 50 mg per day, and sulfadiazine, 2 to 4 g per day orally in four equally divided doses, with 10 mg per day of oral folic acid, is recommended based on the low relapse rate associated with this combination. In sulfa-allergic patients, clindamycin is used. The combination of clindamycin and pyrimethamine has a higher relapse rate than pyrimethamine and sulfadiazine. Prophylactic use of anticonvulsants is not recommended. Corticosteroids should not be used routinely but are indicated if there is evidence of increased intracranial pressure. The use of corticosteroids may complicate the interpretation of the response to empirical therapy because clinical and radiographic involvements may be related to reduced cerebral edema or the size of a steroid-sensitive CNS lymphoma. The same chemotherapeutic regimens are used for extraneural toxoplasmosis; however, there are limited data available on the optimal length and outcome of treatment.

Primary chemoprophylaxis is a very attractive therapeutic option for patients known to be at risk of developing toxoplasmosis (e.g., HIV-infected patients with known CD4 counts less than 100 per cubic millimeter and seropositive for *T. gondii* antibodies). Based on retrospective data, oral TMP-SMX (1 double-strength tablet per day, 160 mg TMP-800 mg SMX) has been shown to be effective. Dapsone and pyrimethamine as single agents are not as efficacious; however, in combination, pyrimethamine (50 mg per week) and dapsone (50 mg per day) plus folic acid provides a good alternative. In sulfa-allergic patients, desensitization is also an option.

Drug regimens currently being studied for their usefulness as initial and maintenance therapy include atovaquone (Mepron). A recent ACTG trial evaluating atovaquone-containing regimens (in combination with pyrimethamine or sulfadiazine) shows greater than 80% initial response to therapy (unpublished data). As salvage therapy, atovaquone alone induced initial clinical response in 50% of study patients. The response to atovaquone has been directly correlated with serum drug levels achieved. The newest formulation of atovaquone is administered as an oral suspension 1.5 g twice daily with food, preferably fatty foods, to increase its bioavailability. The new macrolide antibiotics clarithromycin (Biaxin) and azithromycin (Zithromax) in combination with pyrimethamine have limited utility as alternative agents.

TOXOPLASMOSIS IN THE PREGNANT WOMAN

It has been shown that early prenatal antibiotic therapy may reduce the incidence and severity of congenital infection. Pyrimethamine plus a sulfonamide or spiramycin (a macrolide antibiotic available in Western Europe, Mexico, Canada, and through the U.S. Food and Drug Administration) appear to decrease the incidence of infection and sequelae in the fetus when given to women who acquire *T. gondii* during pregnancy. Pyrimethamine is teratogenic and should not be used during the first trimester. The sulfonamides should be offered during the first trimester as they have been shown to be effective in animal models. If spiramycin can be

obtained, pregnant women acutely infected in the first trimester may be treated with 30 to 50 mg per kilograms per day orally in three divided doses until fetal infection is documented or excluded. Treatment with spiramycin alone decreases the incidence of transmission but not the severity of established congenital infection. Maternal treatment with pyrimethamine and sulfadiazine plus folinic acid appears to attenuate the clinical manifestations in the fetus. If fetal infection is suspected or confirmed after the first trimester, pyrimethamine, sulfadiazine, and folinic acid should be used to treat the maternal infection ([Table 326.2](#)).

Antimicrobial	Adverse Effects	Recommended Dose (Pregnancy—1st Trimester)	Recommended Dose (Pregnancy—2nd & 3rd Trimester)	Recommended Dose (Congenital)
Spiramycin* Oral	Nausea, vomiting	30–50 mg/kg/d in 3 divided doses	30–50 mg/kg/d in 2 divided doses; if fetal infection confirmed or suspected, pyrimethamine and sulfadiazine may be superior for treatment of fetus	30–100 mg/kg/d in 2 equally divided doses; if 4-wk course showing with 2 wk course of pyrimethamine and sulfadiazine for up to 1 yr
Pyrimethamine Sulfadiazine Oral	Cheilitis, rash, GI intolerance	Not recommended—teratogenic	loading dose = 100 mg/m ² for 2 d, then 50 mg/m ² with folinic acid 10 mg orally 3 times a week (sulfadiazine or trisulfapyrimidine)	loading dose = 2 mg/kg for 2 d, then 1 mg/kg with folinic acid 10 mg orally 3 times a week for up to 1 yr (sulfadiazine or trisulfapyrimidine)
Sulfadiazine or Trisulfapyrimidine Oral	GI intolerance, rash, Stevens-Johnson syndrome, leukopenia, agranulocytosis, nephritis, encephalopathy	50–100 mg/kg/d in 2 equally divided doses (adults)	50–100 mg/kg/d in 2 equally divided doses (adults)	50–100 mg/kg/d in 2 equally divided doses for up to 1 yr with pyrimethamine

*Spiramycin is available in several oral (1.5, 3, and 6 mg) and intravenous (400 mg) formulations.

TABLE 326.2. DRUGS USED IN TREATMENT TOXOPLASMOSIS IN PREGNANT WOMEN AND FOR CONGENITAL TOXOPLASMOSIS

CONGENITAL TOXOPLASMOSIS

Optimal treatment for congenital toxoplasmosis is not yet established. However, a National Institute of Allergy and Infectious Diseases Collaborative Treatment trial based in Chicago yielded a favorable preliminary outcome with the use of pyrimethamine, sulfadiazine, and folinic acid in infants with congenital infection. Medications were given to infants 2.5 months old and continued for 1 year. Two different doses of pyrimethamine were compared. The most significant adverse effect was transient neutropenia, which responded favorably to the withholding of increasing doses of folinic acid or pyrimethamine. Preliminary results indicate that this therapeutic regimen can be safely administered to children. Interestingly, the majority of the treated children had normal development on follow-up despite severe initial findings of CNS and ophthalmologic disease. Longitudinal follow-up studies are still in progress. The current guidelines for treatment of congenital toxoplasmosis are oral pyrimethamine (loading dose of 2 mg per kilogram for 2 days, then 1 mg per kilogram per day) plus sulfadiazine or trisulfapyrimidine (50 to 100 mg per kilogram per day orally, in two equally divided doses) plus folinic acid (10 mg orally, 3 times a week) for up to 1 year. If the patient has evidence of an inflammatory process (chorioretinitis, high CSF protein content, generalized infection, jaundice), then corticosteroids (prednisone and methylprednisolone, 1 to 2 mg per kilogram per day orally, as two equal portions, 12 hourly) should be prescribed until the inflammation subsides.

PREVENTION

Humans are an incidental host in the life cycle of *T. gondii*. One can help to prevent infection by only eating meat that has been well cooked (more than 60°C; when no longer pink in the center) or frozen (less than –20°C for at least 24 hours) and thawed. It is important to be aware that home freezers do not achieve this temperature. Consistent hand washing after the handling of cats or their feces should help to decrease the ingestion of oocysts. Also, cat litter boxes should be emptied daily, before the oocysts can become infectious. Cat owners should keep their cats indoors, if possible, and feed them commercial cat food or well-cooked table food only. Pregnant women and immunocompromised hosts, especially HIV-infected individuals, should observe these prevention strategies.

CHAPTER 327: PNEUMOCYSTOSIS

DONALD ARMSTRONG AND EDWARD M. BERNARD

[Epidemiologic Factors](#)
[Pathogenesis](#)
[Diagnosis](#)
[Prevention](#)
[Treatment](#)

EPIDEMIOLOGIC FACTORS

Pneumocystis carinii, while long considered to be a protozoan parasite, is now recognized as a fungus that appears to be passed from person to person by the respiratory route. Animals other than humans harbor similar organisms in their lungs. Morphologically, the organisms that infect humans, rats, ferrets, and mice are indistinguishable, but there are genetic and antigenic differences. There is no evidence of transmission of the organism from other animals to humans. Reports of clusters of cases and of rises in antibody titers among health care workers exposed to heavily infected patients suggest that person-to-person transmission can occur.

Research findings based on ribosomal gene sequences and gene regulatory mechanisms provide strong evidence that *P. carinii* is a fungus rather than a protozoa. This raises the possibility that the organism may be found in soil or other environmental sources. Like the most common opportunistic fungus, *Candida albicans*, *P. carinii* may colonize or latently infect humans and cause infection from colonizing sites.

There is no convincing evidence of seasonal variation in the incidence of pneumocystosis. The infection appears to be less common among immunocompromised patients in nonindustrialized countries. This may be attributable to the higher incidence of other, more virulent infections, such as tuberculosis and cryptococcosis, and to different standards of medical care.

In summary, *Pneumocystis* is an unusual fungus that resides in the lower respiratory tract of humans and spreads by the respiratory aerosol route. It usually is not pathogenic until it has the opportunity to multiply and invade because of a T-helper cell defect.

PATHOGENESIS

The organisms are found in the alveolar space during both asymptomatic infection and disease. Multiplication is unleashed in the setting of T-helper cell depletion or dysfunction and induces a frothy alveolar exudate that is acellular or contains mononuclear cells. A plasma cell exudate has been described in epidemics of pneumocystosis among malnourished children. Extrapulmonary disease rarely was described in immunocompromised hosts before the advent of AIDS and now is recognized increasingly in patients with AIDS. Disseminated disease appears to be a rare complication of *Pneumocystis* pneumonia. However, its frequency is uncertain because most patients with pneumonia receive systemic agents that should be effective at both extrapulmonary and pulmonary sites of infection. Reports of the organisms causing granulomas in the external auditory canal suggest the possibility of contiguous spread from the upper respiratory tract. The finding of organisms in liver, spleen, brain, and other organs demonstrates that hematogenous dissemination can occur.

Granulomatous lesions occur in nonpulmonary sites and, rarely, in the lung. Pulmonary lesions range from the usual mononuclear infiltrate to a neutrophil infiltrate and even necrosis with cavity formation. Pneumothorax usually is the result of necrotizing lesions in the lung pleura. It should be assumed, unless proven otherwise, that a pneumothorax in a patient at risk for pneumocystosis is caused by active disease that requires immediate and appropriate treatment.

DIAGNOSIS

The symptoms and signs of pneumocystosis usually are those of an acute diffuse pneumonia. It has become apparent, with the increasing number of cases, that a variety of pulmonary presentations occur, including solitary lesions, patchy infiltrates, lobar pneumonias, and cavitary pneumonias ([Fig. 327.1](#)). Patients receiving aerosol pentamidine for prophylaxis tend to have apical pneumonias and fewer clinical symptoms and signs. The pulmonary disease can progress slowly or rapidly. In some cases, pulmonary symptoms are absent and the primary complaint is fever, night sweats, or diarrhea. Any persistent constitutional symptom in a patient at risk for the development of *P. carinii* pneumonia (PCP) should prompt consideration of the diagnosis of pneumocystosis. There are other infections that can mimic PCP, and these should be ruled out as the cause of the patient's illness ([Table 327.1](#)). Concurrent infections can complicate pneumocystosis, and investigation of clinical specimens should include appropriate tests for other organisms.

TABLE 327.1. PATHOGENS AND CONDITIONS THAT MAY ACCOMPANY OF MIMIC *PNEUMOCYSTIS CARINII* INFECTIONS

Unexplained anemia, adenopathy, hepatosplenomegaly, or external auditory canal lesions can be caused by extrapulmonary pneumocystosis; biopsy specimens or exudates should be stained with methenamine silver and immunohistochemical reagents to detect *P. carinii* as well as other opportunistic pathogens.

The diagnosis of PCP usually is made by bronchoalveolar lavage followed by examination of the lavage fluid using various stains. The methenamine silver, Gram–Weigert, and toluidine blue O stains are used to detect cyst-like forms, and the Giemsa stain is used to detect trophozoite-like forms. The direct fluorescence antibody test detects both forms of the organism. Application of the polymerase chain reaction to the diagnosis of pneumocystosis appears to offer improved sensitivity over conventional methods. All of these methods are highly sensitive and specific in the hands of an experienced laboratory. Our preference is to use several methods. Bronchoalveolar specimens are sent to the microbiology laboratory for toluidine blue O staining and to the cytology laboratory for Gram–Weigert staining; transbronchial biopsy specimens are sent to the pathology laboratory for Gram–Weigert and methenamine silver staining. Some laboratories have reported remarkable success using sputum induction to make a diagnosis of PCP. This should be attempted if there is sufficient time. Transbronchial biopsy can be helpful in detecting cytomegalovirus, drug toxicity, lymphocytic interstitial pneumonia, or neoplasms.

The diagnosis of extrapulmonary pneumocystosis usually is made by examining biopsy specimens of the tissue involved using appropriate stains such as methenamine silver. The organism cannot be recovered by culture of clinical specimens.

PREVENTION

Because prevention of PCP reduces mortality and morbidity and decreases costs, every effort should be made to identify patients who are at risk and to provide them with safe and effective chemoprophylaxis ([Table 327.2](#)).

Drug	Dose	Utility
Trimethoprim-sulfamethoxazole	Single- or double-strength tablet, daily or 3 times/week	Highly effective, inexpensive, also prevents other infections
Dapsone	100 mg/d	Good to poor tolerance, moderately effective
Aerosol pentamidine	300 mg/qm, Respigard nebulizer	Well tolerated, moderately effective
Atovaquone	1,500 mg/d	Good to poor tolerance, moderately effective

TABLE 327.2. PREVENTION OF PNEUMOCYSTOSIS

Patients who are at risk for the development of PCP and who should receive prophylaxis include adults and adolescents with HIV infection and fewer than 200 CD4⁺ T-helper cells per μ L; children with HIV, regardless of their CD4⁺ T-helper cell count; all newborns of HIV-infected mothers; patients with leukemia or lymphoma who are receiving cytotoxic therapy; patients with solid tumors or other conditions who are taking high doses of adrenocorticosteroids (see later); and organ or bone marrow transplant recipients. We recommend prophylaxis for all patients being treated with adrenocorticosteroids at dosages of prednisone equivalents of 20 mg per day or higher for more than 2 weeks. Prophylaxis should be continued during tapering of corticosteroid therapy and for 1 month thereafter.

Trimethoprim–sulfamethoxazole (TMP-SMX) is almost always effective in preventing PCP. It can virtually eliminate the risk of PCP among patients with cancer or HIV infection. Several dosing regimens have been used successfully for this indication. One double-strength tablet given daily or 3 days per week has been shown to prevent PCP. A double-strength tablet contains 160 mg of TMP and 800 mg of SMX. Advantages of TMP-SMX include high efficacy, systemic action, activity against bacterial pathogens and against toxoplasmosis, and low cost. Use of folinic acid is not recommended because it raises costs and does not increase efficacy or significantly reduce toxicity.

The major limitation of TMP-SMX is that some patients cannot tolerate it. It can cause rash, nausea, fever, neutropenia, and other adverse reactions. Hypersensitivity to the sulfonamide component is the most common adverse reaction. Intolerance of TMP-SMX occurs more often among patients with HIV infection than among other patients. This reflects a higher rate of allergic reactions to medications and an increased opportunity to become sensitized because of the longer period for which prophylaxis is needed. In most cases, patients can be desensitized, and this should be attempted before considering alternative agents.

Aerosol pentamidine and dapsone are alternative methods for prophylaxis of PCP. Although not as reliably effective as TMP-SMX, they have been shown to reduce the risk of PCP among HIV-infected patients. Aerosol pentamidine also has been used successfully in bone marrow transplant recipients and in patients with cancer who cannot tolerate sulfonamides.

Dapsone has been administered for PCP prophylaxis at daily oral doses of 100 mg; some clinicians add pyrimethamine at 50 mg once a week. Patients should be tested for glucose-6-phosphate dehydrogenase deficiency before taking dapsone because this genetic deficiency increases the risk of dapsone-induced hemolysis. Methemoglobinemia occurs with dapsone therapy and may be clinically significant in patients with anemia or lung disease. The most common side effects of dapsone are rash, pruritus, nausea, and fever.

Dapsone, a sulfone, is chemically related to the sulfonamides, and many patients who are allergic to SMX experience hypersensitivity reactions to dapsone. There is reasonably good evidence that dapsone plus pyrimethamine and TMP-SMX also provide some protection against toxoplasmosis. Dapsone is an inexpensive and effective alternative agent for PCP prophylaxis.

Aerosol pentamidine is tolerated better than TMP-SMX or dapsone. It is less effective than TMP-SMX but equal or superior to dapsone. Because pentamidine has a long half-life in tissue, protective levels can be maintained with low and infrequent dosing. Administration by the aerosol route delivers the drug to the desired site of action while limiting toxicity to other organs. Systemic side effects are rare, although rash, pancreatitis, and hypoglycemia have been reported.

The only regimen approved in the United States for aerosol pentamidine involves the administration, every 4 weeks, of 300 mg of pentamidine through the Respigard II nebulizer. The jet nebulizer requires a compressor or source of compressed air or oxygen. Some practitioners recommend that this regimen be given every 2 weeks to patients at highest risk for PCP. We recommend that the monthly regimen of 300 mg be preceded by a loading regimen of five doses of 300 mg given over 2 weeks. The use of a loading regimen is particularly important in bone marrow transplant recipients and patients receiving cytotoxic therapies. If a loading regimen is not used, it may take 1 to 3 months to establish protective levels in the lungs. Patients cannot afford to wait for protection when they have a high and immediate risk for this life-threatening infection.

There is disagreement about whether pneumothorax is more common among patients receiving aerosol pentamidine. We believe that aerosol pentamidine, by increasing the likelihood of apical pneumonia and pleural involvement, can be an indirect contributory factor. Because aerosol pentamidine provides protection to the lung and not to other organs, extrapulmonary pneumocystosis is a rare but significant complication of this method of prophylaxis. The most common side effects are cough and bronchospasm; both usually can be prevented by pretreatment of susceptible patients with an inhaled bronchodilator such as albuterol.

Careful and frequent examination of patients for communicable respiratory diseases such as tuberculosis is essential. In the United States, occupational safety regulations require that patients receiving aerosol pentamidine or other aerosol medications or therapies be treated individually; these regulations mandate the use of barriers, filters, and masks that prevent exposure of health care workers and other patients to potentially infectious aerosols and to aerosol medications. These measures add to the expense and can cause anxiety and discomfort for patients.

Other potential agents for PCP prophylaxis are atovaquone or clindamycin–primaquine, and sulfadoxine–pyrimethamine (Fansidar). The long-acting sulfonamide sulfadoxine should not be used because adverse reactions can be severe. Atovaquone is less effective than TMP-SMX but appears to be similar in effectiveness to dapsone. Clinical studies have yet to provide evidence of a role for clindamycin–primaquine in prophylaxis against PCP.

It has been recommended that once prophylaxis is indicated, for an HIV-infected patient, it should be continued for life. The advent of highly active antiretroviral therapy (HAART) has prompted reexamination of the need for lifelong prophylaxis. There is mounting evidence that patients who experience immune reconstitution as a result of successful HAART therapy may be able to discontinue prophylaxis against PCP and other opportunistic infections. Additional studies are needed before the recommendation can be definitively changed. At this time, the decision to discontinue must be made on a case-by-case basis.

TREATMENT

The preferred therapy for pneumocystosis is TMP-SMX ([Table 327.3](#)). Although other agents have been shown to be effective in the treatment of PCP, most are less effective and none is superior to TMP-SMX. Except in mild cases, intravenous pen- tamidine is the treatment of choice for patients who cannot tolerate SMX. Several oral therapies provide alternatives to intravenous pentamidine: dapsone-TMP, atovaquone, or clindamycin–primaquine. These agents should be considered only for the treatment of patients with mild episodes of PCP (PaO₂ greater than 70 mm Hg or A-a gradient less than 35 mm Hg). Trimetrexate plus leucovorin can be used in moderate to severe cases of PCP in patients who cannot tolerate TMP-SMX or pentamidine. Early treatment with adjunctive corticosteroids is recommended for patients with AIDS who have PCP and hypoxia (PaO₂ less than 70 mm Hg). On completion of therapy, patients should receive prophylaxis to prevent recurrence of pneumocystosis for as long as they remain immunocompromised.

Drug	Dosage
Initial Therapy	
Trimethoprim-sulfamethoxazole	15/75 mg/kg to 20/100 mg/kg, IV (preferred) or PO, in 4 divided doses, 14–21 d
Alternative Therapy for Mild to Severe Disease	
Pentamidine	3–4 mg/kg, IV, 14–21 d
Alternative Therapy for Mild to Moderate Disease	
Dapsone-trimethoprim	Dapsone at 100 mg/d, PO, plus trimethoprim at 20 mg/kg/d, PO in 3 divided doses, 14–21 d
Atovaquone	750 mg PO tid with food, 14–21 d
Clindamycin-primaquine	Primaquine 15 mg PO tid for 21 d, plus clindamycin 600 mg tid for 10 d, followed by 400 mg PO qid for 11 d
Alternative Therapy for Moderate to Severe Disease When Standard Therapies Cannot Be Used	
Trimetrexate-leucovorin	Trimetrexate 45 mg/m ² -leucovorin 20 mg/m ² q9h

TABLE 327.3. TREATMENT OF PNEUMOCYSTOSIS

For the treatment of acute PCP, TMP-SMX can be administered orally or intravenously. Unless the episode is exceedingly mild and there is no evidence or suspicion of gastrointestinal dysfunction, we prefer to use the intravenous route. Intravenous or oral treatment should be administered at dosages of 15 to 20 mg per kilogram per day of TMP and 75 to 100 mg per kilogram per day of SMX; it can be given in three to four divided doses. We recommend continuation of treatment for 21 days. Initial treatment with intravenous doses can be followed by oral dosing in responsive patients. Careful monitoring for clinical response and for adverse reactions is needed throughout the treatment period. Hospitalization is recommended during the induction phase of treatment; some patients with mild episodes can be treated as outpatients, and many patients can complete therapy successfully using oral medications at home.

The most common toxicities with TMP-SMX are rash, fever, hepatic dysfunction, and leukopenia. These reactions do not always require discontinuation of the drug. If the side effects are moderate or severe, or if symptoms are not improved after 5 to 7 days of treatment, alternative therapies must be considered. In most cases, the alternative therapy of choice is intravenous pentamidine. Many patients who have had allergic reactions to TMP-SMX can receive initial therapy with intravenous pentamidine while being desensitized to SMX over a 3- to 7-day period. This allows completion of therapy with oral TMP-SMX and its continuation as prophylaxis.

Intravenous pentamidine appears to be as effective as TMP-SMX in the treatment of PCP. It should be administered by intravenous infusion at 3 to 4 mg per kilogram per day over 1 to 2 hours. Response to pentamidine therapy often is slow; it may take four or more doses to achieve effective pulmonary concentrations of the drug. Treatment should be continued for 2 to 3 weeks. Pentamidine is reserved for patients who cannot tolerate or fail to respond to TMP-SMX because pentamidine can cause hypotension, renal dysfunction, hypoglycemia, fever, or pancreatitis. Although these potential toxicities require careful monitoring, it is our experience that most patients who require intravenous pentamidine can be treated successfully with this alternative therapy. Pentamidine should not be administered by intramuscular injection because this route is associated with the formation of painful and debilitating sterile abscesses at the site of injection.

There are several proven alternatives to intravenous pentamidine that should be considered for the treatment of mild episodes of PCP in patients who cannot tolerate TMP-SMX. Oral dapsone (100 mg per day) with TMP (20 mg per kilogram per day) is effective for this indication. Although dapsone is chemically related to SMX, some patients who are allergic to SMX can tolerate dapsone. Patients receiving dapsone should be observed carefully for rash, fever, liver function abnormalities, and methemoglobinemia.

Atovaquone (750 mg orally 3 times a day) is a hydroxynaphthoquinone that is effective therapy for mild to moderate PCP. It usually is better tolerated than TMP-SMX or intravenous pentamidine, but therapeutic failures occur with greater frequency. The higher failure rate may be attributable to the fact that absorption of the drug is poor among some patients. Improved formulations have mitigated this significant problem.

Clindamycin plus primaquine is another option for the treatment of sulfa-intolerant patients with mild PCP. Controlled clinical trials with this combination have shown that it is effective but can cause adverse reactions, including rash, diarrhea, anemia, and neutropenia. Trimetrexate plus leucovorin is available as salvage therapy for patients with moderate to severe PCP. It is effective in some patients and should be considered if standard therapies fail or cannot be tolerated.

Aerosol pentamidine, although shown to be effective in the prevention of PCP, is markedly less effective than standard therapies for acute PCP. Aerosol pentamidine should not be used for the treatment of this life-threatening infection.

Adjunctive corticosteroids improve survival and decrease the likelihood of respiratory failure in patients with AIDS who have confirmed PCP and hypoxia (PaO₂ < 70 mm Hg). The recommended dosage of prednisone is 40 mg twice daily for 5 days, followed by 40 mg daily for 5 days, then 20 mg daily until completion of therapy for PCP. There was concern that corticosteroid therapy might increase the risk for developing other opportunistic infections or neoplasms, but this risk seems to be outweighed by the benefits of this adjunctive therapy.

CHAPTER 328: TRICHOMONIASIS

JOSE A. PRIETO AND JORGE D. BLANCO

[Definition and Epidemiology](#)
[Clinical Features and Diagnosis](#)
[Treatment](#)
[Trichomonas and Human Immunodeficiency Virus Infection](#)

DEFINITION AND EPIDEMIOLOGY

Trichomonas vaginalis, a unicellular, flagellated protozoan first described in 1836, is a major cause of infectious vulvovaginitis, occurring in 25% of symptomatic women. The organism also can be found in a significant percentage of asymptomatic, sexually active women. In men, *T. vaginalis* can colonize and invade the prostate, urethra, or seminal vesicles, but it rarely produces symptoms. About 5% of all episodes of nongonococcal urethritis in men are caused by this organism.

The prevalence of trichomoniasis ranges from 3% of patients attending student health clinics to 37% of patients attending sexually transmitted disease clinics. Because the only established mode of transmission is sexual intercourse, patients should be evaluated for other sexually transmitted diseases, such as gonorrhea, syphilis, chlamydial infection, and HIV infection.

CLINICAL FEATURES AND DIAGNOSIS

Among symptomatic women, common presenting complaints include vaginal discharge (white, yellow, or green), vulvar itching, dyspareunia, malodor, and dysuria. The supposedly classic frothy, yellow–green discharge associated with vaginal wall erythema and a “strawberry” cervix is seen in only 10% of cases. Because the presentation can vary, the clinician should not rely on clinical symptoms alone in making the diagnosis.

Vaginal, prostatic, or urethral secretions should be examined for the presence of *Trichomonas* organisms. A positive wet mount prepared with fresh normal saline reveals the motile organisms. The sensitivity of this method varies from 22% to 76%, but it is highly specific when positive. Spence and colleagues found the sensitivity of cultures (Diamond's medium) to be greater than that of wet mounts. However, culture diagnosis is labor-intensive, expensive, and not commonly available.

TREATMENT

Metronidazole (Flagyl) is the effective therapy for trichomoniasis. Initially, the recommended dosage was 250 mg orally three times a day for 7 to 10 days. However, controversial studies suggesting possible carcinogenicity of metronidazole led to the development of other treatment regimens. In 1972, Csonka compared a single 2-g oral dose with prolonged multidose regimens and found similar effectiveness. Aubert and Sesta reported comparable adverse effects with the two regimens. Based on these and subsequent studies, the U.S. Centers for Disease Control and Prevention in 1985 began recommending a single 2-g oral dose as the treatment of choice. The cure rate with this regimen exceeds 90%.

Because *Trichomonas* is transmitted sexually, partners of infected patients should be treated concurrently. Preventive measures, such as the use of condoms, also should be prescribed.

Pregnant patients with trichomoniasis present a treatment challenge. Most authorities agree that metronidazole should not be used during the first trimester. However, investigations suggest that trichomoniasis may be associated with premature birth and premature rupture of the membranes. Therefore, most clinicians treat symptomatic patients during the second and third trimesters with a single 2-g dose or three 250-mg doses every day for 7 days.

Although rare, treatment failures can occur. However, repeated exposure is the most common cause for recurrent disease. In such cases, a prolonged oral regimen, intravaginal administration, or intravenous therapy may be necessary. A reasonable first step is a regimen of 500 mg to 1 g orally twice a day for 7 days. Alternatively, intravaginal therapy with two uncoated 500-mg tablets twice a day for 7 days may be useful.

TRICHOMONAS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Trichomonas and HIV are transmitted by sexual contact and share the same behavioral risk factors. In a prospective study by Laga and associates, incident gonorrhea, chlamydial infection, and trichomoniasis were associated with an increased risk of HIV seroconversion in women, even after the number of sexual partners and level of condom use were considered. Nonulcerative sexually transmitted diseases such as trichomoniasis may facilitate the acquisition of HIV infection by causing mucosal disruption of the genital tract.

Screening for HIV infection is justified in both symptomatic and asymptomatic patients with trichomoniasis. Likewise, early detection and treatment of trichomoniasis is essential in HIV-infected patients.

CHAPTER 329: NAEGLERIA, ACANTHAMOEBA, AND LEPTOMYXID AMEBIC INFECTIONS

RICHARD J. DUMA

[Central Nervous System Infections](#)
[Other Infections](#)

CENTRAL NERVOUS SYSTEM INFECTIONS

The most commonly recognized infection caused by free-living amoebae (FLA), in both humans and other animals, is meningoencephalitis. *Naegleria* organisms, and occasionally *Acanthamoeba* organisms, produce an acute, fulminating, almost always fatal infection, referred to as primary amebic meningoencephalitis (PAM), whereas *Acanthamoeba* species and leptomyxid amoebae of the genus *Balamuthia mandrillaris* produce a subacute or chronic meningoencephalitis, referred to as granulomatous amebic meningoencephalitis (GAE).

MICROBIOLOGY, PATHOGENESIS, AND EPIDEMIOLOGIC FACTORS

Although *Naegleria* and *Acanthamoeba* belong to the order Amoebida, families Vahlkampfiidae and Acanthamoebidae, respectively, leptomyxid amoebae belong to the order Leptomyxida, family Leptomyxidae. Pathogenic amoebae in all three groups are biologically distinct but differ from *Entamoeba histolytica* in that they are highly aerobic, possess a large karyosome within a single nucleus, have no known intermediate hosts, are not considered parasites, are commonly found as trophozoites in soil and water, and are highly resistant to a wide array of chemotherapeutic agents, especially those used to treat *E. histolytica*.

Naegleria fowleri is the only species of *Naegleria* reported to infect humans. However, other potentially pathogenic species exist (e.g., *Naegleria australiensis*). Under light microscopy, trophozoites measure 10 to 20 μm , have a single contractile vacuole, and possess food vacuoles that may contain ingested red blood cells; they have blunt or lobose pseudopodia. Their movement is active and slug-like. Cysts are uninucleate and circular, and possess smooth, doubly contoured walls with pores for excystation. Most importantly, trophozoites can transform into characteristic flagellates, distinguishing them from *Acanthamoeba* and other FLA. However, only trophozoites are found in infected tissues.

At least five species of *Acanthamoeba* infect humans: *A. polyphaga*, *A. culbertsoni*, *A. rhyodes*, *A. astronyxis*, and *A. castellani*. Under light microscopy, trophozoites are 15 to 40 μm long, have a single contractile vacuole, may contain red blood cells, and possess pseudopodia that taper to finely rounded ends (acanthopodia). In addition, their nuclei are indistinguishable from those of *Naegleria*. Their movement is sluggish and, at times, barely perceptible. Cysts are uninucleate and characteristically appear stellate or wrinkled. Both trophozoites and cysts can be found in infected tissues.

Balamuthia mandrillaris is the only leptomyxid amoeba reported to infect humans. Trophozoites are irregularly shaped, range in length from 12 to 60 μm , and are predominantly uninucleate. Although locomotion is generally sluggish, at times they exhibit a spider-like walking movement. Cysts are circular, 6 to 30 μm in diameter, and possess a very thick wall that on ultrastructural examination consists of three layers. Both trophozoites and cysts are found in infected tissues, but distinction from *Acanthamoeba* is difficult and is usually accomplished with immunologic staining techniques.

Naegleria and *Acanthamoeba* can be cultured axenically in artificial media, nonaxenically on plain agar seeded with Enterobacteriaceae as a food source, or in a variety of tissue culture cell lines. However, *B. mandrillaris* does not grow well with bacteria as a food source, and inoculation of tissue culture cell lines, such as African green monkey kidney cells (E6), is needed. Pathogenic FLA are stable at room temperature (23°C), grow well at 33°C to 37°C, and may withstand 44°C. Most tolerate temperatures below 5°C poorly; hence, clinical specimens containing organisms should not be refrigerated if isolation is desired.

Naegleria fowleri organisms invade the central nervous system (CNS) of mammals directly through the olfactory nerve pathways after penetrating the nasal mucosa (Fig. 329.1). *Acanthamoeba* species invade the CNS directly by the nasal route or indirectly by hematogenous spread from a site outside the CNS (e.g., lung, skin, uterus, prostate, eye). The portal of entry for *B. mandrillaris* is unknown. The risk of infection from almost all FLA is related to the size of the inoculum and the site of instillation. In a variety of tissue culture cell lines, a cytopathogenic effect (CPE) is initiated by contact of amoebae with cells (contact-dependent cytolysis), and portions of cell cytoplasm also appear to be removed by a “nibbling-out” process referred to as *trogocytosis*. In vitro, *N. fowleri* organisms migrate preferentially toward nervous tissue (tropism).

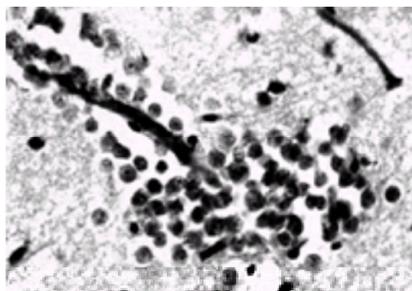

FIGURE 329.1. Perivascular collection of *Naegleria* in the frontal cortex of a patient with primary amebic meningoencephalitis (×500). Prominent, dark karyosomes and surrounding halos within the nuclei of the organisms are visible. (From Duma RJ, Ferrell HW, Nelson CE, et al. Primary amebic meningoencephalitis. *N Engl J Med* 1969;281:1315, with permission.)

Examination of brain tissue from patients with GAE often reveals extensive demyelination associated with trophozoites of *Acanthamoeba*, suggesting the release of cytotoxic enzymes. Pathogenic *Acanthamoeba* species contain more phospholipase A than do nonpathogenic species. Brain infection due to *B. mandrillaris* is usually associated with considerable arteritis or angiitis, with perivascular cuffing and necrotizing granulomas.

The first line of host defense against invasion by *Naegleria* appears to be the polymorphonuclear leukocyte; against *A. culbertsoni*, however, polymorphonuclear leukocytes appear to be ineffective unless they are preexposed to activated macrophages. Fresh human serum lyses *N. fowleri* and *Acanthamoeba* organisms through activation of the alternate pathway for complement, and mice depleted of hemolytic complement are more susceptible to infection from *Naegleria* than are those with normal levels of complement. The roles of cell-mediated immunity and humoral antibodies against *Naegleria* are unclear, but humoral antibodies and complement activation appear to be primary mechanisms of defense against *Acanthamoeba*. Antibodies to *Acanthamoeba* are present in healthy individuals and in some patients with nonspecific respiratory tract infections. Host defense mechanisms against *B. mandrillaris* are as yet poorly defined, but they probably are similar to those involved with *Acanthamoeba*.

Infections caused by *Naegleria* species usually occur during the hottest times of the year, may be epidemic, and are acquired almost invariably from intimate contact with fresh or brackish water (swimming, diving, water skiing). The incubation period is predictably 5 to 7 days. Infections occur worldwide and often in epidemics (point source).

The epidemiology of infections caused by *Acanthamoeba* and *Balamuthia* species are unclear; however, immunocompromised individuals appear to be infected more often than normals. The incubation periods are unknown. Infections occur worldwide. CNS infections occur sporadically, although epidemics of ocular infections due

to *Acanthamoeba* species related to contaminated contact lenses or their cleaning solutions have been reported.

CLINICAL FEATURES AND DIAGNOSIS

Naegleria fowleri produces an acute, fulminant meningoencephalitis (PAM) that in the early stages of infection resembles bacterial meningitis (Table 329.1). Male individuals are involved more often than female individuals (3:2), and healthy children or young adults are at greatest risk. Examination of the cerebrospinal fluid (CSF) reveals a preponderance of neutrophils, low glucose, and elevated protein; bacteria are absent. Because amoebae soon invade the brain, causing hemorrhagic necrosis of CNS tissues, signs of encephalitis appear. Computed tomography (CT) scanning can be helpful if it demonstrates a hemorrhagic lesion of the brain in the presence of a purulent meningitis. Untreated infections last 24 to 72 hours. Death usually results from cerebral edema and brain stem herniation or from heart failure caused by unexplained myocarditis. The diagnosis can be established by finding characteristic amoebae in unstained CSF; occasionally flagellate forms are seen, which is diagnostic. Fluorescein-tagged antibody directed against *Naegleria* can be applied directly to CSF or tissues, but serologic tests are of little value. At autopsy, the diagnosis is usually not difficult, since many rounded amoebae without cyst forms are found throughout the brain.

Factor	Meningitis	Acanthamoeba/Balamuthia
Age	Child or young adult	Any age, but often extremes of life
Sex ratio	2:1 (male:female)	Male:female
Host health	Healthy	May be normal, but often underlying disease or immunodeficiency present, e.g., AIDS
Etiology	History of recent intracranial contact with freshwater	Unknown
Incubation period	3-7 d	Unknown, but highly variable, usually 10-30 days for GAE
Portal of entry	Olfactory nerves	Site probably diverse with long, but unknown, latency for <i>Acanthamoeba</i> ; may be due to <i>Balamuthia</i> for <i>Balamuthia</i> usually hematogenous but occasionally via the olfactory nerve, unknown for <i>Acanthamoeba</i>
Location inside the CNS	Olfactory nerves	Neocortex, brain abscess or space-occupying mass; brain abscess with meningoencephalomyelitis; clinical picture, especially severity, unlike other forms
Clinical picture	Diffuse meningoencephalitis	Diffuse meningoencephalitis
Diagnosis	CSF light microscopy, clinical picture, and culture	CSF light microscopy, clinical picture, and culture
Clinical course	Rapidly fatal (1-2 d)	Variable; may be fatal or chronic course
Treatment	Amphotericin B and rifampin (rifampin)	Amphotericin B, rifampin, pentamidine, and possibly others
Pathology	Neurophagocytosis (macrophages) and necrosis with involvement primarily of focal areas; neuronal injury, only in severe cases	Neurophagocytosis (macrophages) and necrosis with involvement primarily of focal areas; neuronal injury, only in severe cases
Prevalence	Amebae seen in and isolated from CSF; flagellate stage important to identify	No amoebae usually seen in CSF, but occasionally can be isolated

TABLE 329.1. COMPARISON OF NAEGLERIA AND ACANTHAMOEBA/BALAMUTHIA MENINGOENCEPHALITIS^a

Acanthamoeba organisms can produce a PAM that is clinically indistinguishable from that produced by *Naegleria* organisms, but they more often produce a picture of subacute or chronic meningoencephalitis (GAE). No patient age preference exists, but males predominate and about half of patients have underlying diseases or immunodeficiency problems. More than a dozen patients with AIDS are reported to have been infected, in which cases the clinical pictures resembled disseminated cutaneous fungal or algal diseases, or CNS toxoplasmosis. The portal of entry varies. The nose, skin, sinuses, and respiratory tract are incriminated most commonly, and preceding or concomitant skin lesions, nasal ulcerations, sinusitis, or pneumonitis containing amoebae may be present. In GAE, examination of the CSF reveals a preponderance of round cells, normal to low-normal glucose, and modestly elevated protein. The clinical picture is one of focal or localized CNS disease (resembling brain abscess); however, as the infection progresses, the involvement of multiple areas, usually in centrally located structures, becomes evident. Death usually results from brain stem herniation. Diagnosis may be difficult because amoebae rarely are found in the CSF. CT scans may be useful for localization of lesions but are not diagnostically specific. Premortem brain biopsy may be necessary. The application of fluorescein-tagged antibody (directed against surface antigens of the amoebae) to infected CSF fluid or tissues may be useful, but false-negative results occur if species not included in the diagnostic preparation are present. Serologic testing may be useful, but only if the infection is chronic.

Infections of the CNS caused by *B. mandrillaris* resemble GAE caused by *Acanthamoeba*, but the clinical course of infection ranges from 14 to 240 days. Patients at the extremes of life and who are immunocompromised appear to be most often infected; however, immunocompetent individuals, particularly children, are occasionally reported. Infants or children presenting with a stroke-like picture of unknown cause should be considered as possibly infected by *Balamuthia*. CT scans and/or magnetic resonance imaging (MRI) may help to differentiate these entities, in which case hyperdense, nonenhancing, multiple- or single-space-occupying masses are seen. Examination of the CSF may also be useful but generally is not diagnostic. A variable pleocytosis (occasionally mononuclear) is present, associated with slightly low sugar, elevated protein, and an absence of bacteria. Amoebae are not generally found in the CSF by light microscopy, but they may be isolated in tissue culture cell lines (vide supra). For definitive premortem diagnosis, brain biopsy is usually necessary.

OTHER INFECTIONS

Ocular infections caused by *Acanthamoeba* species are not uncommon and usually are chronic, refractory to therapy, and extremely painful. They first appear as shaggy, irregular corneal ulcers resembling those of herpes. *A. castellanii* and *A. polyphaga* are the organisms most commonly involved. Almost always, a history of injury containing a foreign body (e.g., dirt or splinters) or the use of a contaminated contact lens is obtained. A characteristic 360-degree or partial paracentral stromal ring infiltrate with recurrent corneal epithelial breakdown typifies the lesion. The diagnosis usually is made from histologic studies of appropriate stains and cultures of ulcer scrapings. A variety of other anatomical sites may also be infected by *Acanthamoeba* (e.g., air sinuses, lungs, skin, uterus, and prostate); and occasionally by *B. mandrillaris* (e.g., lungs and skin), and for *Acanthamoeba* these infected sites are believed to represent the source of hematogenous seeding of the CNS.

TREATMENT AND PREVENTION

The treatment of choice for PAM caused by *Naegleria* is amphotericin B. A daily dose of 1 mg per kilogram is given intravenously over 1 to 2 hours. Because the drug diffuses poorly into the CSF, direct intraventricular instillation may be used, but not without risk. Rifampin may be added, but its value is not established. Standard antiamebae agents (those used against *E. histolytica*) are useless and may be toxic.

Medical therapies for infections caused by *Acanthamoeba* usually are unsatisfactory. Most CNS infections (PAM and GAE) are fatal, although an insufficient number of patients have been studied carefully before death to allow an accurate assessment of presumed mortality rates. For early localized disease, excision of the lesion may be useful, but surgical dissemination of amoebae is a distinct risk. Sulfur, 5-fluorocytosine, and the imidazoles may be effective in preventing infections in animals, but their therapeutic usefulness in humans (once disease appears) is essentially unproved. Rifampin and pentamidine were used together in the successful treatment of one renal transplant recipient with disseminated *Acanthamoeba* infection, but more studies are needed to confirm the value of these drugs.

GAE due to *B. mandrillaris* is universally fatal, and to date no medical therapy is available to treat this disease. However, like infections due to *Acanthamoeba*, early surgery may be tried.

Similar problems exist for the treatment of ocular infections caused by *Acanthamoeba*. Some patients appear to benefit from imidazoles and propamidine isethionate. Hexamidine (0.1% hexamidine isethionate eyedrops) also appears to be effective. Surgery usually is necessary and may be curative, but often a penetrating keratoplasty or corneal transplantation is necessary.

Prevention of infections caused by FLA is difficult because the organisms are ubiquitous in nature. The risk of PAM from *Naegleria* may be reduced by wearing nose clips or avoiding swimming or bathing in warm (more than 30°C) freshwaters or brackish waters. Halogenation of natural bodies of water is difficult, but chlorination of enclosed swimming pools effectively kills *Naegleria* organisms. *Acanthamoeba* organisms, especially cysts, are highly resistant to chemical agents and survive chlorination.

After an ocular injury is sustained, the incidence of keratitis and infection from FLA can be reduced by ensuring that foreign bodies are removed immediately and that the injured eye, if washed out, not be rinsed with water containing FLA. Finally, soft contact lenses should always be cleansed in sterile, amoeba-free water.

The epidemiology of *B. mandrillaris* or how it infects humans is unclear, but infections are believed to be more common than reported. Little is known about disinfectants for leptomyxid amoebae.

CHAPTER 330: INTRODUCTION TO HELMINTHIC DISEASES

ADEL A.F. MAHMOUD

Parasitic metazoa (worms) constitute an important group of infectious diseases worldwide. The unique biologic features of these agents result in significant epidemiologic and clinical characteristics. Worms are multicellular organisms that vary in size from a few millimeters to several meters. They are capable of parasitizing a restricted or wide range of mammalian hosts and may need more than one host to complete their life cycle. Infection is acquired by ingestion or by direct penetration of human skin. Except for *Strongyloides* and *Echinococcus*, worms do not multiply within the human host; increase of parasite population in a specific mammalian host occurs only upon reexposure to the infective stage of the helminth.

Because of the complexity of the antigenic structure of worms and the multiplicity of their stages within the host, the immunologic sequelae of these infections are considerable. The host immune response to worms may play a protective role in limiting infection or disease, or it may cause immunopathologic reactions. In addition, eosinophilia is a prominent feature of the clinical course of tissue-invading worm infections. Eosinophils have been shown to have a significant protective effect against the invasive or tissue-residing stages of worms.

Individuals with suspected worm infections usually have non-specific complaints. Both a detailed geographic history and epidemiologic information are important. Specific organ system disease, such as hepatomegaly, splenomegaly, or the presence of peripheral blood or sputum eosinophilia, usually is suggestive of worm infection. Definitive diagnosis depends on the identification of a stage of infection in body fluids or tissues. In some situations, serologic evidence of infection is helpful.

FILARIASIS AND TROPICAL EOSINOPHILIA

Filarial infection in humans can cause clinically significant pathology in the lymphatic system, lungs, skin, or eyes. The causative organisms are endemic only in tropical and subtropical areas of the world. They can be divided broadly into three groups based on the major anatomical sites of pathology in the parasitized human host (Table 331.1).

Organism	Vector	Geographic Distribution	Clinical Features	Treatment
<i>W. bancrofti</i> , <i>B. malayi</i> , <i>B. timori</i>	Mosquito	Tropical Africa, Asia, South Pacific, South America	Nearly asymptomatic, lymphatic obstruction, Tropical Africa	Diethylcarbamazine, ivermectin
<i>O. volvulus</i>	Blackfly (Simulium sp.)	West and Central Africa, Central and South America	Dermatitis, eye disease, lympho- genic	Ivermectin
<i>L. loa</i>	Housefly or stablefly (Chrysops sp.)	West and Central Africa	Calabar swelling, renal disease, CNS disease	Diethylcarbamazine
<i>M. ozzardi</i>	Midge (Culicoides sp.)	Africa, Caribbean, Central and South America	Usually asymptomatic, dermatitis	Diethylcarbamazine or no treatment required

TABLE 331.1. FEATURES OF MAJOR HUMAN FILARIAL INFECTIONS

ETIOLOGIC FACTORS

Wuchereria bancrofti, *Brugia malayi*, and *Brugia timori* are commonly referred to as lymphatic-dwelling filariae because adult worms are localized primarily to the afferent lymphatic vessels and cause disease in these sites. Microfilariae of lymphatic-dwelling filariae circulate in the bloodstream. Adult worms of *Loa loa* are located in subcutaneous tissues and induce pathologic reactions there. Adult worms and microfilariae of *Onchocerca volvulus* dwell in subcutaneous tissue and the skin or eye, respectively. The major pathologic reactions in onchocerciasis result from pathologic processes induced by microfilariae in the skin and eye.

The complex life cycle of these filarial nematodes includes an obligate intermediate insect vector that inoculates infective or third-stage larvae into humans during blood feeding. Infective larvae subsequently molt to fourth-stage larvae and develop over about 6 to 12 months into sexually mature adult male or female worms. The latter can live for more than 5 years and release microfilariae, which subsequently are taken up by the insect vector. Microfilariae molt and develop into infective larvae in the insect in 7 to 15 days.

WUCHERERIA BANCROFTI, BRUGIA MALAYI, AND BRUGIA TIMORI INFECTIONS

EPIDEMIOLOGIC FACTORS

Infections with *W. bancrofti*, *B. malayi*, and *B. timori* affect some 120 million people worldwide. *W. bancrofti* infection is endemic in focal areas of the Caribbean, such as Haiti; tropical areas of South America, Africa, and the South Pacific; and Southeast Asia, particularly India and Indonesia. Malayan filariasis is limited in its distribution to India, the Philippines, Malaysia, Indonesia, and China. *B. timori* occurs in the Indonesian islands of Timor and Flores.

Wuchereria bancrofti, the most widespread of these filariae, infects only humans and is transmitted predominantly by culicine mosquitoes. *Anopheles* and *Aedes* mosquitoes also transmit *W. bancrofti*, largely in rural areas. These mosquitoes feed at night, a behavior coincident with the nocturnal periodicity of *W. bancrofti* microfilaremia in many endemic areas. Usually, less than 1% to 2% of mosquitoes in an endemic area harbor infective larvae. Furthermore, less than 20% of such larvae develop into adult worms in the nonimmune host. Therefore, multiple mosquito bites are required for the successful development of a few adult worms. *B. malayi* may be a zoonotic infection because cats can act as a reservoir.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Infection with lymphatic filariae produces a wide spectrum of disease manifestations in residents of endemic areas. Most children younger than 10 years of age and a smaller proportion of adults (20% to 80% in various endemic areas) have no symptoms. Filarial fevers usually are the initial manifestation of symptomatic infection in teenagers and young adults. Abrupt onset of fever greater than 38°C is associated with myalgia and a peculiar retrograde lymphangitis. Swelling proceeds distally from the inguinal area and produces inflamed cordlike lesions and lymphedema. Occasionally, regional lymph nodes enlarge to a diameter of several centimeters. These eventually may rupture and form abscesses. Symptoms persist for 5 to 10 days and may reappear several times per year. Filarial fevers commonly are misdiagnosed as acute attacks of malaria that fail to respond to antimalarial chemotherapy. After recurrent attacks of filarial fevers and acute lymphedema and lymphangitis, lymphedema may not regress and lymph flow from the affected site may become severely limited. The end stage of the process results in chronic obstructive pathology or classic elephantiasis of the upper or lower extremities. The skin is brawny and thickened, with a doughy consistency. Fissures may appear, with breakdown of the skin and secondary bacterial infections. In males with *W. bancrofti* infection, hydroceles and permanent scarring of the spermatic cords occur. Such hydroceles may reach immense size. Obstruction of lymphatic draining of the renal pelvis may produce intermittent chyluria with significant proteinuria.

The pathologic lesions in the lymphatics include intact or remnants of degenerating adult worms surrounded by plasma cells, eosinophils, and macrophages. Granulomas consisting of giant cells, macrophages, eosinophils, and collagen deposits obliterate the lumina of lymphatic vessels. Studies suggest that lymphatic obstruction results in part from these T-cell-mediated granulomatous reactions and from secondary bacterial infections of the extremities. At an epidemiologic level, transmission intensity correlates with the prevalence of lymphatic disease.

Nonresidents of endemic areas have a pattern of clinical manifestations that is different from that of residents. Based on observations of U.S. servicemen stationed in endemic areas during World War II and of migrant adults displaced from nonendemic to endemic areas of Indonesia, it appears that brief, intense exposure (6 months or more) to infective larvae can result in acute manifestations of infection. These include lymphangitis of the lower extremities or genitalia. Such individuals rarely have microfilaremia. Biopsy of affected lymph nodes reveals eosinophil-rich inflammatory lesions surrounding adult worms and sexually immature parasites. Signs and symptoms do not recur if these individuals leave the areas where infection is transmitted. These acute, allergic-type manifestations are thought to result from lack of neonatal immunologic tolerance conferred by maternal infection.

In the case of tropical eosinophilia, the major pathologic reactions are to microfilariae localized in the lung. For reasons that are unclear, microfilariae in such individuals are trapped in the small pulmonary blood vessels and elicit initially histiocyte-rich alveolar and interstitial responses. These evolve into eosinophilic abscesses and infiltrates surrounding degenerating microfilariae. Multiple eosinophil-rich granulomatous lesions eventually may develop in the lung and, in untreated individuals, progress to interstitial fibrosis. Similar lesions with eosinophilic precipitates may be present in lymph nodes and are referred to as *Meyers-Kouwenaar bodies*.

OPTIMAL MANAGEMENT

The definitive means of diagnosis is by demonstration of microfilariae in the blood. Because parasitemia often has a nocturnal periodicity, blood should be obtained between midnight and 4 a.m. to optimize the likelihood of detecting parasites. In the case of bancroftian filariasis, infection in the absence of microfilaremia can be detected by the presence of circulating parasite antigens.

The mainstay of therapy for lymphatic filariasis is the drug diethylcarbamazine (DEC). DEC is administered to a cumulative dosage of 72 mg per kilogram (orally twice a day for 10 to 14 days), beginning with dosages of 50 and 200 mg per day for the first 2 days in adults. The drug reduces the level of parasitemia by more than 90% within 1 or 2 days and also kills a proportion of adult-stage worms. The major side effects of DEC are fever and acute adenolymphangitis, most commonly in patients with high-intensity parasitemia. Microfilaremia may reappear within 12 to 24 months, especially in patients who continue to be exposed to mosquitoes containing infective larvae. It is not clear as to whether DEC given in conventional dosages reverses lymphatic obstruction, although single annual doses of DEC have been shown to reduce the prevalence of hydroceles in endemic communities. Physiotherapy of the affected extremities and treatment of secondary bacterial infections decreases the degree of limb swelling in patients with elephantiasis.

Ivermectin given as a single oral dose has been shown to be as effective as DEC in lowering the intensity of microfilaremia, although it does not kill adult worms. There are no differences between the two drugs in regard to the severity of side effects.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia occurs primarily in young adult men who are lifelong residents of endemic areas of bancroftian or Malayan filariasis. The disease is especially common in areas of southern Asia. Patients often have asthmatic symptoms, especially at night. Sputum production is scant. The physical examination may be normal except for rhonchi, wheezing, and, particularly in children, lymphadenopathy and splenomegaly. Chest radiography shows transient pulmonary infiltrates in the early stages of the disease, which may progress to a mottled appearance (representing granulomatous reactions to trapped microfilariae) and eventually interstitial fibrosis in untreated individuals. The results of pulmonary function tests initially are consistent with mixed restrictive and obstructive airways disease, followed by a restrictive picture.

Other diagnostic criteria include absence of microfilaremia, elevated total and filarial-specific IgE (total IgE levels often greater than 3,000 units per milliliter), high titers of IgE antimicrobial antibodies, eosinophilia (usually more than 3,000 cells per microliter of blood), and a beneficial response to DEC given in a 2-week course. Pulmonary function test results and eosinophilia also return rapidly to normal and are sustained for at least 1 year after administration of the drug. Repeated treatment with DEC is necessary in some cases.

LOIASIS

Loa loa infection is limited to equatorial areas of Central and West Africa. The obligate insect vector is the deerfly (*Chrysops*). After deposition of infective larvae in the skin by the blood-feeding fly, adult worms develop over a period of several months and migrate throughout subcutaneous tissues, including the conjunctiva. *L. loa* microfilariae circulate in the blood with a diurnal periodicity, such that peak intensities occur at noon.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

The most prominent clinical manifestations of loiasis are migratory angioedema and Calabar swellings. Calabar swellings are egg-like lesions that are 0.5 to 3 cm in diameter, red, and commonly located over bony prominences of the extremities such as the elbows or wrists. They are painful and believed to represent angioedematous reactions to antigens released from adult *L. loa* migrating through the subcutaneous tissues. The swellings resolve over 2 to 4 days but usually recur. Adult worms may be visible as the nematode passes through the bulbar conjunctiva. Immunologically "naive" individuals, such as recent immigrants to endemic areas, may have severe disease manifestations if their exposure is intense.

OPTIMAL MANAGEMENT

Definitive diagnosis is made by demonstration of microfilariae in blood obtained during the daytime. Microfilariae of *L. loa* can be readily distinguished from those of *W. bancrofti* on morphologic grounds. DEC (8 to 10 mg per kilogram per day in three divided doses for 21 days) is the appropriate treatment. The drug kills both microfilariae and adult worms of *L. loa*. Side effects such as fever, malaise, and subcutaneous nodules may develop. On initiation of DEC therapy, a neurologic syndrome characterized by changes in the level of consciousness and signs of meningitis may develop in patients with high intensities of microfilaremia (more than several thousand parasites per milliliter of blood). These patients should be treated with low doses of DEC (1 mg per kilogram over 1 to 2 days) in conjunction with corticosteroids (1 mg per kilogram per day of prednisone) for the first 3 days. DEC (300 mg once per week) has been shown to be an effective prophylactic agent in previously uninfected individuals who have moved to endemic areas.

MANSONELLA OZZARDI, MANSONELLA PERSTANS, AND MANSONELLA STREPTOCERCA INFECTIONS

Several filarial parasites uncommonly infect humans. *Mansonella ozzardi* infection occurs in the Caribbean and in Central and South America, and is transmitted by biting midges and blackflies. Adult-stage parasites inhabit the peritoneal cavity and microfilariae are present in the bloodstream. Infection usually is asymptomatic and associated with eosinophilia. Joint pain has been suggested as a disease manifestation in some individuals.

Mansonella perstans infection is endemic in tropical West and Central Africa and northeastern South America. It is transmitted by biting midges. Adult worms are found in the peritoneal and pleural cavities. Microfilariae circulate in the blood. Most infected individuals have no symptoms. There is clear documentation, however, that *M. perstans* infection may cause angioedematous lesions similar to Calabar swellings, fever, and headache. Treatment of *M. perstans* infection diagnosed on the basis of microfilaremia is by administration of DEC at the dosage described for lymphatic filariasis. Multiple courses of DEC may be necessary to eliminate microfilariae from the blood.

Mansonella streptocerca infection is transmitted in the rain forests of West and Central Africa by biting midges. Adult worms and microfilariae migrate in the skin and induce inflammatory reactions, consisting of many eosinophils and macrophages. Clinical diagnosis is made by identification of the parasites in biopsy specimens. Manifestations include macular eruptions, hypopigmentation, pruritus, and lymph node enlargement. DEC (6 mg per kilogram per day for 21 days) kills both adult worms and microfilariae.

ONCHOCERCIASIS

Onchocerciasis ("river blindness") is caused by chronic infection with the filarial parasite *O. volvulus*. It usually is manifested by skin or ocular disease, and is a leading cause of socioeconomic disruption in endemic areas.

ETIOLOGIC FACTORS

Onchocerca volvulus is transmitted from person to person by the bite of female blackflies of the *Simulium* species. The adult male and female worms, located in the subcutaneous tissues and deeper fascial planes, coil up into spherical bundles and reproduce sexually to yield millions of larvae, called microfilariae, which migrate through the skin and ocular tissues. Microfilariae are ingested by the fly and develop into infective larvae in 6 to 8 days. Infective larvae are transmitted to a new human host when the fly bites again. The larvae then take 9 to 18 months to develop into adult worms. Adult females measure 20 to 70 cm in length and males

measure 3 to 5 cm. Microfilariae are unsheathed and measure 210 to 320 μm in length. Infective larvae are about 600 μm in length. The average life span of the adult worm in humans is about 6 to 10 years.

EPIDEMIOLOGIC FACTORS

Onchocerca volvulus infects an estimated 20 million individuals in endemic foci that are scattered across West, Central, and East Africa. The major focus in Latin America is in Guatemala, with additional foci in southern Mexico, Venezuela, northwestern Brazil, Colombia, and Ecuador. Small, scattered foci exist in Yemen and Saudi Arabia near the Red Sea.

Blackflies deposit eggs on objects in freely flowing streams and rivers, and these subsequently develop into larvae and pupae. Because of the dependency of the *Simulium* vector on waterways for reproduction, flies concentrate around streams and rivers and usually are found within a few kilometers of waterways. Humans are exposed to biting flies during daily activities such as farming, fishing, bathing and washing, and water collection.

Because blindness resulting from severe ocular disease or debility associated with severe skin disease often affects productive adults during the third and fourth decades of life, the effect of the disease on the economic viability of the community is particularly devastating. About 1% to 4% of infected individuals become blind, and onchocerciasis ranks as the fourth leading cause of blindness in humans. In some hyperendemic areas, more than half of all adults become blind, and a much higher percentage have skin disease or some ocular involvement.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

The basis of most of the pathologic changes in onchocerciasis is believed to be the host reaction to microfilariae in dermal and ocular tissues. In involved tissues, the pathologic appearance of the lesions reflects a low-grade chronic inflammatory process.

Onchocerca dermatitis is recognized microscopically by the presence of increased numbers of fibroblasts throughout the dermal layer and a moderate infiltrate of lymphocytes, histiocytes, plasma cells, and eosinophils. Microfilariae are relatively difficult to find. The end stage of disease in the skin includes loss of elastic fibers, atrophy, and fibrosis. In the eye, neovascularization and scarring of the cornea lead to loss of transparency and blindness. The remainder of the eye often is involved by a chronic nongranulomatous inflammatory process. Onchocercoma, which are subcutaneous nodules containing live adult worms surrounded by a collagenous stroma, show chronic inflammation with fibrosis and extensive capillary infiltration.

Clinically, onchocercomas are firm, nontender, and freely movable if not attached to periosteum. Common locations of palpable nodules include the superior iliac crests, the coccyx, the greater trochanter of the femur, the bony thorax, and the scalp and head region.

Differences in the clinical manifestations of disease between individuals native to endemic areas and those newly arrived or only briefly resident in the areas result from the relatively light infections in the latter individuals. Nodules often are not palpable in lightly infected individuals. The earliest signs of infection include pruritus and an intermittent papular rash with some thickening of the skin, which may be localized in one area of the body. Transient episodes of localized rash, erythema, and edema are common.

In more chronic disease, permanent skin changes include loss of elasticity and a chronic, scaling, hyperkeratotic, maculopapular, pruritic rash with mottled hypopigmentation or hyperpigmentation. Atrophy may lead to areas of ulceration with the risk of superinfection. In Central America, the dermal manifestations are most prominent around the head and neck, whereas in Africa they more commonly involve the trunk, buttocks, and lower extremities. Enlargement of femoral and inguinal lymph nodes with secondary obstructive changes in the groin region or in an extremity is a common problem in Africa and Yemen.

Early ocular manifestations include conjunctivitis, punctate keratitis, and anterior uveitis. Chronic changes include sclerosing keratitis, chorioretinitis, optic atrophy, and complications resulting from persistent anterior uveitis, such as glaucoma. In general, the severity of disease correlates with the intensity and duration of infection.

OPTIMAL MANAGEMENT

The diagnosis is established by demonstration of microfilariae of *O. volvulus* in the skin. Skin snipping to the level of the tips of the dermal papillae is the optimal method of diagnosis. The technique for this type of skin biopsy involves the use of a corneoscleral biopsy instrument or a razor blade to yield 1 or 2 mg of skin in a bloodless manner. The skin snips are placed in tissue culture medium or saline solution in microplate wells and the microfilariae that emerge are counted after a 3-hour or overnight incubation. Skin snipping has the advantage of providing a measure of intensity of infection, with fewer than ten microfilariae per milligram of skin constituting a light infection and more than 100 constituting a heavy infection. For greatest reliability, four to six biopsies are done in different areas, including the hips, calves, and shoulders.

A presumptive diagnosis can be made clinically by the presence of onchocercoma, typical skin changes, or ocular findings of onchocerciasis, including microfilariae in the cornea or anterior chamber in otherwise normal-appearing eyes. Although elevated titers of antifilarial antibodies may support the diagnosis of onchocerciasis, a standardized immunodiagnostic technique has not been perfected.

Ivermectin has no effect on adult worms and has replaced DEC as the standard therapy. It is well tolerated and is given as a single oral dose of 150 μg per kilogram. It should be taken orally on an empty stomach and at least 2 hours before the next meal. Most patients have little or no reaction in response to dying microfilariae. One percent to 10% (up to one-third in some endemic areas) have mild cutaneous edema and pruritus. A maculopapular rash develops in less than 5% of patients, and bullous lesions develop over the extremities or in the groin area in rare cases. Symptomatic hypotension develops in about 1 patient per 10,000, and ocular reactions are rare. The frequency and severity of reactions after ivermectin treatment probably are related to the intensity of infection. Contraindications to ivermectin treatment include breast-feeding within the first 3 months after birth and central nervous system disorders (particularly meningitis), and other conditions that may increase penetration of ivermectin into the central nervous system (e.g., age younger than 5 years). Special caution is warranted in patients with asthma because ivermectin therapy may precipitate bronchospasm.

Because ivermectin does not eradicate adult parasites and significant microfilariae production begins again about a year after treatment, skin snips should be taken yearly to document the effect and establish the need for retreatment. In lightly infected expatriates, who often remain symptomatic, treatment can be given every 6 months even in the absence of recurrent microfilariae in skin snips.

DRACUNCULIASIS

Dracunculus medinensis is a spiroid nematode with a wide distribution in West Africa from Mauritania to Cameroon, the Nile Valley and eastern equatorial Africa, India, and the Arabian Peninsula. Ten million cases of dracunculiasis are estimated to occur annually, although this number has diminished markedly with worldwide efforts to eradicate this infection.

Human infection results from the ingestion of drinking water contaminated with copepods (cyclops) containing third-stage larvae of the parasite. The prepatent period is about 12 months, during which larvae develop into adult worms in the peritoneal cavity. A fertilized adult female migrates superficially to form a blister; then a loop of uterus prolapses through the body wall or mouth, and first-stage larvae are released. These larvae are ingested by cyclops present in the water and develop into infective third-stage larvae over about 10 days. Adult females measure about 70 to 120 cm in length and males measure about 3 to 5 cm.

Symptoms relate to the local ulcer that develops when the adult female penetrates the skin and to associated infectious complications, including tetanus. Before the worm penetrates the skin, various systemic symptoms often occur, including vague dysphoria and urticaria. The local lesion initially is erythematous and pruritic. It subsequently becomes papular and then vesicular, measuring several centimeters in diameter. Rupture of the blister is followed by protrusion of the adult female. The healing process commonly takes several weeks or even months. The affected individual usually is disabled during this time. Chronic complications include contracture of the limbs. Common locations of lesions include the ankles, the soles of the feet, and peripherally in the upper extremities.

Treatment consists of manually extracting the worm by winding it onto a stick with gentle traction. The administration of metronidazole may facilitate the extraction.

Local care should be used to prevent bacterial superinfection, and tetanus precautions are warranted. Simple preventive measures can be effective, including providing safe drinking water in bore holes, filtering water through a 100- μ m or finer mesh fiber, and boiling water. Infected individuals should avoid sources of drinking water.

TOXOCARIASIS

The ingestion of embryonated eggs of the dog roundworm *Toxocara canis* may lead to visceral larva migrans (VLM) or ocular larva migrans (OLM). VLM and OLM are cosmopolitan in their distribution and occur predominantly in children. The roundworms of cats (*Toxocara cati*) and raccoons (*Baylisascaris procyonis*) are rare causes of a syndrome similar to VLM.

ETIOLOGIC FACTORS

Toxocara canis is a roundworm of dogs and foxes. Adult worms inhabit the upper small intestine of these definitive hosts and release embryonated eggs, which are passed in feces. Humans are infected when they ingest soil or other materials contaminated with embryonated *T. canis* eggs. After ingestion, embryonated eggs hatch in the upper bowel and release larvae. These do not develop into adult roundworms but instead migrate to multiple sites, including muscle, liver, lung, eye, and, occasionally, brain.

EPIDEMIOLOGIC FACTORS

Several factors account for the observation that exposure to *T. canis* eggs is much greater in children than in adults. Pica and geophagia are particularly common in children. Proximity to areas where dogs defecate, such as playgrounds and sandboxes, also enhances the opportunity to ingest parasite eggs. Intimate contact and playing with puppies is important because they may be infected from dams by the transplacental route and by larvae contained in maternal milk, feces, and vomitus.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Most *T. canis* infections are asymptomatic. Surveys of healthy children between 1 and 11 years of age residing in several areas of the United States show that the seroprevalence of anti-*Toxocara* antibodies ranges from about 4% to 13%, with the highest values occurring in rural children of low socioeconomic status. Symptomatic infection presumably results from the ingestion of many *T. canis* eggs.

Tissue damage results from the necrotic and hemorrhagic tracts produced by migratory larvae. Eosinophil-rich granulomatous reactions also develop around trapped larvae and cause local organ damage. *T. canis* larvae eventually encyst in human tissue and do not undergo further development. Long-term follow-up of seropositive children suggests that there are no sequelae to asymptomatic infections.

Visceral larva migrans is the most common clinically detectable form of *T. canis* infection. The disease occurs predominantly in children younger than 8 years (mean age, 5 years) and is characterized by the gradual onset (1 to 2 weeks) of low-grade fever, wheezing, cough, and, occasionally, right upper quadrant pain. These symptoms may persist for several weeks. In exceptional cases, heart failure or seizures associated with the invasion of many larvae and eosinophils into the myocardium and brain occur. Physical examination of children with VLM reveals rhonchi and wheezes, with no signs of consolidation. The liver is slightly enlarged and tender to palpation in about 25% of cases.

Ocular larva migrans accounts for less than 10% of the reported cases of symptomatic *T. canis* infection of humans. Patients with OLM have changes in vision that are not clinically distinct from other, more common ocular diseases of children. Examination of the eye shows intraretinal and posterior pole granulomas, endophthalmitis, and leukokoria. In some patients, larvae periodically migrate in the retina over years and cause intermittent signs and symptoms of OLM. OLM usually occurs in children older than those with VLM. VLM and OLM rarely develop in the same individual.

OPTIMAL MANAGEMENT

Eosinophilia (more than 500 cells per microliter of blood), moderate leukocytosis, hypergammaglobulinemia, and transient infiltrates on chest radiography suggest the diagnosis of VLM. Elevated antibody titers to *Toxocara* larvae as determined by enzyme-linked immunosorbent assay is the most specific laboratory indicator available, but high titers persist after the resolution of acute disease. Definitive diagnosis can be made only by identification of larvae in tissue such as lung or liver. However, biopsy is not recommended.

The approach to management of VLM is controversial. In patients with acute symptoms of VLM and high-grade eosinophilia (more than 80% of the total leukocyte count), antihelminthics such as DEC (6 mg per kilogram per day in three doses over 7 to 10 days) or mebendazole (300 mg twice daily over 14 to 21 days) may more rapidly diminish eosinophilia and laboratory abnormalities relative to untreated patients; however, their effects on symptoms are not well established. Anti-inflammatory agents such as corticosteroids have no proven benefit but may be warranted in severely ill children with myocardial or central nervous system disease.

Ocular larva migrans represents a diagnostic challenge because the lesions can be confused with retinoblastomas, which require enucleation. Measurement of anti-*Toxocara* antibodies in aqueous fluids is warranted if the diagnosis cannot be made by clinical examination and other laboratory tests, such as fluorescein angiography and computed tomography. Antibody titers in the ocular fluids of patients with OLM are higher than the simultaneous values in sera.

Treatment of OLM requires ophthalmologic expertise. The utility and safety of antihelminthic drugs in the management of OLM have not been established. VLM and OLM may be prevented by deworming puppies within 6 weeks of birth and limiting contact between children and dogs.

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans, or creeping eruption, is caused by the larval stage of animal hookworms such as *Ancylostoma braziliense*, *Uncinaria stenocephala*, and *Bunostomum phlebotomum*, or by human nematodes, such as *Necator americanus*, *Ancylostoma duodenale*, and *Strongyloides stercoralis*. Infections occur most commonly in the setting of intimate skin contact with moist surfaces that contain fecal material from dogs, cats, or humans, such as under porches or in vegetation on beaches. Initial symptoms include the rapid onset of intense pruritus at the site of larval penetration. The larvae penetrate to the epidermal–dermal junction and migrate laterally, producing pruritic, serpiginous, red tracts that move 1 to 2 cm every few days. The diagnosis is made by obtaining a history of exposure (many patients recall the exact time of infection because pruritus can appear within hours) and observing the characteristic physical findings. Creeping eruption can be treated by the topical application of thiabendazole suspension or one oral dose of ivermectin (200 μ g per kilogram).

TRICHINOSIS

Trichinosis is a helminthic infection with a worldwide distribution, including arctic, temperate, and tropical climates. The prevalence of trichinosis in the United States has decreased markedly over the past several decades, largely because of legislation prohibiting the practice of feeding garbage (contaminated with carcasses of *Trichinella spiralis*-infected rodents) to hogs.

ETIOLOGIC FACTORS

Trichinella spiralis is a nematode with an enteric and systemic phase of its life cycle in the mammalian host. Human infection is initiated by the ingestion of third-stage larvae encysted in striated muscle. The larvae escape from their cysts in the acid–pepsin environment of the stomach and develop into adult male and female worms that lie coiled in the small intestinal mucosa. Female worms then release many newborn larvae; these migrate through the intestinal wall to the systemic circulation and invade host myocytes. The helminths eventually encyst in these sites and can remain dormant for years.

Humans are infected most commonly by the ingestion of poorly cooked pork products (especially when purchased from a noncommercial source), bear, boar, and walrus. Undercooked horse meat has been documented as a source of infection in France and Italy. Encysted *Trichinella* larvae remain viable in flesh held at 4°C and

at temperatures associated with the cooking of meat to rare. The practice of smoking uncooked meat or microwaving does not kill encysted third-stage larvae.

EPIDEMIOLOGIC FACTORS

Trichinosis usually occurs in common outbreaks associated with the ingestion of homemade and undercooked meat products, such as pork sausage and wild game.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

The severity of illness resulting from *T. spiralis* infection is related to the number of parasites ingested and the associated inflammatory response to tissue-dwelling larvae. The mean interval from exposure to initial complaints is 8 days, with a range of 1 to 34 days. Gastrointestinal symptoms such as cramps and diarrhea often are the initial manifestation of trichinosis. These symptoms have been reported in 10% to 58% of cases and usually last 1 to 2 weeks, although a report of trichinosis in Arctic Inuits eating raw walrus meat indicates that prolonged diarrhea (13 to 98 days) can be the major and sole manifestation of *T. spiralis* infection. Two to eight weeks later, myalgia, periorbital edema, peripheral blood eosinophilia, and fever (higher than 38°C) appear. These signs and symptoms are coincident with invasion of muscle by newborn larvae and elicitation of eosinophil-rich inflammation reactions in these sites. These symptoms occur in 60% to 88% of cases confirmed by serologic or parasitologic testing. Heavily infected individuals may have myocardial involvement leading to heart failure and dysrhythmia, or central nervous system involvement causing seizures. In most cases, fever and myalgia resolve spontaneously over several weeks. Eosinophilia exceeding 500 cells per microliter of blood usually develops and can persist for several months after the resolution of myalgia and periorbital edema. Nonspecific elevations of the erythrocyte sedimentation rate and serum immunoglobulin level also occur, as in many other acute infections. Muscle damage is accompanied by elevations in creatine phosphokinase.

OPTIMAL MANAGEMENT

The diagnosis of trichinosis should be investigated when the described signs and symptoms occur in the setting of possible ingestion of *T. spiralis*-infected meat. In the United States, most cases, occurring in outbreaks, have been associated with the ingestion of smoked homemade pork sausage or wild game such as bear, boar, and cougar. Meat must reach a temperature of 81.2°C (177°F) to kill *T. spiralis* larvae.

Serologic tests for trichinosis are performed by the U.S. Centers for Disease Control and Prevention. The results of these antibody-based tests usually become positive within 2 to 4 weeks of infection. In situations in which a history of infected meat ingestion cannot be clearly documented and the results of serologic tests are negative or equivocal, muscle biopsy (e.g., from the gastrocnemius) to identify larvae may be useful.

The treatment of trichinosis depends on the phase of infection at which the diagnosis is made. If a patient is suspected of having ingested contaminated meat within the previous 1 to 3 weeks, the administration of mebendazole (200 to 400 mg 3 times daily for 3 days, then 400 to 500 mg 3 times daily for 10 days) may be useful because this drug kills gut-dwelling adult worms. Treatment of the larval phase of infection is primarily symptomatic and includes the administration of antipyretics and analgesics. In patients with myocarditis or central nervous system disease, corticosteroids may be administered with the intent of diminishing the local inflammatory response to larvae. However, the benefit of corticosteroids in this situation has not been established in controlled trials. Case reports suggest that benzimidazoles also may kill muscle-stage larvae.

ANGIOSTRONGYLIASIS

Angiostrongylus (more recent taxonomy: *Parastrongylus*) *cantonensis* is the most common cause of eosinophilic meningitis worldwide. Endemic areas of angiostrongyliasis include the South Pacific (American Samoa, Papua New Guinea, New Caledonia); southeast Asia; Egypt; and areas of West Africa, such as Côte d'Ivoire. Other helminths less commonly associated with eosinophilic meningitis include *T. spiralis*, *Taenia solium* (cysticercosis), *T. canis* (VLM), *Gnathostoma spinigerum*, and *Paragonimus westermani*.

ETIOLOGIC FACTORS

Infection of humans occurs through the ingestion of raw or poorly cooked slugs, snails, freshwater prawns, and mollusks, which are intermediate hosts of *A. cantonensis*. Vegetables and fomites contaminated with *A. cantonensis* larvae also may be sources of infection. Ingested larvae burrow through the intestinal wall and migrate through the systemic circulation to blood vessels in the brain, occasionally the spinal cord, and rarely the eye. Unlike infection in the definitive rat host, the nematodes do not complete their life cycle in humans.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Migrating *A. cantonensis* larvae elicit eosinophil-rich inflammatory reactions in the brain and leptomeninges. Necrotic tracks attributable to migrating parasites have been observed in specimens of brain and spinal cord. About a week after the ingestion of *A. cantonensis* larvae, headache, stiff neck, and fever appear. In one series, headache was a major presenting symptom in half of all cases, whereas fever exceeding 38°C occurred in less than half. Paresthesia, vomiting, extraocular muscle weakness, and papilledema are less common. Most patients recover from these symptoms in 1 to 2 weeks.

OPTIMAL MANAGEMENT

Angiostrongylus cantonensis infection of the central nervous system should be suspected in a patient who has a history of eating a potential carrier of parasite larvae, symptoms of angiostrongyliasis, and typical findings on examination of cerebrospinal fluid. The most important cerebrospinal fluid finding is eosinophilia (usually more than 20% of the differential cell count). Cerebrospinal fluid protein levels also may be slightly elevated (60 to 100 µg per deciliter). Glucose levels usually are normal relative to blood values. *A. cantonensis* larvae rarely are identified in cerebrospinal fluid. Serologic tests for antibodies to *A. cantonensis* have not been examined rigorously for sensitivity or specificity and are not widely available.

No specific antihelminthic drug is recommended for this self-limited disease. Corticosteroids have no proven benefit. Analgesics should be used to alleviate headache. Preventive measures include education regarding the possible hazards of eating raw or poorly cooked snails and mollusks from endemic areas.

CHAPTER 332: INTESTINAL NEMATODES

ROBERT A. SALATA

Nematodes, or roundworms, consists of over 500,000 species and are generally classified as those that infect primarily the gastrointestinal tract or those that infect deep tissue. In this chapter, the most frequently encountered intestinal nematode infections of humans including enterobiasis, trichuriasis, ascariasis, hookworm infection, and strongyloidiasis are described. The causative agents along with their geographical distribution, means of infection, and major clinical manifestations are summarized in [Table 332.1](#).

Organism	Common Name	Geographic Distribution	Means of Infection	Major Clinical Manifestations
<i>Enterobius vermicularis</i>	Pinworm	Worldwide, especially in temperate zones	Oral-fecal	Anal pruritus
<i>Trichuris trichiura</i>	Whipworm	Worldwide, most common in poor, tropical, rural communities that lack sanitary facilities	Oral-fecal	Widely anemia, bloody diarrhea, growth retardation, rectal prolapse with heavy infection
<i>Ascari lumbricoides</i>	Large roundworm, ascaris	Worldwide, but most prevalent in tropics	Oral-fecal	Liver fibrosis, malnutrition, obstruction of biliary or intestinal tracts
<i>Angiostrongylus cantonicus</i>	Hookworm	Tropics, subtropics between 45°N and 35°S	Skin	Iron-deficiency anemia and hyperinflammation
<i>Strongyloides stercoralis</i>	Threadworm	Tropics and subtropics	Skin	Abdominal pain, diarrhea, rash, eosinophilia, Löffler's-like syndrome, hyperinfection syndrome in immunocompromised hosts

TABLE 332.1. MAJOR INTESTINAL NEMATODE INFECTIONS OF HUMANS

ENTEROBIASIS

Etiology

Enterobius vermicularis (pinworm) is a small, white, threadlike worm that inhabits the cecum and adjacent colon in infected individuals. Gravid female worms detach from the colonic mucosa and migrate at night to the perianal and perineal areas and lay sticky eggs. The final developmental phase of *E. vermicularis* larvae within the egg shell occurs upon contact with an aerobic environment and is continued in temperatures of 30° to 40°C. Eggs containing fully developed larvae are infectious within 4 to 6 hours. The most common mode of transmission is through the hands of the individual by scratching or handling bed clothes and linen. On ingestion, eggs hatch into larvae, which develop into adult worms in 36 to 54 days.

Epidemiology

Enterobiasis is highly prevalent throughout the world, especially in temperate climates. It is the most common helminthic infection in the United States and Europe, with an estimated 42 million cases and infecting individuals at every socioeconomic level. Infection with *E. vermicularis* is most frequent in children between the ages of 5 and 14 years and is commonly seen in families, in overcrowded conditions, and institutionalized groups. Because the life-span of adult worms is relatively short, long-standing infection probably results from continuous reinfection.

Pathogenesis and Clinical Manifestations

Enterobius worms cause little mechanical injury to the colonic mucosa. No evidence suggests that infection with *E. vermicularis* is associated with a hypersensitivity reaction, as no eosinophilia or increased IgE levels have been observed. Most *Enterobius* infections are light and asymptomatic. The most common complaints in 25 percent of infected individuals include perianal and perineal pruritus and restless sleep. Occasionally, the migrating worms may produce appendicitis, salpingitis, and predispose to secondary bacterial perianal skin and urinary tract infections.

Management

Diagnosis of enterobiasis by detecting worms or/eggs is made by examination of an adhesive cellophane tape pressed to the perianal area early in the morning ("scotch tape test"). A single examination detects 50% of infections, and five examinations detect 99%. In contrast, *E. vermicularis* eggs are found in feces in only 10% to 15% of infected individuals. Occasionally, adult worms, mainly female, can be observed in the perianal area or during anoscopy, proctoscopy, on vaginal inspection, or in the feces during diarrhea or after antihelminthic therapy.

Drug therapy of enterobiasis with mebendazole (100 mg once) or pyrantel pamoate (11 mg/kg once) or albendazole (400 mg once) results in cure rates of 90% to 100% percent. For heavy and symptomatic infections, repeat treatment after 2 weeks may be necessary. Drug therapy is recommended for all infected members of families with intense or symptomatic infections.

TRICHURIASIS

Etiology

Adult *Trichuris trichiura* (whipworm) are located in the cecum of infected individuals. Female worms with a life expectancy of 1 year, shed 3,000–20,000 eggs per day. After excretion in the stool, embryonic development of eggs takes place under optimal moisture and shade conditions in 15 to 30 days. When humans ingest embryonated eggs through contaminated food or water, the larvae hatch and mature into ovipositing adults in 1 to 3 months.

Epidemiology

More than 800 million people are infected with *Trichuris trichiura* worldwide, most living in tropical or subtropical areas. In the rural southeastern part of the United States, over 2.2 million individuals have been estimated to be infected with whipworm. Children in the 5 to 15 year age group have the highest prevalence and probably have higher worm burdens than do adults.

Pathogenesis and Clinical Manifestations

Adult *Trichuris* worms are primarily found in the cecum and ascending colon but may be present from the terminal ileum down to the rectum in heavy infection. Colonic pathologic findings, which may be seen in heavily infected individuals, resembles that seen with inflammatory bowel disease.

The human immunologic response in *Trichuris* infection is not fully known. Infection induces a specific human antibody response, but no evidence indicates that this is effective in controlling or eliminating disease. Murine infection with *T. muris* stimulates both humoral and cellular immunity, which results in expulsion of the worms.

Infection with *T. trichiura* is most commonly asymptomatic. A form of acute dysentery associated with malnutrition has been ascribed to heavy *Trichuris* infection. Clinically, this presentation may be indistinguishable from bacterial or amebic dysentery or inflammatory bowel disease. Children in the 2 to 10 year age group are most frequently affected. In addition, these children may have growth retardation. In cases of massive infantile trichuriasis, there is often mucosal or full-thickness

prolapse of the rectum on defecation and worms may be visualized on the bloody, edematous surface. Anemia may also complicate this presentation. Worm burden in this syndrome is usually greater than 500 and can reach 5,000 or more.

Chronic *Trichuris* colonic infection in children presents with growth retardation and failure to thrive. This presentation may continue for years and occasionally evolves into the classical acute dysentery syndrome.

Management

The presence of the characteristic lemon-shaped eggs in stool is diagnostic of *Trichuris* infection (Table 332.2). Given the correlation between worm burden and colonic abnormality, quantitation of infection can also be assessed most conveniently by the Kato method.

Infection	Diagnosis	Therapy	
		Drug of Choice	Adult Dosage
Ascariasis	"Stool tape test" or Kato-Katz	Mebendazole	100 mg PO once
Ascariasis			100 mg PO once for children <12 y
Ascariasis	Looking for worms (Stool floats)	Piperazine citrate or Mebendazole	11 mg/kg (maximum, 1 g) once 400 mg once (once in 2 weeks) 100 mg b.i.d. = 2 g for children
Trichuriasis	Stool examination for eggs	Mebendazole	100 mg b.i.d. = 2 g
Trichuriasis	Stool examination for eggs	Mebendazole	400 mg once
Ascariasis	Stool examination for eggs	Mebendazole	100 mg b.i.d. = 2 g
Ascariasis	Stool examination for eggs	Mebendazole	400 mg once
Ascariasis	Stool examination for eggs	Piperazine citrate for sedation of intestines	11 mg/kg (maximum, 3.3 g) = 2 g
Ascariasis	Stool examination for eggs	Mebendazole	100 mg b.i.d. = 2 g
Ascariasis	Stool examination for eggs	Piperazine citrate or Mebendazole	11 mg/kg (maximum, 1 g) = 2 g 400 mg once
Ascariasis	Larvae in sputum or gastric fluid	Mebendazole	11 mg/kg b.i.d. (maximum, 3 g) = 2 g
Ascariasis		Mebendazole	400 mg once
Ascariasis		Mebendazole	100 mg b.i.d. = 2 g
Ascariasis		Mebendazole	400 mg once

TABLE 332.2. DIAGNOSIS AND TREATMENT OF INTESTINAL NEMATODE INFECTIONS

Mebendazole is the drug of choice in treating *Trichuris* infection with cure rates of 70% to 90% and reduction in egg output of 90% to 99%; (see Table 332.2). Although single-dose oral therapy with 100 mg of mebendazole is convenient for chemotherapeutic control programs and adequate for asymptomatic infection, therapy over 3 days increases the probability of complete cure in symptomatic cases. Albendazole and ivermectin are also well tolerated and effective drugs for this condition.

ASCARIASIS

Etiology

Ascaris lumbricoides (giant roundworm) adults reside in the lumen of the small bowel, most commonly the jejunum and middle ileum, and have a life span of 10 to 24 months. More than 200,000 ova per day are produced by mature female worms. The fertile egg is broadly oval and has a thick shell with an outer mammillated albuminous covering. After passage with feces, embryogenesis occurs in soil under favorable environmental conditions, and fully developed infective larvae develop within the eggs in 5 to 10 days. When these eggs are ingested by humans, larvae hatch in the small intestine, penetrate through the intestinal mucosa, and migrate through the venous circulation to the heart and lungs. They then break into the alveolar spaces and pass up through the bronchi and trachea. After being swallowed, the larva mature into adult worms in the small intestine. The time required to produce a mature female has been estimated to be 2 months.

Epidemiology

Ascariasis infection is the most common helminthic infection of humans, with an estimated prevalence of 1 billion. This parasitic infection is cosmopolitan in distribution but is most common in tropical and subtropical areas occurring most commonly in malnourished individuals. In the United States, it infects an estimated 4 million people mainly in the southeast. Schoolaged children are most commonly infected. Transmission of *A. lumbricoides* is through a fecal-oral route and usually hand to mouth. Infection is facilitated by the extremely high output of eggs by mature females and the ability of eggs to resist unfavorable environmental conditions. *Ascaris* ova can live for 2 years at 5° to 10°C, can survive anaerobic conditions for up to 3 months, and can resist desiccation for 2 to 3 weeks at 22°C. In loose, moist, sandy soil, ova can live 6 years and survive freezing winter temperature.

Pathogenesis and Clinical Manifestations

During the passage of larvae through the intestinal mucosa, some larvae are covered with eosinophils and may be enveloped in eosinophilic granulomas and destroyed. Hypersensitivity reactions are pronounced during pulmonary migration with alveolar sacs being filled with serous exudate and eosinophilic infiltration of peribronchial tissue. The intensity of this host reaction varies greatly, but is usually correlated with the number of larvae destroyed during migration. General hypersensitivity reaction observed during pulmonary larval migration include asthma, transient pulmonary infiltrates (Loeffler's syndrome), angioneurotic edema, and urticaria. The symptoms of asthma and urticaria have been associated with circulating IgE antibodies.

Overt disease in established *Ascaris* infection is infrequent. The most common clinical manifestations are pulmonary and nutritional disorders, and obstruction of the intestinal or biliary tracts. Pulmonary symptoms which occur during the stage of larval migration through the lungs include cough, wheezing, pulmonary infiltrates and peripheral eosinophilia. Children with heavy gastrointestinal infection may exhibit malabsorption. Most of these observations have occurred in the developing world, in which polyparasitism and multiple nutritional deficiencies cannot be excluded. Masses of *Ascaris* worms may occasionally obstruct the lumen of the small bowel. These children present with obstructive symptoms including abdominal pain, distention, and vomiting. Another complication that may be encountered is obstruction of the biliary tract, mostly the common bile duct, with a single worm. Clinically, these patients complain of abdominal pain (right upper quadrant or epigastric), nausea, and vomiting. Jaundice is uncommon.

Management

Ascariasis is diagnosed by finding adult worms, larvae, or eggs (Table 332.2). With pulmonary symptoms, larvae may be found in sputum or gastric washings between days 8 and 16 after exposure and are occasionally identified in lung biopsy material. Eggs appear in the feces 60 to 75 days after exposure. Because of the enormous output of eggs by gravid female ascarids, direct smear of fecal material is usually sufficient for diagnosis.

The drug of choice for treatment of ascariasis is mebendazole (100 mg twice daily for 3 days; see Table 332.2). Albendazole given 400 mg once is an effective alternative. In cases associated with intestinal or biliary obstruction, piperazine citrate has been recommended. This agent narcotizes the worms and helps relieve obstruction. Surgery is sometimes necessary in patients with complete obstruction, an acute surgical abdomen, or complications of perforation, peritonitis or volvulus.

HOOKWORM INFECTION

Etiology

Adult hookworms of two species, *Ancylostoma duodenale* (old world hookworm) and *Necator americanus* (new world hookworm), are small, grayish-white roundworms. These helminths live mainly in the upper small intestine, attached to the mucosa by their strong buccal capsules. Hookworms cause significant daily blood loss from the gut; 0.03 mL for *N. americanus* and 0.26 mL for *A. duodenale*. Adult hookworms have a mean life-span of 2 to 5 years, and lay an average of 7,000 eggs daily. Under suitable conditions of soil, humidity, and temperature, the eggs hatch into infective larvae. Humans become infected through the skin by contact with larvae-infected soil. On penetration, these organisms circulate to the lungs, break through the alveolar walls and ascend the trachea. The larvae follow a pathway similar to *Ascaris* and are carried to their final place of habitat in the small intestine. Mature female worms begin to produce eggs 4 to 6 weeks after skin

penetration.

Epidemiology

Hookworm infection is estimated to affect at least one quarter of the world's population and remains a significant problem in the developing world with 500 million to 1 billion estimated infections. In the United States, a low frequency of infection is still encountered in the southeast. Immigrants and foreign visitors often harbor hookworms and may be symptomatic. In the soil, larvae are found mainly in superficial layers facilitating penetration of human skin. Hookworm larvae will not develop at temperatures below 13° to 15°C. Larvae are destroyed by drying and direct sunlight. Other epidemiological factors associated with hookworm infection include methods of fecal waste disposal, and the habit of walking barefoot.

Pathogenesis and Clinical Manifestations

The most important pathophysiological features of hookworm infection are due to attachment of the worms to the intestinal mucosa. Blood is sucked by the worms as well as being spilled around. This leads to iron-deficiency anemia as the predominant clinical feature of hookworm infection. Associated symptoms may include fatigue, edema, heart failure, and palpitations. There is a strong association between anemia and the intensity of hookworm infection as well as the amount of absorbable dietary iron. The relationship between iron deficiency and hookworm infection may be complicated by severe malnutrition and hypoproteinemia and an enteropathy endemic to the tropics. Malabsorption has been described more frequently in infected children than in adults and can be associated with growth and developmental retardation.

During skin penetration, disease manifestations may include intense pruritis, erythema and a papular-vesicular rash ("ground itch") at the site of larval penetration. With pulmonary migration, cough, wheezing and transient pulmonary infiltrates associated with eosinophilia (Löffler's syndrome) may be observed; these pulmonary features are much less common than in other migrating nematode infections.

Management

Diagnosis depends upon identification of eggs in the stool (see [Table 332.2](#)). Direct fecal smears are usually adequate to diagnosis moderate to heavy infections; concentration techniques may be necessary for light infections.

Mebendazole, 100 mg twice daily for 3 days or albendazole 400 mg once are the drugs of choice for hookworm infection. This regimen has resulted in cure rates of 95%, with an egg count reduction by 99.9%. Iron therapy should also be given when anemia is present. In preliminary studies, ivermectin has been well tolerated and effective.

STRONGYLOIDIASIS

Etiology

Strongyloides stercoralis is unique among intestinal nematodes because of the ability to cause hyperinfection syndrome in the immunosuppressed host. Adult worms inhabit the upper small intestine, where the females burrow through the mucosa. Females deposit ova, which hatch into larvae. These organisms bore through the intestinal epithelium to the gut lumen and are passed with feces. Larvae in the outside environment can either molt and differentiate into free-living adult males and female worms or metamorphose into the infective filariform larvae. Free-living adults can either continue their cycle in the soil or produce filariform infective larvae.

The most common route of human infection is through skin contact with contaminated soil. Humans may also be infected through the mucosa of the lower gastrointestinal tract or in the perianal area from larvae that have transformed into the filariform infective form during their passage with feces. This capacity to replicate within the host is the basis for persistence of infection for many years and the hyperinfection that is seen in overwhelming strongyloidiasis in compromised hosts.

After penetration of skin or gut mucosa, larvae pass through the circulation to the lungs, break into the alveolar spaces, ascend the trachea and are then swallowed to their final residence in the small bowel. Deposition of eggs by gravid females begins about 28 days after initial infection.

Epidemiology

Strongyloidiasis, although uncommon in comparison to other major intestinal nematodes, is widely distributed in the tropics and subtropics. In the United States, transmission still occurs at a very low rate in the southern states. Infection is also seen among residents of institutions for the mentally retarded.

Infection is acquired most commonly when infective larvae in soil come in contact with skin. The patient's worm burden in strongyloidiasis is dependent on the size of the larval inoculum and the degree of autoinfection. Because this helminthic parasite can increase its numbers within the human host, all infected people are at risk for developing potentially fatal disseminated strongyloidiasis if suppression of their immune system occurs.

Pathogenesis and Clinical Manifestations

The factors mediating host susceptibility and pathogenesis in *Strongyloides* infection are not well understood. In chronic infection, a balance is reached whereby worms are restricted in number and confined principally to the gastrointestinal tract, but the organism is not eradicated. With depression of host defenses, worms may multiply rapidly and disseminate.

The cutaneous reactions seen with strongyloidiasis appear to be mediated by an immediate hypersensitivity skin reaction to migrating worms or their products. Enteritis that is observed may result from direct mechanical trauma as well as the host inflammatory response and secondary bacterial infection of ulcerated lesions. In mild infection, diarrhea may occur while abdominal pain and malabsorption are usually seen with heavy infection. In disseminated infection, migrating larvae may damage tissues directly, resulting in widespread secondary bacterial infections as bacteria are carried by migrating larvae or enter the circulation through ulcerative lesions in the gastrointestinal tract.

Over one-third of patients infected with *S. stercoralis* have no symptoms. Symptoms of acute infection probably reflect the intensity of infection. Local cutaneous manifestations include a pruritic, erythematous, papular rash at the site of larval penetration. With pulmonary migration of larvae, a Loeffler's syndrome with cough, wheezing, pulmonary infiltration and eosinophilia can be observed.

Chronic infections are usually asymptomatic, but gastrointestinal manifestations may be encountered. Burning or colicky abdominal pain, often epigastric in location, may be associated with diarrhea, vomiting, weight loss and evidence of malabsorption or a protein-losing enteropathy. Eosinophilia is typically prominent. Cutaneous manifestations may be seen in as many as two-thirds of chronically infected individuals. A localized or generalized urticarial rash perianally and extending to the buttocks, abdomen, and thighs is common.

Massive larvae invasion of the lungs and other organs may occur with autoinfection, especially in patients immunocompromised by hematological malignancies, therapy with corticosteroids and cytotoxic agents, as well as infection with the human immunodeficiency virus. In disseminated strongyloidiasis, high fever, severe generalized abdominal pain, diffuse pulmonary infiltrates, ileus or small bowel obstruction, jaundice, shock, and meningitis or sepsis from gram-negative enteric bacilli may be seen. Eosinophilia may not be present.

Management

A high clinical index of suspicion for strongyloidiasis should be maintained in patients presenting with abdominal pain, diarrhea, or urticaria particularly if they have lived at some time in their life in an endemic area. Diagnosis of strongyloidiasis depends on the demonstration of *S. stercoralis* larvae in the feces or duodenal fluid. Concentration techniques should be employed to improve diagnostic yield. Repeated examinations may be required to confirm the diagnosis. The presence of eosinophilia or an elevated IgE serum level can be useful indicators of strongyloidiasis, but neither are constant features in chronic infection. Furthermore, the

eosinophil count is frequently normal in patients with disseminated strongyloidiasis. Immunodiagnostic assays may occasionally be helpful for the diagnosis of chronic strongyloidiasis.

All individuals infected with *S. stercoralis* should be treated because of the threat of autoinfection and disseminated disease. Thiabendazole (25 mg/kg twice a day for 2 days) is a readily available effective agent. In disseminated strongyloidiasis, early diagnosis is critical. Therapy with thiabendazole should be continued for 2 to 3 weeks; mortality rates remain high despite treatment. Preliminary studies have suggested that ivermectin is extremely well tolerated and probably more effective than thiabendazole in disseminated disease. Supportive therapy as well as treatment of secondary gram-negative bacterial infections is essential in the hyperinfection syndrome. Individuals with a past history of exposure to *S. stercoralis* should be comprehensively examined and treated before undergoing immunosuppressive therapy.

CHAPTER 333: CESTODE INFECTIONS

RONALD BLANTON

[Definition](#)
[Taeniasis \(Beef and Pork Tapeworm Infection\)](#)
[Cysticercosis](#)
[Diphyllobothriasis \(Fish Tapeworm Infection\)](#)
[Echinococcosis \(Hydatid Disease\)](#)
[Other Cestode Infections](#)

DEFINITION

Adult cestodes are descriptively referred to as tapeworms. They consist of 3 to 3,000 flattened segments (*proglottids*), each relatively independent and mainly dedicated to the production of eggs. The organism anchors itself to the intestinal mucosa by a set of specialized hooks and/or suckers attached to its first segment (*scolex*). While the adults cause little direct morbidity, the larval stages of these parasites are invasive and can produce severe, life-threatening disease. Humans can be infected with one or both stages, depending on the parasite species.

TAENIASIS (BEEF AND PORK TAPEWORM INFECTION)

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The highest prevalence of *Taenia saginata* (beef tapeworm) occurs in Africa, Southwest Asia, and Eastern Europe. In Western countries, uncooked beef dishes, such as steak tartare, have resulted in tapeworm infections, particularly where inspection of beef is inadequate. *Taenia solium* (pork tapeworm) infection is most prevalent in Central America, South America, and Asia.

ETIOLOGIC FACTORS

Humans become infected when they consume parasite larvae embedded in raw or undercooked beef or pork. Adult *T. saginata* and *T. solium* develop in the small intestine and reach an average length of 4 to 6 m. The adults are long-lived, and spontaneous cure is unusual.

PATHOGENESIS AND CLINICAL FINDINGS

The adult worms are not usually pathogenic. Due to their size, however, *T. saginata* and *T. solium* may rarely obstruct the small bowel, the pancreatic duct, or the common duct. In contrast, larval forms of *T. solium* are a common and important cause of morbidity (see section “Cysticercosis”).

LABORATORY FINDINGS

The laboratory findings in adult beef or pork tapeworm infection are not specific. The diagnosis depends on identification of the organisms or their eggs in stool, although the eggs will not permit distinction between these two species. It is important to identify the species for public health reasons since *T. solium* carriers may infect others and cause serious morbidity. Diagnostic characteristics of *T. saginata* are the presence of 15 to 30 uterine branches in proglottids and the absence of hooks on the scolex. In contrast, *T. solium* has 7 to 12 uterine branches and a scolex armed with hooks.

OPTIMAL MANAGEMENT

The treatment of choice for taeniasis is a single dose of praziquantel (10 mg per kilogram). A single dose of niclosamide is also effective given at 2 g for adults, 1.5 g for children weighing more than 34 kg, and 1 g for children weighing 11 to 34 kg. Niclosamide tablets should be chewed thoroughly and then swallowed. Since this drug is not absorbed, it will not affect the invasive intermediate form of *T. solium*, which may or may not be desirable (see section “Cysticercosis”). Infection can be prevented by improved inspection of beef and pork and by thorough cooking of meat. The side effects of both drugs are mild abdominal discomfort, nausea, headache, and dizziness.

CYSTICERCOSIS

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Cysticercosis is the most common parasitic infection of the brain. Its distribution in the Americas, India, Southeast Asia, parts of Africa, and Eastern Europe follows that of *T. solium* infections, since cysticercosis is caused by the invasive intermediate form of this tapeworm. In areas of high prevalence, more than 2% of autopsies show evidence of infection. Serologic assays indicate that in highly endemic areas more than 10% of persons have been exposed. The number of cases is rising in the United States as a result of increased immigration from endemic areas and increased recognition.

ETIOLOGIC FACTORS

Pigs harbor only the tissue stage (*cysticercus*) of the parasite, whereas humans may be infected with either the intestinal or the tissue stages. Cysticerci develop in humans or pigs after they ingest food or water contaminated with parasite eggs. Invasive larvae hatch from eggs in the proximal small bowel, then penetrate the gut wall, and are carried in the bloodstream to multiple tissues (most notably brain and muscle). Individuals infected with adult worms can infect themselves with the larval stage by the fecal–oral route or by retrograde movement of eggs into the upper small bowel and stomach. Most studies have shown low rates of dual infection with both larval and adult stages, suggesting that autoinfection is uncommon.

PATHOGENESIS

The cysticercus is a 6- to 10-mm cystic structure containing a single (proto)scolex. Morbidity is caused by compression of adjacent tissues, obstruction of cerebrospinal fluid (CSF), or the immunopathologic response to dying parasites. Viable organisms induce only a mild reaction, whereas dying parasites produce marked inflammation and severe swelling. In muscles, cysticerci survive for months or years, then collapse and calcify within 4 to 5 years. Cysts in the brain also collapse and calcify, but more slowly. Cyst location, intensity of infection, and immune response are so varied that any neurologic, cognitive, or personality disorder in an individual from an endemic area may represent neurocysticercosis. All areas of the central nervous system can be affected, but parenchymal lesions predominate.

CLINICAL FINDINGS

Parenchymal Neurocysticercosis

Parenchymal neurocysticercosis accounts for 50% of cases of neurocysticercosis. This form most commonly presents with focal seizures or focal neurologic deficits. More diffuse symptoms of intellectual deterioration with dementia or parkinsonism may not suggest the diagnosis until focal signs appear. There is a fulminant encephalitis–like presentation most often seen in children, characterized by showers of cysticerci, an acute inflammatory response, and diffuse cerebral edema.

Subarachnoid Neurocysticercosis

Chronic basilar arachnoiditis due to cysts in the basal cisterns accompanies many forms of neurocysticercosis and makes up some 30% of cases. The lack of

surrounding tissues allows the cysts at times to expand into a large mass of interconnected cysts without protoscolices (*racemose cysticercosis*). Inflammation or external mechanical obstruction of ventricles by subarachnoid cysts produces hydrocephalus. Rarely, there is cerebral infarction from the obstruction of small terminal arteries or vasculitis.

Intraventricular Neurocysticercosis

Intraventricular neurocysticercosis composes 15% of cases of neurocysticercosis, and when cysts obstruct CSF it can be associated with hydrocephalus and acute or subacute signs of increased intracranial pressure including headache, nausea, vomiting, change in mental status, loss of balance. The symptoms may be positional, since cysts are free-floating in the CSF. The fourth ventricle is most often affected.

Spinal Cysticercosis

Spinal cysticercosis accounts for 3% to 15% of cases of neurocysticercosis and presents as cord compression, nerve root pain, transverse myelitis, or meningitis.

Ocular Cysticercosis

Ocular infection is seen in less than 1% of cases and causes decreased visual acuity as a result of cysticerci floating in the vitreous humor, retinal detachment, iridocyclitis, or muscle involvement.

LABORATORY FINDINGS

The most important diagnostic tools are a history that includes travel and personal contacts, neuroimaging, and blood serologic testing. Parenchymal cysts are easily seen by magnetic resonance imaging (MRI; [Fig. 333.1](#)) or head computed tomography (CT). MRI is more sensitive than CT for subarachnoid or intraventricular cysts, but less sensitive for calcifications. The serum enzyme-linked immunoelectrotransfer blot (EITB) is the most sensitive and specific serologic test available. The sensitivity of EITB decreases when there is no inflammation, when there is a single or few parenchymal cysts, and when all lesions are calcified. Examination of CSF is often less helpful, but the presence of eosinophils is highly suggestive.

FIGURE 333.1. Magnetic resonance imaging T1-weighted image with gadolinium showing multiple cysticerci at various stages of development in the parenchyma and ocular muscle. Note presence of a protoscolex (*arrow*) within the left parenchymal cysticercus. (Courtesy of Nelson Ferreira, Hospital Beneficência Portuguesa, Med. Imagem, São Paulo, Brazil.)

OPTIMAL MANAGEMENT

Treatment decisions must be individualized with each patient and based on the viability and location of cysticerci. There is general agreement that when hydrocephalus is present, ventricular shunting should precede any antiparasitic therapy. Furthermore, the encephalitic form of disease should be treated with anticysticercal drugs after shunting if there is hydrocephalus. When imaging shows resolved or largely resolved lesions, no antiparasitic therapy is indicated. Beyond these points, management of parenchymal disease is controversial. A large prospective study indicated that the frequency of seizures and seizure control was better in those who received antiparasitic drugs. However, subjects in this study were largely self-selected and not randomized. In contrast, there are natural history studies that conclude that the outcome is unchanged by specific therapy.

Albendazole, the drug of choice, is administered at 15 mg per kilogram per day in two or three divided doses for 15 days. It has few undesirable interactions with other drugs, and there is some evidence that it has higher efficacy than praziquantel. Praziquantel is also effective at 50 mg per kilogram per day in three divided doses for 15 days. Transient worsening of inflammation occurs in 20% of cases after treatment, as a response to rapidly dying parasites. To prevent or blunt some of this effect, dexamethasone should be given at 10 to 20 mg intramuscularly once daily for the first 4 days of therapy. As a further benefit, steroids increase plasma levels of albendazole by as much as 50%. Corticosteroids and antiepileptics, however, reduce plasma concentrations of praziquantel. When using praziquantel, corticosteroids should either be withheld until symptoms develop or administered with cimetidine to reduce activity of the hepatic P-450 system. Imaging should be repeated 3 months after therapy to evaluate response. Patients who do not respond initially should be treated once more and observed for evidence of progression before another course is given.

There is growing use of medical therapy for extraparenchymal disease, although surgery is usually needed for disease that is intraventricular, ocular, or spinal. Ventricular cysts should be removed surgically or by neuroendoscopy, since they frequently become symptomatic or obstruct shunt function. Some cases are known to resolve with albendazole or praziquantel, but there is a risk of precipitating ependymitis and chronic obstruction. It is prudent in most cases to place a ventricular shunt prior to therapy for even asymptomatic ventricular cysticerci. Surgery is also the preferred therapy for spinal and ocular disease.

DIPHYLLOBOTHRIASIS (FISH TAPEWORM INFECTION)

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Transmission occurs near freshwater lakes in northern climates, such as Scandinavia, Alaska, and the Great Lakes areas of the United States and Canada. The fish tapeworm has also become established in some temperate regions of Africa and South America. In this country, infection is usually associated with the ingestion of raw salmonid fish.

ETIOLOGIC FACTORS

Infection with the adult fish tapeworm, *Diphyllobothrium latum*, occurs after the consumption of raw or undercooked freshwater fish carrying the infectious stage of the parasite. Megaloblastic anemia is a notable but uncommon complication of infection.

PATHOGENESIS AND CLINICAL FINDINGS

Diphyllobothrium latum may produce megaloblastic anemia by competing with the host for the absorption of vitamin B₁₂ and blocking absorption by dissociating the B₁₂-intrinsic factor complex in the gut. Complaints are relatively nonspecific even when anemia is present. Hematologic disorders may be masked in patients who have a good intake of vitamin B₁₂ and folate, but deficiency may then present as glossitis or neurologic signs due to degeneration of the spinal cord dorsal and lateral columns.

LABORATORY FINDINGS

The presence of normal gastric acid and intrinsic factor combined with folate-resistant anemia is characteristic of the megaloblastic anemia caused by *D. latum* infection. Examination of the stool reveals abundant ovoid eggs with a distinctive cap structure (*operculum*) (Fig. 333.2) or worm segments.

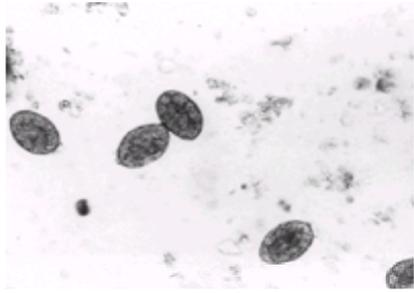

FIGURE 333.2. Fish tapeworm (*Diphyllobothrium latum*) eggs, 70 × 45 mm

OPTIMAL MANAGEMENT

Therapy for diphyllobothriasis is the same as for taeniasis. Cooking fish at temperatures higher than 50°C for at least 5 minutes or completely freezing at –18°C kills infective larvae. Proper sewage disposal decreases transmission because humans are the most important definitive host.

ECHINOCOCCOSIS (HYDATID DISEASE)

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Echinococcus granulosus and *Echinococcus multilocularis* are responsible for unilocular and alveolar hydatidosis, respectively. Although both forms are serious, alveolar hydatidosis carries the worst prognosis. *E. granulosus* has a worldwide distribution concentrated in sheep herding regions of the world, such as North Africa, Southwest Asia, Southern Europe, and Australia. Some of the highest prevalences of disease, however, have been reported in Kenya and Western China. In highly endemic areas, more than 1% of all surgical admissions are for hydatidosis. In North America, transmission occurs in a sylvatic moose–wolf cycle in Alaska and Canada and between dogs and sheep in the western states. Transmission of *E. multilocularis* in a rodent–fox cycle is maintained primarily in the sub-Arctic regions of Alaska, Canada, and Northern and Eastern Europe and China.

ETIOLOGIC FACTORS

Dogs develop the adult stage after eating the viscera of slaughtered game or livestock. The adult parasite is a small tapeworm (3 to 6 mm) of three or four segments that develops in the intestine of canine hosts and is shed in their feces. Intermediate hosts for *E. granulosus* include most domestic and wild herd animals, pigs, and humans. These hosts become infected through the ingestion of pasture or food contaminated with eggs or through close contact with infected dogs. In unilocular disease, infecting larvae of *E. granulosus* invade the host's lung or liver and form solitary cysts with a tough fibrous capsule that sometimes will contain internal daughter cysts. Protoscolices, the infective form for the dog, can be found in the cyst fluid or attached to the cyst wall. They have a characteristic ring of hooklets when viewed from above (Fig. 333.3). Infection with *E. multilocularis* produces a larval form that multiplies by external budding from the primary cyst. The result is an expanding cluster of lobules instead of the single encapsulated mass produced by *E. granulosus*. Adult worms of *E. multilocularis* develop in foxes, wolves, and sled dogs, and are similar in appearance to those of *E. granulosus*.

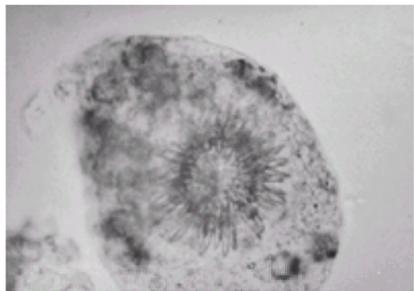

FIGURE 333.3. *Echinococcus granulosus* protoscolex.

PATHOGENESIS

The pathology associated with hydatid disease is a result of pressure effects, obstruction, or allergic responses to cyst fluid. Cysts can grow to enormous proportions but average 0.5 to 1 L. Pressure on adjacent tissues leads to pain, organ dysfunction, or obstruction. Spontaneous or traumatic rupture of a cyst or spillage of cyst fluid during surgery into the peritoneum disseminates daughter cysts. Cyst leakage or rupture can provoke minor urticarial reactions in the host, peritonitis, or anaphylaxis. The hydatid of *E. multilocularis* is a cluster of firm gelatinous cysts that invades adjacent tissue and produces distant metastases, similar to a malignant tumor. Enlargement occurs rapidly and most infections are fatal if untreated.

CLINICAL FINDINGS

Hydatid cysts are found in liver (50% to 70%), lung (20%), and, infrequently, other organs or the skin. As the cysts enlarge, the liver becomes palpable and obstruction of the biliary tree can occur. In the lung, the lack of surrounding tissue allows cysts to become much larger. Rupture of lung cysts induces cough and hemoptysis, and hydatid membranes are occasionally coughed up. A cyst in bone thins the cortex and can cause a pathologic fracture. In the kidney, cysts cause pain and hematuria. Spinal cord and brain hydatid cysts are very rare and result in clinical syndromes similar to cysticercosis. Cysts also become secondarily infected with bacteria and can present as abscesses. Untreated alveolar hydatid disease produces liver failure.

LABORATORY FINDINGS

The radiologic appearance of uncomplicated unilocular hydatid cysts on plain films, ultrasonography (Fig. 333.4), and CT is that of a smooth, well-circumscribed cystic mass that may be partially calcified and may have internal septae representing daughter cysts. In contrast, alveolar disease displays a loose collection of infiltrating lobules. The immunoblot assay is the most specific for *Echinococcus* species, except for cross-reactions with *T. solium* infections. The sensitivity is approximately 30%.

FIGURE 333.4. Ultrasound image of a hydatid cyst, 10.5 × 8.4 cm.

OPTIMAL MANAGEMENT

The World Health Organization has produced an excellent set of guidelines for the management of hydatid disease. Importantly, not all cysts require removal. Some are small, do not enlarge, and cause no symptoms unless secondarily infected. Surgery is recommended for large, complex cysts (involution or multiple daughter cysts present) or very superficial cysts that are apt to rupture. Surgical removal is also the treatment of choice for cysts that are symptomatic, enlarging, or infected. Albendazole prophylaxis is recommended, and during surgery scolecidal agents such as hypertonic saline are infused into the cyst cavity. However, scolicides should not be used in the presence of bile-stained cyst fluid because of the risk of inducing sclerosing cholangitis. The mortality rate is 1% to 3% with the first operation for hydatid disease and increases dramatically with each subsequent operation.

A major complication is spillage of cyst contents, since each liberated protoscolex can form a secondary cyst. Morbidity and mortality are significantly lower in centers that are experienced with hydatid surgery. Some centers report a normal life span compared with matched control subjects for their patients who undergo surgery for unilocular cysts. Surgery rarely is successful for alveolar hydatid disease, except in early lesions that can be removed completely. Liver transplant may be an option if metastatic disease is not present.

Percutaneous aspiration with instillation (of a scolecidal agent) and repeat aspiration (PAIR) in experienced hands has little morbidity and excellent results when the cyst is without internal structures or daughter cyst and is not superficial. Ethanol, hypertonic saline, and cetrimec are acceptable scolecidal agents; however, formalin is contraindicated. The scolecidal agent should remain in contact with the cyst for at least 15 minutes. Cyst fluid should be hypotonic and crystal clear, but it should contain protoscolices or free hooks. Liver cysts with bile-stained fluid and lung cysts should be managed with surgery or chemotherapy. The procedure can be complicated by bleeding, spillage of cyst fluid, ethanol toxicity, or hypernatremia.

Albendazole is the drug of choice where surgery or PAIR is contraindicated, refused, or the cysts have low potential for morbidity. A recommended drug regimen is three to six cycles of albendazole (10 to 15 mg per kilogram per day) twice daily for 28 days, followed by 14 days rest. There is some evidence that 3 to 6 months of continuous therapy is more efficacious without an increase in side effects (hepatotoxicity, neutropenia, thrombocytopenia, alopecia). For surgical prophylaxis, at least 4 days of therapy before and for 1 month afterward are recommended. The collective experience with albendazole indicates that 30% of patients are cured and 50% improve. Albendazole therapy can halt the progression of alveolar hydatid disease but does not appear capable of curing this condition.

OTHER CESTODE INFECTIONS

HYMENOLEPIASIS (DWARF TAPEWORM INFECTION)

Hymenolepis nana is a small tapeworm (30 mm) found throughout the world under conditions of poor hygiene. No symptoms can be attributed to light infections with *H. nana*, but heavy infections are associated with anorexia, diarrhea, and abdominal pain. Recommended therapy is a single dose of niclosamide or praziquantel.

MULTICEPS MULTICEPS (BLADDER WORM INFECTION)

Multiceps multiceps is a pathogen of sheep that rarely infects humans. In humans, it causes a disease similar to cysticercosis, with intermittent increased intracranial pressure or epilepsy. Praziquantel is thought to be useful, but surgery usually is impossible because of the organism's size, lobular morphology, and close association with host tissues.

SPARGANOSIS (SPIROMETRA SPECIES)

Spirometra species are tapeworms of dogs and cats whose intermediate stage (*sparganum*) is found in frogs, snakes, and rodents. Infection in humans occurs through the ingestion of contaminated water, the uncooked flesh of infected animals, or through the folk practice of applying crushed or split amphibians or reptiles to sites of inflammation. Although distributed worldwide, the majority of cases are from Asia. Infected individuals have painful inflammatory masses around the larvae. Treatment is by incision and removal of the parasite. Common sites are subcutaneous areas of the chest, abdomen, or thighs, and sometimes the brain. Praziquantel is used to treat inoperative infections.

CHAPTER 334: TREMATODE INFECTIONS

CHARLES H. KING

[Blood Flukes: Schistosomiasis](#)
[Liver, Lung, and Intestinal Flukes](#)

BLOOD FLUKES: SCHISTOSOMIASIS

DEFINITION

Schistosomiasis, also known as bilharziasis, is caused by infection with parasitic trematodes (flukes) that colonize the venous circulation ([Fig. 334.1](#)). The five *Schistosoma* species that cause human infection are *S. mansoni*, *S. haematobium*, *S. japonicum*, *S. intercalatum*, and *S. mekongi*. Each parasite has a distinct geographic zone of transmission defined by the distribution of its snail vector, and each causes a specific clinical syndrome according to its preferred anatomical distribution in the human host. In some areas of the world, humans also may become infected transiently by the schistosomal parasites of other animals, especially birds (i.e., *Trichobilharzia* and *Bilharziella* species). These latter schistosomes do not mature into adult worms but may cause significant dermatitis.

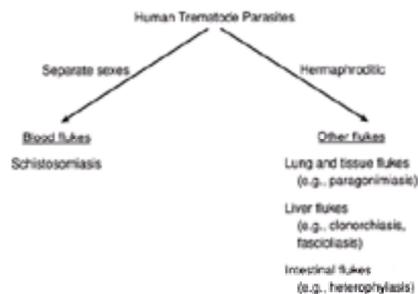

FIGURE 334.1. Human trematode parasites.

EPIDEMIOLOGIC FACTORS

Mature schistosomal worms, like most other helminthic parasites, cannot multiply inside the human host. Therefore, environmental factors that promote continued patient exposure to infected water can help to determine the intensity of chronic infection. Areas endemic for schistosomiasis are characterized by three factors: the presence of a reservoir of human infection, the availability of suitable snail intermediate hosts, and socioeconomic conditions or breaks in sanitation that allow contamination of and exposure to local bodies of water. *Schistosoma* species are endemic within specific geographic regions: *S. mansoni* in Africa, the Middle East, the Caribbean (including Puerto Rico), and South America; *S. haematobium* in Africa and the Middle East; *S. japonicum* in the Far East; *S. mekongi* in scattered foci in Southeast Asia; and *S. intercalatum* in Central and West Africa.

Typical epidemiologic features of schistosomiasis include an increase in age-specific prevalence from birth to about 15 to 20 years. This is followed by a small but significant decline in prevalence in older age groups. In distinction, estimates of intensity of infection (based on standardized egg counts) indicate that worm burden increases progressively up to 15 to 20 years of age, after which there is a dramatic decline in intensity of infection among adults. This decrease has been taken as evidence that older individuals acquire immunity to infection with time, but it also may reflect changes in water use and duration of water contact in older age groups. The distribution of infection intensity in endemic populations is not uniform: most infected individuals (50% to 75%) carry light infections, and a small percentage (1% to 5%) carry extremely heavy infections and pass thousands of eggs daily. This is clinically significant in that morbidity from parasitic infection is correlated with infection intensity. Disease caused by schistosomal infection is more common in children and young adults, and is particularly common among those few individuals who have heavy infections.

ETIOLOGIC FACTORS

Schistosomal infection is acquired when humans enter bodies of fresh water that contain infected snails ([Fig. 334.2](#)). Free-swimming schistosome cercariae, released by these snails, seek human skin and penetrate through the epidermis to initiate infection. Cercarial transformation into schistosomula is completed in the dermis or capillary circulation. During the next 6 to 9 weeks, maturing schistosomula migrate through the lungs, liver, and other tissues to reach their final destination in the portal, periureteral, or perivesicular veins. Individual schistosomula mature into male or female worms. After mating, mature female worms deposit several hundred (*S. haematobium*, *S. mansoni*) to several thousand (*S. japonicum*) eggs each day into the host's venous circulation. About half of the deposited eggs are trapped permanently within host tissues. The remainder penetrate through the tissues to reach the lumina of the ureters or bowel. Eggs mixed with feces or urine then pass into the environment to reach bodies of freshwater. There the eggs hatch, releasing motile miracidia that in turn infect snail intermediate hosts to complete the parasite life cycle. Miracidia in the snail tissues undergo extensive (200- to 400-fold) asexual multiplication, then transform into cercariae (the parasite stage that is infective for humans).

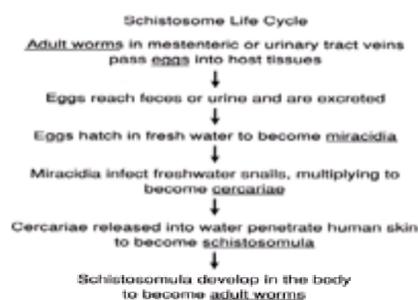

FIGURE 334.2. Schistosome life cycle.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Disease caused by schistosomal infection is the result of many factors, the most significant of which is the interaction of the host immune response with the parasite and its eggs. Clinical manifestations are related to the duration and intensity of previous exposure, the intensity of current infection, and the age, gender, and nutritional status of the infected host. The earliest form of disease, *cercarial dermatitis*, is seen most commonly after exposure to *S. haematobium*, *S. mansoni*, or the avian schistosomal species. Clinically, it is manifested by a maculopapular eruption in the areas of skin exposed to cercariae-infested water. The dermatitis is caused

by an immediate or late cutaneous hypersensitivity reaction that begins 1 or 2 days after exposure and lasts for a few days. Symptoms are reported more commonly by newcomers to an endemic area than by local inhabitants. Cercarial dermatitis is self-limited and responds to local care.

The migratory period and the early phases of parasite egg deposition are associated, in some infected individuals, with *acute schistosomiasis* (also known as snail fever or Katayama fever). This syndrome is seen most commonly in travelers from temperate zones who visit areas in which schistosomiasis is endemic. In acute schistosomiasis, patients have fever, generalized lymphadenopathy, hepatosplenomegaly, and peripheral blood eosinophilia. The cause of the syndrome may be related to allergic hypersensitivity to the parasite and to the formation of soluble immune complexes that cause an illness resembling serum sickness. Although usually self-limited and rarely fatal, the disease manifestations can be severe and may be exacerbated by antiparasitic therapy. Symptomatic treatment with anti-inflammatory agents is recommended before treatment of the parasitic infection.

The next phase of disease, called *chronic schistosomiasis*, develops as parasite eggs remaining in host tissues become surrounded by a delayed-type hypersensitivity granulomatous inflammation formed by host lymphocytes, eosinophils, and macrophages. This response, regulated by acquired humoral and cellular immunity, kills and destroys the eggs. Subsequent resolution of the inflammation is, however, associated with the deposition of collagen scar. The accumulation of scar tissue within an organ, especially near vascular beds, can lead to significant venous hypertension or organ dysfunction. In addition, inflammation near the ureters and bowel wall can lead to ulceration and significant blood loss into the urine or feces, resulting in iron and protein malnutrition. In chronic schistosomiasis, the severity of disease is determined both by the intensity of parasite infection and by the intensity of host immunity; paradoxically, disease often is modulated by a spontaneous down-regulation of host cell-mediated immune response to parasite eggs.

The clinical syndromes associated with chronic schistosomiasis occur months to years after initial infection. They are species-dependent because different anatomical locations are preferred by different parasite species. Occasionally, unusual symptomatology is related to the aberrant migration of developing worms (e.g., in the central nervous system) or is a by-product of host immune response, as in glomerulonephritis related to the deposition of immune complexes in the kidney.

For *S. haematobium* infection, the main clinical symptoms are related to egg deposition in the bladder and lower ureters. More than half of those infected complain of dysuria, frequency, and terminal hematuria. Evidence of obstructive uropathy can be demonstrated by ultrasonographic or contrast radiographic examination. Findings include bladder wall thickening, granulomas, calcification, hydroureter, and hydronephrosis. In some endemic areas, there is an epidemiologic association between *S. haematobium* infection and squamous cell carcinoma of the bladder. During the course of chronic *S. haematobium* infection, repeated bacteremia, particularly with *Salmonella* species, also may be observed.

In individuals infected with *Schistosoma* species that localize to the intestinal circulation (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*), two stages of disease can evolve. The more common and milder form of disease usually manifests as cramping abdominal pain and diarrhea, which may contain blood. The less common presentation of severe disease includes hepatosplenomegaly, portal hypertension, and hematemesis. Unlike postviral or alcoholic cirrhosis, liver disease caused by mesenteric schistosomes is a unique form of presinusoidal fibrosis that preserves liver function until late in the course of illness. Characteristic *Schistosoma*-associated organ damage is readily detected on ultrasonographic examination. Because hepatocyte nutrition and respiration are preserved (as a result of arterialization of the liver blood supply), most organ functions remain normal. Only late in *Schistosoma*-induced liver disease or when intercurrent insults such as viral hepatitis intervene is there evidence of widespread liver cell damage.

Other syndromes associated with chronic schistosomal infection include cor pulmonale and central nervous system (CNS) disorders. Cor pulmonale occurs in *S. mansoni* or *S. japonicum* infection after the onset of portosystemic shunting; because of retrograde venous flow, parasite eggs are swept into the pulmonary circulation, causing local pneumonitis and vascular hypertension. CNS disorders associated with schistosomiasis are caused by the inadvertent deposition of eggs into the brain, spinal cord, meninges, or ventricles. Resulting syndromes include seizures, transverse myelitis, cord compression, and hydrocephalus. Other sites of schistosomal egg deposition (skin and genital tracts) have been described, along with associated inflammatory disorders, but these are rare.

OPTIMAL MANAGEMENT

The preferred method for diagnosing schistosomiasis is by identification of parasite eggs in urine or feces. Nucleopore filtration of urine or Kato thick smear of fecal samples provides an effective concentration of eggs and an appropriate measurement of egg output. In individuals with low worm loads or low egg excretion rates, examination of tissue biopsy material may be necessary to diagnose infection. Rectal snips are less invasive than bladder or liver biopsies and are obtained more easily in general practice. The identification of schistosomal eggs in tissue or excreta is based on their size and characteristic morphology. *S. haematobium* eggs measure 140 × 60 μm and have a terminal spine, whereas *S. mansoni* eggs measure 150 × 60 μm but have a lateral spine. *S. japonicum* eggs are 90 × 60 μm with a terminal knob that often is not seen. *S. mekongi* organisms resemble *S. japonicum* but are smaller (about 57 μm). *S. intercalatum* organisms are 170 × 58 μm in size, with a terminal spine similar to that of *S. haematobium*. *S. intercalatum* eggs can be distinguished from *S. haematobium* eggs by positive Ziehl-Neelsen staining after fixation in Bouin's fluid. In individuals who have been treated for infection or who have only remote exposure to infection, nonviable eggs may be passed in excreta or detected in biopsy specimens. This finding may or may not reflect active infection, and viability testing by vital staining or miracidial hatching may be necessary to establish the presence of active infection.

Serologic tests for *Schistosoma* infection are available. When used in schistosomiasis-endemic areas, serologic testing tends to be sensitive but not specific for active infection. In this setting, a negative serologic test result is useful to exclude exposure, but a positive result does not establish infection. In travelers from nonendemic zones who have had only brief, defined periods of exposure, positive serologic test results may prove useful in establishing the presence of infection. Serologic testing also is useful in demonstrating previous exposure in patients who have aberrant manifestations of disease (e.g., cerebral disease) and no other evidence of active infection on tissue biopsy or on stool and urine examination.

Antischistosomal treatment should be given to all individuals with active schistosomal infection and to all individuals with manifestations of chronic schistosomiasis who have not previously received specific chemotherapy. The drug of choice is praziquantel, which is active against all *Schistosoma* species that infect humans. Praziquantel is administered orally at 40 mg per kilogram as a single dose for *S. haematobium*, *S. mansoni*, and *S. intercalatum*, or at 60 mg per kilogram in two or three divided doses over a day for *S. japonicum* and *S. mekongi*. Praziquantel treatment has a high degree of effectiveness (70% to 90% cure) with limited side effects. Specific therapy results in the eradication of adult parasites and, if given early in the course of infection, can result in the reversal of infection-associated morbidity, including hepatosplenomegaly, bladder deformity, and hydronephrosis. In older individuals with established fibrotic or obstructive sequelae, reversal of pathologic changes may not be possible. Other supportive endoscopic or surgical interventions may be necessary, particularly for hematemesis, hepatic cell failure, or bladder carcinoma.

Travelers visiting areas in which *Schistosoma* is endemic can avoid infection by staying out of infected bodies of freshwater. For practical purposes, all bodies of freshwater in endemic areas, whether still (ponds, lakes) or flowing (rivers, streams), should be considered infected and should be avoided. No other prophylactic measures are available.

Control of schistosomal infection and infection-associated morbidity has proven an elusive goal in most endemic areas. Attempts at using chemicals to kill vector snails have not provided consistent or long-lasting results. In contrast, chemotherapy given selectively to those with heavy infection (e.g., school-age children) has resulted in significant reductions in transmission and in the prevalence of infection-associated morbidity. With the development of safe, orally administered, effective antischistosomal agents, this control modality assumes an important role.

LIVER, LUNG, AND INTESTINAL FLUKES

DEFINITION

The tissue and intestinal flukes that commonly cause human disease are listed in [Table 334.1](#). These trematode parasites have a complex life cycle that involves the passage of parasite eggs (in sputum or feces) into freshwater or brackish water, the infection of an intermediate aquatic snail host, and the release of parasite larvae (cercariae) from infected snails. Cercariae of the tissue and intestinal flukes must encyst as metacercariae in a second intermediate host (water plants, fish, crabs, crayfish, or insects) and be consumed to produce human infection.

edema of the trunk, face, and extremities, with ascites.

OPTIMAL MANAGEMENT

The diagnosis of liver fluke infection should be considered in individuals with the triad of fever, hepatomegaly, and eosinophilia. For established intrabiliary infections, the diagnosis is made by examination of stool or duodenal aspirates for parasite eggs. Density separation and egg concentration techniques enhance the sensitivity of egg detection in light infections. In endemic areas, it is important to restrict the patient's diet before testing to exclude spurious recovery of eggs in the stool resulting from the consumption of meat (especially liver) from infected animals. Early or ectopic infection requires serologic testing (which is not completely sensitive or specific) or surgical biopsy to establish the diagnosis.

The diagnosis of lung fluke infection is suggested by a history of travel or residence in an endemic area and by the presence of a chest x-ray film containing patchy infiltrates or ringlike shadows (early disease), or pleural thickening and calcification (late disease). The diagnosis should be confirmed by sputum and stool examination for parasite eggs. Nonpulmonary infection may require serologic testing or biopsy to establish the diagnosis.

The diagnosis of intestinal fluke infection is made by parasitologic examination of stool or duodenal aspirates for parasite eggs, or by fluke recovery on endoscopy.

The recommended therapy for all active fluke infections (except *F. hepatica*) is praziquantel (25 mg per kilogram 3 times a day for 1 or 2 days). To ensure cure, follow-up stool or sputum examinations should be obtained 1, 6, and 12 months after therapy, and a second praziquantel regimen should be given if the first course is unsuccessful. Localized or generalized inflammatory lesions, particularly of the CNS, may require corticosteroid therapy or surgical removal to relieve symptoms. Although praziquantel therapy may prove successful in some cases of *F. hepatica* infection, the drug of choice for *F. hepatica* is bithionol (30 to 50 mg per kilogram given on alternate days, for a total of 10 to 15 doses). In the United States, bithionol is classified as an investigational drug and is obtained through the U.S. Centers for Disease Control and Prevention in Atlanta, Georgia. Successful therapy of *F. hepatica* and of paragonimiasis has also been reported with the investigational drug triclabendazole (see WHO Fact Sheet 191, April 1998; www.who.int/inffs/en/fact191.html).

CHAPTER 335: ANTIMICROBIAL THERAPEUTIC AGENTS

WILLIAM A. CRAIG

[Factors That Influence Antimicrobial Selection and Outcome of Therapy](#)
[Individual Agents](#)
[Other Agents](#)

In the 60 years since the beginning of the modern era of chemotherapy, a large variety of antimicrobial agents have become available for the treatment and prevention of infectious diseases. The introduction of sulfonamides in 1936 was followed by penicillin, the first β -lactam antibiotic, in the early 1940s. The “golden era” for antimicrobial agents during the 1950s saw the introduction of chloramphenicol, erythromycin, streptomycin, and tetracycline. The emergence of penicillin-resistant staphylococci led to the discovery of new agents, such as methicillin, cephalothin, lincomycin, and vancomycin. Similarly, the emergence of multiply resistant gram-negative bacilli stimulated the search for ampicillin, gentamicin, and nalidixic acid. During the past 25 years, most new antimicrobials have been modifications of older agents and provide enhanced antimicrobial activity or improved pharmacokinetic characteristics. This has led to antimicrobials with potent activity against *Pseudomonas aeruginosa* and other gram-negative bacilli, enhanced penetration into the cerebrospinal fluid (CSF), prolonged elimination half-lives, and excellent oral absorption. Despite the large number of available agents, the emergence of multiply resistant pneumococci, staphylococci, enterococci, and mycobacteria demonstrates a need for further antimicrobials, including those with new sites of action.

FACTORS THAT INFLUENCE ANTIMICROBIAL SELECTION AND OUTCOME OF THERAPY

INFECTING ORGANISM AND SUSCEPTIBILITY TESTING

Cultures obtained from appropriate sites of patients with suspected infection and the Gram's stains of these cultures usually identify the infecting pathogen. Because therapy often is required before culture and susceptibility test results are known, the clinician must formulate the probable pathogens for the site and severity of infection and the underlying diseases in the patient. Knowledge of the local susceptibility patterns helps the clinician decide whether initial therapy should address the possibility of special problem pathogens, such as penicillin-resistant *Streptococcus pneumoniae* and methicillin-resistant *Staphylococcus aureus*. Subsequent modifications in therapy are made after the culture and susceptibility findings are known.

The standard method for measuring antimicrobial activity in vitro is determination of the *minimal inhibitory concentration* (MIC) and the *minimal bactericidal concentration* (MBC). By definition, the MIC is the lowest concentration of drug that prevents visible bacterial growth over an 18- to 24-hour incubation period. The MBC is the lowest concentration that kills 99.9% of the organisms over the same period. In the past, these determinations were too complicated and time-consuming to be used routinely in clinical microbiology laboratories. Instead, qualitative methods, such as the disk diffusion test, were used to classify organisms as susceptible, intermediate, or resistant. Automated techniques now allow many laboratories to report MIC values routinely. MBC determinations also can be performed readily, but usually are reserved for infections in which bactericidal activity is necessary. In general, the MBC of a bactericidal agent is one to four times the MIC. An organism that is not killed by an antibiotic that usually kills that species is said to be tolerant; *tolerance* usually is defined as an MBC greater than 16 times the MIC.

ANTIMICROBIAL RESISTANCE

A major limitation to the continued success of almost all antimicrobial agents has been the emergence of resistance. The mechanisms of resistance are varied and include drug inactivation, alteration of the drug's site of action, decreased permeability of the outer cell membrane, and active drug efflux from the cell. The genes that account for these resistance mechanisms are acquired by the mutation of existing DNA or by the acquisition of new DNA. For example, the emergence of resistance in staphylococci and mycobacteria to rifampin is by mutation, whereas the resistance in gonococci and *Haemophilus influenzae* to penicillins is by the acquisition of genes encoding β -lactamases. New genes mediating resistance usually are spread from organism to organism by plasmids or *transposons*, the so-called jumping genes. The ability of different bacteria to share certain antibiotic resistance genes explains the remarkable speed at which some resistance mechanisms spread and increase.

SITE OF INFECTION AND HOST DEFENSES

Most tissues in the body are supplied by capillaries with pores that readily allow the passage of antimicrobials. If therapeutic drug concentrations can be obtained in serum, they usually can be obtained at most extracellular sites of infection. Even antimicrobial penetration into abscesses usually is adequate, although low pH and other factors may reduce drug efficacy when drainage is not performed. Foreign bodies such as prosthetic valves and prosthetic hips provide niduses where bacteria can be protected from antibiotics.

The penetration of antimicrobial agents into cells and into tissues that lack porous capillary beds, such as the central nervous system and ocular vitreous humor, depends much more on the lipid solubility of the drugs than on their pharmacokinetics in serum. Rifampin and the macrolides are examples of drugs with high intracellular penetration and activity against intracellular pathogens, such as mycobacteria and *Legionella pneumophila*. The most important factor for increasing antibacterial concentrations in the CSF is inflammation. For drugs such as penicillin G and ampicillin, inflammation enhances the influx of drug into the CSF and reduces the active transport of drug from the CSF. Rifampin, metronidazole, and chloramphenicol are examples of lipid-soluble drugs that have adequate CSF penetration in the absence of inflammation. The aminoglycosides, clindamycin, and the early cephalosporins are drugs that exhibit marginal or inadequate penetration even with inflamed meninges.

Whether a drug is bacteriostatic or bactericidal has little importance for many infections. The antimicrobial drug needs only to slow or inhibit the growth of the organism, because the body's host defenses (neutrophils, macrophages, antibodies) will kill and eliminate the infecting pathogen. However, endocarditis, meningitis, and osteomyelitis are infections that occur in areas of impaired host defenses. Bactericidal drugs are required for effective treatment of these infections. Patients with neutropenia or significant defects in neutrophil function also should receive bactericidal drugs.

PHARMACODYNAMICS AND DOSING REGIMEN

Although MIC and MBC values can reflect the potency of different antimicrobials against a pathogen, these parameters poorly describe the time course of antimicrobial activity. The MBC does not express the rate of bacterial killing and whether it can be enhanced by increasing concentrations. For some drugs, such as the aminoglycosides and the fluoroquinolones, bactericidal activity is concentration-dependent. The higher the drug level, the faster is the rate of killing. The ratios of the peak concentration or the area under the serum concentration-versus-time curve (AUC) to the MIC are important determinants of efficacy for these drugs. On the other hand, bacterial killing with β -lactams usually is slower, with little dependence on the drug concentration. The duration of time that drug concentrations exceed the MIC is the major determinant of efficacy for the β -lactams.

Another potentially important parameter not assessed by MIC and MBC testing is the postantibiotic effect. This term refers to a persistent suppression of bacterial growth after limited drug exposure. The presence or absence of a postantibiotic effect may be an important determinant of the frequency of antimicrobial dosing. Some antimicrobials, such as the aminoglycosides exhibit prolonged postantibiotic effects with gram-negative bacilli, which provide a rationale for widely spaced dosing regimens. In contrast, β -lactams produce short or no postantibiotic effects with gram-negative bacilli. The frequency of dosing with these drugs depends largely on the speed at which they are eliminated from the body.

Parenteral administration is preferred in serious infections and those that require high dosages, such as endocarditis and meningitis. The high oral bioavailability of certain antimicrobials makes oral therapy an acceptable alternative to parenteral therapy for certain moderately severe infections. For example, the fluoroquinolones are effective orally for the treatment of osteomyelitis. In the setting of renal impairment, the dose or frequency of administration of an antimicrobial may need to be reduced. Any drug that is excreted primarily unchanged in the urine requires a downward adjustment in proportion to the decrease in renal function. Similar modifications are necessary in the setting of hepatic impairment for antimicrobials with major hepatic metabolism or biliary excretion. The usual dosage regimens for

the various antimicrobial drugs and the need for dosage modification in patients with renal and hepatic impairment are shown in [Table 335.1](#).

TABLE 335.1. PHARMACOLOGIC ASPECTS OF SELECTED ANTIMICROBIAL AGENTS

ANTIBIOTIC COMBINATIONS

The primary reason for using drugs in combination is to enhance antimicrobial activity. For example, the addition of an aminoglycoside to penicillin improves the killing effect against most enterococci. This combination also results in better efficacy for enterococcal endocarditis than is obtained with monotherapy. Antimicrobial combinations also are used to treat mixed infections, to broaden coverage in infections with unknown causes, and to prevent the emergence of resistant organisms. Tuberculosis is the primary infection for which drug combinations have been shown to prevent the emergence of resistant organisms.

The major disadvantages of antimicrobial combinations are the added cost and enhanced side effects. Furthermore, the combination of bacteriostatic and bactericidal drugs can exhibit antagonism, as has been shown with the use of penicillin plus tetracycline for pneumococcal meningitis.

INDIVIDUAL AGENTS

b-LACTAMS

The b-lactam antibiotics are the most commonly used antimicrobial agents because of their high potency, low incidence of serious adverse reactions, and proven effectiveness. All members of the group contain the four-member b-lactam ring that must remain intact to express antimicrobial activity. Variation in the rings attached to the b-lactam ring divides the b-lactams into various subgroups (penicillins, cephalosporins, carbapenems, and monobactams). The further addition of different side chains to the basic nucleus generates analogues with altered in vitro activity and pharmacokinetic properties. The in vitro activities of selected b-lactams are shown in [Table 335.2](#).

TABLE 335.2. RELATIVE IN VITRO ACTIVITIES OF SELECTED b-LACTAMS

Penicillins

The penicillins can be divided into three main groups: the natural penicillins, the penicillinase-resistant penicillins, and the extended-spectrum penicillins.

Mechanisms of Action and Resistance

Penicillins inhibit growth by interfering with the synthesis of the cell wall. Penicillins bind covalently to various enzymes (also called penicillin-binding proteins) involved in cell wall synthesis. For most bacteria, inhibition of cell wall synthesis indirectly activates bacterial enzymes (murein hydrolases) that cause killing by cell lysis.

The primary mechanism for resistance to the penicillins is enzymatic cleavage of the b-lactam ring by b-lactamases. Most penicillins are susceptible to inactivation by the penicillinase produced by most strains of *S. aureus*. Penicillinase production in staphylococci is plasmid mediated and apparently has spread to enterococci. In gram-negative bacilli, b-lactamases are located in the periplasmic space between the outer and inner cell membranes. In general, the extended-spectrum penicillins have enhanced penetration across the outer membrane rather than a reduced rate of drug inactivation. The spread of b-lactamase genes among the Enterobacteriaceae and to *H. influenzae* and *Neisseria gonorrhoeae* has greatly altered susceptibility to the penicillins. The selection of stable clones that produce large amounts of a chromosomally mediated b-lactamase has increased resistance to penicillins in *P. aeruginosa*.

New or altered penicillin-binding proteins with decreased affinity for penicillin also can lead to the development of resistance. This mechanism accounts for methicillin resistance in staphylococci and penicillin resistance in pneumococci and other streptococci. Altered permeability of the outer membrane of gram-negative bacilli provides another mechanism for resistance to the penicillins. Organisms that exhibit tolerance to the killing activity of penicillins, such as the enterococci, appear to have reduced or altered autolytic activity with exposure to these drugs.

Activity and Clinical Use

Penicillin G is still the drug of choice for many streptococcal infections, meningococcal infections, actinomycosis, anthrax, rat-bite fever, erysipeloid, fusospirochetal infections, gas gangrene, tetanus, *Pasteurella multocida* infections, periodontal infections, leptospirosis, and treponemal infections, including all stages of syphilis. Penicillin V has a similar spectrum of activity against gram-positive organisms, but is less active than penicillin G against gram-negative bacteria.

The penicillinase-resistant penicillins include methicillin, nafcillin, oxacillin, cloxacillin, and dicloxacillin. These agents have bulky side chains that greatly reduce their susceptibility to inactivation by penicillinase. They are the drugs of choice for infections caused by *S. aureus*, except for methicillin-resistant strains. Penicillinase-resistant penicillins are slightly less potent than penicillin G against streptococci.

Ampicillin and amoxicillin have a spectrum of activity similar to that of penicillin G, except that they are more potent against certain gram-negative bacteria, including *Escherichia coli*, *Proteus mirabilis*, *Shigella*, *Salmonella*, and *H. influenzae*. Amoxicillin is also the most potent penicillin against penicillin-resistant pneumococci.

These drugs provide effective therapy for otitis media, sinusitis, and exacerbations of chronic bronchitis. Their use for severe *H. influenzae* infections, *Salmonella* and *Shigella* infections, and urinary tract infections has been reduced by the appearance of resistant strains. Ampicillin is preferred over penicillin G for enterococcal and listerial infections.

Even greater activity against gram-negative bacteria is obtained with carbenicillin, ticarcillin, mezlocillin, and piperacillin. Carbenicillin is available only in an oral form used for urinary tract infections. Ticarcillin, mezlocillin, and piperacillin are used to treat serious gram-negative infections, including those caused by *P. aeruginosa*. Piperacillin is more potent than ticarcillin and mezlocillin against *P. aeruginosa*, but this has not resulted in any major increase in clinical efficacy.

Pharmacology

Penicillin G and several other penicillins are unstable in acid and largely restricted to parenteral administration. Penicillin V, amoxicillin, cloxacillin, and dicloxacillin are acid stable and are the major penicillins used orally. The indanyl ester of carbenicillin is also well absorbed.

The distribution of the penicillins within the body is governed to some degree by the extent of protein binding. Avidly bound drugs tend to exhibit high serum levels and low tissue concentrations. In general, the penicillins are confined to extracellular fluids. Concentrations of unbound drug in various tissues and inflammatory fluids are close to those in serum. In the absence of infection, penetration into the CSF is less than 3%; infection usually results in adequate CSF levels for the common organisms producing meningitis, except penicillin-resistant pneumococci.

Penicillins are eliminated primarily by glomerular filtration and tubular secretion. They also are excreted into bile, but only nafcillin, oxacillin, cloxacillin, dicloxacillin, mezlocillin, and piperacillin exhibit significant elimination by this route. Because the elimination half-life of the penicillins varies from only 30 to 60 minutes, the usual dosing intervals for these drugs are 4 to 6 hours.

Benzathine and procaine salts of penicillin G are relatively insoluble preparations that are absorbed slowly from intramuscular injection sites. These formulations result in lower, more sustained serum concentrations than those obtained with aqueous penicillin G. Serum concentrations of benzathine penicillin are so low that this preparation is used only for syphilis and streptococcal pharyngitis and for prophylaxis against rheumatic fever.

Adverse Reactions

Hypersensitivity reactions are the most common adverse effects of the penicillins. Immediate hypersensitivity reactions vary from mild urticaria to severe anaphylaxis. Morbilliform rashes also are common, especially with ampicillin and in patients with infectious mononucleosis or those receiving concomitant allopurinol. Erythema multiforme, vasculitis, serum sickness, drug fever, and Coombs'-positive hemolytic anemia are uncommon adverse effects of the penicillins. Adverse reactions with an increased incidence for specific drugs are hepatotoxicity with oxacillin, interstitial nephritis with methicillin, and neutropenia with nafcillin. Platelet dysfunction can result from high doses of ticarcillin, but clinical bleeding is rare. Neurotoxicity also can be seen with high-dose penicillin therapy, particularly in patients with renal impairment. Drug interactions with the penicillins are uncommon.

b-LACTAMASE INHIBITORS

Clavulanic acid, sulbactam, and tazobactam are b-lactams with weak antibacterial activity. However, they are potent, irreversible inhibitors of the b-lactamases of staphylococci, *Bacteroides fragilis*, *Klebsiella*, and most of the common plasmid-mediated enzymes found in *H. influenzae*, *E. coli*, and other gram-negative bacteria. They do not inhibit the chromosomal b-lactamases produced by *Enterobacter*, *Citrobacter*, *Serratia*, and *Pseudomonas*.

The combinations of amoxicillin with clavulanic acid and ampicillin with sulbactam have been useful for otitis media, sinusitis, and lower respiratory tract infections caused by *H. influenzae* and *Moraxella catarrhalis*. They are effective in staphylococcal and streptococcal skin infections and in bite wound infections. Ticarcillin with clavulanic acid and piperacillin with tazobactam have provided effective therapy in nosocomial pneumonia, intra-abdominal infections, and severe skin and soft-tissue infections. The half-lives of clavulanic acid, sulbactam, and tazobactam are similar to those of the penicillins with which they are combined. Their adverse reactions also are similar to those of the penicillins, except that amoxicillin with clavulanic acid produces more diarrhea than does amoxicillin alone.

Cephalosporins

The cephalosporins differ from the penicillins in that they have another site for the attachment of side chains that can alter the activity or pharmacology of the drug. The cephalosporins can be divided into four generations based on variations in antimicrobial activity.

Mechanisms of Action and Resistance

The cephalosporins inhibit cell wall synthesis and exhibit bactericidal activity by the same mechanisms as do the penicillins. Resistance to the cephalosporins results from b-lactamase production, decreased permeability, and altered penicillin-binding proteins. b-Lactamases that hydrolyze the cephalosporins are encoded on the chromosomes of certain gram-negative bacilli, especially *Enterobacter* and *Pseudomonas* species. Mutation of the regulatory genes controlling the synthesis of these enzymes can lead to overproduction and resistance to the cephalosporins. Mutations of common plasmid-mediated b-lactamases that hydrolyze penicillins have extended their spectrum to include many cephalosporins. These enzymes, found primarily in *Klebsiella* species and *E. coli* are called *extended-spectrum b-lactamases* (ESBLs).

Activity and Clinical Use

The first-generation cephalosporins are active against staphylococci, most streptococci, *E. coli*, *Klebsiella pneumoniae*, and *P. mirabilis*. However, these drugs are used primarily as an alternative to penicillin for staphylococcal and streptococcal infections and for surgical prophylaxis. The second-generation cephalosporins can be divided into two groups. Cefoxitin, cefotetan, and cefmetazole have increased activity against *B. fragilis* and are used primarily for the prevention and treatment of mixed aerobic and anaerobic infections. The other group of drugs includes many oral and parenteral cephalosporins with increased activity against *H. influenzae*, including b-lactamase-producing strains. These drugs are used for upper and lower respiratory tract infections. The third-generation cephalosporins are 10 to 100 times more potent against enteric bacteria than are the earlier cephalosporins. Ceftazidime and cefoperazone also have activity against *P. aeruginosa*. These drugs are used for a variety of serious gram-negative bacillary infections. All the third-generation drugs are less active against gram-positive bacteria than are the first-generation cephalosporins. Cefepime, a fourth-generation cephalosporin, combines the activity of first- and third-generation cephalosporins, as well as being less susceptible to chromosomal b-lactamases in gram-negative bacilli. Enterococci and *Listeria* remain resistant to all the cephalosporins.

Pharmacology

The pharmacology of the cephalosporins is similar to that of the penicillins, with a few exceptions. The half-lives of most of the second-, third- and fourth-generation agents are longer than those of the penicillins. Ceftriaxone, cefonicid, cefotetan, ceforanide, and cefixime have half-lives ranging from 3 to 8 hours, which allows for once- or twice-daily dosing. Although most cephalosporins are eliminated by the kidney, cefoperazone and ceftriaxone are excreted extensively into bile. Cefuroxime and all the third-generation drugs, except cefoperazone, provide adequate CSF concentrations in the presence of inflamed meninges and are approved for bacterial meningitis. The third-generation drugs also are effective for gram-negative meningitis.

Adverse Reactions

The cephalosporins can produce the same adverse reactions as the penicillins. Allergic reactions are most common, and cephalosporins usually are avoided in patients with prior anaphylactic reactions to penicillins. Prolongation of the prothrombin time and a disulfiram-like reaction can occur with drugs that have a methylthiotetrazole side chain. This includes cefamandole, cefmetazole, cefoperazone, and cefotetan. Superinfection with enterococci, including vancomycin-resistant strains, has also been associated with use of the third-generation cephalosporins.

Carbapenems

of gastrointestinal infections, including traveler's diarrhea and bacterial gastroenteritis.

Pharmacology

All the quinolones are well absorbed orally, and most are eliminated by urinary excretion. Grepafloxacin, moxifloxacin, sparfloxacin, and trovafloxacin have major hepatic clearance. The quinolones are distributed widely in tissues and body fluids, including the CSF. Intracellular concentrations are higher than serum levels, which accounts for their activity against intracellular pathogens. The elimination half-lives of the quinolones vary from 3 to 4 hours for norfloxacin and ciprofloxacin to 6 to 18 hours for other quinolones. This permits once- to twice-daily dosing of these drugs.

Adverse Reactions

The incidence of adverse effects to the quinolones is low, with gastrointestinal disturbances being most common. Central nervous system reactions such as dizziness, headache, and insomnia can occur, but seizures are rare. Nephrotoxic reactions caused by crystalluria and hepatotoxicity also are rare. Moderate to severe phototoxicity is observed infrequently, primarily with lomefloxacin and sparfloxacin. Enoxacin and, to a lesser extent, ciprofloxacin and grepafloxacin increase theophylline and caffeine levels. Because the quinolones have been reported to produce cartilage damage in young animals, none of these drugs is approved for use in children.

OTHER AGENTS

VANCOMYCIN

Vancomycin is a glycopeptide antibiotic that inhibits cell wall synthesis at an earlier step than do the β -lactam drugs. Vancomycin is active against most gram-positive bacteria, including methicillin-resistant *S. aureus* and *Staphylococcus epidermidis*, penicillin-resistant pneumococci, *Clostridium difficile*, and enterococci; gram-negative organisms usually are resistant. The increased use of vancomycin over the past decade has contributed to the emergence of vancomycin-resistant enterococci. Resistance can occur by several mechanisms and may be transferred by plasmids and transposons.

Because of its poor absorption, vancomycin can be used orally for the treatment of *C. difficile* colitis. After intravenous administration, it distributes to most body fluids and has marginal to adequate penetration into the CSF in the presence of inflamed meninges. The drug is eliminated almost entirely by the kidney, with a half-life of 6 hours. In patients with normal renal function, dosing is every 12 hours. The dosing frequency in patients with renal impairment is determined by drug level monitoring.

Vancomycin use has been associated with nephrotoxicity and ototoxicity, but this problem has decreased with more recent and purer preparations. Rapid infusion can cause histamine release that produces a syndrome somewhat similar to anaphylaxis. Even with slower infusion, thrombophlebitis can occur.

MACROLIDES

Erythromycin, clarithromycin, dirithromycin, and azithromycin are bacteriostatic agents that inhibit protein synthesis. Resistance among gram-positive cocci usually results from methylation of the ribosomal site of action, which prevents the binding of all three macrolides. Resistance resulting from active efflux and drug inactivation also has been described. The macrolides are broad-spectrum agents with primary activity against gram-positive bacteria. The newer macrolides, clarithromycin and azithromycin, have increased activity against *H. influenzae* and nontuberculous mycobacteria. Erythromycin is used clinically for mild to moderate streptococcal and staphylococcal infections, *Legionella* infections, *Mycoplasma* and *Chlamydia* pneumonitis, *Campylobacter* enteritis, and pertussis. The broader spectrum of activity of the newer agents has fostered their use for a variety of upper and lower respiratory tract infections. These drugs also have become major agents in the treatment and prophylaxis of atypical mycobacterial infections.

The macrolides, especially the newer agents, are absorbed adequately after oral dosing. The drugs are well distributed to most tissues and body fluids; the high intracellular tissue concentrations account for their efficacy against intracellular pathogens. Most of the drug is excreted in the bile. The half-lives vary from 1.5 hours for erythromycin to more than 24 hours for azithromycin. As a result, erythromycin, clarithromycin, and azithromycin usually are given every 6, 12, and 24 hours, respectively. Erythromycin is an extremely safe drug, although gastrointestinal disturbances with oral use and thrombophlebitis with intravenous administration are common. The incidence of gastrointestinal symptoms is decreased markedly with the newer macrolides.

CLINDAMYCIN

The mechanism of action and resistance of clindamycin is similar to that of the macrolides. It is active against most staphylococci, streptococci, and anaerobes. The drug also has activity against *Pneumocystis carinii*, *Toxoplasma gondii*, and *Plasmodium falciparum*. It is used primarily in anaerobic infections, especially lung abscesses, and as an alternative agent in mild to moderate streptococcal and staphylococcal infections.

Clindamycin is well absorbed orally; it is widely distributed in most tissues, but penetrates poorly into the CSF. The drug is metabolized in the liver and excreted largely in the bile. The major complication of clindamycin therapy is the development of antibiotic-associated colitis resulting from the overgrowth of *C. difficile*. This problem is not unique to clindamycin and has been observed with many other antimicrobial agents.

TETRACYCLINES

The tetracyclines are bacteriostatic agents that inhibit protein synthesis. Resistance results primarily from the acquisition of genes that cause active efflux of the drug from the cell. The tetracyclines have a broad spectrum of antimicrobial activity. They are useful drugs for sexually transmitted diseases, such as nongonococcal urethritis, granuloma inguinale, and lymphogranuloma venereum. The drugs also are indicated for rickettsial infections, Lyme disease, brucellosis (with streptomycin or rifampin), *Mycoplasma* and *Chlamydia* pneumonitis, and chronic bronchitis. In addition, the tetracyclines are used as alternative agents for infections such as syphilis, plague, and malaria.

All the tetracyclines are well absorbed orally; doxycycline and minocycline are the least affected by food. These agents also have the longest half-lives, allowing for once- or twice-daily dosing. Although the older tetracyclines are excreted largely by the kidneys, doxycycline and minocycline are eliminated primarily in the bile. Because tetracycline can worsen azotemia by inhibiting protein synthesis, dosage modification is required even in patients with mild renal impairment. Doxycycline does not accumulate in patients with renal failure and can be used safely without dosage adjustment. High doses of tetracycline, especially in pregnant women, can induce hepatotoxicity. The tetracyclines should not be used in pregnant women or children because of discoloration of teeth and bones. All the tetracyclines have the potential for phototoxicity, diarrhea, and vaginal candidal overgrowth. Minocycline can cause vestibular toxicity.

CHLORAMPHENICOL

Chloramphenicol exerts a bacteriostatic effect by binding to the bacterial ribosome and inhibiting protein synthesis. Resistance results primarily from inactivating enzymes that acetylate the drug. The antimicrobial spectrum of chloramphenicol is similar to that of the tetracyclines. Because of its potential to produce bone marrow suppression, the use of chloramphenicol is restricted to specific situations in which alternative agents are unavailable. The main indications for chloramphenicol are for the treatment of typhoid fever, brain abscesses, meningitis caused by ampicillin-resistant strains of *H. influenzae*, and pneumococcal and meningococcal meningitis in penicillin-allergic patients.

Chloramphenicol is well absorbed orally, distributed widely into tissues and fluids (including the CSF), and metabolized in the liver. With prolonged use, reversible inhibition of bone marrow function develops in most patients. Irreversible aplastic anemia occurs rarely (about 1 per 40,000 patients).

METRONIDAZOLE

Metronidazole is used clinically for the treatment of giardiasis, amebiasis, trichomoniasis, and anaerobic infections. The drug is converted only in anaerobic bacteria to a series of compounds that damage DNA. Metronidazole must be used with other agents in mixed aerobic and anaerobic infections. Oral and parenteral dosing of metronidazole produce comparable serum concentrations; the drug also is metabolized by the liver. Its bactericidal activity and excellent penetration into the CSF and

tissues make metronidazole an ideal choice for endocarditis and meningitis caused by anaerobic bacteria. Side effects include gastrointestinal intolerance, a disulfiram-like reaction, and peripheral neuropathy with prolonged use. Although metronidazole is carcinogenic in animals and mutagenic in bacteria, it has not been associated with carcinogenesis in humans.

SULFONAMIDES AND TRIMETHOPRIM

The sulfonamides and trimethoprim are synthetic compounds that inhibit different enzymes involved in the bacterial synthesis of folic acid. Resistance results from the acquisition of genes that encode for enzymes not inhibited by these drugs. Both agents are broad-spectrum drugs that inhibit many gram-positive and gram-negative bacteria, chlamydia, and certain protozoa. As monotherapy, the sulfonamides are used primarily for urinary tract infections and nocardiosis. The combination of sulfamethoxazole and trimethoprim is used for urinary tract infections, typhoid fever, traveler's diarrhea, and *P. carini* infections. The trimethoprim analogue, pyrimethamine, is combined with the sulfonamides for the treatment of *T. gondii* and some *P. falciparum* infections.

The sulfonamides and trimethoprim are readily absorbed orally. These drugs penetrate well into the CSF and other fluids, are metabolized partially in the liver, and are excreted as intact drug and metabolites in the urine. Both the sulfonamides and trimethoprim can produce rash and drug fever; more severe skin reactions are observed in patients with HIV infection. Trimethoprim can produce bone marrow suppression, and the sulfonamides can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. Crystalluria can occur with high doses of sulfadiazine. The sulfonamides also can displace bilirubin from albumin and produce kernicterus in newborns.

RIFAMPIN

Rifampin interferes with protein synthesis by inhibiting DNA-dependent RNA polymerase. Resistant mutants, which occur commonly with most bacteria, have altered RNA polymerase that no longer binds the drug. Despite its broad-spectrum and bactericidal activity, rifampin's propensity for resistance keeps it from being used alone. It is given in combination with other drugs for mycobacterial, staphylococcal, *Brucella*, and *Legionella* infections. Short courses of rifampin alone are useful as prophylaxis for contacts of patients with severe meningococcal infections and for reducing carriage of *S. aureus*. A related drug, rifabutin, is used for the prophylaxis of mycobacterial infections in HIV-infected patients with low CD4 counts.

Rifampin is well absorbed orally; it also is distributed widely in tissues and body fluids, including the CSF. The drug is metabolized and excreted by the liver. Side effects include hepatitis, orange discoloration of the urine, interstitial nephritis, and a flulike syndrome with erratic use. Rifampin is a potent stimulator of the hepatic metabolism of other drugs, such as warfarin, oral hypoglycemics, and oral contraceptives.

URINARY ANTISEPTICS

Nitrofurantoin is a nitrofur derivative used to treat and prevent urinary tract infections. It is active against most gram-positive and gram-negative urinary pathogens, except *Proteus* and *P. aeruginosa*. Adverse reactions include gastrointestinal disturbances, an acute hypersensitivity pneumonitis, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. A single, large oral dose of fosfomycin also provides similar efficacy to nitrofurantoin for uncomplicated urinary tract infections in females.

Methenamine breaks down at an acid pH to form formaldehyde, which is active against most bacterial species. The drug is used to suppress or prevent recurrent bacteriuria. Although methenamine is available in combination with mandelic or hippuric acids, urine acidification by ammonium chloride or ascorbic acid usually is required.

CHAPTER 336: APPROACH TO THE TREATMENT OF SYSTEMIC FUNGAL INFECTIONS

JOHN H. REX

[Antifungal Agents](#)
[Choice of Antifungal Therapy](#)

The frequency of serious fungal infections is rising as a result of the increasingly successful use of antineoplastic therapy, the growing number of patients infected with HIV type 1, and the widespread use of broad-spectrum antibacterial agents. The number of drugs available to treat such infections also has increased, and their use is reviewed in this chapter.

ANTIFUNGAL AGENTS

AMPHOTERICIN B

Long the mainstay of antifungal therapy, amphotericin B remains an important agent. Its antifungal effect results from its ability to bind to fungal membrane sterols, especially ergosterol, and alter membrane permeability. Although it is potent against almost all fungal infections, its use is limited by its toxicity. Because amphotericin B is otherwise insoluble in aqueous solutions, it is made soluble by the addition of deoxycholate. It is reconstituted in water or water-containing dextrose; any addition of sodium or potassium salts causes aggregation. Amphotericin B must be given intravenously, and phlebitis almost invariably develops unless it is administered through a central venous catheter. The addition of heparin (500 to 1000 units) to the infusion is thought to ameliorate the phlebitis. Single daily doses of 0.5 to 1.5 mg per kilogram are given, to total doses of 15 to 30 mg per kilogram, with the precise daily and total doses depending on the severity of infection, the infecting agent, and the patient's response to therapy.

Fever, chills, and hypotension are common during the initiation of therapy. Occasionally, the reaction is striking, and many clinicians begin therapy with a 1-mg test dose to identify patients who have severe reactions to the drug. Patients usually adjust to amphotericin B after a few doses, but acetaminophen (650 mg) or diphenhydramine (50 mg) can be administered before each dose to alleviate fever and nausea, and meperidine (25 to 50 mg) can be administered intravenously to interrupt profound rigors.

The addition of 25 to 50 mg of hydrocortisone to each infusion also may help prevent these symptoms. After the acute adverse effects resolve, many patients have persistent malaise, mild nausea, and weight loss. Later in the course of therapy, nephrotoxicity often develops. Elevation of the creatinine level to 2.5 to 3 mg per deciliter is common and does not warrant discontinuation of therapy. The azotemia is accompanied by renal tubular acidosis, hypokalemia, and hypomagnesemia. The electrolyte losses can be severe, but are predictable, and a regular program of electrolyte replacement is required. Salt loading with 500 to 1000 mL of normal saline before each dose of amphotericin B appears to reduce nephrotoxicity. Administering twice the daily dose every other day or three times a week also ameliorates nephrotoxicity somewhat. Concomitant with the renal dysfunction, a normochromic, normocytic anemia develops. The hemoglobin falls to 8 to 10 mg per deciliter and the erythropoietin level is low. Although amphotericin B causes irreversible renal damage in some patients (especially those with preexisting renal dysfunction or those receiving other nephrotoxic agents), the azotemia and anemia usually abate completely within a few months of the cessation of therapy.

LIPID-ASSOCIATED FORMULATIONS OF AMPHOTERICIN B

Three lipid-associated formulations of amphotericin B are now licensed for use in humans: amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD), and liposomal amphotericin B (L-AmB). All are mixtures of amphotericin B with lipids, but only L-AmB has the molecular configuration of a spherical lipid bilayer. Regardless of configuration, all three preparations are associated with significantly reduced nephrotoxicity, and the licensed doses are significantly higher than for standard amphotericin B deoxycholate: 5 mg per kilogram per day (ABLC), 3 to 5 mg per kilogram per day (AmBisome), or 3 to 4 mg per kilogram per day (ABCD). These compounds are at least equipotent with 0.5 to 1 mg per kilogram amphotericin B deoxycholate. Although all three compounds cause less nephrotoxicity, creatinine elevation and electrolyte losses still develop and must be monitored. ABLC and L-AmB are also associated with reduced acute administration-related toxicity. The principal advantage of these compounds is that their reduced nephrotoxicity often permits extended usage, even in patients with preexisting renal dysfunction or in those receiving therapy with other nephrotoxic agents. These agents are, however, very costly and are in general most appropriate for patients who are refractory to or intolerant of therapy with standard amphotericin B deoxycholate.

AZOLE ANTIFUNGAL AGENTS

The development of azole antifungal agents has proceeded rapidly, and three agents now are used to treat systemic infections ([Table 336.1](#)). These agents have their effect by inhibiting an enzyme in the fungal sterol biosynthetic pathway. All the azole antifungal agents have oral formulations, which is one of their principal advantages over amphotericin B. All are given at dosages ranging from 100 to 400 mg per day, although data suggest that fluconazole can be given safely at dosages up to 800 mg per day. The principal adverse effect of the azoles is occasional hepatotoxicity, typically with a hepatocellular injury pattern. Slight elevation of transaminase levels (up to 1.5 times the upper limit of normal) is common, and progressive elevation associated with clinical symptoms of hepatitis and jaundice occurs occasionally. This hepatitis resolves with discontinuation of the drug, but continued azole therapy in the face of hepatitis or rechallenge after an episode of hepatitis can lead to substantial hepatic dysfunction or even death. Hepatitis most often manifests during early therapy and is not clearly dose related. Most clinicians recommend serial transaminase determinations during therapy, but these do not consistently predict late-onset hepatitis and should not be relied on exclusively. Patients receiving azoles should be instructed to report promptly any symptoms of hepatitis and to discontinue the drugs until they can see their physicians.

Disease	First-Line Agents ^a	Second-Line Agents ^b
Aspergillosis	AmB, LAFB ^c	Itra
Blastomycosis	AmB, Itra	Keto, Fluco
Candidiasis	AmB, Fluco	Itra
Coccidioidomycosis	AmB, Fluco	Keto, Itra
Cryptococcosis	AmB, 5-FC, Fluco	Itra
Histoplasmosis	AmB, Itra, Keto	Fluco
Mucormycosis	AmB, LAFB ^c	
Paracoccidioidomycosis	Keto, Itra	AmB, Sulfadiazine
Sporotrichosis	AmB, Itra, Keto	Fluco

AmB, amphotericin B; LAFB, lipid-associated formulation of amphotericin B; Keto, ketoconazole; Itra, itraconazole; Fluco, fluconazole.
^a Proved active in one or more clinical trials.
^b May be active, but their efficacy has either not been fully established or appears inferior to the first-line agents.
^c The lipid-associated formulations of amphotericin B may be especially useful for these diseases and should be considered promptly if standard therapy is not immediately effective.

TABLE 336.1. GUIDELINES FOR ANTIFUNGAL AGENT SELECTION IN INVASIVE MYCOSES

Nausea is another common adverse effect of the azoles, especially at higher doses of ketoconazole and itraconazole. Cutaneous reactions include pruritus, rash, and Stevens–Johnson syndrome. Ketoconazole can interfere significantly with corticosteroid hormone biosynthesis and produce decreased libido, gynecomastia, menstrual irregularities, and, rarely, symptomatic adrenal insufficiency. Itraconazole occasionally causes edema, hypokalemia, and hypertension.

The azoles have several notable pharmacologic properties. First, predictable absorption of ketoconazole and itraconazole requires attention. Ketoconazole absorption requires gastric acidity. Itraconazole is available both as a capsule and a solution. Absorption of the capsule form, although modestly sensitive to gastric acidity, is increased if taken with food. Itraconazole solution is best absorbed if taken on an empty stomach and has a bioavailability approximately 30% greater than the capsule form. Ketoconazole and itraconazole are cleared by hepatic metabolism and do not require dosage adjustment in the face of renal dysfunction. In contrast, fluconazole is predictably well absorbed when given orally, but is cleared by the kidneys and requires dosage adjustment for renal dysfunction. Unlike ketoconazole

and itraconazole, fluconazole also has a parenteral form.

The azoles have the potential for pharmacokinetic interaction with many other agents. Particularly important interactions include decreased ketoconazole and itraconazole levels with the simultaneous use of antacids, H₂-blockers, or sucralfate; decrease in the levels of all azoles with concomitant rifampin therapy; and increased cyclosporine, phenytoin, and terfenadine levels with the use of any of the azoles.

FLUCYTOSINE

Flucytosine, also known as 5-fluorocytosine, is a fluorinated pyrimidine analogue that often is used in combination with amphotericin B. In susceptible fungi, it is deaminated to 5-fluorouracil, which subsequently is incorporated into DNA or RNA. Such incorporation interferes with DNA and RNA function and leads to cell death. Flucytosine can be given orally or parenterally, although the parenteral form is not available in the United States. The dosage is 25 to 37.5 mg per kilogram given four times per day. Flucytosine is cleared by the kidneys and may accumulate in patients with renal dysfunction. If blood levels exceed 50 to 100 (g per milliliter, leukopenia and thrombocytopenia may occur. Colitis and hepatitis also may be seen, particularly when blood levels of flucytosine rise.

CHOICE OF ANTIFUNGAL THERAPY

The choice of antifungal therapy for individual patients requires careful thought. In general, amphotericin B is preferred as initial therapy in profoundly ill patients. The azoles are used as primary therapy in less acutely ill patients and as long-term therapy after a brief course of amphotericin B. However, the application of these general rules is evolving rapidly as new studies continue to demonstrate that azoles can be used as first-line therapy for certain fungal infections (e.g., itraconazole for disseminated histoplasmosis and fluconazole for candidemia in nonneutropenic patients). Some guidelines for antifungal selection are given in [Table 336.1](#), but expert advice should be obtained for all but the most straightforward systemic fungal infections.

CHAPTER 337: ANTIMICROBIAL CHEMOPROPHYLAXIS

F. MARC LAFORCE

[General Principles](#)
[Group A Streptococcal Infections and Rheumatic Fever](#)
[Meningococcal Infections](#)
[Recurrent Urinary Tract Infections](#)
[Influenza](#)
[Pneumocystis Infections](#)
[Malaria](#)
[Tuberculosis](#)
[Endocarditis](#)

GENERAL PRINCIPLES

In the early 1940s, it was noted that when sulfadiazine was administered to closed populations with epidemic meningococcal disease, the result was an immediate cessation of cases of the disease and the virtual disappearance of carriers. This dramatic success stimulated interest in the concept of chemoprophylaxis. A half-century later, we have learned more about the limits of chemoprophylaxis. For example, the most successful prophylactic regimens are generally those that prevent infection from a single type of organism for a relatively brief period. Conversely, the least success is achieved when prophylaxis is aimed against multiple species for an extended period.

The strategy of prevention by chemoprophylaxis has important drawbacks that have been understated. Antibiotics and their administration are expensive, and some agents are inappropriately and extravagantly overused. Perhaps the most serious consequence of the widespread use of antibiotics as prophylactic agents is the emergence of resistant organisms. One common example of inappropriate chemoprophylaxis is the attempt to suppress bacteriuria in the patient with a chronic indwelling bladder catheter. All prophylactic regimens that use antibiotics fail in this setting, and organisms that finally colonize the urinary tract are invariably resistant to the prophylactic agent being used. In such circumstances, it is more prudent to ensure that there are no obstructions to urine flow and to treat acute infections as they occur.

Some medical indications for antimicrobial chemoprophylaxis are presented in this chapter. Other chapters in this text deal with specific infectious agents and should be consulted for more detailed information. Perioperative chemoprophylaxis is discussed in [Chapter 273](#).

GROUP A STREPTOCOCCAL INFECTIONS AND RHEUMATIC FEVER

Patients with poststreptococcal rheumatic heart disease require continuous prophylaxis to prevent streptococcal infections ([Chapter 275](#)). The preferred regimen is monthly injections of 1.2 million units of benzathine penicillin G. Oral penicillin V also is an acceptable prophylactic regimen, but is less effective than monthly penicillin injections because of compliance problems. Patients who are allergic to penicillin can be treated with erythromycin. The optimum duration of continuous antibiotic prophylaxis is unclear. The risk of rheumatic fever recurrences decreases with age and the length of time since the last episode. Some experts suggest that prophylaxis should not be discontinued until a patient is in his or her 20s and until at least 5 years have elapsed since the last attack.

MENINGOCOCCAL INFECTIONS

Household contacts of patients with meningococcal infections are at risk for infection with *Neisseria meningitidis* ([Chapter 279](#)). Similar high-risk conditions occur in closed populations such as college dormitories and nursery schools. Hospital personnel do not have increased risk, except for those who have had intimate exposure, such as mouth-to-mouth resuscitation. Recommended therapy for meningococcal prophylaxis in adults is with rifampin (600 mg every 12 hours for 2 days).

RECURRENT URINARY TRACT INFECTIONS

Several studies have shown that nightly use of trimethoprim-sulfamethoxazole (½ tablet consisting of 40 mg of trimethoprim and 200 mg of sulfamethoxazole) or nitrofurantoin (50 mg) can decrease significantly the incidence of recurrent urinary tract infections in women ([Chapter 271](#)). In some women, recurrences are associated with sexual activity, and a single dose of trimethoprim-sulfamethoxazole or nitrofurantoin taken after sexual intercourse is effective.

INFLUENZA

Amantadine and rimantadine are effective chemoprophylactic agents against influenza A, but not influenza B ([Chapter 310](#)). During an influenza A epidemic, amantadine or rimantadine prophylaxis can be initiated at the same time that susceptible persons receive influenza vaccine. Prophylaxis can be discontinued 2 weeks later when antibody titers presumably are protective. Amantadine use in the elderly has been associated with central nervous system side effects, and the recommended prophylactic dosage is 100 mg per day. Rimantadine has fewer central nervous system side effects. Amantadine or rimantadine also can be used in patients who cannot receive influenza vaccine because of egg sensitivity or in high-risk persons when the vaccine does not contain a good antigenic match to the circulating influenza A virus.

PNEUMOCYSTIS INFECTIONS

Patients recovering from *Pneumocystis* pneumonia remain at high risk for the development of recurrent disease as long as the predisposing immunosuppression persists ([Chapter 327](#)). Trimethoprim-sulfamethoxazole has proved effective as chemoprophylaxis against *Pneumocystis* infection. In addition, this agent decreases the incidence of toxoplasmosis and may lower infection rates from *Streptococcus pneumoniae* and *Haemophilus influenzae*. Patients with AIDS have a high rate of reaction to trimethoprim-sulfamethoxazole, and many cannot tolerate it. Effective alternative agents include dapsone, dapsone plus pyrimethamine, and monthly aerosolized doses of pentamidine.

MALARIA

Malaria is an important health risk for travelers to tropical nonindustrialized countries ([Chapter 322](#)). Chloroquine (300 mg once weekly) is the drug of choice in areas without chloroquine-resistant malaria. Chloroquine-resistant *Plasmodium falciparum* occurs in most of Africa, Southeast Asia, and the Amazon region of South America. Travelers to chloroquine-resistant areas should use mefloquine (250 mg per week). Travelers who cannot take mefloquine should take doxycycline (100 mg per day). Travelers should also carry a three-tablet treatment dose of pyrimethamine-sulfadoxine (Fansidar) to be taken in the event of a febrile illness. Prophylactic antimalarial regimens should be initiated 2 weeks before departure except for doxycycline, which can be begun at the time of entry into a malarious area. All prophylactic regimens should be continued for 4 weeks after the traveler has returned home.

TUBERCULOSIS

Isoniazid (300 mg per day for 1 year) is effective prophylactic therapy for most adults whose tuberculin skin test results have become positive ([Chapter 294](#)). Tuberculin skin reactors with radiographic changes suggestive of tuberculosis but with negative culture results, and those with special risk factors such as diabetes, gastrectomy, or immunosuppression also should receive isoniazid chemoprophylaxis. Exposure to isoniazid-resistant tuberculosis can be managed with rifampin (600 mg per day).

ENDOCARDITIS

Recommendations for prophylaxis against bacterial endocarditis have recently been changed and are summarized in [Table 337.1](#) (see [Chapter 270](#)). Persons

considered to be at high risk for bacterial endocarditis include those with prosthetic valves, histories of endocarditis, aortic or mitral valve lesions, congenital heart diseases (except atrial septal defects), and alimentary catheters or arteriovenous fistulas.

- Prophylactic regimens for dental, oral, respiratory tract, or esophageal procedures
- Amoxicillin, 2 g PO 1 h before procedure
- Allergic to penicillin:
 - Clindamycin, 600 mg PO 1 h before procedure
 - or
 - Azithromycin or clarithromycin, 500 mg PO 1 h before procedure
- Prophylactic regimens for genitourinary and gastrointestinal procedures
- High-risk patients: ampicillin 2 g intravenously (IV) or intramuscularly (IM) plus gentamicin 1.5 mg/kg within 30 minutes of starting procedure; 6 h later ampicillin 1 g IM/IV or amoxicillin 1 g orally
- High-risk patients allergic to ampicillin/amoxicillin: vancomycin 1 g IV over 1–2 h plus gentamicin 1.5 mg/kg (not to exceed 120 mg); complete infusion within 30 minutes of starting procedure

[Outbreak Investigation](#)
[Isolation Precautions](#)
[The New Hospital Epidemiology: Expansion to Other Interests](#)

HISTORICAL PERSPECTIVE

Hospital epidemiology is rooted in the principles of infectious disease epidemiology and antisepsis developed by investigators such as Semmelweis, Nightingale, Lister, and Holmes. The term *hospital epidemiologist* first appeared in the 1940s in relation to controlling institutional outbreaks of diarrhea, then disappeared during the initial successes of antibiotic therapy. The term and the practice of hospital epidemiology reappeared with the emergence of penicillinase-producing staphylococci and outbreaks of nosocomial staphylococcal infections during the late 1950s and 1960s. Eventually, the Hospital Infections branch of the Centers for Disease Control (CDC) was established to address the problem of nosocomial infections. The role of infection control nurses was recognized as critical to hospital programs and a professional organization of these practitioners, the Association for Professionals in Infection Control (APIC; previously the Association for Practitioners in Infection Control), was established and is still thriving. The role of hospital epidemiologists, physicians with expertise in epidemiology and infection control, evolved more slowly, but now is recognized as essential to a successful infection control program. The Society for Healthcare Epidemiology of America (SHEA; previously the Society for Hospital Epidemiology of America) has grown rapidly with the increased demand for physicians with expertise in this field.

SURVEILLANCE, PREVENTION, AND CONTROL

The function of hospital epidemiology and infection control is the surveillance, prevention, and control of nosocomial infections. Several studies show an association between decreased nosocomial infection rates and effective infection control programs. The most notable is the Study on the Efficacy of Nosocomial Infection Control (SENIC), a nationwide controlled trial that was performed by the CDC in the late 1970s. The SENIC documented a 32% decrease in nosocomial infection rates associated with specific components of surveillance and infection control programs, including an infection control practitioner for every 250 beds and a physician with expertise in infection control. Routine surveillance components of infection control programs have evolved with institutional needs. Previously, whole-house (i.e., total) nosocomial infection surveillance was done in many hospitals, but this no longer is considered practical or necessary in many settings.

Hospitals may select high-risk areas for surveillance based on their specific needs. This often includes intensive care units (ICUs) and other high-risk units that house immunocompromised patients and those with specific infections such as surgical wounds. A form of whole-house surveillance may be used by the infection control staff, who review the clinical microbiology reports to detect clusters of multiply resistant or other epidemiologically significant organisms. To obtain national data on nosocomial infections, the CDC established the National Nosocomial Infections Surveillance System (NNIS), a collaborative system that includes about 150 hospitals in the United States. The NNIS provides data for comparison rates for hospitals in the United States (even those outside the system) and is useful for identifying nationwide trends. Four surveillance components are used in this system: hospital-wide, ICU, high-risk nursery, and surgical patient.

The NNIS has incorporated device-associated infection rates to control for exposure to the principal risk factor for infection, and reports these rates in device days to control for the duration of hospitalization. For example, catheter-associated bloodstream infections are reported per 1,000 central catheter days and ventilator-associated pneumonias are reported per 1,000 ventilator days. Many hospitals outside the NNIS have begun to report infection rates in device days so that NNIS data can be used to generate comparison rates.

NOSOCOMIAL INFECTIONS

A nosocomial infection is defined as an infection that is not present or incubating at the time of admission to a health care facility. Although many infections that are detected more than 48 hours after hospital admission are nosocomial, diseases with longer incubation periods (e.g., viral exanthems, legionellosis, aspergillosis, hepatitis) often are recognized only after hospitalization. Several nationwide studies document the universality of nosocomial infections in health care institutions and suggest that about 5% of hospitalized patients will have at least one nosocomial infection. These infections contribute significantly to extended hospital stays. Hospital-acquired infectious complications result in 1 to 7 extra days of hospitalization and in \$1,000 to \$7,000 in extra charges per patient per infection. Astute hospital administrators have become interested in improving infection control programs to improve quality of care, increase cost savings, and meet risk management incentives.

NOSOCOMIAL PATHOGENS

The overall pathogen distribution for major sites of nosocomial infection reported to the NNIS from 1986 to 1989 is shown in [Table 338.1](#). *Escherichia coli* is the most common pathogen because of the predominance of urinary tract infections, but other organisms are increased significantly from previous comparison periods. Enterococci are the second most common nosocomial pathogens overall. *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the next most prevalent, followed by coagulase-negative staphylococci. Coagulase-negative staphylococci increased from 4% in 1980 to 9% from 1986 to 1989, primarily as causative agents of bloodstream infection. *Candida albicans* also increased in all major sites of infection from 2% in 1980 to 5% from 1986 to 1989. *Enterobacter* and *Klebsiella* species are some of the next most prevalent gram-negative nosocomial pathogens.

Pathogen	Urinary Tract Infection	Wound	Pneumonia	Bloodstream	Total
<i>Escherichia coli</i>	28	10	6	6	50
Enterococci	16	13	2	8	39
<i>Pseudomonas aeruginosa</i>	12	8	17	4	41
<i>Staphylococcus aureus</i>	2	17	16	16	51
Coagulase-negative staphylococci	4	12	2	27	45
<i>Enterobacter</i> species	6	8	11	5	30
<i>Candida parapsilosis</i>	6	3	7	4	20
<i>Candida albicans</i>	7	2	4	5	18
<i>Pseudomonas</i>	5	4	3	1	13
<i>Streptococcus</i> species	6	3	1	4	14
<i>Citrobacter</i> species	2	2	1	1	6
<i>Candida</i> species	2	0	1	3	6
<i>Erwinia</i> species	1	1	4	1	7

TABLE 338.1. PATHOGEN DISTRIBUTION (PERCENTAGE) FOR MAJOR SITES OF NOSOCOMIAL INFECTIONS 1986-1989 NATIONAL NOSOCOMIAL INFECTIONS SURVEILLANCE SYSTEM

Trends in the epidemiology and antimicrobial resistance of these nosocomial pathogens are troubling. Most hospital isolates and many community isolates of *E. coli* are resistant to ampicillin. The enterococci have acquired numerous new mechanisms of resistance in the past decade, including high-level aminoglycoside resistance and vancomycin resistance. Vancomycin-resistant enterococci have been deemed the nosocomial pathogens of the decade, because these organisms usually are multiply resistant to alternative antibiotics and cause infection in seriously ill hospitalized patients. In addition, vancomycin-resistant enterococci can persistently

colonize the gastrointestinal tract and become prevalent on environmental surfaces, allowing for ready cross-transmission in the hospital setting.

Methicillin-resistant *S. aureus* (MRSA) has increased in prevalence among all hospital *S. aureus* isolates from 2.4% in 1975 to 47% in 1998. Recent studies document that a significant percentage of MRSA isolates are present at the time of hospital admission, suggesting that MRSA is found in both the community and the hospital. In addition, DNA typing studies have documented the heterogeneity of MRSA isolates in both hospital and community isolates. Because of these changes in the epidemiology of MRSA, infection control programs using MRSA cases for surveillance must determine whether cases are nosocomial and must use a marker of strain identity, such as DNA typing, to determine whether cross-transmission actually is occurring. Emerging reports of vancomycin intermediate *S. aureus* (glycopeptide intermediate *S. aureus*; GISA) are of particular concern. Such isolates reported to date have also been methicillin-resistant, raising therapeutic dilemmas and justifying stringent control measures if these organisms are identified.

The prevalence of *C. albicans* in the hospital continues to increase, particularly in ICUs and among immunocompromised patients. Studies also have shown a worrisome increase in other species of *Candida*, some of which are intrinsically resistant to azoles or amphotericin B. Among *Enterobacter* species, resistance to third-generation cephalosporins has increased during the past decade, and many reports exist of the emergence of resistance on therapy with these agents. Extended-spectrum β -lactamases have emerged in *Klebsiella pneumoniae* and other Enterobacteriaceae, conferring resistance to broad-spectrum cephalosporins and other agents. Many of these evolving patterns of antimicrobial resistance in nosocomial pathogens represent a response to patterns of antimicrobial drug use in the hospital. The hospital epidemiology program is an important link to the hospital antibiotic use program.

NOSOCOMIAL PNEUMONIA

Nosocomial pneumonia is a substantial cause of morbidity and mortality and is the second most common nosocomial infection in US hospitals. It accounts for 15% to 24% of nosocomial infections overall with higher rates in the ICU, but it may be responsible for up to 60% of those that are fatal. Major patient risk factors include endotracheal intubation or mechanical ventilation, severe underlying disease, decreased mental status, cardiac or pulmonary disease, immunosuppression, thoracoabdominal surgery, and age over 70 years. Other risk factors are ventilator circuit changes every 24 hours, fall or winter season, stress ulcer prophylaxis with a histamine-2 (H_2) antagonist with or without an antacid, use of a nasogastric tube, and recent bronchoscopy. After stratifying the incidence density of ventilator-associated pneumonias by ventilator days, the NNIS reported that the median rate of ventilator-associated pneumonia ranged from 4.2 per 1,000 ventilator days in pediatric ICUs to 21.1 per 1,000 ventilator days in burn ICUs. Reported mortality rates include crude rates of 20% to 50% and attributable rates of 30%.

The diagnosis of nosocomial pneumonia is difficult, and the criteria used for surveillance have been based on clinical findings of fever, cough, and the development of purulent sputum in combination with a new or progressive infiltrate. Sputum cultures are nonspecific, especially in ventilated patients, but often are monitored in conjunction with clinical criteria to detect potentially cross-transmitted organisms. Blood or pleural fluid cultures are more specific, but are not sensitive methods of detection. Consensus recommendations for standardizing more specific methods of diagnosing pneumonia for clinical research studies include the use of bronchoscopic techniques, such as quantitative cultures of protected specimen brushings, bronchoalveolar lavage, and protected bronchoalveolar lavage. The reported sensitivity and specificity of these methods are 70% to 100% and 60% to 100%, respectively. These techniques are invasive and are not used routinely in all institutions; many institutions still rely on clinical criteria for the surveillance of nosocomial pneumonia.

The microbial causes of nosocomial pneumonia vary somewhat, depending on the diagnostic method used. Most documented organisms are aerobic bacteria, but anaerobic and viral cultures are not done routinely. Using clinical criteria, enteric gram-negative bacilli (e.g., *Enterobacter* species, *Klebsiella pneumoniae*, *E. coli*) account for most cases. *S. aureus*, particularly MRSA, and *P. aeruginosa* also are important causes. In addition, *Streptococcus pneumoniae* and *Haemophilus influenzae* are recognized as significant isolates. In studies using bronchoscopic criteria for diagnosis, enteric gram-negative bacilli are less common, and *S. aureus*, *S. pneumoniae*, and *H. influenzae* are more common.

Control measures are difficult to assess because many risk factors are related to the severity of the patient's illness. Gastric bacterial overgrowth resulting from antacids or H_2 antagonists given as prophylaxis against stress gastritis has been implicated as a preventable risk factor. Sucralfate has been studied as a substitute because it has a cytoprotective effect on the gastric mucosa without affecting gastric pH. However, clinical trials comparing the two regimens have produced variable results. In most studies, mechanically ventilated patients in the ICU who are given antacids with or without H_2 blockers have increased gastric pH, high gastric bacterial counts, and an increased risk of pneumonia compared with patients who are given sucralfate. Meta-analyses of several studies and a study comparing ranitidine with sucralfate have not shown a significant difference.

Selective decontamination of the digestive tract also has been studied as a way of decreasing oropharyngeal and gastric bacterial colonization, and the incidence of lower respiratory tract infections in the ICU. A combination of a nonabsorbable antimicrobial agent (i.e., polymyxin, an aminoglycoside, quinolone) and nystatin or amphotericin B is administered locally to the oropharynx and orally or by nasogastric tube. In many studies, a systemic antibiotic such as cefotaxime or trimethoprim also is administered intravenously. Although most studies have demonstrated reduced rates of nosocomial pneumonia, study designs and patient populations have varied and follow-up periods have been short.

The diagnosis of pneumonia is based on clinical criteria in most studies. In addition, two large trials have demonstrated no benefit with selective decontamination of the digestive tract. An extensive meta-analysis shows this technique to be expensive and to have only an equivocal effect on patient mortality. Further, there are significant concerns regarding the development of antibiotic-resistant bacteria with these regimens. Selective decontamination of the digestive tract is not recommended for routine use in all patients in the ICU, but may be beneficial in certain high-risk subsets such as patients with severe immunosuppression.

Routine measures such as elevating the head of the bed and withholding enteral feedings when there is gastric residue are recommended to minimize aspiration. Devices used in the respiratory tract, particularly in mechanically ventilated patients, may be a reservoir for nosocomial pathogens. Proper cleaning and disinfection or sterilization of reusable respiratory equipment is important. The use of an aseptic technique during suctioning and proper maintenance of the ventilator circuit also are recommended. In many hospitals, ventilator circuit condensate is emptied periodically. Another option is to use a heat-moisture exchanger within the ventilator circuit that eliminates condensate formation. Earlier studies showed that ventilator circuit changes every 48 hours were advantageous compared with changes every 24 hours. More recent studies have shown no increase in the rate of ventilator-associated pneumonia when the interval for circuit changes is longer than 48 hours. CDC recommendations call for ventilator circuit changes every 48 hours or more. The maximum time a circuit may be left unchanged is unknown.

NOSOCOMIAL LEGIONNAIRES' DISEASE

Because the environment is the reservoir for infections caused by *Legionella* species, a nosocomial case of legionellosis warrants further investigation to prevent such infections in other patients. The mortality rate of patients with nosocomial *Legionella* pneumonia is twice that of patients with community-acquired disease, probably because of the increased severity of illness in hospitalized patients. To determine whether a case is nosocomial, the incubation period of 2 to 10 days for legionnaires' disease must be considered. By CDC guidelines, a case of laboratory-confirmed legionellosis occurring in a patient who has been hospitalized at least 10 days before the onset of illness is a definite nosocomial case of legionnaires' disease. A case of laboratory-confirmed infection occurring 2 to 10 days after hospitalization is a possible nosocomial case. The inhalation or aspiration of water contaminated with *Legionella* species is thought to be the major mode of entry of these organisms into the respiratory tract. In early hospital outbreaks, suspected environmental sources were cooling towers, showers, room air humidifiers, and respiratory therapy equipment. More recent investigations identify contaminated potable water supplies as significant reservoirs.

The diagnosis of *Legionella* pneumonia requires laboratory confirmation by one of the following methods: culture isolation from a respiratory specimen, visualization by immunofluorescent microscopy from a respiratory specimen, detection of *Legionella* urinary antigen on radioimmunoassay, or a fourfold rise in antibody titer to 1:128 or higher on an indirect immunofluorescent antibody test.

Prevention and control strategies vary by institution and depend on the identification of nosocomial cases, the immunologic status of the patients, the design and construction of the facility, and the available resources. One approach is routine, periodic culturing of the hospital's potable water supply for *Legionella* species. When a threshold level of 30% of samples are positive, decontamination of the water supply is undertaken, and active laboratory surveillance of cases begins. Advantages of this approach are that active surveillance of patient cases is driven by environmental surveillance, and infrequent periodic environmental sampling may be less expensive than routine laboratory testing for *Legionella*. Uncertainties of this approach include the unclear relation between water culture results and the risk of legionellosis in an institution without detected cases. *Legionella* occurs commonly in water systems, including those of hospitals, without causing disease.

A second approach is to maintain a high index of suspicion in patients at risk for the disease, particularly if a nosocomial pneumonia is unresponsive to routine empiric antibiotic therapy. Epidemiologic investigation is initiated for one laboratory-confirmed definite nosocomial case or for two laboratory-confirmed possible

cases. The advantage of this approach is that environmental and epidemiologic investigation is problem-focused. The disadvantage is that cases may be missed if an index of suspicion is not maintained and laboratory diagnoses are not made.

Decontamination of the hospital's potable water supply is a formidable task. Options include superheating, pulse thermal disinfection (flushing the system for several minutes with water at 65° C or higher), and hyperchlorination (flushing the system with water containing at least 10 mg per liter of free residual chlorine). All these methods are difficult and expensive and should be considered in collaboration with the engineering department. Physical cleaning of water storage tanks, water heaters, faucets, and showerheads also may be required. For patients with severe immunosuppression, such as bone marrow transplant recipients, a combination of sterile water for ingestion or systemic decontamination and point-of-use decontamination (i.e., filtration or ultraviolet treatment) may be considered.

NOSOCOMIAL ASPERGILLOSIS

Nosocomial aspergillosis also is associated with environmental reservoirs and is a particular problem for immunocompromised patients. Those at highest risk include patients with bone marrow transplants or hematologic malignancies. However, *Aspergillus* infection also occurs in patients with solid organ transplants, corticosteroid regimens, AIDS, and no apparent immunodeficiency. Pulmonary infection results from the inhalation of *Aspergillus* fungal spores.

Outbreaks have been associated with hospital renovation, contaminated ventilation systems, and high airborne fungal spore counts. The diagnosis of *Aspergillus* pneumonia is difficult without an invasive procedure and often is presumptive. Although bronchoalveolar lavage is useful, transbronchial biopsy is the most reliable means of diagnosis. The isolation of *Aspergillus* species may represent colonization or contamination in many samples from patients with intact immune systems, but positive cultures for *Aspergillus* in immunocompromised (particularly granulocytopenic) patients must be considered significant.

Preventive measures are directed toward those at highest risk, including bone marrow transplant recipients and other severely immunocompromised patients. Patient care areas designed for these patients should include high-efficiency particulate filtration systems that are 99.97% efficient for the filtration of particles measuring 0.3 µm or larger, directed air flow, positive-pressure rooms, and high rates of room air exchange (at least 15 air changes per hour).

VIRAL PNEUMONIAS

Nosocomial outbreaks of viral respiratory diseases usually are associated with respiratory diseases in the community. Respiratory syncytial virus is a problem in the hospital during its peak season, because it spreads readily among patients and health care workers. Although infants and young children are affected most commonly, the disease can occur in adults. The diagnosis is based on laboratory evaluation by culture or antigen detection. Respiratory droplets are the mode of spread, with contaminated hands of health care workers or fomites serving as vectors of transmission. A combination of cohorting, contact isolation, emphasis on compliance with control measures, limitation of visitors, and the temporary exclusion of health care workers with respiratory diseases has contributed to successful control in hospital outbreaks of respiratory syncytial virus.

Influenza viruses also are seasonal and pose a significant threat to hospitalized immunocompromised patients. Cohorting and contact isolation can be used to control outbreaks. Antiviral therapy or prophylaxis with amantadine hydrochloride or rimantadine can be used for influenza A, but not influenza B. Routine seasonal vaccination should be emphasized each year for high-risk patients and the health care workers who care for them.

CATHETER-RELATED BLOODSTREAM INFECTIONS

Catheter-related (or primary) bloodstream infections are a major cause of high costs and long stays in the hospital and of morbidity and mortality. According to CDC NNIS data, they account for 8% of all nosocomial infections. Significant increases in these infections were observed during the past decade in every type of hospital monitored by the NNIS (small nonteaching, small teaching, large nonteaching, and large teaching). The increases resulted largely from the following pathogens: coagulase-negative staphylococci, *S. aureus*, enterococci, and *Candida* species. The rate of bloodstream infections caused by gram-negative bacilli was the same in all types of hospitals. Although the rate of nosocomial secondary bacteremia (caused by urinary tract infection, surgical site infection, and pneumonia) has remained the same over the past decade, the rate of nosocomial primary bacteremia (primarily caused by intravascular devices) has doubled.

Short-term, noncuffed central venous catheters (CVCs) are associated with the highest rates of bacteremia, ranging from 1% to 10%. Peripheral intravenous catheters, arterial catheters, and long-term catheters are associated with substantially lower rates of infection ([Table 338.2](#)). The highest rates of CVC septicemia are associated with hemodialysis catheters, and the lowest with subcutaneous central venous ports.

Type of Device	Representative Rate	Range
Short-Term Temporary Access (Number of Septicemias Per 100 Devices)		
Peripheral IV catheter	<0.2	0-1
Winged steel needles		
Peripheral IV catheters		
Percutaneously inserted	0.2	0-1
Cutdown	5	—
Arterial catheters	1	0-1
Central venous catheters		
All-purpose, multilumen	3	1-7
Swan-Ganz	1	0-5
Hemodialysis	10	3-18
Long-Term Indefinite Access (Number of Septicemias Per 100 Device-Days)		
Peripherally inserted central venous catheters	0.20	—
Cuffed central catheters (e.g., Hickman, Broviac)	0.20	0.10-0.53
Subcutaneous central venous ports (e.g., Infus-A-Port, Port-A-Cath)	0.04	0.00-10

Adapted from Maki DG. Infections due to infusion therapy. In Bennett JE, Brachman PS (eds): Hospital Infections, Third ed. Boston: Little, Brown, 1992.

TABLE 338.2. APPROXIMATE RISKS OF SEPTICEMIA ASSOCIATED WITH INTRAVASCULAR ACCESS DEVICES

Definitions of catheter-related infections vary, complicating surveillance for these nosocomial infections and making comparison of various clinical studies difficult. Local catheter infections include exit or insertion site infections, tunnel infections, and significant catheter colonizations. Using a semiquantitative roll-plate culture technique, Maki and colleagues showed a correlation between the recovery of 15 or more colony-forming units from a catheter tip and inflammation of the catheter site. For routine nosocomial infection surveillance of primary catheter-related bacteremias, many institutions use the definitions provided in the CDC guidelines. Most infections detected by this method have positive blood cultures or signs of infection at the catheter site, evidence of clinical sepsis, and 15 or more colony-forming units recovered from an intravascular catheter tip using the semiquantitative method. The CDC Guidelines for Nosocomial Infections should be consulted for specific criteria.

Definitions of systemic catheter-related bacteremias are more rigorous in some research studies. Many hospitals report rates of catheter-related bacteremias in terms of device days (number of infections per 1,000 central catheter days), as suggested by the CDC. According to NNIS data, these rates range from 5 to 10 per 1,000 central-line days, depending on the type of ICU monitored.

Quantitative catheter culture techniques have proved useful in differentiating colonization from infection. In addition, quantitative blood cultures have been used to identify sepsis associated with a central line. In this technique, quantitative blood cultures are drawn simultaneously through the central catheter and a peripheral vein. Sepsis associated with a CVC is suggested by a differential colony count of 10:1 when the central catheter specimen is compared with the peripheral vein specimen.

The pathogenesis of catheter-related infections is important in the selection and implementation of preventive measures. The skin insertion site and the catheter hub are thought to be the most important initial sources of infecting pathogens. It is hypothesized that skin flora, such as coagulase-negative staphylococci and *S. aureus*, migrate from the skin insertion site to the catheter tip, resulting in catheter colonization and infection. In addition, pathogens introduced into the catheter hub by health care workers can migrate internally along the catheter, resulting in bloodstream infection. Decreasing the colonization of pathogens at the skin insertion site and interrupting the migration of microorganisms along the catheter are important preventive measures. Hematogenous seeding of the central catheter from a secondary site, such as the urinary tract, has been suggested but appears to be uncommon. Episodes of bacteremia related to contaminated infusate may appear as local or

regional epidemics. In addition, these bacteremias usually are caused by gram-negative bacilli (*Serratia*, *Enterobacter*, *Citrobacter*, and *Pseudomonas* species other than *P. aeruginosa*).

Proposed risk factors for catheter-related infections include catheter location, use of aseptic technique during insertion or maintenance of the line, number of catheter lumina, number of catheter manipulations, type of catheter dressing, and contamination or lack of effectiveness of antiseptic solutions. Short-term CVCs present a greater risk for infection than do peripheral or tunneled CVCs. In addition, some studies suggest that internal jugular CVCs have higher rates of infection than do subclavian CVCs, although other studies have produced contradictory evidence. Several investigations have documented higher rates of infection with triple-lumen compared with single-lumen CVCs, whereas others have found no significant differences. Certain types of impermeable transparent dressings have proved to be risk factors compared with gauze dressings. However, newer transparent dressings with greater permeability and less moisture retention are under evaluation and appear promising. The number of catheter manipulations appears to be important, particularly with Swan–Ganz catheters. Prolonged catheterization also is a well-documented risk factor for certain types of CVCs. The risk of infection increases at 72 hours with peripheral venous catheters and at 96 hours with Swan–Ganz and peripheral arterial catheters. Many institutions have policies limiting the amount of time these catheters can be used, but few agree on the optimal duration of use for short-term CVCs because infection rates related to length of placement have varied among studies based on institution-specific factors. Most investigators believe that signs of infection warrant the removal of short-term CVCs. Exchanging CVCs over guide wires is a controversial practice because some investigators have documented colonization of the new CVCs with pathogens from the previous CVCs.

Several protective factors have been documented to help prevent catheter-related infections. Placement and maintenance of peripheral and central catheters by infusion therapy teams have been associated with significantly lower rates of infection in many studies. An aseptic technique incorporating maximal sterile barriers for the insertion of CVCs has been documented by Raad and associates to decrease infection rates. Maki and colleagues also have demonstrated the superiority of chlorhexidine gluconate for antiseptic at the skin insertion site compared with 70% alcohol and 10% povidone-iodine. The rate of catheter-related bacteremia is about four times lower with chlorhexidine gluconate antiseptic than with the other two agents. An attachable silver-impregnated cuff that prevents the migration of pathogens on the surface of the catheter has been shown to reduce short-term CVC bacteremia but has not been as helpful for long-term tunneled catheters.

SURGICAL SITE INFECTIONS

Surgical wound surveillance is a routine part of nosocomial infection surveillance at many hospitals, and several large studies have shown that sharing such data with surgeons helps reduce infection rates. National infection control organizations such as SHEA and APIC recommend surgical wound infection surveillance, and the Joint Commission for Accreditation of Healthcare Organizations has proposed that it be made a mandatory practice. Definitions for surgical site infections vary, but most institutions use those established by the CDC. The CDC definitions were modified in 1992, and the term was changed from *surgical wound infection* to *surgical site infection*. The changes were made so that the anatomical site of a deep infection could be specified and because the word “wound” connoted only the incision from the skin to the deep soft tissues, whereas a postoperative infection may involve an organ or space other than the incision that is opened or manipulated during the operative procedure. Surgical site infections are divided into superficial incisional surgical site infections, deep incisional surgical site infections, and organ/space surgical site infections. To be classified as a surgical site infection, the infection must occur within 30 days of the operative procedure if no implant is in place or within 1 year if an implant is in place. Postdischarge surveillance (a method of detecting surgical site infections after hospital discharge) is an important component of surgical site infection surveillance programs now that hospital stays are becoming shorter. The confidential and timely reporting of specialty-specific wound rates and surgeon-specific wound rates is endorsed by the Surgical Infection Society and recommended by a consensus panel with representatives from the Surgical Infection Society, SHEA, APIC, and CDC.

Surgeons and nurses have been classifying surgical wounds in the operating room for 30 years, ever since the National Research Council study on surgical wounds that introduced the use of four wound classes. The National Research Council classification is based on the risk level and type of contamination that are expected or observed at the time of operation. A surgical wound classified as clean (class I) is one in which only exogenous, airborne contamination is expected; the predicted wound infection rate is 2% or less; and anticipated pathogens are primarily gram-positive organisms such as *S. aureus*. Clean-contaminated wounds (class II) are those in which endogenous and exogenous contamination is anticipated or observed. These infections usually are caused by polymicrobial endogenous (aerobic and anaerobic) flora and occur at a predicted rate of 5% to 15%. Wounds are classified as contaminated (class III) when early endogenous leakage or delayed exogenous contamination occurs without a clinical infection at the time of surgery. These wounds are associated with a 15% or higher infection rate. Dirty (class IV) wounds are those in which active infection is present in the operating field at the time of surgery, and postoperative infection rates are high (30% or higher).

In the 1980s, problems were identified with this wound classification system because of differences in the risk of infection and the severity of illness among patients in each wound class. There are recognized host and operative risk factors for surgical wound infection. Host risk factors include obesity, infection at other sites, diabetes mellitus, malnutrition, immunosuppressant therapy, American Society of Anesthesiology class higher than 3, and severity of illness. Operative risk factors include prolonged duration of surgery, surgical wound class, emergency surgery, lack of surgical experience or skill, low procedure volume, tissue trauma, prolonged hospital stay, timing of preoperative shaving, intraoperative microbial contamination, surgical wound class, lack of prophylactic antibiotics, and number of persons in the operating room. A composite risk index for predicting surgical site infections more accurately than the National Research Council classification has been sought. The SENIC proposed that patients be stratified according to the number of discharge diagnoses, presence of abdominal surgery, duration of surgery, and wound class. However, the use of discharge diagnoses as criteria made the SENIC index difficult to use for timely analysis. A CDC NNIS risk index that stratifies patients by the American Society of Anesthesiology score, surgical wound class, and duration of surgery (specific to type of surgery) is easier to use and is being assessed in the NNIS program.

URINARY TRACT INFECTIONS

Catheter-associated urinary tract infections are the most common nosocomial infections, accounting for about 40% of all cases. The pathogenesis of these infections is the migration of pathogens into the catheterized urinary tract by the periurethral route in women and the intraluminal route in men. *E. coli* is the most common pathogen, followed by enterococci, *P. aeruginosa*, and enteric gram-negative bacilli. Studies consistently reveal four independently significant risk factors for catheter-associated urinary tract infections: female gender, absence of systemic antibiotics, duration of catheterization, and violations in catheter care and drainage. Systemic antimicrobial agents have been shown to decrease the risk of urinary tract infection during the first 4 to 5 days of catheterization. However, their routine use is precluded by concern over antimicrobial resistance, superinfection with pathogens such as enterococci and *Candida*, cost, and potential adverse drug reactions. These antibiotics may be helpful in high-risk patients who require short-term catheterization. Catheters coated with silver ions have not been consistently effective in reducing bacteriuria. Likewise, catheter bag decontamination can be accomplished with various agents (e.g., hydrogen peroxide, iodophors, chlorhexidine) but does not decrease urinary tract infection rates, suggesting that the bag rarely is the source of infection. Disconnection of catheter junctions and other errors in catheter care are common and have been identified as risk factors, necessitating ongoing staff education regarding catheter care. Sealed junctions have been proposed as an alternative approach.

GASTROINTESTINAL INFECTIONS

Routine microbiologic surveillance of enteric pathogens is worthwhile to facilitate the early detection of potential outbreaks of enteric pathogens. Nosocomial outbreaks of *Salmonella* species have been well documented and are common in health care institutions. These outbreaks usually derive from index cases that are acquired in the community, then cross-transmitted in the hospital, particularly on the pediatric ward. Cross-transmission usually results from transient hand carriage by health care personnel. Occasionally, however, personnel become colonized in the gastrointestinal tract. In some cases, health care workers have acquired infection in the community and become chronic carriers of *Salmonella* species. Many states have public health laws that prohibit health care workers who carry *Salmonella* from having direct patient contact. In addition, food-borne outbreaks are relatively uncommon in health care institutions, but food workers who carry *Salmonella* usually are restricted from food preparation. Hospital employees who have stool cultures that are positive for *Salmonella* should undergo serial cultures every 1 to 2 months or until they are established as chronic carriers (i.e., cultures are positive for more than 1 year). State law may forbid certain personnel such as food workers from returning to work until their culture results are negative. If epidemiologic evidence implicates a chronic carrier as the source of an outbreak, the worker should be removed from the site until carriage is eliminated or should be reassigned to a low-risk area. Personnel with acute disease should be restricted from patient care and personnel contact until they are asymptomatic. *Shigella* infections also can be transmitted in the institutional setting, but are less common than *Salmonella* infections. Outbreaks of *E. coli* O157:H7 have been reported in extended-care facilities and should be suspected and ruled out in investigations of diarrhea in this setting. Nosocomial transmission of diarrhea caused by rotavirus has been reported on numerous occasions, primarily on pediatric, maternity, and geriatric wards. Transmission is difficult to prevent because viral shedding can occur and persist for long periods in asymptomatic personnel and immunocompromised patients. Cohorting of patients and personnel is useful in controlling such outbreaks.

For all patients with enteric pathogens, barrier precautions should be used for contact with feces and other body fluids and secretions. Because such precautions are

now standard for all patients in most institutions, the previously used CDC isolation category of “Enteric Precautions” is superfluous, but standard precautions should be reviewed and emphasized with hospital staff when an enteric pathogen is identified on a unit. If patient compliance or hygiene is poor, a private room may be required for management.

The nosocomial transmission of *Clostridium difficile* has been well documented and presents a difficult problem. Although the use of systemic antibiotics may select for *C. difficile* colitis, cross-transmission related to environmental reservoirs and transient hand carriage has been documented with molecular typing techniques. High-level disinfection with 2% glutaraldehyde for appropriate intervals is performed routinely for semicritical equipment, such as endoscopes, and reduces the possibility of transmission by this route. However, this spore-forming organism survives readily on environmental surfaces in affected patients' rooms and serves as a persistent reservoir for hand carriage by transient personnel. Surveillance for *C. difficile* toxin titers may be helpful in determining whether a cluster of patients with *C. difficile* colitis occurs on a specific ward or unit, suggesting potential cross-transmission of this pathogen. In these instances, contact precautions, with particular regard to environmental cleaning or special organism isolation, may be helpful in controlling transmission. Daily environmental cleaning of horizontal surfaces in proximity to affected patients using hospital-grade disinfectants may limit the endemicity of this organism. In addition, barrier precautions and hand-washing measures must be reemphasized to personnel.

OUTBREAK INVESTIGATION

Effective surveillance methods should lead to the early identification of increased rates or outbreaks of problem nosocomial infections or organisms. The primary objective of outbreak investigation is to identify ways of preventing further transmission of or exposure to the disease-causing agent. In the investigation of any outbreak or cluster, the principles of epidemic investigation apply. The first question to be answered is whether an epidemic is occurring. An *epidemic* is an increase in the number of cases compared with past experience for a given population, time, and place. To answer this question, the previous endemic, baseline rate of the problem must be known. This can be determined easily for infections or microorganisms that are surveyed routinely. For other identified problems, computerized laboratory records or discharge diagnoses may be required to establish previous rates. A timeline of cases and statistical determination of whether the perceived increase is significant is warranted at this stage. For specific pathogens, laboratory typing methods are critical. If DNA typing techniques are available in a timely fashion, these should be used early. For instance, if DNA typing techniques suggest that the isolates in question are distinct strains, further epidemiologic investigation may not be warranted. Likewise, if a common strain is documented, epidemiologic investigation should proceed.

When a problem is documented, several steps should be taken immediately ([Table 338.3](#)). During the first 24 hours, the extent of the outbreak should be determined, the cause should be identified if possible, persons at risk should be recognized, and the key clinical and epidemiologic features of the cases should be described. For pathogens that are identified and the mode of spread known, appropriate isolation precautions should be used and hospital staff should be educated regarding the situation and intervention measures. The laboratory should be notified and asked to save any relevant isolates or clinical specimens. Data on environmental samples should be obtained if pertinent. The investigative team should be organized, including the hospital epidemiologist, the infection control staff, clinicians, the laboratory, and, possibly, an environmentalist. Depending on the extent and seriousness of the outbreak, public relations must be arranged. Additional help should be requested if needed from local and state health departments and the CDC.

Is It An Outbreak?
Assess previous rate of problem
Use laboratory typing to determine strain identity
Initial Steps
Make a timeline
Define cases
Identify key clinical and epidemiologic features
Institute isolation precautions if appropriate
Notify laboratory and ask them to save isolates
Organize investigative team
Depending on extent and seriousness:
Arrange for public relations
Notify local and state health departments, and the Centers for Disease Control and Prevention

TABLE 338.3. INITIAL STEPS IN OUTBREAK INVESTIGATION

Existing data should be assessed and a case definition developed. The potential mode of transmission, incubation period, and common denominators or unusual exceptions among the cases must be determined. The outbreak should be characterized by time, place, and patient. Case-control study methods commonly are used at this point in hospital outbreak investigations to identify specific risk factors that can be modified or prevented. A hypothesis should be formulated regarding the source of infection and method of spread, and control measures such as vaccines or prophylaxis should be instituted, if relevant. The hypothesis should be tested using the case-control study and relevant laboratory investigations such as DNA typing of further isolates or serologic tests. Finally, a report documenting the investigation, interventions, outcome, and plans for future surveillance and prevention should be written and documented with the institution's infection control committee or quality improvement committee. Such feedback also should be given directly to the wards or units involved in the outbreak.

ISOLATION PRECAUTIONS

The CDC first published isolation guidelines in 1970, and substantial changes were made in the 1983 CDC Guidelines for Isolation Precautions in Hospitals. Category-specific isolation was simplified to include contact isolation, tuberculosis isolation, drainage/secretion precautions, and blood/body fluid precautions. Disease-specific isolation also was offered as an alternative for hospitals that wanted to direct precautions at specific, identified diseases. Recognition of the AIDS epidemic drastically affected precautions in all United States health care institutions. The 1987 CDC document, “Recommendations for Prevention of HIV Transmission in Health Care Settings,” outlined blood and body fluid precautions for all patients. Barrier precautions were recommended for blood, certain body fluids, and body fluids containing blood.

The application of blood and body fluid precautions to all patients was referred to as *universal blood and body fluid precautions* or *universal precautions*. In 1988, the CDC published an update, “Universal Precautions for Prevention of Transmission of Human Immunodeficiency Virus, Hepatitis B Virus, and Other Bloodborne Pathogens in Health Care Settings.” This document clarified that the potential transmission of blood-borne pathogens other than the human immunodeficiency virus, such as hepatitis B, also should be prevented. Category- or disease-specific guidelines were recommended for dealing with non-blood-borne pathogens. The Occupational Safety and Health Administration became involved in the regulation and enforcement of these guidelines. Many infection control programs recognized the need to reduce the transmission of non-blood-borne pathogens because CDC-defined universal precautions were directed primarily at blood-borne pathogens. A system of “Body Substance Isolation” previously had been introduced by Jackson and Lynch to control the transmission of non-blood-borne pathogens. This system designated all body fluids and tissue as potentially infectious and provided an alternative to the category- and disease-specific system. Confusion ensued in many institutions because the term “universal precautions” was used to apply to barrier precautions for all body fluids, not just blood and certain body fluid, as originally defined.

STANDARD PRECAUTIONS

CDC isolation guidelines underwent revision by the CDC's Hospital Infection Control Practices Advisory Committee and were published in 1996. The guidelines contain two levels of precautions. The first is termed *standard precautions* and combines the major features of universal precautions and body substance isolation. These precautions apply to all patients, regardless of disease or known infection status. Standard precautions apply to blood; all body fluids, secretions, and excretions, regardless of whether they contain visible blood; nonintact skin; and mucous membranes. This first level of precautions decreases the risk of transmission from recognized or unrecognized infection.

TRANSMISSION-BASED PRECAUTIONS

The second level of precautions apply to patients with documented or suspected transmissible or epidemiologically significant pathogens that require more than standard precautions to prevent cross-transmission. Transmission-based precautions are of three types: airborne precautions, droplet precautions, and contact

precautions. These can be combined for diseases that have several routes of transmission. Each type is used in addition to standard precautions. The previous category-specific types of isolation (strict isolation, contact isolation, respiratory isolation, tuberculosis isolation, enteric precautions, and drainage/secretion precautions) and disease-specific isolation precautions have been combined into the three types of transmission-based precautions. As with previous guidelines, the CDC acknowledges that no guidelines address every hospital's needs. Hospitals are encouraged to review the guidelines and to modify them as necessary.

AIRBORNE PRECAUTIONS

Airborne precautions are designed to decrease the risk of transmitting infection by the airborne route, through airborne droplet nuclei (measuring 5 µm or less) or dust particles containing the infectious agent. Organisms that are transmissible by this route can be dispersed widely by air currents. Diseases in this category include varicella, measles, and tuberculosis. Patients should be kept in private rooms with monitored negative airflow, a minimum of six air changes per hour, and exhaust that is directed outside or to a high-efficiency particulate air filtration system. Doors should be kept closed. Patients should leave their rooms wearing masks and for necessary purposes only. Respiratory protection should be worn for patients with known or suspected tuberculosis according to current guidelines. The type of mask or respirator that should be worn for tuberculosis protection is controversial. Persons who are susceptible to measles or varicella (chickenpox or disseminated varicella) should not enter the rooms of patients who have these infections.

DROPLET PRECAUTIONS

Droplet transmission occurs when the mucous membranes of the nose, mouth, or conjunctivae of susceptible persons come in contact with large particle droplets (measuring more than 5 µm) from individuals colonized or infected with the infectious agent. Transmission through large-droplet nuclei differs from airborne transmission in that it requires close contact between sources and recipients, because droplet nuclei do not remain suspended in the air and usually travel only short distances. Some diseases that require droplet precautions are meningococcal meningitis, multiply drug-resistant pneumococcal meningitis or pneumonia, pertussis, streptococcal pharyngitis or pneumonia, influenza, and parvovirus B19 (with aplastic crisis or chronic infection). Patients should be placed in private rooms. If this is not possible, cohorting may be done with patients who have active infections with the same microorganisms but no other infections. If private rooms or cohorting are not available, spatial separation of at least 3 feet between infected patients and other patients is suggested. Patients should leave their rooms only when necessary and should wear masks.

CONTACT PRECAUTIONS

Contact precautions are used for patients who are known or suspected to harbor epidemiologically significant microorganisms that are transmitted by direct patient contact (by hand or skin contact that occurs during routine patient care or indirect contact [touching] of environmental surfaces). Patients should be placed in private rooms when possible. If this is not feasible, cohorting is recommended. If neither private rooms nor cohorting is possible, the epidemiology of the organism must be considered and infection control professionals consulted. Gloves should be used as a barrier against contact with blood and body substances, as in standard precautions. In addition, gloves should be changed after contact with infective material carrying high concentrations of microorganisms (i.e., feces, wound drainage), as in contact precautions. Gloves should be removed before leaving patients' rooms and hands should be washed using antiseptic solution. Clean, nonsterile gowns should be worn if substantial patient contact is anticipated.

Diseases for which contact precautions are recommended include infection or colonization with multiply drug-resistant bacteria; *C. difficile* colitis; respiratory syncytial virus in children; skin infections caused by scabies, impetigo, or herpes zoster (disseminated); and viral hemorrhagic fevers (Lassa fever or Marburg virus). Disseminated varicella is an example of an infection that requires two transmission-based precautions—airborne and contact.

Vancomycin-resistant enterococci have emerged and are prevalent in many areas. Patients colonized or infected with these organisms are cared for according to contact precautions in some institutions. Guidelines for preventing the transmission of vancomycin-resistant enterococci have been published by the CDC and emphasize the use of contact precautions and designated patient equipment or careful disinfection between patients. In addition, a multidisciplinary approach to controlling this organism is recommended, including appropriate vancomycin use. Because the guidelines are in transition, some have found it helpful to use a category of *special organism isolation*. This may be used for multiply resistant organisms, including some vancomycin-resistant *Enterococcus faecium*, *Acinetobacter anitratus*, and epidemiologically significant organisms such as *C. difficile*. The policy includes barrier precautions for all contact with the patient, the bedside equipment, and the patient's immediate environment. Special emphasis is placed on environmental control measures, such as designating individual rather than shared equipment and carefully cleaning the environment, because these are important with organisms such as vancomycin-resistant enterococci and *C. difficile*.

THE NEW HOSPITAL EPIDEMIOLOGY: EXPANSION TO OTHER INTERESTS

Infection control and classic hospital epidemiology techniques have served as an early model for the quality improvement process in hospitals. The field of hospital epidemiology has expanded to health care epidemiology. Epidemiologic methods and hospital epidemiologists now evaluate noninfectious quality of care issues using the same principles: surveillance, prevention, and control. This time-tested methodology, enhanced in the computer age and exercised by personnel with experience in the field, will lead to continued improvement in all areas of health care delivery and efficiency.

CHAPTER 339: APPROACH TO THE PATIENT WITH HIV EXPOSURE

ELISE M. JOCHIMSEN AND DENISE M. CARDO

[Presentation](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care Management](#)

PRESENTATION

The most reliable estimates for the risk of human immunodeficiency virus (HIV) transmission after a single exposure are from occupational exposures involving health care workers (HCWs) studied prospectively after exposure. Such studies have estimated that the risk of HIV infection after a single occupational percutaneous exposure to HIV-infected blood is approximately 0.3% and after a mucous membrane exposure 0.09%. The risk of transmission after skin exposures, while not precisely quantified, is believed to be even smaller. The risk of transmission after a nonoccupational exposure has been more difficult to estimate, due in part to difficulties in determining the time, source, nature, and frequency of exposures. However, available data suggest that the per-episode risk is within the same order of magnitude as that associated with percutaneous exposure.

It must be emphasized that these estimates are averages and may be affected by a variety of factors. For example, a retrospective case-control study found that HCWs who sustained a percutaneous exposure to HIV-infected blood were more likely to become infected if they were exposed to a larger quantity of blood (deep injury, device visibly contaminated with blood, or device previously placed in the patient's vein or artery). In addition, transmission of HIV also was associated with injuries in which the source patient was terminally ill with AIDS. Several risk factors for sexual transmission have been identified, including genital ulcer disease and other coexisting sexually transmitted diseases.

PATHOPHYSIOLOGIC FACTORS

Within hours to days after exposure, cutaneous or submucosal dendritic cells are believed to transport HIV to CD4⁺ T cells in regional lymph nodes, where productive infection is established. The premise underlying postexposure prophylaxis (PEP) is that in the presence of antiretroviral drugs, productive infection may be prevented or inhibited, allowing the host immune system to destroy infectious virions and infected cells while they are localized and relatively small in number. This premise is consistent with knowledge that HIV virions are rapidly cleared by the human immune system while the immune system is still intact. The demonstration of HIV-specific cytotoxic T-lymphocyte activity in a small number of HIV-exposed but non-seroconverting HCWs (and in other groups of HIV-exposed but uninfected persons) is consistent with the possibility that host immune responses may sometimes be able to prevent or eradicate HIV infection after an exposure.

Information from a variety of sources suggests the possibility that PEP may be efficacious in preventing infection after HIV exposure. PEP has prevented or ameliorated retroviral infection in some studies in animals, particularly when administered soon after exposure. However, the application of animal studies using nonhuman retroviruses is uncertain since these viruses have pathogenic mechanisms different from those of HIV. There are some indirect data with which to assess the efficacy of PEP in humans. In a multicenter, double-blind, placebo-controlled clinical trial of zidovudine (ZDV) to prevent maternal-infant HIV transmission, ZDV therapy was associated with a 67% reduction in the risk of mother-to-infant HIV transmission. The protective effect of ZDV was only partly explained by a reduction of HIV titer in maternal blood; ZDV also may have a direct protective effect on the fetus and/or act as postexposure prophylaxis for the infant. Additional studies have shown reductions in the rates of perinatal transmission of HIV even with the use of abbreviated regimens that are begun intrapartum or in the first 48 hours of life. Also, a retrospective case-control study found that PEP with ZDV was associated with a decrease of approximately 81% in the risk for HIV seroconversion among HCWs who had a percutaneous exposure to HIV-infected blood. However, any protection afforded is not absolute. Failure of ZDV PEP to prevent HIV infection after an occupational exposure has been reported in at least 18 instances.

HISTORY AND PHYSICAL EXAMINATION

The prompt reporting of HIV exposures is important, not only for management of the exposure but also for identification and evaluation of preventive measures. The exposed person should be evaluated and counseled regarding the risk of HIV infection, the potential usefulness of PEP, and the need for follow-up evaluation. First aid, if necessary, should be administered as quickly as possible. After an exposure, efforts should be made to identify and evaluate the source clinically and epidemiologically for evidence of HIV infection. The circumstances of the exposure should be recorded in a confidential medical record. Data collection should include details about the exposure, information about the source, and details about postexposure management, counseling, and follow-up.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

In persons with known exposure dates, the estimated median time from initial infection to the development of detectable antibody is 2.4 months; 95% of individuals develop antibody within 6 months of infection. The two antibody tests commonly used to detect HIV are the enzyme immunoassay (EIA) for screening and the Western blot for confirmation. Assays for detection of HIV RNA in plasma (e.g., polymerase chain reaction) are sensitive methods for the detection of HIV infection. However, problems with laboratory contamination, false-positive rates, and increased costs limit their routine use. At present, the false-positive and false-negative rates of HIV RNA detection methods are too high to warrant a broader role for them in either routine screening or in the confirmation of diagnosis of HIV infection.

All persons with exposure to HIV should receive postexposure testing. HIV antibody testing should be performed at baseline and for at least 6 months following exposure (e.g., at 6 weeks, 12 weeks, and 6 months). HIV testing using EIA should be performed on any exposed person who has an illness that is consistent with an acute retroviral syndrome.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

MANAGEMENT

All persons exposed to HIV should receive follow-up counseling and medical evaluation, regardless of whether they receive PEP. The U.S. Public Health Service (PHS) recommends PEP for certain occupational HIV exposures but cannot definitively recommend for or against antiretroviral agents in preventing nonoccupational HIV exposures.

Postexposure prophylaxis should be recommended to exposed HCWs after occupational exposures associated with a known risk for HIV transmission (e.g., needlestick injuries to HIV-infected blood), should be considered for exposures with a negligible risk (e.g., mucous membrane exposures to HIV-infected blood), and may not be warranted for exposures that do not pose a known risk for HIV transmission (e.g., intact skin exposures) ([Fig. 339.1](#)). For exposures for which PEP is considered appropriate, exposed workers should be informed that knowledge about the efficacy and toxicity of drugs used for PEP is limited. Exposed HCWs who choose to take PEP should be advised of the importance of completing the prescribed regimen. They should know the side effects of the drugs that have been prescribed, what can be done to minimize these effects, and how clinical monitoring for toxicity during the follow-up period will be implemented. HCWs who have HIV occupational exposures for which PEP is not recommended should be informed that the potential side effects and toxicity of PEP outweigh the negligible risk of transmission posed by the type of exposure.

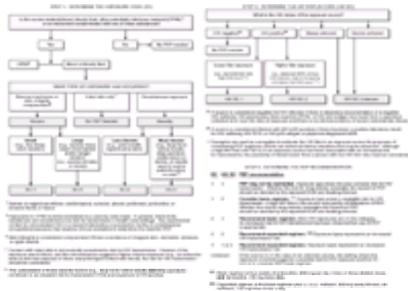

FIGURE 339.1. This algorithm is intended to guide initial decisions about PEP and should be used in conjunction with other guidance provided in this report.
EVIDENCE LEVEL: C. Expert Opinion.

Most occupational HIV exposures will warrant only a two-drug regimen, using two nucleoside analog reverse transcriptase inhibitors, usually ZDV and lamivudine. The addition of a third drug, usually a protease inhibitor (e.g., indinavir or nelfinavir), should be considered for exposures that pose an increased risk for transmission or when resistance to the other drugs used for PEP is known or suspected. Over time, new antiretroviral agents will be available for the treatment of HIV infection and may offer increased potency for PEP. The inclusion of new drugs in a PEP regimen should be carried out in consultation with a clinical expert in the treatment of HIV infection.

In general, PEP should be initiated as soon as possible (within hours of the exposure). The interval within which PEP should be started for optimal efficacy is not known. The optimal duration of PEP also is unknown. Because 4 weeks of ZDV appears protective in HCWs, PEP probably should be administered for 4 weeks, if tolerated. When PEP is used, drug toxicity monitoring should include a complete blood count and renal and hepatic chemical function tests at baseline and 2 weeks after starting PEP.

The psychological impact of HIV exposure may be considerable and should be addressed during counseling and follow-up. Experts have found that supportive counseling is an important part of management. To prevent the possibility of further transmission to others, the exposed person should be advised to refrain from donating blood, semen, or organs during the follow-up period and to refrain from breast-feeding when safe and effective alternatives are available. To prevent HIV transmission to sexual contacts, all exposed persons should abstain from, or use latex condoms during, sexual intercourse throughout the follow-up period, especially during the first 6 to 12 weeks after the exposure when most HIV-infected persons are expected to seroconvert.

Many of the principles for management of occupational exposures also apply to management of sexual and other nonoccupational HIV exposures, although these instances require the consideration of additional factors. The first step in managing a reported nonoccupational event that may have led to HIV exposure is the determination of the infection status of the reported source. Unlike occupational exposures, the putative source in these cases may not be available to clinicians to provide documentation of HIV status or clinical information on antiretroviral use or viral load. Even in cases where partner notification or timely arrest of assailants (e.g., rape or child abuse) would potentially allow HIV testing of an identified source, delays in seeking care and obtaining test results may necessitate decisions based on estimating the likelihood of infection in the source. If it is determined that the source is, or is likely to be, HIV-infected, the next step is to determine the risk of transmission given the details of the reported exposure. Factors that would either increase (e.g., bleeding and visible mucosal tears in a rape patient) or reduce (e.g., condom used without leak or tear detected) the risk of transmission should be ascertained. If the source is HIV-infected and the exposure event presents an appreciable risk of transmission, it will be important to determine how frequently such exposures occur for a given patient. PEP is not appropriate for persons who frequently put themselves at risk; these patients should be provided or referred urgently for intensive risk reduction intervention.

The use of PEP for nonoccupational exposures should be judicious and only in the context of a comprehensive program of HIV prevention. Results from a program for PEP after nonoccupational exposures in San Francisco, where participants are provided risk reduction counseling in addition to an option to take a 28-day PEP course, have shown that it is possible to provide PEP within 72 hours after exposure and that 80% of persons taking a 4-week PEP regimen completed it.

COMPLICATIONS AND PITFALLS

HIV antiretroviral drug resistance is increasing. Unfortunately, it is difficult to predict the likelihood of drug resistance in the source and the implications for transmission. There are still relatively few data on the prevalence of resistance, and the data are difficult to translate into PEP recommendations. Laboratory evidence of drug resistance does not necessarily imply clinical drug failure. However, a high or rising viral load in the absence of other causes (e.g., treatment discontinuation, intercurrent illness, or vaccination) strongly suggests that drug-resistant virus may be present. Many experts believe that the PEP regimen should include at least two drugs to which the source HIV strain(s) are likely to be susceptible. While probably optimal based on virologic considerations, this recommendation must be tempered by two particularly critical considerations in prescribing PEP: drug toxicity and the complexity of the regimen. Since the great majority of exposed persons will not become infected, even if they receive no PEP, drugs used for PEP should have a very low incidence of moderate or serious toxicity. They also should be well tolerated; incomplete adherence due to unpleasant side effects could render a seemingly highly potent regimen less effective than a less potent regimen. Some side effects that limit adherence (e.g., nausea or diarrhea) can be managed with symptomatic therapy.

When a pregnant woman is exposed to HIV, the evaluation of risk and need for PEP should be approached as with any other person who has had an HIV exposure. The decision to use any antiretroviral drug during pregnancy should be made following discussion between the woman and her health care provider regarding the benefits and potential risks to her and her fetus. Since indinavir may cause indirect hyperbilirubinemia, this drug should not be used in newborns or for PEP in pregnant women if delivery is expected shortly. Efavirenz should not be used during pregnancy.

When the HIV status of the source is unknown or the source cannot be identified, decisions regarding appropriate follow-up and PEP should be individualized, based on factors such as whether potential sources are likely to include an individual at increased risk of HIV infection and the severity of the exposure. If additional information becomes available, these decisions can be modified.

CHAPTER 340: APPROACH TO THE PATIENT WITH ASYMPTOMATIC HIV INFECTION (AND COUNSELING)

ABRAHAM VERGHESE

[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Counseling](#)
[Strategies for Optimal Care Management](#)

HIV infection is a disease of young people, many of whom have had little or no prior contact with health care providers. The first visit is critical in establishing a therapeutic patient–physician relationship. Most asymptomatic patients with recently diagnosed HIV infection experience anger, anxiety, guilt, and denial for weeks, months, or even years. Suicidal ideation peaks shortly after diagnosis and may persist over the next year. Identifying the social support available to these patients, such as parents, spouses, lovers, and children, is a critical aspect of patient care. Many patients are unaware of the dramatic new advances in the therapy of HIV that have occurred in the last few years. The laboratory tests that document HIV infection should be scrutinized and repeated if necessary. There have been reports of patients with factitious HIV infections.

PATHOPHYSIOLOGIC FACTORS

Even when patients are clinically asymptomatic, tremendous immunologic activity is occurring within the lymphatic system. Although there may be a period of clinical latency, there is no viral latency. The term *acquired immunodeficiency syndrome*, or “AIDS,” is in a sense outmoded and now has only epidemiologic utility, even though it is ingrained in medical parlance. Nonspecific predictors of progression from a clinically latent stage to symptomatic infection or AIDS are listed in [Table 340.1](#). With the availability of tests to measure the viral load in the blood, it has become apparent that the viral load is the best predictor of prognosis. The Multicenter AIDS Cohort Study showed that patients with more than 36,000 viral copies per milliliter had a 62% risk of progressing to AIDS in 5 years compared to those with viral loads less than 4,530 copies per milliliter whose risk was 8%. The CD4⁺ cell count is also an important clinical predictor of progression, particularly when combined with the viral load. For example, in the Multicenter AIDS Cohort Study, 73% of patients with a CD4 count of less than 350 cells per cubic millimeter who had over 30,000 viral copies per milliliter (measured by B-DNA assays) developed an AIDS-defining event in 3 years, compared to 32% of patients with the same viral load but with more than 500 CD4 cells per cubic millimeter progressed to AIDS in the same time period.

Clinical
Thrush
Oral hairy leukoplakia
Herpes zoster (?)
Fever, fatigue, weight loss
Peripheral general lymphadenopathy that develops rapidly (?)
Laboratory Studies
High viral load
Decreased CD4 leukocyte count
Anemia
Elevated β_2 -microglobulin, neopterin
Elevated erythrocyte sedimentation rate
Anergy
Detection of p24 antigenemia
Elevated immunoglobulin levels (IgG and IgA)

TABLE 340.1. CLINICAL AND LABORATORY FEATURES OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION THAT INDICATE DISEASE PROGRESSION

HISTORY AND PHYSICAL EXAMINATION

An important element in the history is information regarding risk behaviors, which may continue unless counseling and intervention is provided. Tuberculosis appears to be more common in intravenous drug users, and these patients also may be less compliant with therapy. Kaposi's sarcoma is seen in homosexual and bisexual men. Perianal problems ranging from reactivation of herpes simplex to the development of cloacal cancer are more common in homosexual men.

Patients should be questioned carefully about symptoms that suggest disease progression ([Table 340.1](#)). Prior exposure to syphilis, tuberculosis, hepatitis B or C, cytomegalovirus, or *Toxoplasma* should be determined. A detailed history of sexually transmitted disease often is useful in predicting future flare-ups of herpes proctitis, venereal warts, or syphilis. A history of prior immunizations, drug allergies, and medication use must be obtained. Many medications, including methadone, can interact with protease inhibitors.

The goal of the initial physical examination is to establish the patient's baseline status and identify important areas to be followed up at future visits. The weight should be measured carefully on a reliable scale with the patient undressed. A flow chart placed on the front of the patient's chart detailing weight, viral load, CD4⁺ cell count, vaccination status, medications, and problems makes it easier for different health care providers in the same clinic to track the patient's progress. Careful attention should be given to the eye examination. Cytomegalovirus retinitis is uncommon until the CD4⁺ count has dropped below 200 cells per microliter. The oral cavity should be examined thoroughly. The tongue is pulled out with a gloved hand and gauze, and the sides are inspected for oral hairy leukoplakia. The oral mucosa is examined for Kaposi's sarcoma, which may be present only in this location. The state of dentition and the health of the gingival tissue should be observed because gingivitis and periodontitis tend to progress in later stages of HIV. Referral for preventive dentistry is helpful. Generalized lymphadenopathy is common in symptomatic patients and does not always indicate disease progression. However, enlargement of one lymph node alone should raise suspicion of lymphoma, tuberculosis, Kaposi's sarcoma, or another process. Enlargement of the liver and spleen are looked for carefully and serve as an important baseline when future abnormalities are detected. Perianal, rectal, and pelvic examinations are performed. Problems such as fistula in ano and perianal abscess should be treated promptly because healing is more difficult at later stages of HIV infection. The presence of ankle and knee reflexes, and intact vibratory sense in the lower extremities, should be established. This provides a baseline for comparison in the event the patient later complains of tingling or numbness in the feet—symptoms that are common side effects of therapy with didanosine and dideoxycytidine, and that can also be caused by HIV and cytomegalovirus. The skin examination is particularly important. Common skin problems include seborrheic dermatitis, molluscum contagiosum, folliculitis, allergic rash, warts, and Kaposi's sarcoma. During the course of the examination, the physician should establish rapport with the patient and try to assess the patient's mental status and coping mechanisms. HIV infection necessitates intense patient–physician interaction, and extra time spent at the initial visit helps gain the patient's confidence. This is also an occasion to educate the spouse, partner, or family members and to help them understand the nature of the illness.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The laboratory workup of the asymptomatic patient with HIV infection is most extensive at the initial visit. Both routine and less common tests are listed in [Table 340.2](#). The complete blood count is useful to detect unsuspected thrombocytopenia or anemia. The serum lactate dehydrogenase level is a helpful baseline measurement and should be normal; this marker tends to increase during *Pneumocystis carinii* infection.

History and physical examination
 Complete blood cell count with differential and platelet counts
 Erythrocyte sedimentation rate
 Serum chemistry profile
 Urinalysis
 Serologic tests
 Hepatitis B and C
 VDRL
*Toxoplasma gondii** antibodies
 Cytomegalovirus antibodies*
 Stool studies for ova and parasites, if indicated
 Chest radiograph
 Tuberculin skin test
 Glucose-6-phosphate dehydrogenase measurement*
 Measurement of prognostic serologic markers
 Viral load by branched DNA or polymerase chain reaction
 CD4⁺ lymphocyte count and percentage of total lymphocytes
 IgM microglobulin concentration*

* = Optional study.
 VDRL, Venereal Disease Research Laboratory.

TABLE 340.2. INITIAL EVALUATION OF ASYMPTOMATIC HIV-SEROPOSITIVE PATIENTS

Most serologic tests are ordered primarily to detect dormant pathogens. Many infections in patients with AIDS result from the reactivation of pathogens already residing in the body, such as *Toxoplasma*, cytomegalovirus, *P. carinii*, herpes simplex, herpes zoster, and *Mycobacterium tuberculosis* (although the last organism is recently acquired in many patients). For example, *Toxoplasma* infection is less probable in a patient who later has encephalopathy or a central nervous system mass lesion if *Toxoplasma* antibodies were not present initially, although newly acquired infection may occur. A purified protein derivative skin test should be done on the first visit. The sensitivity of this test correlates inversely with the degree of immune suppression. Induration of 5 mm is interpreted as indicative of tuberculosis infection and the patient is treated with isoniazid (INH) for 12 months.

Viral load testing is becoming a routine part of HIV care and follow-up. HIV RNA determination can be done by polymerase chain reaction (PCR) or branched-chain DNA methods. PCR-based values are up to 2.5 times higher than B-DNA values. The two tests correlate well with each other, but the physician must pick one of the two methodologies and have it performed at the same laboratory in order to make meaningful interpretations of changes over time. Testing for resistance is not routinely done but is increasingly being performed in patients who have failed therapy.

The CD4⁺ cell count should be done at the same time of day to account for circadian variations. The presence of intercurrent illness affects the results and should delay test performance for 2 to 3 weeks. Patients and physicians often focus excessively on the CD4⁺ cell count. Trends in the count over time are more useful than are absolute numbers as diurnal variations in CD4 numbers by as much as 100 cells per cubic millimeter have been reported. Some studies have suggested that the CD8 cell count may be useful. Other markers of HIV progression, such as b₂-microglobulin, p24 antigen, and neopterin, are no longer obtained routinely. The Venereal Disease Research Laboratory (VDRL) test is particularly important because patients with HIV are more likely to have a history of syphilis and because early syphilis in these patients is more likely to present as secondary syphilis. If there is a history of incomplete treatment or if the VDRL is reactive, aggressive treatment is indicated.

The second visit takes place a week after the first and allows the patient to obtain test results and meet other members of the HIV health care team (nurses, nurse-practitioners, physician's assistants, social workers, and clinic volunteers). The second visit provides an opportunity to reinforce preventive health care recommendations, such as stopping smoking and joining a support group. At least one study has suggested that belonging to a support group and maintaining an active interest in the treatment program correlates with longevity in patients with HIV infection. The influenza vaccine should be offered at the appropriate time of year and the pneumococcal polysaccharide vaccine should be used. It is not clear as to whether the *Haemophilus influenzae* type B vaccine should be given routinely because most adults are protected. The hepatitis B vaccine should be given if serologic tests show lack of protection. The patient should be advised that children living in the household should receive inactivated polio vaccine rather than live oral vaccine. If the patient has not previously received standard "childhood" immunizations (measles, mumps, and rubella; diphtheria; tetanus; inactivated polio), these should be given.

COUNSELING

GENERAL COUNSELING

It is useful to ask patients what they understand about the disease. Pamphlets and informational brochures can be helpful in patient education. Guidelines for preventing virus transmission and explicit instructions about safe-sex practices should be provided. Sex with other HIV-infected patients often is considered harmless, and patients should be informed that, on the contrary, unprotected intercourse may result in the acquisition of another strain of HIV, another sexually transmitted disease, or an increased viral load. Identifying others who are at risk and arranging for their testing and follow-up also is important. Knowledge of state and local laws concerning confidentiality and disease reporting is essential; social workers can assist with these issues and with housing, funding for medication, and qualifying for state and federal assistance. Women of childbearing age should be counseled about the risk of transmitting HIV to the fetus and encouraged to prevent pregnancy. Patients should be advised to refrain from donating blood, plasma, or other body tissues or organs. Patients should be instructed not to share razors or toothbrushes, and both patients and their family members should be told how to clean up accidental spills of blood or body fluids using household bleach diluted in water at a ratio of 1:10. Patients can be reassured that casual contact with family members and co-workers will not result in HIV transmission. Patients should be questioned about pet ownership, especially cats and birds, and should be advised to exercise care in cleaning cat litter (if serologic tests for *Toxoplasma* are negative) and to seek prompt attention for cat scratches or bites. The consumption of raw fish or meat and of uncooked eggs is discouraged.

PSYCHIATRIC COUNSELING

Patients often manifest signs of emotional distress such as cognitive dysfunction and social withdrawal. Episodic anxiety and depression are common; depression often responds well to antidepressant therapy. Suicidal ideation always must be sought. Many of these problems can be improved remarkably through participation in support groups and use of medications pre-scribed by the primary physician, but psychotherapy and formal psychiatric consultation occasionally is required.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

Patients should be encouraged to continue working as long as they are physically able. Physicians should expect patients to approach them aggressively with demands for information about new treatments receiving coverage in the news media. Physicians should not resent these questions, but should attempt to convey what they know while also pointing out the delay between a laboratory observation or a lay press report and a clinically applicable therapy. Patients can obtain additional information from multiple sources; useful newsletters are published by Project Inform and the Gay Men's Health Crisis (GMHC) Department of Medical Information. In addition, the National Directory of AIDS Care and the National Institutes of Health AIDS Clinical Trials Group have toll-free numbers that provide information on resources, services, and clinical trials. A number of web sites (Johns Hopkins, University of San Francisco, and many others) provide current information for both patients and physicians. It is important that physicians adopt nonjudgmental attitudes toward alternative therapies, particularly if such therapies appear to cause no harm to patients and if patients believe in them. Clear evidence of fraud or quackery requires intervention. Practices such as meditation, acupuncture, prayer, and the use of vitamins can be encouraged; the effect of Chinese herbs and other treatments, though probably harmless, may interfere with concomitant antiviral therapy.

SPECIFIC TREATMENT ISSUES

Pneumocystis carinii Pneumonia Prophylaxis

The earliest success in the treatment of HIV disease came with the realization that one could prevent *P. carinii* pneumonia by the administration of antibiotics to patients at risk. The initial popularity of monthly aerosolized pentamidine has given way to some concern about its inability to prevent extrapulmonary *Pneumocystis* infection. Oral trimethoprim-sulfamethoxazole is easier to use and more effective for both primary and secondary prophylaxis. It may also diminish the incidence of *Toxoplasma* infection and *Nocardia* infection, and may prevent some infections with common bacterial pathogens. Dapsone is a useful alternative agent, but patients must be screened for glucose-6-phosphate dehydrogenase deficiency. Prophylaxis of *Mycobacterium avium* complex is discussed in a later section; patients who

require such prophylaxis usually have symptoms and CD4⁺ cell counts of less than 100 cells per microliter.

Antiretroviral Therapy

The discovery of potent new antivirals and the realization that by combining drugs one could suppress viral production heralded a new era in antiviral therapy. The question of when to begin antiretroviral therapy in asymptomatic patients with HIV infection is controversial. Clearly early treatment will control viral replication, prevent immune destruction, and perhaps decrease the risk of viral transmission. On the other hand, early treatment in an asymptomatic patient can cause drug resistance to occur earlier, exposes patients to long-term toxicity of medications, and affects their quality of life. Prior to the advent of routine viral load testing and potent antiviral therapy, a CD4 count of less than 500 cells per cubic millimeter was considered the threshold for beginning treatment. Although there is no clear consensus, most experts agree that patients with more than 500 CD4 cells per cubic millimeter and a viral load less than 10,000 (B-DNA) can be observed. Patients with higher viral loads or a CD4 count below 500 cells per cubic millimeter should probably be offered treatment.

Patients must have a very clear idea of what is involved in treatment. They must understand that they must be committed to the regimen once it begins; noncompliance clearly can result in resistant strains and worsen the prognosis. Patients must realize that they will be taking up to 15 pills a day and will have some side effects, some of which (such as the syndrome of lipodystrophy and insulin resistance) are only beginning to be catalogued. Therapy is expensive, and few patients can afford it without some form of assistance such as the AIDS Drug Assistance Program or Medicaid. Patients who seem unreliable or have ongoing problems with addiction are generally not good candidates, although they may be counseled and could become good candidates for therapy. The final choice about initiating therapy therefore has to be made by the patient.

It seems axiomatic that in beginning therapy three drugs must be used, and it has been typical to use a protease inhibitor (PI) combined with two nucleoside analogs (NRTIs), such as indinavir with zidovudine and lamivudine. New studies, however, suggest that it may be possible to substitute a non-nucleoside reverse transcriptase inhibitor (NNRTI) for the PI and thereby save the PI for later use if there is resistance and disease progression. Newer agents and older agents that can be taken less often will probably continue to simplify therapy and result in fewer pills for the patient to swallow. A major challenge to patients and physicians is to stay abreast of rapid developments in this area. The specific details of therapy are discussed later in this text.

CHAPTER 341: APPROACH TO THE SYMPTOMATIC PATIENT WITH HIV INFECTION

HENRY MASUR

[Fever and Other Constitutional Manifestations](#)
[Lymphadenopathy](#)
[Oral and Esophageal Disease](#)
[Ocular Manifestations](#)
[Hematologic Abnormalities](#)
[Renal Abnormalities](#)
[Skin Disorders](#)
[Genital Tract Disorders](#)
[Musculoskeletal Disorders](#)

Patients with HIV infection develop a wide range of clinical manifestations due to opportunistic pathogens, immunologic processes, direct effects of HIV, and due to therapies which these patients are administered. These manifestations vary considerably depending on the degree of the patient's immunologic decline, age, sex, pathogen exposure as well as the management strategy that has been pursued. When these patients develop new symptoms, signs, or laboratory abnormalities, it is important to approach them expeditiously and methodically so that complications can be diagnosed and treated early, before disability is severe, which is the time when therapeutic intervention is most likely to be successful. Patients need to be educated about the natural history of their disease, how to recognize complications, and how to participate in management so that they can contribute productively to their health care.

Patients with HIV infection are clearly susceptible to almost all of the infectious and noninfectious disease processes that non-HIV-infected individuals develop. Thus, common infectious causes of pulmonary disease such as influenza, mycoplasmosis, or legionellosis must be considered in patients even though these entities are generally not more severe or more common in HIV-infected patients than in HIV-uninfected patients. Similarly, in patients with central nervous system mass lesions, glioblastoma multiforme must enter into the differential diagnosis regardless of CD4⁺ T-lymphocyte count, although at low CD4⁺ T-lymphocyte counts such a diagnosis would be far less likely than other entities.

The best indicator of patient susceptibility to opportunistic infection is still the circulating CD4⁺ T-lymphocyte count ([Fig. 341.1](#)). The likelihood of developing an opportunistic infection can be assessed by clinical parameters (e.g., a history of oral candidiasis, persistent and unexplained fever, wasting, prior episode of pneumonia, or any prior AIDS-defining disease), by virologic parameters (e.g., HIV RNA viral load as measured by polymerase chain reaction or B-DNA technique is the most commonly employed) or by immunologic parameters. Among the latter, there is considerable interest in lymphocyte proliferation assays, in cytotoxic T-cell assays, and in T-lymphocyte phenotypic assays (e.g., measurements of CD45 RO⁺ and CD45 RO⁻ cells), but there is no evidence that these research tools provide clinically relevant information beyond what CD4⁺ T-cell enumeration provides. The absolute number of circulating CD4⁺ T-lymphocyte cells is the parameter that most clinicians follow, even though the CD4⁺ T-lymphocyte percentage (a number that is a direct measurement rather than a number derived from this measurement and the absolute lymphocyte count) is a more reproducible and reliable parameter.

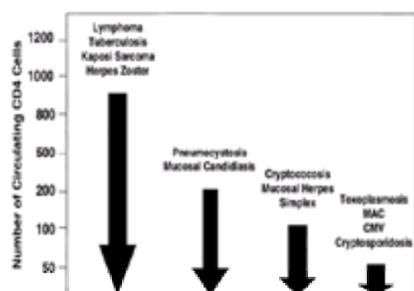

FIGURE 341.1. Typical relationship of clinical manifestation to CD4 count in HIV-infected patients.

EVIDENCE LEVEL: A. Reference: Farizo KM, Buegler JW, Chamberland ME, et al. Spectrum of disease in persons with human immunodeficiency virus infection in the US. *JAMA* 1992;267:1798–1805.

In an era when many patients have responded to highly active antiretroviral therapy in terms of both decreasing their HIV RNA viral load and increasing their CD4⁺ T-lymphocyte counts, concern has been raised that such counts might no longer be reliable indicators of patient susceptibility. In fact, CD4⁺ T-lymphocyte counts still appear to be excellent predictors of host susceptibility to infection either in patients receiving antiretroviral therapy or in patients receiving interleukin-2. Patients appear to derive substantial protection from their CD4 cells that is comparable to the protection that same number of cells would have provided a patient with the same count who had never received antiretroviral therapy. If the nadir CD4⁺ T-lymphocyte count has any influence on host susceptibility to infection, for patients whose counts have risen to a given level, that influence is small. These observations imply that patients who respond to highly active antiretroviral therapy by elevating their CD4⁺ T lymphocytes well above the CD4⁺ T-lymphocyte “threshold” for a given infection may be able to discontinue some opportunistic infection primary prophylaxis (e.g., for *Pneumocystis pneumonia*), or even some chronic maintenance regimens (e.g., for cytomegalovirus retinitis), if specific criteria, detailed in [Chapter 83](#), [Chapter 84](#), [Chapter 85](#), [Chapter 86](#) and [Chapter 87](#), are met.

As clinicians focus on common diseases, on direct effects of HIV, on immunologically mediated syndromes, and on opportunistic infections, they must have a strong appreciation of the potential for drug toxicities and drug interactions to cause clinically important syndromes. Patients with HIV infection may be taking a daunting number of drugs, some prescribed by health care providers and some that are self-prescribed. In addition to toxicities defined for the drug regimens prescribed, these drugs can interact by a variety of mechanisms that may either increase or decrease drug exposure. This is a particular problem with drugs that share hepatic metabolic pathways mediated by the cytochrome P450 system. Rifabutin-induced uveitis is a good example of a complication that occurred with greater frequency in patients receiving other agents that interfered with rifabutin metabolism, greatly increasing its area under the curve.

FEVER AND OTHER CONSTITUTIONAL MANIFESTATIONS

A persistent or intermittent rise in temperature is often one of the first symptomatic manifestations of HIV infection. Virtually every patient experiences episodes of fever at some juncture during his or her disease. A systematic approach including history and physical examination with routine laboratory studies and chest radiograph often reveals a site of infection ([Table 341.1](#)). It is important to recognize that the infection may be an ordinary, community-acquired process due to a common virus or bacteria that could respond to conservative management (without antimicrobial therapy) or to a short course of an appropriate narrow spectrum antimicrobial agent. It is also important to be cognizant that drugs such as trimethoprim–sulfamethoxazole, abacavir, or isoniazid may be the cause of fever. Patients may thus warrant a trial off all medications to determine if one of their drugs is the cause of the fever, while obtaining appropriate cultures, stains, and serologic and radiologic tests. However, special caution is necessary before reintroducing abacavir if there is a possibility that the febrile episode represented an “abacavir hypersensitivity syndrome” since rechallenge in that situation has resulted in fatalities.

Initial evaluation
Chest radiograph
Blood culture for routine bacteria
Blood culture for fungus
Blood culture for mycobacteria
Serum cryptococcal antigen
Liver function tests
Urine analysis
PPD test
Follow-up evaluation (if initial workup is nonrevealing)
Abdominal CT scan or MRI
Chest CT scan or MRI
Arterial blood gas measurement
Sinus film (plain film, CT scan, or MRI)
Lipase and amylase determinations
Urine for <i>Histoplasma</i> antigen
Stool for culture, ova and parasites, <i>Clostridium difficile</i>
Lumbar puncture
RPR test
Lymph node biopsy
Bone marrow biopsy
Liver biopsy
Blood culture or PCR for <i>Bartonella</i>
Dental films

PPD, purified protein derivative; CT, computed tomography; MRI, magnetic resonance imaging; RPR, rapid plasma reagin; PCR, polymerase chain reaction.

TABLE 341.1. RADIOLOGIC AND LABORATORY EVALUATION OF FEVER IN PATIENTS WITH HIV INFECTION AND CD4⁺ LYMPHOCYTE COUNTS OF LESS THAN 200 CELLS/mm³

If a cause is not apparent from this initial evaluation, a more extensive and invasive evaluation is appropriate. The urgency of the evaluation depends on the patient's clinical status (how acutely ill the patient is and if there are concomitant processes, such as substantial inability to perform daily activities, considerable weight loss, or localizing signs). The patient's CD4 count and history of exposure (geographic exposure as well as lifestyle exposure) should also influence the extent and direction of the evaluation. A rapidly rising HIV titer in the circulating blood, as determined by a quantitative method, may also indicate that a patient needs special attention since the CD4 count may be in the process of declining precipitously. Special attention should focus on the pulmonary system because this is often the site of infectious complications; any persistent symptoms should be pursued, even in the absence of radiographic manifestations, as detailed in [Chapter 83](#), especially if the CD4 count is below 200 per cubic millimeter. Subtle neurologic abnormalities, such as persistent headache, aberrant behavior, or cognitive dysfunction, need to be carefully followed (see [Chapter 85](#)) with appropriate imaging techniques and cerebrospinal fluid analysis. Gastrointestinal diseases, especially esophagitis, hepatitis, and biliary disease, need to be sought and enteric infections of the small and large bowel considered (see [Chapter 84](#)). Evidence for cutaneous disease, such as herpes simplex virus (HSV), varicella-zoster virus (VZV), or *Bartonella*, must also be carefully assessed. Screening laboratory tests are indicated in [Table 341.1](#).

Cultures of the blood, as well as serum cryptococcal antigen determination, are an important part of the evaluation. Routine blood cultures may reveal an enteric pathogen such as *Salmonella*, a complication of intravenous drug abuse such as *Staphylococcus aureus*, a complication of an indwelling line such as *Staphylococcus epidermidis*, or an unsuspected fungus such as *Cryptococcus neoformans* or *Histoplasma capsulatum*. Special blood culture media for mycobacteria may be useful for identifying *Mycobacterium avium* complex (MAC), as well as *M. tuberculosis* or various other atypical mycobacteria. Whether blood should be cultured or assessed by nucleic acid amplification for cytomegalovirus (CMV) is less certain: the presence or absence of CMV does not definitely determine whether fever is due to CMV or whether therapy for CMV is warranted.

Cultures of other sites should be done if there are suggestive symptoms, signs, or laboratory tests. If no source of the fever is apparent, routine histologic studies and culture of a bone marrow aspirate, and perhaps biopsy, is probably worth pursuing with particular attention to fungi, mycobacteria, or lymphoma. Liver biopsies in the absence of suggestive signs or impressive laboratory abnormalities are rarely productive as part of a fever evaluation.

A comprehensive evaluation of a persistent fever also includes a methodical radiologic evaluation, including at least abdominal computed tomography (CT) or magnetic resonance imaging (MRI) with contrast. Some centers would include a CT scan or MRI of the brain and sinuses, and perhaps a chest CT scan as well. However, in the absence of any other suspicious evidence, these are expensive, time consuming, and less likely to be helpful. Nuclear scans such as bone scans, liver scans, gallium scans, or tagged white blood cell studies can be considered, but many clinicians do not find these to be useful or cost-effective.

If fever persists and no cause is discovered, empirical therapy might be considered, focusing on MAC or CMV if the patient's CD4 count is below 75 to 100 per cubic millimeter. Given the broad range of possible causes for fever, however, it is probably preferable to follow the patient carefully and reassess periodically unless the patient is extremely symptomatic, or has substantial concomitant weight loss or "wasting."

Some patients may note fatigue, anorexia, chills, sweats, or weight loss in the absence of fever. These manifestations should probably be approached in a way similar to that for fever, with additional attention given to endocrinologic abnormalities such as thyroid and adrenal dysfunction. The evaluation of wasting is considered in [Chapter 84](#). With regard to patients who describe fatigue or weight loss, the influence of psychological factors such as depression must be considered as one aspect of a methodical and comprehensive evaluation.

LYMPHADENOPATHY

Generalized lymphadenopathy was one of the manifestations of HIV infection recognized early in the history of the AIDS epidemic. Lymphadenopathy may reflect a wide array of infectious agents, including fungi, mycobacteria, and viruses. Lymphadenopathy may also be a manifestation of lymphoma or of an immunologic reaction to HIV itself. Nodes may be apparent by exam in multiple superficial chains, including cervical, axillary, and inguinal. Radiologic evaluation may reveal mediastinal and abdominal nodes as well, although large hilar nodes are not characteristics of the "generalized lymphadenopathy syndrome" caused by HIV. When nodes are less than 1 cm in diameter and symmetrical and stable, it may be reasonable to follow the patient closely without needle aspiration or biopsy if he or she is truly asymptomatic. If the nodes are asymmetrical or tender, or if the patient has fever or fatigue or weight loss, needle aspiration or biopsy for culture and histologic examination (focusing on mycobacterium, fungi, viruses, and lymphoma) is appropriate ([Table 341.2](#)). The evaluation often does not reveal a specific pathogen or tumor. Biopsy most often shows a nonspecific follicular hyperplasia. There is no evidence that generalized lymphadenopathy due to HIV correlates with an unfavorable progress.

Asymptomatic patient (symmetrical and homogeneous nodes)
VDRS test
PPD test
Chest radiograph
Symptomatic patient (fever, constitutional manifestations, or nodes that are symptomatic or nonhomogeneous)
VDRS test
PPD test
Chest radiograph
Chest CT or MRI scan
Abdominal CT or MRI scan
Liver function tests
Blood culture for bacteria
Blood culture for fungi
Blood culture for mycobacteria
Serum cryptococcal antigen test
Needle aspirate of node
Bone marrow biopsy
Urine <i>Histoplasma</i> antigen

VDRS, Venereal Disease Research Laboratory; PPD, purified protein derivative; CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 341.2. RADIOLOGIC AND LABORATORY EVALUATION OF LYMPHADENOPATHY

ORAL AND ESOPHAGEAL DISEASE

Patients commonly complain of white plaques in their oral cavity, altered sensation of taste, pain, foul breath, dental problems such as caries or loosening of teeth, or dysphagia. Careful examination of the oropharynx may reveal white plaques, mucosal ulcers, atrophic mucosa, caries, pyorrhea, or masses arising from mucosal or lymphoid tissue. Mucosal abnormalities should be swabbed; a direct smear should be examined for *Candida*; culture for fungi is not helpful diagnostically regarding *Candida* since many otherwise healthy individuals may grow small quantities of candida from their oropharynx. *Candida* can cause three major types of mucosal abnormalities: the typical white plaques, atrophic mucositis, and angular cheilitis. The oral lesions can usually be distinguished by clinical examination from hairy leukoplakia, a lesion characteristically seen on the lateral aspect of the tongue that is caused by Epstein-Barr virus (EBV). It is important to diagnose these lesions accurately because they have prognostic implications and because candidiasis can be treated specifically. Hairy leukoplakia is a clinical diagnosis; while it is

etiologically related to EBV, cultures for EBV and serologies are not helpful. Biopsy is not clinically warranted for hairy leukoplakia, nor is specific therapy. Lesions may regress if patients are given effective antiretroviral therapy, ganciclovir, foscarnet, or high-dose acyclovir for some other indication.

Examination of the oropharynx may also reveal ulcerative lesions. These may be due to herpes simplex, which can be recognized with reasonable accuracy on a clinical basis and can be diagnosed specifically by Tzanck prep, by biopsy, or, most commonly and conveniently, by culture. When ulcerative herpetic lesions do not respond to acyclovir therapy, they may be caused by acyclovir-resistant virus, but other causes of the lesions should also be considered, including *Treponema pallidum* and endemic fungi. Ulcers that are large, deep, painful, and few in number (one to three) may be aphthous; biopsies with histologic and microbiologic examination are not specific for identifying aphthous ulcers but are useful to exclude neoplastic processes (lymphoma or Kaposi's sarcoma) or specific infections (fungi, herpesviruses, mycobacteria, and others).

Dental complaints are common. Patients with HIV are clearly predisposed to pyorrhea and gingivitis, which can be quite severe, and which may be associated with fetid breath, tooth decay, dental abscesses, and loss of teeth. These processes can be ameliorated with local therapies and surgical management, and thus their recognition is important.

Dysphagia, a common complaint for patients with HIV, becomes an increasingly frequent occurrence as the CD4 count declines. *Candida* esophagitis is responsible for a large fraction of these cases and may be present even if there is no evidence for oral involvement. Many clinicians treat patients empirically for candidiasis, with an azole such as fluconazole. If there is not prompt symptomatic improvement, usually within 1 to 2 weeks, endoscopy with cultures and biopsies is appropriate since many infectious and neoplastic processes are clinically indistinguishable from *Candida* esophagitis. The differential diagnosis includes CMV, aphthous ulcers of the posterior pharynx and esophagus, herpes simplex virus, mycobacteria, endemic fungi, lymphoma, and Kaposi's sarcoma, as well as ulcers due to drugs (e.g., zalcitabine, zidovudine, and dapson) or radiation. There is an increasing incidence of azole-resistant disease due to *Candida albicans* or other *Candida* species. Thus, endoscopy may reveal smears or biopsies consistent with candidal disease despite azole therapy. Susceptibility testing of the candidal isolates can be useful to confirm the need for an alternative therapy such as amphotericin B.

OCULAR MANIFESTATIONS

Patients often complain of "floaters," decreased visual acuity, or reduced field of vision. Dilated fundoscopic examination is indicated. Patients almost never develop retinochoroiditis due to an opportunistic infection until their CD4 + T-lymphocyte count is below 50 to 75 per cubic millimeter. CMV retinitis is responsible for the vast majority of cases of retinochoroiditis and is so characteristic on fundoscopic examination that a clinical diagnosis is usually established without further testing. These patients almost all have positive IgG titers for CMV. Retinal lesions due to other pathogens such as *Toxoplasma*, *Pneumocystis*, *M. tuberculosis*, VZV, HSV, and endemic fungi do occur. Lymphoma and Kaposi's sarcoma will occasionally present in the globe.

For patients who have been treated for CMV retinitis and who are receiving chronic maintenance therapy when started on highly active antiretroviral therapy, an ocular syndrome, designated as immune restitution vitritis, has been recognized. This syndrome needs to be distinguished from active CMV retinitis since the management of these two disorders is substantially different. Thus, ophthalmologic consultation to confirm the diagnosis of any retinal abnormality is usually appropriate. In difficult cases, microbiologic evaluations may be helpful. If a patient has negative titers against CMV or *Toxoplasma*, for instance, these etiologic factors would be extremely unlikely. Rarely is a vitreal tap or retinal biopsy indicated. Clinicians need to recognize that some drugs such as rifabutin and ethambutal have ocular toxicities that must be considered, either as a predictable result of the administration of a drug or as a result of drug interaction.

HEMATOLOGIC ABNORMALITIES

A wide variety of hematologic abnormalities have been described in patients with HIV infection. Thrombocytopenia often is brought to clinical attention because of a routine screening test and, less commonly, because of petechial bruising or gross bleeding. Thrombocytopenia can be caused by peripheral destruction of platelets (e.g., associated with immune complexes or platelet-associated antibodies) or by decreased production from the bone marrow (e.g., due to infection, tumor, or drugs). Thus, evaluation (Table 341.3) generally includes examination of a peripheral smear for assessment of red cell and platelet morphology and bone marrow examination for megakaryocytes, as well as for infectious and neoplastic processes. Measurement of antiplatelet antibodies is not usually helpful diagnostically. A wide variety of processes can cause thrombocytopenia including opportunistic infections and tumors (e.g., endemic mycoses, tuberculosis, lymphoma), HIV itself, drugs (including prescribed drugs as well as self-administered drugs or alcohol or heroin); thrombotic thrombocytopenic purpura; hypersplenism; disseminated intravascular coagulation; and various other viral infections. The presence of fever or weight loss should suggest an infectious cause, or perhaps lymphoma, especially if there is pancytopenia. Medications may have to be discontinued, depending on the severity of the thrombocytopenia, to assess their role. If patients have a measurable HIV viremia, improved antiretroviral therapy may have a beneficial effect on the platelet count if the thrombocytopenia is related to HIV itself.

Pancytopenia
Review peripheral smear
Bone marrow biopsy
Blood culture for fungi, mycobacteria
Neutropenia
Review peripheral smear

Vitamin B ₁₂ level
Bone marrow biopsy
Anemia
Review peripheral smear
Coombs' test
Haptoglobin
Stool guaiac test
Erythropoietin level
Bone marrow biopsy
Blood culture for fungi, mycobacteria
Antinuclear antibody test
Thrombocytopenia
Review peripheral smear
Bone marrow biopsy

TABLE 341.3. LABORATORY EVALUATION OF CYTOPENIA

Anemia is a common manifestation of HIV disease, especially in advanced stages of AIDS; it can have a substantial impact on quality of life. It is useful to examine a peripheral smear to determine whether the anemia is normocytic, microcytic, or macrocytic, and to search for evidence of hemolysis. Diagnostic evaluation should include assessment for blood loss, nutritional deficiencies, autoimmune processes, hemolysis, and deficient bone marrow production. The influence of concurrent infections, drugs, and splenomegaly must be assessed. A serum erythropoietin level is often useful as part of the diagnostic evaluation and for assessing the likelihood that therapeutic erythropoietin will be useful. A bone marrow aspirate or biopsy is probably most appropriate when the anemia is moderate or severe. A search for the cause of anemia, as well as for other cytopenias, is appropriate before hematopoietic growth factors are utilized.

Neutropenia is associated with an increased incidence of bacterial infections and is recognized most often in patients with advanced disease. While marrow infiltrative processes due to tumor or infection may occur, most cases are due either to drugs (e.g., zidovudine, ganciclovir, or trimethoprim-sulfamethoxazole) or advanced HIV disease. A trial stopping likely offending agents may be in order, especially if the neutrophil count is below 1,000 per cubic millimeter. Nutritional assessment (e.g., regarding folate and vitamin B₁₂) may also be appropriate. Granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor can reverse neutropenia and may conceivably have a beneficial effect in terms of reducing the incidence of bacterial infections and prolonging survival.

RENAL ABNORMALITIES

Renal abnormalities often come to medical attention because of abnormal screening tests of blood or urine. Glomerular, tubular, and interstitial processes occur. Proteinuria is particularly common among the observed laboratory abnormalities. Patients with HIV infection need to be approached with the perspective that their renal disease may be due to a process unrelated to HIV, such as hypertension, heroin abuse, or hepatitis B. However, renal dysfunction may be related to opportunistic infection, neoplastic processes, drug toxicity, or HIV itself. Drugs of particular note regarding various forms of nephrotoxicity include trimethoprim-sulfamethoxazole (for *Pneumocystis*), foscarnet (for CMV), pentamidine (for *Pneumocystis*), amphotericin B (for fungi), and intravenous dye (used in radiologic procedures). It may be prudent if patients have renal dysfunction and are receiving drugs capable of causing compatible renal lesions to consider discontinuing drug therapy if feasible alternatives are available. For patients with severe proteinuria and mild to moderate elevation in serum creatinine levels, renal biopsy most often shows focal and segmented glomerulosclerosis. Biopsies are rarely performed, however, because rarely do they influence therapy. Renal calculi

CHAPTER 342: HIV/AIDS: APPROACH TO THE PATIENT WITH PULMONARY DISEASE

PHILIP C. HOPEWELL

[Presentation](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Differential Diagnosis](#)
[Approach to the Diagnostic Evaluation](#)

PRESENTATION

Pulmonary disorders in patients with HIV infection present with cough, shortness of breath, and, occasionally, chest pain. In addition, infectious disorders usually are marked by fever. Data from a large multicenter study, the Pulmonary Complications of HIV Infection Study (PCHIS), have indicated that screening for lung diseases among patients with HIV infection who do not have respiratory symptoms is not useful. The yield from chest radiographs, examinations of induced sputum for *Pneumocystis carinii* and acid-fast bacilli, pulmonary function tests, and frequent interviews to elicit symptoms was extremely low, and the value of the few instances in which diagnoses were established was offset by false-positive results.

In the PCHIS cohort, an analysis of symptoms showed that cough and shortness of breath were present in a high proportion of patients subsequently shown to have lung disease, whereas constitutional symptoms such as fever and weight loss in the absence of respiratory symptoms were highly unlikely to be associated with lung disease.

In addition to HIV-associated lung diseases, patients with HIV infection may have lung diseases such as asthma or chronic obstructive airway disease, which cause cough, shortness of breath, and wheezing that are not associated with HIV infection. Symptoms and findings caused by these disorders do not entail the same diagnostic approach as symptoms and findings that are suggestive of an HIV-associated disease.

PATHOPHYSIOLOGIC FACTORS

The pulmonary disorders that occur in patients with HIV infection all relate in some fashion to the immune compromise that is produced by the virus. In general, the frequency and types of lung diseases increase with decreasing immune responsiveness, which is reflected most directly by the CD4⁺ lymphocyte count. Both cell-mediated and humoral immune responsiveness decrease as the CD4 count decreases, making patients with HIV infection progressively more vulnerable to a wide variety of pathogens. Similarly, the degree of immunocompromise increases as the amount of circulating HIV increases.

HISTORY AND PHYSICAL EXAMINATION

The salient points in the history related to presumed HIV-associated lung diseases are listed in [Table 342.1](#). Respiratory disorders are heralded by the presence of cough and shortness of breath. The rate of symptom progression tends to be more rapid with bacterial pneumonia and slower with *P. carinii* pneumonia. Other infections also tend to be more indolent than bacterial pneumonia. In a patient with acute bronchitis or bacterial pneumonia, the cough usually is productive of purulent sputum. The cough in a patient with *P. carinii* pneumonia typically is nonproductive. This is an important distinction because the diagnostic approach may vary depending on whether a patient produces purulent sputum.

Presence or absence of cough
Production of sputum (purulent or clear?)
Presence or absence of shortness of breath
Presence or absence of fever or chills
Duration, tempo, and severity of symptoms
Previous respiratory diseases
CD4 lymphocyte count (if known)
Presence of weight loss, diarrhea, sore mouth or throat
Use of anti-*Pneumocystis* prophylaxis
Exposure to individuals with tuberculosis
Places of residence currently and in recent past
Previous tuberculin skin tests and results
Use of antituberculous prophylaxis
Previous or current residence in areas endemic for histoplasmosis or coccidioidomycosis

TABLE 342.1. SALIENT POINTS IN THE HISTORY OF HIV-INFECTED PATIENTS WITH PULMONARY DISEASE

The main risk factor for *P. carinii* pneumonia is a CD4 count of less than 200 cells per microliter. Presumably a high circulating viral burden is also indicative of increased risk, but this presumption is not well quantified. Most patients with diagnosed HIV infection are aware of their most recent CD4 count, indicating whether they are at risk for *P. carinii* infection. *P. carinii* pneumonia developed in a few patients in the PCHIS cohort who had CD4 counts higher than 200 cells per microliter. All but one of these patients had symptoms or findings relating to HIV infection (significant weight loss, unexplained diarrhea, or oral thrush), in addition to respiratory symptoms. It also is important to inquire about the use of prophylactic therapy for *P. carinii*. Although anti-*Pneumocystis* prophylaxis does not entirely prevent *P. carinii* pneumonia, the disease does not occur in patients receiving preventive therapy until there is more advanced immunodeficiency compared with patients who are not receiving prophylaxis.

The history is of particular relevance in the identification of risk factors for tuberculosis. These include exposure to individuals with tuberculosis, a history of a positive tuberculin skin test, residence in an area of high tuberculosis incidence, and previous use of isoniazid preventive therapy. It also is important to determine whether the patient has lived in areas that are endemic for the fungal diseases histoplasmosis and coccidioidomycosis.

Because Kaposi's sarcoma involving the lungs is uncommon in patients who have not had cutaneous lesions, it is important to ask about prior diagnosis of Kaposi's sarcoma and, if present, whether any therapy has been given.

The physical examination of the lungs by itself is not especially helpful in elucidating the cause of respiratory symptoms in a patient with HIV infection. However, wheezing suggests airways obstruction as the cause for the symptoms. Other findings add little that is not provided by the chest radiograph.

In contrast, nonpulmonary findings may assist in the formulation of a differential diagnosis. For example, evidence of weight loss or oral thrush is indicative of an increased risk for *P. carinii* pneumonia, even if the CD4 count is higher than 200 cells per microliter. Lymphadenopathy or hepatosplenomegaly suggests that the pulmonary disease may be part of a disseminated infection or neoplastic process. Cutaneous or mucous membrane Kaposi's sarcoma is present in many patients who have pulmonary involvement with the neoplasm. As the listing summarized in [Table 342.2](#) suggests, findings that do not emanate from the lungs themselves often are more helpful than pulmonary findings.

Fever
 Evidence of weight loss
 Presence or absence of oral candidiasis
 Lymphadenopathy
 Hepatic and/or splenic enlargement
 Cutaneous or mucous membrane Kaposi's sarcoma
 Findings related to the lungs (e.g., wheezing, rales, evidence of consolidation or pleural fluid)

TABLE 342.2. RELEVANT FINDINGS ON PHYSICAL EXAMINATION IN PATIENTS WITH HIV INFECTION AND PULMONARY SYMPTOMS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of respiratory symptoms varies depending on the severity of HIV-induced immune compromise ([Table 342.3](#)). Data from the PCHIS cohort indicate that acute bronchitis is the most common cause of pulmonary symptoms in early (CD4 count 500 cells per microliter or higher) and middle (CD4 count 200 to 499 cells per microliter) HIV disease, and bacterial pneumonia is increasingly common during these stages. When the CD4 count falls below 200 cells per microliter, *P. carinii* pneumonia becomes the most common lung disease and bacterial pneumonia continues to increase in frequency. Acute bronchitis is common, but less common than *P. carinii* pneumonia or bacterial pneumonia. The incidence of tuberculosis also increases as the CD4 cell count declines. In the PCHIS cohort, the median CD4 cell count for the 31 patients in whom tuberculosis developed during the study was 230 cells per microliter. Because of the location of the clinical centers for the PCHIS, neither histoplasmosis nor coccidioidomycosis was seen, but these diseases are common in their endemic areas.

Early (CD4 lymphocyte count \geq 500 cells/mm³)
 Acute bronchitis
 Bacterial pneumonia
 Midcourse (CD4 lymphocyte count 200–499 cells/mm³)
 Acute bronchitis
 Bacterial pneumonia
 Tuberculosis
 Late (CD4 lymphocyte count <200 cells/mm³)
Pneumocystis carinii pneumonia
 Bacterial pneumonia
 Acute bronchitis
 Tuberculosis
 Fungal infections
 Kaposi's sarcoma

TABLE 342.3. MOST COMMON CAUSES OF RESPIRATORY SYMPTOMS IN PATIENTS WITH HIV INFECTION

Kaposi's sarcoma involving the lungs is uncommon and occurs when there is advanced immunosuppression. Among 168 patients with pulmonary Kaposi's sarcoma diagnosed during a 7-year period at San Francisco General Hospital, the median CD4 cell count was 19 cells per microliter. Other neoplastic processes involving the lungs are even less common, with non-Hodgkin's lymphoma seen most often.

APPROACH TO THE DIAGNOSTIC EVALUATION

Once it is determined that the history and physical examination suggest an HIV-associated lung disease, the next step usually is to obtain a chest radiograph. If a CD4 cell count has not been performed recently, one should be obtained. The major categories of radiographic findings are a normal film, peribronchial thickening, focal infiltration/consolidation, and diffuse infiltration. Additional findings of interest include intrathoracic lymphadenopathy, pleural effusion, parenchymal cysts or cavities, nodules, and pneumothorax.

The finding of a normal film or peribronchial thickening in a patient who has a productive cough is sufficient to establish a diagnosis of acute bronchitis. The patient should be followed up with or without antimicrobial therapy to ensure that the symptoms resolve.

Focal infiltration in a patient with a productive cough and purulent sputum is most consistent with a diagnosis of bacterial pneumonia. In this setting, sputum should be obtained for Gram stain and culture, and in general a blood specimen should be obtained for culture. A variety of organisms, as shown in [Table 342.4](#), were isolated from patients in the PCHIS cohort who had bacterial pneumonia.

	Number	Percentage
<i>Streptococcus pneumoniae</i>	28	42
<i>Haemophilus influenzae</i>	10	15
<i>Staphylococcus aureus</i>	8	12
Gram-negative aerobic bacilli	8	12
Other	12	18

TABLE 342.4. PATHOGENS THAT CAUSE BACTERIAL PNEUMONIA IN PATIENTS WITH HIV INFECTION

The most likely diagnosis in a patient with a CD4 count of less than 200 cells per microliter who has a pattern of diffuse infiltration is *P. carinii* pneumonia. However, there are many other disorders in the differential diagnosis of this set of circumstances. At this point, essentially three approaches could be used. The most simple is to begin empirical treatment with acute anti-*Pneumocystis* agents, observe the patient closely, and undertake a diagnostic evaluation only if the patient's response is suboptimal. Although this appears to be the least expensive option, the costs of delayed diagnosis must be taken into account. Moreover, the relative frequency of *P. carinii* as a cause of this constellation of findings varies between areas and populations.

The second approach is to seek a specific diagnosis beginning with an examination of sputum induced by the inhalation of a mist of hypertonic saline generated by an ultrasonic nebulizer. The use of this approach is shown in [Fig. 342.1](#). Sputum obtained in this manner is examined for *P. carinii* and acid-fast bacilli, and is cultured for mycobacteria. If *P. carinii* or acid-fast organisms are not seen and another diagnosis has not been established, fiberoptic bronchoscopy and bronchoalveolar lavage are performed. The lavage specimen is examined for *P. carinii* and acid-fast organisms, and is cultured for mycobacteria and fungi. Transbronchial lung biopsy is not performed unless the radiograph is in some way unusual or no diagnosis is established with the bronchoalveolar lavage.

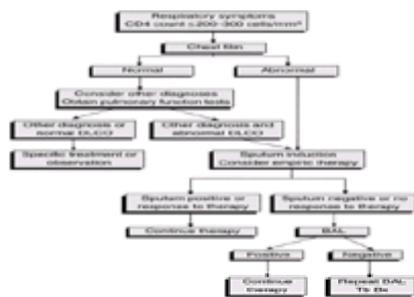

FIGURE 342.1. Algorithm describing the approach to establishing the cause of respiratory symptoms in patients with HIV infection. DLCO, diffusing capacity for carbon monoxide; BAL, bronchoalveolar lavage; Tb Bx, transbronchial lung biopsy. (From Hopewell PC, Masur H. *Pneumocystis carinii* pneumonia: current concepts. In: Sande MA, Volberding PA, eds. *The medical management of AIDS*, fourth ed. Philadelphia: WB Saunders, 1995:367, with permission.)

EVIDENCE LEVEL: B. Reference: Hopewell PC, Masur H. *Pneumocystis carinii* pneumonia: current concepts. In Sande MA, Volberding PA. *The medical management of Aids, fourth edition*. Philadelphia: WB Saunders, 1995:367.

The third approach to diagnosis is to go directly to fiberoptic bronchoscopy and bronchoalveolar lavage with or without transbronchial lung biopsy. Overall, this method probably is the most costly, but also the most rapid, way to establish a specific diagnosis.

Several approaches have been used to determine whether patients who have convincing respiratory symptoms but normal chest films should undergo further expensive and perhaps invasive diagnostic studies. Data from the PCHIS cohort show that measurement of the diffusing capacity for carbon monoxide is a sensitive means of identifying patients who are likely to have *P. carinii* pneumonia. Gallium citrate lung scanning also has been used to indicate the presence of lung inflammation and the need for further diagnostic studies. However, this test is costly and has a built-in delay of 48 to 72 hours. More recently, high-resolution computed tomographic scanning has been used to identify areas of disease not evident on plain chest radiographs. In an analysis of a small number of patients, this approach provided accurate identification of patients with *P. carinii* pneumonia. Computed tomographic scanning has the advantage of being fast; however, the cost implications of this method have not been fully analyzed.

As long as a system for performing outpatient bronchoscopy is readily available, hospitalization is not required for the evaluation itself. The indications for hospitalization relate to the tempo and severity of the illness, not to the need for evaluation.

The cost-effectiveness of various diagnostic approaches has been subjected to analysis in several reports. However, these analyses are based on assumptions that vary between locales and institutions. What may be more important than cost-effectiveness analyses is for each institution to examine the accuracy of the diagnostic studies it uses and to develop an approach that is accurate and expeditious. Such an approach probably will be the most cost-effective.

Foscarnet is indicated for patients who are infected with acyclovir-resistant strains.

No effective antimicrobial agent is available for the treatment of *Cryptosporidium*, although paromomycin and azithromycin have been associated with some clinical improvement. The immune reconstitution associated with the use of highly active antiretroviral therapy can result in a complete clinical and microbiologic resolution of HIV-associated cryptosporidiosis and microsporidiosis. Isosporiasis responds to treatment with trimethoprim–sulfamethoxazole or pyrimethamine, but up to 50% of patients have relapses after the cessation of therapy. Trimethoprim–sulfamethoxazole also has been effective in treating primary *Cyclospora* infection and preventing relapses. The common use of trimethoprim–sulfamethoxazole for the prevention of other opportunistic infections in HIV-infected patients may explain the rarity of isosporiasis and *Cyclospora* infection among these patients in the United States. Albendazole (400 mg twice a day for 1 month) has resulted in resolution of the diarrhea and elimination of the organism in AIDS patients with diarrhea caused by *Encephalitozoon intestinalis*. Studies on *Enterocytozoon bieneusi* infection have not been as successful. Despite the uncertain pathogenic role of *Blastocystis hominis*, metronidazole or iodoquinol may be indicated when high concentrations of *B. hominis* are the only organism found in the stool. Metronidazole is effective to treat giardiasis.

The treatment of *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* infection in HIV-infected patients follows the standard guidelines. The use of one of the new macrolides (clarithromycin or azithromycin) is an essential component in the treatment of *Mycobacterium avium* complex. Because of the emergence of resistance, a macrolide should be given with at least one or two other drugs that have microbiologic activity against *M. avium* complex, such as ethambutol, rifabutin, rifampin, quinolones (ciprofloxacin and ofloxacin), or amikacin.

CHAPTER 344: HIV/AIDS: APPROACH TO THE PATIENT WITH NEUROLOGIC SYMPTOMS

RICHARD W. PRICE

[Neurologic Disease in “Early” HIV Infection](#)
[Neurologic Complications of Late HIV Infection](#)
[Major CNS Diseases Complicating Late HIV Infection](#)
[Major Peripheral Nervous System and Muscle Diseases](#)

Both the central nervous system (CNS) and the peripheral nervous system (PNS) may be injured in the course of HIV-1 (referred to hereinafter simply as HIV) infection as a result of several types of disease processes, including particularly opportunistic infections but also autoimmunity, disturbed systemic organ function, and, more fundamentally, effects of the AIDS retrovirus itself. Despite these several pathways leading to neurologic injury and the potential for perturbed function at all levels of the neuraxis, a logical and sequential clinical approach usually leads to correct diagnosis. Although it is fortunate that the widespread use of combination antiretroviral therapy has considerably reduced the neurologic burden of HIV infection, this group of diseases remains important, and accurate diagnosis is critical in reducing mortality, preventing important morbidity, and predicting prognosis.

[Table 344.1](#) outlines a classification of the neurologic complications of HIV infection that combines two of the most useful diagnostic variables: background *stage of systemic HIV infection* and *neuroanatomical localization*. The stage of systemic infection, and particularly the degree of immunosuppression, strongly determines the spectrum of disease vulnerabilities, whereas anatomical localization predicts the range of differential diagnosis because of the predilection of individual disease processes to involve particular parts of the nervous system or in characteristic spacial and temporal patterns.

TABLE 344.1. CLASSIFICATION OF THE NEUROLOGIC COPLICATIONS OF HIV INFECTION

NEUROLOGIC DISEASE IN “EARLY” HIV INFECTION

A variety of CNS and PNS disorders have been described in the setting of primary HIV infection and seroconversion. Some of these (headache and aseptic meningitis) may relate to direct HIV infection of the meninges and brain as a component of the initial viremia, whereas others (encephalopathy, polyneuropathy, brachial plexitis) likely relate to autoimmune responses triggered by HIV infection and thus resemble other postinfectious encephalitides or neuropathies. Serious or lasting morbidity from these is uncommon and indeed most are insufficiently severe to trigger special medical evaluation.

Despite the direct exposure of the CNS to HIV that begins during primary infection and continues throughout the course of infection, patients usually remain neurologically asymptomatic during the period of “clinical latency.” However, examination of cerebrospinal fluid (CSF) often shows evidence of ongoing infection. Viral RNA is detectable in the CSF, although in lower amount than in the plasma, and host responses may be present including mononuclear pleocytosis and protein elevation. While this meningeal infection appears to be clinically benign, these background CSF abnormalities must be taken into account when interpreting results of diagnostic lumbar puncture in this setting.

There are at least two notable exceptions to this freedom from neurologic disease during this phase of systemic infection. One of these is a very rare, multiple sclerosis–like CNS disease in which patients develop demyelinating lesions with remissions and exacerbations and may be responsive to corticosteroid medication. The second exception involves demyelinating polyneuropathies that can evolve either subacutely (Guillain–Barré syndrome) or chronically (chronic idiopathic demyelinating polyneuropathy). These polyneuropathies are sufficiently common as a complication of HIV infection that patients presenting with these conditions should be queried regarding risk of infection and, as appropriate, undergo serologic testing. These neuropathies have an autoimmune pathogenesis and respond to plasma exchange or intravenous immunoglobulin in a fashion similar to that of their non-HIV counterparts.

NEUROLOGIC COMPLICATIONS OF LATE HIV INFECTION

While the incidence of neurologic disease has been reduced by combination antiretroviral therapy, it is still high in those who suffer progressive immunosuppression either because such treatment is unavailable or because this therapy fails. In those who reach the late stage of HIV infection, as measured by reduced CD4⁺ T-lymphocyte counts, diagnosis begins with anatomical localization of symptoms and signs. The first step involves separating CNS from PNS disease based on the type and distribution of complaints and the findings on examination. Further anatomical subdivision then separates CNS disorders according to presenting manifestations of headache without brain dysfunction, predominantly focal brain dysfunction, predominantly nonfocal brain dysfunction, and myelopathy (which also may be segmentally focal or more diffuse). Likewise, PNS disorders are usefully divided into focal neuropathies and radiculopathies, polyneuropathies, and myopathies.

MAJOR CNS DISEASES COMPLICATING LATE HIV INFECTION

HEADACHE AND MENINGITIS

Headache is common in HIV infection and can be of diverse origin, including both benign and severe conditions. New-onset headache should always be taken seriously and evaluated carefully. If accompanied by focal or nonfocal neurologic dysfunction, it should be approached along a path similar to that used for patients presenting with these abnormalities without headache, although often more rapidly. The clinician must also consider that focal diseases may not present with obvious neurologic dysfunction when they involve “noneloquent” brain regions (e.g., anterior frontal lobes), or are small and multiple; hence, neuroimaging may be needed to rule them out.

In the absence of neurologic dysfunction or focal parenchymal disease, there are a limited number of major considerations. These include meningitis, most notably that due to *Cryptococcus neoformans*, but also an aseptic meningitis seemingly caused by HIV. Cryptococcal meningitis is the most common meningitis afflicting AIDS patients and may present with remarkably mild symptoms; recognition is critical since treatment is usually effective. “Aseptic” meningitis may be acute or chronic in onset and is accompanied by mononuclear pleocytosis and meningeal irritation. So-called “HIV headache” may be clinically similar but is not accompanied by CSF pleocytosis. It can nonetheless be quite severe and difficult to treat.

FOCAL CNS DISORDERS

Nearly all of the common focal CNS disorders complicating AIDS evolve subacutely. In contrast, acute CNS disease is uncommon in AIDS, although it can be caused by ischemic stroke, hemorrhage, or migraine-like disease. While transient ischemic attacks and strokes can complicate AIDS, their pathogenesis is usually unclear;

protein-S disturbance or other coagulopathies may be involved in some patients, and varicella-zoster virus (VZV) may cause CNS vasculitis in some. Hemorrhage uncommonly complicates some of the focal lesions discussed below.

The subacute course of the common focal CNS disorders relates to similar pathogenetic process, particularly the time course of DNA replication of either invading pathogens or host cells. The three most common focal diseases, comprising perhaps three-fourths or more of such cases, are cerebral toxoplasmosis, primary CNS lymphoma (PCNSL) and progressive multifocal leukoencephalopathy (PML). All of these present subacutely, though they tend to differ somewhat in their temporal profiles. Typically, cerebral toxoplasmosis is the most rapidly evolving, usually presenting within days of onset. PCNSL is intermediary, presenting within several days to two weeks after onset. PML is the most indolent, evolving over several weeks. There are some other differences as well. For example, cerebral toxoplasmosis often has an encephalitic component that produces confusion or lethargy, which in some patients can overshadow focality, as well as fever. The deep location and slow growth of PCNSL may lead to patients being mentally slow along with their focal manifestations (e.g., hemiparesis). In contrast, PML patients usually are alert despite very clear focal abnormalities.

Brain neuroimaging is essential in diagnosis of these focal brain diseases. In general, magnetic resonance imaging (MRI) is superior to computed tomography since it better detects small lesions and white matter abnormalities, and also provides superior definition of the character of lesions. Among the common focal brain diseases, usually the most important issue is to distinguish between toxoplasmosis and PCNSL. Both show focal mass lesions, although the lesions of toxoplasmosis tend to be more numerous, involve cortex and basal ganglia, and exhibit ringlike contrast enhancement at times with an eccentric target sign (a nodule of contrast enhancement at or near the surrounding ring). PCNSL lesions have a predilection for the periventricular white matter and tend to extend along the ventricular ependyma.

However, since these appearances may overlap and may not be distinguished with certainty, most patients require additional diagnostic evaluation. Earlier in the epidemic, it was recommended that all such patients first undergo a trial of anti-*Toxoplasma* therapy before other testing. This has changed with advances in both diagnostic interpretation and methodology along with a relative decrease in the incidence of toxoplasmosis related to antibiotic prophylaxis against *Pneumocystis carinii*, which also effectively reduces the incidence of toxoplasmosis. In brief, we take the current approach. If subjects are *Toxoplasma* antibody-seropositive, not taking prophylaxis, and MRI shows lesions characteristic of *Toxoplasma* abscesses, we begin management with a trial of therapy; if patients respond within a week or two, we consider this diagnostic. However, if the subjects are *Toxoplasma*-seronegative or the MRI lesions are not typical, then PCNSL is considered to be the most likely diagnosis. Polymerase chain reaction (PCR) detection of Epstein-Barr virus (EBV) sequences in CSF has been shown to be highly sensitive and specific for PCNSL, at least in the investigative setting; if this is available, then it can be used to establish this diagnosis. Thallium single photon emission computed tomography (SPECT) scanning has been advocated as helpful as well, though it is not as specific as EBV PCR and in many patients adds little to the information available from MRI. Our current approach in the absence of EBV PCR is to advocate early brain biopsy in those suspected of PCNSL. This avoids needless delay and attendant worsening neurologic status. While the overall prognosis of PCNSL is poor, radiation therapy and concomitant antiretroviral therapy in those not optimally treated can lead to a very gratifying outcome in some.

Progressive multifocal leukoencephalopathy can usually be diagnosed on the basis of the clinical history and examination with gradually evolving distinct focal abnormalities and MRI images showing corresponding focal white matter lesions. PCR detection of nucleic acid of JC virus, the etiologic agent, confirms the diagnosis in 70% to 80% of cases. Where uncertainty continues, brain biopsy may be needed. The remaining, less common causes of focal CNS disease usually are diagnosed by the presence of disease in other organs, characteristic neuroimaging, or direct brain biopsy.

NONFOCAL CNS DISORDERS

It is helpful to subdivide the nonfocal disorders into two subgroups: those in which patients remain fully awake and those in which there is reduced alertness. The most important disorder in the first category is the AIDS dementia complex (ADC, also called HIV-associated cognitive-motor complex), a subacutely or indolently progressive CNS disorder affecting cognition, motor performance, and behavior. The salient aspects of the cognitive dysfunction in these patients include difficulty with speed of thought, attention, and concentration. When mildly affected, patients complain of difficulty remembering appointments or attending to tasks such as reading, as well as needing to remind themselves with notes or by repeating the same task. When more severe, most aspects of mentation are compromised, so that daily activities and self-care no longer are possible. While motor symptoms usually occur later, the concomitant involvement of motor systems can usually be detected earlier on examination by looking for slowing of rapid finger opposition, toe tapping, or ocular saccades. Later, particularly in those with the vacuolar myelopathy variant (see below), gait may be compromised with spasticity and ataxia, and may progress to an end stage of paraparesis. Deep tendon reflexes are increased and abnormal "release" reflexes including a snout response appear. Behavioral manifestations include apathy, blunting of personality and drive, and, in those most severely affected, mutism.

Several pathogenetic questions remain, but the most widely prevalent theory is that the AIDS dementia complex is caused by HIV itself rather than another opportunistic pathogen. This may involve "indirect" mechanisms of brain injury whereby infection of brain macrophages and microglia leads to activation of cytokine and other endogenous neurotoxic pathways in the brain. Antiretroviral therapy has been reported to reverse, arrest, and prevent ADC and likely accounts for its declining incidence.

Among the nonfocal disorders that concomitantly suppress alertness and cognition, metabolic and toxic encephalopathies related to systemic organ compromise and neuroactive drugs are most important. As noted, in some patients with cerebral toxoplasmosis, diffuse encephalopathy may characterize presentation, usually due to widespread small lesions. Cryptococcal meningitis may also present in this way. Cytomegalovirus (CMV) encephalitis is another important cause of nonfocal brain dysfunction. Its presentation can range from impaired cognition with little focality or impairment of consciousness to impaired consciousness with nystagmus and other minor focal abnormalities. Diagnosis may be difficult but is essential to implement specific treatment. Some patients may have a characteristic MRI image showing altered signal adjacent to the ventricles related to subependymal infection, and some will exhibit CSF pleocytosis, including the presence of neutrophils. With or without these findings, detection of CMV nucleic acid using PCR or other amplification techniques has greatly aided diagnosis.

MYELOPATHIES

Myelopathies are also divided into focal and diffuse types. The most common cause of focal (or segmental) myelopathy is VZV in which the level of spinal cord dysfunction is usually centered at or near the level corresponding to a preceding dermatomal rash. Onset is usually delayed for days to a week or two after the rash. The pathogenesis involves a varying combination of direct spinal cord infection and local vasculitis, which may account for the explosive onset or progression in some. Other rare focal myelopathies may relate to spinal or meningeal lymphoma or to the infections described above that characteristically cause focal brain lesions. Tuberculosis of the spine also can cause cord compression. In active intravenous drug abusers, spinal epidural abscess may enter into differential diagnosis but its incidence is independent of the CD4⁺ T-cell count.

Vacuolar myelopathy was defined as part of the AIDS dementia complex, although it can be clinically segregated in some because of the prominence of gait impairment in relation to that of cognition. It is a nonfocal myelopathy in that it is usually symmetrical and without clear definition of a segmental level of spinal cord involvement. Motor abnormalities predominate with spasticity and hyperreflexia, whereas sensation is relatively preserved unless there is concomitant neuropathy. Bladder and bowel dysfunction are usually late manifestations. Diagnosis depends largely on clinical findings since MRI of the spinal cord is usually unremarkable. Human T-lymphotrophic virus types I and II can cause a similar nonfocal myelopathy, although this is independent of the stage of HIV infection and develops in the same population because of overlapping transmission risk; serology is helpful in this diagnosis.

MAJOR PERIPHERAL NERVOUS SYSTEM AND MUSCLE DISEASES

FOCAL NEUROPATHIES

The focal neuropathies are of several types, and most are uncommon. They include facial palsy, at times associated with aseptic meningitis. Peripheral root or nerve involvement may also complicate metastatic systemic lymphoma. Of greater importance is more widespread nerve involvement with mononeuritis multiplex, which can be of two types, differing in cause, prognosis, and treatment. The first occurs earlier in HIV infection, when blood CD4⁺ T-lymphocyte counts are in the 150 to 400 cells per cubic millimeter range. It is more benign and self-limited, may relate to a vasculitis involving immune complex formation, and may respond to immunosuppression. The second is more severe, occurs at very low CD4⁺ cell counts, and is caused by CMV infection. If recognized and treated early, it may respond to anti-CMV therapy.

A second type of severe CMV infection of nerve is also important. This is a severe, subacute ascending radiculopathy or radiculomyelopathy. It usually begins with sacral involvement and spreads rostrally. It is painful and induces a nearly pathognomonic neutrophil-predominant CSF pleocytosis. Its progression can be arrested

and partially reversed by aggressive anti-CMV treatment.

POLYNEUROPATHIES

The most common and important polyneuropathy—indeed the most common neuropathy overall in HIV infection—is a distal sensory polyneuropathy. This disorder affects axons and their sensory ganglion cell bodies rather than myelin and presents with paresthesias and pain in the feet. Indeed, the discomfort (“positive symptom”) of the sensory nerve involvement exceeds the extent of functional impairment related to sensory loss or weakness (“negative symptoms”). In mild form this neuropathy is very common. In its less common severe form it can be a source of great morbidity related to intractable, disabling neuropathic pain. Its etiologic process and pathogenesis are uncertain, although speculation now centers on a triggering role of HIV and the effects of dysregulated local production of cytokines. Autonomic neuropathy also occurs and may involve similar processes.

A second type of sensory neuropathy relates to the toxicity of some of the antiretroviral nucleosides, including zalcitabine, didanosine, and stavudine. This axonal neuropathy is dose-related, largely reversible if the medication is stopped early, and may be mediated by an effect of these drugs on the DNA polymerase of nerve mitochondria. It may also be difficult to distinguish clinically from the spontaneous HIV-related distal sensory polyneuropathy and may require drug interruption for diagnosis.

These and other neuropathies can usually be diagnosed clinically but may require help from the electrophysiology laboratory evaluating electromyograms and nerve conduction. Other than those related to CMV infection or drug effects, treatment is often symptomatic.

MYOPATHIES

While uncommon, several types of myopathy have been identified in AIDS patients. These include an inflammatory polymyositis and non-inflammatory myopathy, at times with nemaline rods noted pathologically. There is controversy as to whether these both respond favorably to corticosteroid medication. Zidovudine also can cause a myopathy after prolonged use, perhaps related to a toxic effect on muscle mitochondrion DNA polymerase; this seems far less common than earlier in the epidemic when higher doses of this drug were used. Many patients with this condition, but perhaps not all, will show ragged red fibers on muscle biopsy and abnormal mitochondria ultrastructurally. Diagnosis of myopathy often involves assessment of blood creatine kinase and electromyographic examination to confirm its presence and biopsy to establish more definitive diagnosis.

CHAPTER 345: PATHOGENESIS OF HIV INFECTION

SHARON LEWIN AND MARTIN MARKOWITZ

[HIV Entry](#)
[Transmission](#)
[Clinical Course of Infection](#)
[Determinants of Disease Progression](#)
[T-Cell Dynamics](#)
[Response to Antiviral Therapy](#)

HIV ENTRY

Human immunodeficiency virus 1 (hereinafter referred to simply as HIV) enters its target cells by interaction of the virion glycoproteins (gp120/41) with the CD4 molecule and an additional receptor now known to be a chemokine receptor. Chemokines are small proteins that serve as chemoattractants in inflammation. The two most important chemoreceptors for HIV are CXCR4 (also called fusin or LESTR) and CCR5. Macrophage tropic (M-tropic) strains of HIV replicate in macrophages and CD4⁺ T cells and use the chemokine receptor CCR5. T-tropic viruses replicate in primary CD4⁺ T cells, established CD4⁺ T-cell lines but not macrophages. T-tropic viruses use the chemokine receptor CXCR4 but can also use CCR5. Fusion of infected and uninfected cells leads to the formation of multinucleated giant cells, or syncytia. Most commonly, isolates derived early in the course of infection are non-syncytium-inducing (NSI), while isolates from approximately 50% of late stage patients have a syncytium-inducing (SI) phenotype. HIV viruses are now classified on the basis of their coreceptor usage ([Fig. 345.1](#)). The classification includes R5 (CCR5-tropic viruses or previously M-tropic, NSI viruses); X4 (CXCR4-tropic viruses or previously T-tropic, SI viruses); and R5X4 (using both receptors with comparable efficiency and those previously called dual tropic).

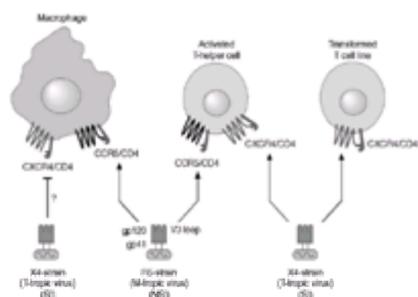

FIGURE 345.1. Basis of HIV cellular tropism. Previous nomenclature for viral tropism is noted at the bottom. R5 strains were previously named macrophage-tropic or NSI (non-syncytium-inducing in T-cell lines), whereas X4 isolates were known as T-cell line-tropic or SI (syncytium inducing). (Adapted from Littman D. Chemokine receptors: keys to AIDS pathogenesis? *Cell* 1998;93:677–680.)

TRANSMISSION

HIV is transmitted by contact with infected body fluids, including blood or blood products; semen; vaginal and cervical secretions; amniotic fluid and breast milk. The precise mechanism of transmission of HIV is not completely understood. The R5 viruses are the strains most commonly transmitted and are present early in the disease. The most likely cellular target in the mucosa for initial viral infection is antigen-presenting cells, particularly macrophage-related cells of the dendritic cell lineage. Dendritic cells residing in skin are called Langerhans' cells (LCs), whereas those in the circulation are known as blood dendritic cells. Even though LCs are not highly permissive to HIV infection, both blood dendritic cells and Langerhans' cells are able to transmit HIV to T cells very efficiently ([Fig. 345.2](#)).

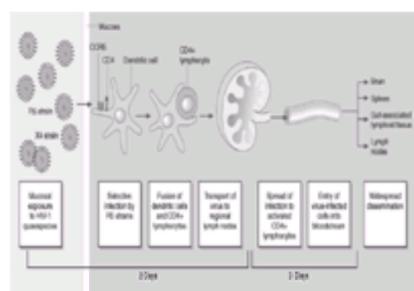

FIGURE 345.2. Early events following transmission of HIV. The arrows indicate the path of the virus. Dendritic cells, which express the viral coreceptors CD4 and CCR5, are selectively infected by R5 strains. Within 2 days after mucosal exposure, virus can be detected in the lymph nodes. Within another 3 days, it can be cultured from the plasma (based on experiments with SIV). (From Kahn J, Walker B. Current concepts: acute human immunodeficiency virus type 1 infection. *N Engl J Med* 1998;339:33–40, with permission.)

CLINICAL COURSE OF INFECTION

PRIMARY INFECTION

Primary HIV infection is associated with a rapid rise in plasma viremia, often to levels in excess of 1 million RNA molecules per milliliter. This is followed by a marked reduction in plasma viremia to a “steady-state” level of viral replication. The peak in viral load is associated with a fall in the level of CD4⁺ T cells in the first 2 to 8 weeks following infection. The levels of CD4⁺ T cells usually rebound toward normal but rarely return to preinfection levels ([Fig. 345.3](#)).

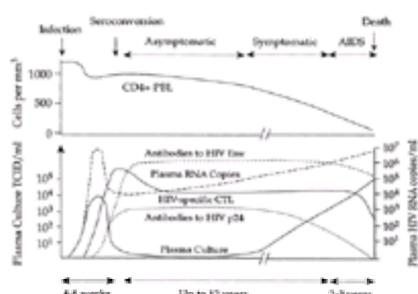

FIGURE 345.3. Typical clinical, virologic, and immunologic course of HIV infection.

The decrease in viral load following acute infection is largely due to virus-specific immune responses that limit viral replication. These include cellular and humoral immunity, the secretion of virus-suppressing cytokines, and the possible exhaustion of suitable CD4⁺ target cells. There is a strong temporal relationship between the appearance of HIV-specific cytotoxic T lymphocytes (CTL) responses and the striking fall in plasma viremia. Although HIV envelope-binding antibodies can be detected in the sera of HIV-infected individuals by 2 to 3 weeks following infection, most of these antibodies lack the ability to inhibit virus infection ([Fig. 345.3](#)).

CLINICAL LATENCY

Following primary infection, there is usually a relatively long period that is characterized by few, if any, clinical manifestations. In adults, the average time between infection and development of AIDS is 7 to 10 years. However, a small number of individuals progress rapidly to AIDS within 5 years. At the other extreme, some infected individuals demonstrate no evidence of immunopathologic processes for more than 16 years.

Although there is an asymptomatic phase in nearly all infected individuals, there is undisputed evidence that throughout this period there is continuous ongoing viral replication. The level of plasma HIV RNA is reasonably stable reflecting a “quasi-steady state” in which virus production was predicted to equal viral clearance. In fact, there is an extremely high rate of viral production throughout the clinically latent phase with an estimated rate of more than 10^{10} viral particles made per day.

CLINICALLY APPARENT DISEASE

Eventually this steady state “breaks down” leading to falling CD4⁺ T cells and increasing viral burdens characteristic of AIDS ([Fig. 345.3](#)). The level of CD4⁺ T cells drops to below 200 cells per milliliter and numerous conditions, namely, opportunistic infections and malignancies occur.

DETERMINANTS OF DISEASE PROGRESSION

Overall, the most important correlate of progression to AIDS, before substantial immune destruction has occurred, is the steady-state viral load, or “set point” seen at the end of primary infection. The determinants of the viral load set point and, consequently, clinical prognosis are complex and dependent on the interplay of both viral and host factors.

VIRAL FACTORS

HIV isolates from the infected individual change over time. Isolates from patients early in the course of HIV infection are generally M-tropic, NSI, R5 viruses. The emergence of T-tropic, SI isolates correlates with increasing viral burden and increasing rate of CD4⁺ T-cell decline. There are also rare examples of genetic defects in the infecting virus playing a role in nonprogression.

HOST FACTORS

Several recent reports have defined the role of chemokine receptors in HIV disease progression. For example, a 32-base-pair deletion in the *CCR5* gene (*CCR5 D32*) confers resistance to HIV infection in homozygotes. *CCR5 D32* heterozygotes are not protected from HIV infection, but the onset of AIDS appears to be postponed by 2 to 4 years. Mutations in other chemokine receptors (e.g., *CCR2 64I*) and chemoreceptor ligands (e.g., *SDF-1*) have also been associated with delays in disease progression.

Other host factors associated with altered disease progression have included human leukocyte antigen types, as well as humoral and cellular immunity. Studies in long-term nonprogressors (LTNPs; HIV-infected individuals with normal CD4⁺ T-cell counts for 12 to 15 years) show neutralizing antibody responses improved in magnitude and breadth and more robust and persistent HIV-specific CTL responses compared with other HIV-infected individuals. In fact, an inverse correlation between HIV-specific CTL frequency and plasma RNA viral load has been demonstrated.

T-CELL DYNAMICS

The central immunopathogenic hallmark of HIV disease is the progressive loss of CD4⁺ T cells. The exact mechanism of this is still incompletely understood. Numerous mechanisms have been proposed, including direct cell killing, syncytium formation, autoimmune destruction, impaired T-cell regeneration, and apoptosis. However, the central question remains whether T-cell decline is due to impaired regeneration, accelerated destruction, or both. Following the administration of antiretroviral therapy to infected individuals, there is not only a rapid fall in plasma viremia but a rise in peripheral CD4⁺ T cells. These observations led to a hypothesis that high levels of viral induced T-cell destruction (1 to 2×10^9 cells per day) placed considerable demand on CD4⁺ T-cell proliferation that resulted ultimately in collapse of the immune system. Another view is that a large number of T and B cells may be “trapped” in peripheral sites (e.g., by antigen, cytokine, or chemokine signals). Following therapy, the amount of HIV antigen declines and the immune response resolves, and sequestered cells leave the inflamed lymph node and return to the circulation. Other abnormalities in advanced disease include depletion of naive cells relative to memory T-cell subsets; restricted diversity of the T-cell receptor repertoire; a greater proportion of CD8⁺ T cells compared with CD4⁺ T cells and reduced functional competence of the T-lymphocyte system.

RESPONSE TO ANTIVIRAL THERAPY

Following effective antiviral therapy, there is an initial rapid fall in plasma viremia with a reduction in plasma virus of approximately 100-fold in the first 2 weeks of therapy. This reflects two processes: the clearance of free virions and the loss of the infected cells that produce most of the plasma virus. Plasma virus then declines at a slower rate, reflecting the turnover of a longer lived viral reservoir, such as macrophages and dendritic cells. Despite the fact that virus is often no longer detectable in the periphery after this phase, recent studies have demonstrated that infectious HIV persists in resting CD4⁺ memory T cells despite 1 to 2 years of combination therapy. This so-called “latent reservoir” is small (estimated to be no larger than 10^7 cells) but is the main obstacle to eradication of HIV infection as it remains uncertain as to how quickly this reservoir decays in patients on effective antiviral therapy. Despite the persistence of HIV, there is clear evidence of immune reconstitution following antiviral therapy as demonstrated by an early rise in memory CD4⁺ T cells, a reduction in T-cell activation with an improved CD4⁺ T-cell reactivity to recall antigens, and, finally, a late rise in naive cells. However, more significantly, effective antiviral therapy has been shown to have a beneficial effect on patient prognosis as demonstrated by a decrease in morbidity and mortality.

CHAPTER 346: HIV/AIDS: CLINICAL CONSIDERATIONS

STEPHEN B. GREENBERG AND CHRISTOPHER J. LAHART

[Etiologic and Pathophysiologic Factors](#)
[Epidemiologic Factors](#)
[Clinical Definition of HIV Infection](#)
[Clinical Presentations of Patients with Symptomatic HIV Disease](#)
[Common Laboratory Abnormalities](#)
[Complications Related to Antiretroviral Therapy](#)

The AIDS pandemic has altered the world's medical system and precipitated a national and international crisis. This pandemic has changed our concepts of immunology and microbiology, and has called into question the responsiveness of our health care system. In the past 20 years, the quantity of information concerning the causative virus, the clinical manifestations of the syndrome, and our therapeutic options have increased greatly. In the coming years, physicians will be challenged to appropriately manage AIDS patients with their myriad complications and provide humane care in this ultimately fatal illness.

ETIOLOGIC AND PATHOPHYSIOLOGIC FACTORS

Since the first reports in 1981, AIDS has been identified as a primarily sexually transmitted disease that also can be transmitted through blood exposure. By 1986, a lentivirus linked to the syndrome was named the human immunodeficiency virus (HIV). HIV is similar to other retroviruses in that it is composed of single-stranded, positively sensed RNA surrounded by a protein envelope. This virus primarily infects cells with a CD4⁺ cell membrane glycoprotein but may infect other cells that do not express CD4⁺. Two recently described coreceptors, CCR5 and CXCR4, appear to be necessary for HIV-1 entry into macrophage-tropic, non-syncytium-inducing strains and lymphocyte-tropic, syncytium-inducing strains, respectively. Once the virus enters the cells, uncoating occurs. A reverse transcriptase enzyme transcribes viral RNA into double-stranded DNA, which is inserted into the host cell chromosome. With activation of the cell by antigenic or viral stimulation, DNA transcription occurs and new viral particles are assembled at the cell surface. The infected cell then dies by mechanisms that are not clearly understood. Potential mechanisms for CD4⁺ cell destruction may include direct lysis, killing of progenitor cells in the thymus and bone marrow, syncytium formation between uninfected and infected cells, apoptosis (programmed cell death), and/or immune-mediated lysis.

Following the initial infection of monocytes, macrophages, and dendritic cells, virus disseminates through the bloodstream and lymphatics to the germinal center of lymph nodes. Most of the virus in the lymph nodes is extracellular and in the form of virus-antibody immune complexes. In lymphoid tissues, the frequency of HIV-infected CD4⁺ cells is approximately tenfold higher than in peripheral blood. Thus, the germinal centers of lymph nodes serve as a large reservoir of replicating virus. With the use of quantitative RNA polymerase chain reaction it has been demonstrated that a relatively constant level of virus can be detected in plasma at all stages of clinical disease.

It is currently believed that quantitative measurement of HIV RNA in plasma is a marker for total body HIV replication and a measure of viral load. Using these quantitative viral load measurements, the half-life of HIV-infected cells in blood has been calculated as 1.1 days. The number of HIV virions produced each day has been estimated at 1×10^{10} . Clearance of the virus and virus-infected cells is quite efficient and effective until late in the disease. Where viral loads have been reduced with effective antiretroviral therapies, CD4⁺ cell counts have increased and life expectancy has been prolonged.

EPIDEMIOLOGIC FACTORS

An estimated 40 million persons have been infected worldwide. In the United States, over 600,000 persons with AIDS have been reported and more than half have died. The mean time from HIV infection to clinical AIDS has been calculated to be 8 to 10 years. High-risk individuals continue to be reported primarily in homosexual and bisexual men, injection drug users, hemophiliacs, blood-product recipients, and sexual partners of these groups. In the United States, new cases of AIDS per 100,000 population were highest in cities with population greater than 500,000, in men (70%), and in black, non-Hispanic individuals (56%). In 1996, there was a 15% decline in mortality due to AIDS compared with 1995 rates, reflecting the impact of new therapies.

Outside the United States, the major route of HIV transmission has been during heterosexual vaginal intercourse. Although transmission efficiency is low, increased transmission has been associated with the presence of genital ulcers or other sexually transmitted diseases and infrequent use of condoms. Male-to-female transmission is more efficient than female-to-male transmission. Sexual intercourse between men accounts for approximately 40% of current AIDS cases in the United States. Oro-genital sex is an uncommon route for HIV infection. However, there have been rare cases of HIV transmission by oral secretions. The probability of transmission from an infected pregnant woman to her infant is about 25%. Neonates have been infected through breast-feeding. Approximately 25% of United States AIDS cases have been related to injection drug use. The majority of cases in heterosexual men has been related to drug use. The risk of receiving an HIV-contaminated unit of blood in the United States is 1 in 500,000. In developing countries with fewer screening resources, the risk of transmission through blood products continues to be high. No credible evidence has been presented to support the transmission of HIV by close or causal contact or by fomites.

HIV-1 transmission in health care workers has been documented by the U.S. Centers for Disease Control and Prevention (CDC) in over 100 cases. Needle-stick injuries among laboratory technicians and nurses have accounted for most of the infections. The risk following percutaneous exposure from a known HIV-infected individual is approximately 2.5 in 1,000 exposures. Mucocutaneous exposures have a lower risk of transmission (1 in 1,000 exposures). Viable HIV-1 has been detected in human tissue up to 16 days post mortem.

CLINICAL DEFINITION OF HIV INFECTION

Depending on the stage of HIV infection, individuals may be asymptomatic or have severe opportunistic infections or cancers. A revised CDC classification system for HIV infection emphasized the CD4⁺ cell count as a marker of disease progression. Three CD4⁺ cell ranges and three clinical groups are arranged into nine categories ([Table 346.1](#)). The CD4⁺ cell categories are (500 per cubic millimeter, 200 to 499 per cubic millimeter, and less than 200 per cubic millimeter). Clinical category A includes (a) asymptomatic HIV infection, (b) persistent generalized lymphadenopathy (PGL), and/or (c) primary HIV illness. Clinical category C includes infections and malignancies that meet the criteria for AIDS. Clinical category B includes symptomatic patients who do not have conditions outlined in categories A or C. Examples of clinical category B conditions include bacillary angiomatosis, poorly responsive vulvovaginal candidiasis, oropharyngeal candidiasis, cervical dysplasia, carcinoma in situ, or unexplained fever or diarrhea for more than a month. Categories A3, B3 and C are reported as AIDS. With this revised classification revision, new AIDS-defining conditions included invasive cervical cancer, pulmonary *Mycobacterium tuberculosis*, and recurrent pneumonias (>2 episodes in one year). No CDC definitions currently utilize viral load calculations.

Classification System	CD4 ⁺ Cell Count			Clinical Category	Clinical Description
	A	B	C		
CDC (1996)	≥ 500	200-499	< 200	A	Asymptomatic HIV infection, persistent generalized lymphadenopathy (PGL), or primary HIV illness
	≥ 500	200-499	< 200	B	Symptomatic patients who do not have conditions outlined in categories A or C
	≥ 500	200-499	< 200	C	Infections and malignancies that meet the criteria for AIDS

TABLE 346.1. 1993 REVISED CDC HIV CLASSIFICATION SYSTEM AND EXPANDED AIDS SURVEILLANCE DEFINITION FOR ADOLESCENTS AND ADULTS^a

CLINICAL PRESENTATIONS OF PATIENTS WITH SYMPTOMATIC HIV DISEASE

ACUTE HIV INFECTION SYNDROME

Although many individuals are asymptotically infected, approximately 20% will report an acute seroconversion syndrome ([Table 346.2](#)). Typically, there is a mononucleosis-like illness of sudden onset. Fever, lethargy, headaches, lymphadenopathy, sore throat, and macular rash are the most common signs and symptoms. Symptoms usually last for 5 to 10 days, but lethargy and malaise are commonly experienced for up to several months. The sore throat is usually not associated with exudates or enlargement of the tonsils. A macular rash may involve the palms and soles. Odynophagia and mucosal ulcers are found in about 50% of patients. A meningitis syndrome has been associated with the acute HIV syndrome and HIV has been recovered from cerebrospinal fluid (CSF) during acute illness. Uncommon clinical manifestations during acute symptomatic HIV infections have included esophageal candidiasis, hepatitis, vasculitis, rhabdomyolysis, myositis, splenomegaly, and red cell aplasia.

Symptom or Finding	Percentage of Patients
Fever	>80–90
Fatigue	>70–90
Rash	>40–80
Headache	32–70
Lymphadenopathy	40–70
Pharyngitis	50–70
Myalgia or arthralgia	50–70
Nausea, vomiting, or diarrhea	30–60
Night sweats	50
Aseptic meningitis	24
Oral ulcers	10–20
Genital ulcers	5–15
Thrombocytopenia	45
Leukopenia	60
Elevated hepatic enzyme levels	21

Kahn JO, Walker BD. Acute human immunodeficiency virus type 1 infection. *N Engl J Med* 1990;323(1):33–39, with permission.

TABLE 346.2. SYMPTOMS AND FINDINGS ASSOCIATED WITH ACUTE HIV-1 INFECTION IN SYMPTOMATIC PATIENTS

Laboratory abnormalities during the acute HIV infection syndrome include lymphopenia (40%), thrombocytopenia (45%), and elevated hepatic enzymes (20%). Atypical lymphocytes are uncommonly detected. CD4⁺ cell counts usually are in the normal range until several weeks later when the CD4⁺ cell count will decrease and the CD8⁺ cell count will increase.

FEVER

The most common complaint in HIV-infected persons is fever. The causes of fever in AIDS include *Pneumocystis carini* pneumonia, *Mycobacterium avium* complex (MAC), bacterial pneumonia, sinusitis, lymphoma, catheter infection, drug allergy, and, occasionally, cytomegalovirus (CMV) infection. Unexplained fever usually lasting for 1 to 2 weeks has been reported in 15% to 30% of AIDS patients. In Spain, the most frequently identified causes of fever were *Mycobacterium tuberculosis*, leishmaniasis, and MAC infection. *Bartonella henselae* and *Bartonella quintana* have been recovered from blood cultures of AIDS patients in certain regions of the United States.

Blood cultures are positive for pathogens in less than 20% of hospitalized febrile AIDS patients. Blood cultures are more likely to be positive if pneumonia, abscess, urinary tract infection, central line leukopenia, or neutropenia is present. Fungi are uncommonly recovered from blood cultures in these patients. When the fever remains unexplained, the most common identifiable causes appear to be MAC, lymphoma, bartonella, *P. carini* pneumonia, or fungus. When fever is accompanied by hypotension, hyponatremia, and hyperkalemia, adrenal insufficiency should be suspected. When this occurs, HIV, CMV, or MAC adrenalitis may be the cause.

LYMPHADENOPATHY

Lymph node enlargement is common in HIV-infected persons. Diffuse lymphadenopathy involving the axillary, inguinal, and cervical areas is common. Generalized lymphadenopathy can be seen in acute HIV infection, with mycobacterial or fungal infections, as well as lymphoma, Kaposi's sarcoma, syphilis, toxoplasmosis, Epstein-Barr virus, and CMV infections. If lymph nodes are fluctuant, aspiration should be performed and material stained and cultured. In patients receiving highly active antiretroviral therapy (HAART), fever and generalized lymphadenopathy have been found secondary to coinfection with MAC. In asymptomatic patients, persistent generalized lymphadenopathy is usually not an indication for lymph node biopsy. If patients have adenopathy detected on chest radiography or abdominal computed tomography, then enlarged peripheral lymph nodes should be biopsied to evaluate for possible lymphoma or opportunistic infection. Lymph nodes tend to decrease in size as HIV infection progresses.

CUTANEOUS MANIFESTATIONS

Both infectious and noninfectious dermatologic complications are common in HIV-infected patients. A wide variety of bacteria, viruses, and fungi have been implicated in several cutaneous infections. The most commonly reported maculopapular rashes include molluscum contagiosum, secondary syphilis, cryptococcosis, histoplasmosis, candidiasis, atypical mycobacteria, and warts. Less common infectious agents include *Penicillium marneffe* and cutaneous *P. carinii*. *P. carinii* has been found in patients who lived or traveled in Southeast Asia. Cutaneous *P. carinii*, though reported rarely, is usually seen with pulmonary symptoms. The most common causes of nodular lesions include bacillary angiomatosis, MAC infection, and Kaposi's sarcoma. Vesiculopustular lesions are typical of herpes simplex and varicella-zoster virus infections. These infectious agents can present at any stage of the HIV infection.

Noninfectious skin disorders include minor conditions, such as dry skin or telangiectasia, or major problems, such as severe psoriasis or extensive seborrheic dermatitis. The prevalence of seborrheic dermatitis, the most common noninfectious skin disorder in HIV, ranges from 7% to 50% in HIV-infected patients. Seborrheic dermatitis is generally more difficult to treat and less responsive to therapy in HIV-infected patients than non-HIV-infected patients. Psoriasis is not more prevalent in HIV-infected patients, but it has different features in these patients. Psoriasis may be the first clinical manifestation of HIV infection. With declining CD4⁺ cell counts, psoriasis appears to become more severe with atypical skin lesions being common. Streptococcal pharyngitis has been reported to precede guttate psoriasis. Acquired ichthyosis involving the lower extremities is common in HIV-infected patients. Other uncommon but associated skin disorders in HIV-infected individuals include porphyria cutanea tarda, eosinophilic pustular folliculitis, and pityriasis rubra pilaris.

Changes in the nails and hair of patients with progressive HIV infection are common. Onychomycosis is often present. A yellow discoloration of the nails has been reported with *P. carini* pneumonia. Thinning of the hair has been observed in addition to alopecia, sudden premature graying, and elongation of eyelashes.

NERVOUS SYSTEM SIGNS AND SYMPTOMS

Dementia

Brain dysfunction has been reported in HIV-1-infected patients throughout all stages of the disease. An AIDS dementia complex has been diagnosed in one-third of adults and half of children with AIDS. Early cognitive changes include inattention and forgetfulness. With declining mental activity, a global dementia may ensue. In 30% of asymptomatic HIV-positive patients, CSF abnormalities have been documented. The severity of AIDS-dementia complex may correlate with the cerebrospinal fluid HIV RNA. Although normal early, magnetic resonance images can show variable cerebral atrophy later in the infection. Other causes of declining mental activity

but without decreases in consciousness include depression or progressive multifocal leukoencephalopathy during its early stages.

Causes of cognitive impairment with alterations in consciousness include advanced AIDS–dementia complex; bacterial, viral, or fungal meningitis; lymphoma; and toxic–metabolic systemic disorder. The most common infectious causes include cryptococcal meningitis, *Toxoplasma* encephalitis, CMV encephalitis, tuberculous meningitis, and herpes simplex encephalitis. Less commonly reported infectious causes include *B. henselae* encephalitis, central involvement with *P. carini*, and neurosyphilis. Primary central nervous system (CNS) lymphoma usually has focal neurologic findings, but clinical presentation and radiographic abnormalities are similar to those of *Toxoplasma* encephalitis.

HIV-infected patients can manifest depressed consciousness because of drugs, hypoxemia, or metabolic abnormalities. Therefore, it is important to look for noninfectious factors in HIV-positive patients with altered levels of consciousness.

Focal Neurologic Signs and Symptoms

The sudden onset of focal neurologic signs, such as hemiparesis and blindness, has been reported in HIV-infected patients. Transient ischemic attacks are usually without long-term neurologic sequelae and are postulated to be secondary to a hypercoagulable state. Illicit drugs such as cocaine are associated with ischemic events. Cerebrovascular accidents have also been reported. Focal neurologic signs developing over several days can be the presentation for *Toxoplasma* encephalitis, primary CNS lymphoma, tuberculosis, and/or cryptococcoma. In *Toxoplasma* encephalitis, altered mental status, hemiparesis and other focal signs, headache, and seizures are commonly reported. The higher the serum IgG antibody to *Toxoplasma* organisms ratio, the greater the incidence of *Toxoplasma* encephalitis. Common radiographic findings include multiple ring-enhancing lesions in the cortex and basal ganglia. Magnetic resonance imaging (MRI) is more sensitive than computed tomography (CT) in detecting cerebral lesions in *Toxoplasma* encephalitis. As the incidence of *Toxoplasma* encephalitis declines secondary to trimethoprim–sulfamethoxazole prophylaxis, primary CNS lymphoma is becoming an increasing cause of focal neurologic disease in AIDS patients. CMV and herpes simplex encephalitis are two viruses that can present with focal neurologic signs and seizures.

Progressive multifocal leukoencephalopathy is caused by a papovavirus, the JC virus. It presents slowly in AIDS patients with CD4⁺ counts ≤ 100 per cubic millimeter. The patient develops altered mentation late in the course. Limb weakness and visual defects are found in less than half of patients. Seizures have been reported in approximately 20%. The findings on MRI or CT scan often appear worse than the clinical condition. Multiple diffuse hypodense non–contrast-enhancing lesions in subcortical white matter without mass effect are the typical findings.

Seizures are usually secondary to mass lesions, encephalopathy, meningitis, or electrolyte disorders, such as hyponatremia. The majority of cerebral mass lesions are due to *Toxoplasma* infection or lymphoma.

Headaches are a commonly reported symptom in AIDS patients. A focal brain pathology can be associated with headaches. In early HIV infection, headaches can be a presenting symptom. A common side effect of antiretroviral drugs is headache. Bacterial and fungal meningitis are frequently associated with headaches as a chief complaint.

Peripheral nerve syndromes are found in early HIV infections. Mononeuritis multiplex, a demyelinating polyneuropathy, and a rare multiple sclerosis–like syndrome have been described. Later in HIV infection, peripheral weakness and spasticity have been observed secondary to either a vacuolar myopathy or CMV polyradiculopathy. An axonal neuropathy has been reported with nucleoside antiretroviral drugs. Non–drug-related, distal sensory symmetrical polyneuropathy with burning feet, distal numbness, and depressed DTRs has also been seen late in symptomatic HIV infections.

Visual Loss

Acute loss of vision in HIV-infected individuals is most commonly due to CMV papillitis, varicella-zoster virus retinitis, secondary syphilis, cryptococcal meningitis, and bacterial/fungal endophthalmitis (Table 346.3). With CMV papillitis, there is rapid loss of visual activity that may respond to ganciclovir or foscarnet and steroids, if administered early in the course. Peripheral retinitis due to CMV has a more gradual loss of vision heralded by “floaters” across the visual field of one eye. The acute retinal necrosis syndrome secondary to herpes zoster can lead to loss of vision in one or both eyes. Secondary syphilis can be associated with necrotizing retinitis with hemorrhage that is similar clinically to CMV retinitis. Several cases of rapid visual loss with optic nerve involvement have been reported with cryptococcal meningitis. In addition to antifungal therapy for these patients, repeated CSF drainage has been found to be effective in reducing high intracranial pressure, which often accompanies the visual changes. Uveitis secondary to rifabutin has been seen with increased frequency in those patients receiving concomitant protease inhibitors. Bacterial retinitis secondary to MAC and *Rhodococcus equi* infection has been reported in a few patients.

CD4 ⁺ Count	Disorder
<500 cells/mm ³	Kaposi's sarcoma Lymphoma Tuberculosis
<250 cells/mm ³	Pneumocystosis Toxoplasmosis
<100 cells/mm ³	Retinal or conjunctival microvasculopathy Cytomegalovirus retinitis Keratoconjunctivitis sicca Varicella-zoster virus retinitis Mycobacterium avium complex infection Cryptococcosis Microsporidiosis HIV encephalopathy Progressive multifocal leukoencephalopathy

TABLE 346.3. CD4⁺ T-LYMPHOCYTE COUNTS IN PATIENTS PRESENTING WITH COMMON HIV-ASSOCIATED DISORDERS INVOLVING THE EYES

GASTROINTESTINAL SIGNS AND SYMPTOMS

Oral Lesions

Oral lesions may involve the lips, buccal mucosa, gums, tongue, and/or pharynx. Both infectious and noninfectious conditions are more common and/or more clinically severe in HIV-infected individuals. The most common infectious cause of oral and pharyngeal lesions is candidiasis. This fungal infection can be asymptomatic or associated with soreness, burning, and dysphagia. Periodontitis may be severe and involve necrosis of the gingiva or may be mild presenting as linear gingival erythema. Good oral hygiene is usually effective in mild cases, but necrotizing periodontitis will require dental surgery, irrigation, and antibiotics.

Oral ulcers may be due to herpes simplex virus or CMV. Aphthous ulcers are seen with increased frequency in HIV infection and usually respond clinically to topical steroids. On rare occasions, non-Hodgkin's lymphoma may present with an oral swelling or nonhealing ulcer. Kaposi's sarcoma may be seen on the gingiva or palate. Oral hairy leukoplakia involves the tongue epithelium and involves Epstein–Barr virus infections of these cells. Although it is not painful and can be treated with acyclovir, recurrences are common.

Dysphagia and Odynophagia

Difficulty and/or pain on swallowing are common symptoms in AIDS patients which should prompt further evaluation by x-ray and/or endoscopy. The most common cause of dysphagia, candidiasis, is often found with oral thrush. Large plaques are usually detected in the esophagus by endoscopy. CMV esophagitis usually presents with odynophagia and little dysphagia. Large, superficial ulcers in the distal esophagus show the typical intranuclear inclusions on histology. Herpes simplex virus can also cause erosive ulcers. Idiopathic esophageal ulcerations are a common cause of odynophagia and respond to 4 weeks of steroids. A few cases have responded to thalidomide. Other rarer causes of esophageal ulcerations include drugs (zalcitabine), lymphoma, Kaposi's sarcoma, and squamous cell carcinoma.

Acute Abdominal Pain

Diffuse abdominal pain without other associated symptoms may be due to pancreatitis or peritonitis. The drugs associated with pancreatitis include didanosine, pentamidine, and lamivudine. Intestinal perforations can be seen with lymphoma, typhilitis, Kaposi's sarcoma, tuberculosis, or salmonellosis. In advanced AIDS, CMV may be a cause of bowel perforations and peritonitis.

Diarrhea and Weight Loss

Both acute and chronic diarrhea are commonly seen during the clinical course of AIDS. The evaluation for the cause of diarrhea depends on persistence of symptoms. Microscopic examination of the stool should include wet mount, modified acid-fast stain, and modified trichrome stain. Stool cultures for routine pathogens and *Clostridium difficile* should also be ordered. Endoscopy of the colon and small bowel is necessary if the cultures and stains are negative. Watery diarrhea with fever and fecal leukocytes has been found with *Campylobacter*, *C. difficile*, *Salmonella*, *Shigella*, and CMV. Chronic watery diarrhea and enteritis are more commonly seen with cryptosporidia, *Cyclospora*, *Giardia*, *Isospora belli*, microsporidia, and MAC. Malabsorption and wasting syndromes can be seen in association with chronic diarrhea. Other, less common causes include bacterial overgrowth, enteric viral infection, Crohn's disease, and HIV disease.

Weight loss is commonly seen in AIDS patients. Once treatable causes of the wasting syndrome are ruled out, then HIV itself may be the cause.

RESPIRATORY TRACT SIGNS AND SYMPTOMS

Sinusitis

Symptoms of nasal congestion, postnasal drip, facial pain, and fever are found in many patients. The diagnosis of sinusitis can be made clinically, but radiographic changes are usually found. The maxillary and ethmoid sinuses are most commonly involved. Although isolates of *Streptococcus pneumoniae* and *Haemophilus influenzae* are often recovered, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are also reported with increased frequency. Chronic sinusitis in HIV-infected patients often have *Moraxella catarrhalis*, gram-negative bacilli, and/or anaerobes recovered in sinus cultures. The severity of sinusitis is greater in patients with low CD4⁺ counts. Treatment with antibiotics may be necessary for periods longer than the usual 10 to 14 days.

Cough and Fever

The HIV-infected patient with cough and fever requires a careful history, physical examination, and chest radiography. If the patient's CD4⁺ count is greater than 200 per cubic millimeter and the chest radiograph is clear, then the patient should be treated for acute bronchitis or sinusitis. If the patient's CD4⁺ count is under 200 per cubic millimeter and the chest radiograph is clear, then bronchitis, sinusitis, as well as *P. carini* pneumonia, tuberculosis, cryptococcosis, and MAC infection should be ruled out. If infiltrates are found by chest radiograph, then the bacteria associated with community-acquired pneumonia should be considered. Active tuberculosis is increased significantly in HIV-infected patients compared to the general population.

Bacterial pneumonia, the most common cause of death in AIDS patients, is caused by *S. pneumoniae*, *H. influenzae*, *P. aeruginosa*, and, uncommonly, *S. aureus*. *S. pneumoniae* has a 150-fold increased incidence over that of healthy controls. Clinically, HIV-infected patients with pneumonia are similar to other patients without HIV. Antibiotic treatment usually leads to good responses if there are no resistant organisms.

Dyspnea

The most common underlying cause of dyspnea in HIV-infected patients is *P. carini* pneumonia. Dyspnea is usually present with other symptoms such as cough and fatigue. Fever and weight loss are reported frequently. Although examination of the chest is usually normal, chest radiographs often reveal diffuse interstitial infiltrates. Less common findings are lobar infiltrates, nodular densities, and pulmonary edema. Respiratory alkalosis with a widened alveolar–arterial gradient is the usual arterial blood gas finding. Induced sputum is positive for *P. carini* in approximately 70% of cases, with the other 30% requiring bronchoalveolar lavage or biopsy for diagnosis.

Dyspnea is also a common symptom in other lung infections, such as community-acquired pneumonia due to *S. pneumoniae* and *H. influenzae*. In patients with AIDS, bacterial pneumonia will present with other typical signs and symptoms and respond to appropriate antimicrobial treatment. Other respiratory pathogens, such as fungi and mycobacteria, can also present with dyspnea as a major symptom.

Noninfectious causes of dyspnea include pulmonary lymphoma, Kaposi's sarcoma in the lung, primary pulmonary hypertension, and cardiomyopathy. Pulmonary Kaposi's sarcoma is usually observed when skin lesions are present, but in 10% to 15% of cases there may be lung involvement without cutaneous lesions. Both diffuse interstitial infiltrates and pleural effusions are frequently identified. Examining for lesions on bronchoscopy is the most common diagnostic method. Primary pulmonary hypertension has been reported with increased frequency in AIDS patients, with resultant right-sided heart failure being reported. No good treatment is available for this unusual complication.

MUSCULOSKELETAL SIGNS AND SYMPTOMS

Arthralgia may be the initial symptom in patients with septic arthritis. Although of low incidence in HIV-infected patients, septic arthritis is the most common infection of the musculoskeletal system in these patients. *S. aureus* is the most commonly isolated organism. Reiter's syndrome is more prevalent in HIV-infected individuals than in the general population. Arthritis is one of the three classic findings in Reiter's syndrome, with the other two being urethritis and conjunctivitis. Symptoms of arthritis may precede other clinical manifestations of HIV infection by several months. The joints of the lower extremities or the sacroiliac joint are most commonly affected. Skin manifestations commonly seen in Reiter's syndrome include keratoderma blennorrhagicum and circinate balanitis. Etretnate and topical steroids are effective treatments in Reiter's syndrome in HIV-infected individuals.

Other musculoskeletal infections include osteomyelitis, pyomyositis, and septic bursitis. *S. aureus* is the most commonly identified pathogen in these infections. As with septic arthritis, clinical presentation, prevalence and treatment outcome do not appear to be different in HIV-infected patients compared with uninfected individuals.

COMMON LABORATORY ABNORMALITIES

Routine laboratory tests often are abnormal in HIV-infected patients ([Table 346.4](#)). The most common electrolyte abnormality is hyponatremia. Extrarenal loss of sodium due to diarrhea and vomiting is common in hospitalized patients. Pulmonary and CNS diseases are also associated with hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone.

Laboratory Tests	Abnormality	Differential Diagnosis
Biochemical	Hypernatremia	Volume depletion, SIADH, Adrenal insufficiency, hypernatremia, hypernatremia, nephrogenic diabetes insipidus, nephroses, drug
	Hyperkalemia	Drug: TMP, trimethoprim, alcohol, insufficient hyperkalemia
	Hypokalemia	Diagnosis
	Hypercalcemia	Drug: heparin, tetracycline, amphotericin B, antiparasitic
Hematologic	Anemia of chronic disease	WBC opportunistic infection, malignancy
	Iron deficiency anemia	GI bleeding secondary to Kaposi's sarcoma, lymphoma, or carcinoma
	Bone marrow infiltration	Myelodysplastic and/or leukemia
	Red cell aplasia	Parvovirus B19
	Drug-induced leukopenia/neutropenia	Diagnosis, antipsychotics, sulfonamides, TMP-SMX
	Neutrophilic anemia	Diagnosis
Immunologic	Neutropenia	Secondary: heparin, foscarnet, sulfonamides, TMP-SMX, amphotericin, pentamidine, interferon- α , nevirapine, drug
	Leukocytopenia	Infective granulomatous, opportunistic
	Thrombocytopenia	DR drug: TMP and nevirapine, amphotericin
	Leukopenia	WBC drug: heparin, parvovirus infection, Kaposi's disease, opportunistic
Liver function tests	Coagulation abnormality	Advanced HIV, liver opportunistic/infectious disease
	Elevated transaminases	Cholelithiasis, cholangitis, viral hepatitis, hepatomegaly with acute hepatitis, yellow fever, drug-associated
Urologic	Elevated alkaline phosphatase	osteomyelitis, lymphoma
	Proteinuria	HIV-associated glomerulonephritis, HIV-associated IgA nephropathy, myeloma, heroin nephropathy, drug

TABLE 346.4. COMMON ABNORMALITIES FOUND IN ROUTINE LABORATORY TESTS FROM AIDS PATIENTS

With severe diarrhea, volume depletion, hypokalemia, and metabolic acidosis are common. Replacement of the fluid losses and potassium supplements are necessary for clinical improvement, but treatment of the cause of diarrhea is most important. Drugs that affect renal tubular function can also lead to hypokalemia.

Renal insufficiency, whether acute or chronic, can lead to hyperkalemia. Type IV renal tubular acidosis, adrenal insufficiency, and isolated mineralocorticoid deficiency are causes of hyperkalemia. Drugs such as trimethoprim and pentamidine can lead to severe hyperkalemia.

Other electrolyte abnormalities have included hypocalcemia secondary to drugs, hypercalcemia secondary to infection or malignancy, and hyperphosphatemia secondary to drug (foscarnet) therapy. Increased uric acid concentration has been reported with the use of antituberculosis drugs and didanosine.

The most common causes of acute renal failure with elevated blood urea nitrogen and serum creatinine in HIV-infected patients are drug toxicity, volume depletion, and shock. The underlying cause of the acute renal failure usually is more important to the outcome than the HIV status of the individual. HIV-associated nephropathy (HIVAN) is thought to be a result of HIV in the kidney. HIVAN is common in African Americans, in men more than in women, and in individuals with a history of intravenous drug use. There is rapid progression to renal failure without treatment. Newer antiretroviral therapies appear to help maintain renal function if begun early. Immune-mediated renal diseases are also reported in HIV-infected individuals. Whether the renal disease is related to HIV immune responses is unclear. The most common pathologic factor found on kidney biopsy has been IgA nephropathy, focal proliferative or membranoproliferative glomerulonephritis. Coinfection with HCV may lead to cryoglobulinemia and membranoproliferative glomerulonephritis.

COMPLICATIONS RELATED TO ANTIRETROVIRAL THERAPY

The advent of more effective antiretroviral therapy has dramatically altered the course of disease in HIV-infected individuals. The potential for extended survival is now very real for the majority of patients treated with HAART. Along with extended survival, however, comes extended exposure to the therapeutic agents, many of which were approved and released for use after relatively short-term clinical trials. Several common and fairly predictable adverse reactions have been described for several of the antiretroviral drugs. Other new reactions are only now becoming apparent. Active investigations are under way to determine prevalence, incidence, etiologic mechanisms, and treatment of these reactions. With multiple therapeutic options available, the choice of which regimen to prescribe in an individual patient will often be based on presumed tolerance of the regimen and its anticipated toxicity.

NEUROPATHY

Several nucleoside analogue reverse transcriptase inhibitors (NRTIs) cause a distal symmetrical polyneuropathy that is indistinguishable from that caused by HIV itself. This is most commonly seen with the dideoxynucleoside analogues didanosine, zalcitabine, and stavudine. The primary symptoms are numbness, tingling, or burning in the feet. Paresthesias and hyperesthesia of the lower extremities can also occur. In more advanced cases, the upper extremities may be affected, although it is very unusual for there to be upper extremity involvement without lower extremity symptoms. On physical exam, there may be decreased or absent ankle reflexes and decreased sensation in a stocking distribution in response to vibration, pin prick, and temperature. Objective weakness is rare. The diagnosis can be confirmed by nerve conduction studies.

It is important to consider other causes of neuropathic symptoms in this setting, and evaluation for diabetes, vitamin deficiency, and alcohol use should take place. Other neurotoxic drugs (e.g., isoniazid) should also be considered as potential etiologic factors.

Initial treatment is withdrawal or dose reduction of the known neurotoxic drugs. Symptomatic improvement may be reported by the patient within 2 to 3 weeks following dose alteration, but resolution may take 2 to 3 months. Complete resolution does not happen in all cases, but is more likely in those whose drug was not continued for a prolonged period despite increasing neuropathic symptoms. Management of the painful neuropathies should be individualized. Nonsteroidal agents should be the initial symptomatic treatment. Tricyclic antidepressants, such as amitriptyline, can be added for those patients with incomplete relief, although efficacy has not been fully demonstrated in HIV-related disease. The anticonvulsants phenytoin and carbamazepine also have a role in advanced cases, and a newer agent, gabapentin, with demonstrated effect in diabetic neuropathy, has shown early promise.

PANCREATITIS

Didanosine and zalcitabine have also been associated with episodes of clinical and subclinical pancreatitis. The cause of this reaction is unclear, but it is more common in those patients with advanced HIV infection and those with prior pancreatic injury or chronic alcohol use. The symptoms are identical to pancreatitis from any other cause. In some cases, asymptomatic hyperamylasemia may be detected. Permanent drug discontinuation, with no rechallenge in the future, should be done immediately. Treatment of this drug-induced pancreatitis is general clinical support as with pancreatitis from other causes.

RASH

Although rash is possible with any medication, it is somewhat common with the use of the non-NRTIs, occurring in 10% to 20% of those treated. It is most common and most important during the use of nevirapine. Both nevirapine and delavirdine are associated with the development of rash in approximately one of five persons taking either medication. With delavirdine the rash is usually mild and many patients can be treated for it. During nevirapine therapy the rash may progress to a severe reaction including widespread dissemination, constitutional symptoms, and mucosal involvement. This occurs in approximately 6% to 7% of treated patients. Stevens–Johnson syndrome can be seen, but it develops in less than 1% of patients. If severe rash develops, discontinuation of nevirapine is necessary and rechallenge should not be attempted.

HYPERGLYCEMIA

The use of protease inhibitors has been associated with the development of hyperglycemia in up to 6% of patients. There may be symptoms related to the hyperglycemia, including ketoacidosis. The onset of hyperglycemia is usually within 6 months of initiation of protease inhibitor therapy, and has been seen within the first week. Laboratory studies indicate a possible insulin resistance in these patients. The use of oral hypoglycemic drugs is generally successful in managing this disorder, and the use of protease inhibitors can usually be continued. Some patients may respond to exercise and diet modification without specific drug therapy.

HYPERTRIGLYCERIDEMIA

Elevated levels of triglycerides are seen in untreated HIV infection; however, the use of protease inhibitors has exacerbated this metabolic complication. Levels of 1,000 mg per deciliter or greater are not uncommon. This abnormality has been seen with all of the protease inhibitors, although it appears to be more common in those patients on ritonavir. Despite remarkably high levels of triglycerides, little in the way of clinical complications has been reported, with no clearly related cases of cardiovascular events or pancreatitis. The long-term significance of hypertriglyceridemia in the setting of HIV infection is unknown. Current guidelines for the management of hypertriglyceridemia in the cardiovascular patient can be applied to HIV-infected patients. Due to the concern of drug interactions with either fibric acid derivatives or 3-hydroxy-3-methylglutaryl reductase coenzyme A inhibitors and protease inhibitors, the use of these agents should be reserved for those patients at higher risk for pancreatitis or those with multiple cardiac risk factors.

MALDISTRIBUTION OF FAT

Several seemingly unrelated disorders of fat distribution have been increasingly described in the era of HAART. Although more common in patients taking regimens including protease inhibitors, these disorders have been seen in HIV-infected patients on all combinations of therapy or none at all. The most common alteration in fat distribution is a wasting, or thinning, of the arms and legs with or without thinning of the face. Also commonly seen is accumulation of abdominal fat. Many women experience breast enlargement of a bra cup size or more. This can be uncomfortable in general or actually locally tender. Less common is an accumulation of fat just

at and below the posterior neck, the so-called buffalo hump. No common cause or therapy is apparent for these disorders. Some patients have experienced a regression of these changes upon the withdrawal of protease inhibitor therapy.

CHAPTER 347: NEOPLASMS IN AIDS

DAVID M. ABOULAFIA AND RONALD T. MITSUYASU

[Kaposi's Sarcoma](#)
[Non-Hodgkin's Lymphoma](#)
[Miscellaneous Cancers](#)

Kaposi's sarcoma (KS), intermediate- and high-grade peripheral non-Hodgkin's lymphoma (NHL), primary central nervous system (CNS) lymphoma, and invasive squamous cell carcinoma of the cervix are included in the U.S. Centers for Disease Control and Prevention case definition of AIDS. A variety of other non-AIDS-defining neoplasms are occasionally seen in the setting of HIV infection.

KAPOSI'S SARCOMA

DEFINITION

The lesions of KS are multifocal, vascular proliferative neoplasms of mesenchymal origin that are characterized by abnormal angiogenesis, leukocytic infiltration, and proliferation of spindle cells, fibroblasts, and endothelial cells.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Unique aspects of the epidemiology of KS include its association with sexually transmitted HIV infection, its male-to-female ratio of roughly 20:1, its rare appearance in individuals at risk for HIV infection but without detectable HIV, and its declining incidence among male homosexuals. It is now presumed that a new herpes virus, termed Kaposi's sarcoma-associated herpesvirus (KSHV), or human herpesvirus 8 (HHV-8), is involved in the pathogenesis of KS. HHV-8 sequences are present in peripheral blood mononuclear cells, spermatozoa, and seminal fluid of AIDS-KS patients but is found infrequently in sputum and stool samples.

Assuming that HHV-8 is acquired through the mucosa during anal intercourse, the declining incidence of KS among male homosexuals may be related to the gradual adoption of safer sex practices that minimize transmission. Partial restoration of the immune system that occurs following the implementation of highly active antiretroviral therapy (HAART) may also contribute to the declining incidence of AIDS-associated KS.

ETIOLOGIC FACTORS AND PATHOGENESIS

Although HIV infection is not required for the development of KS, it clearly increases the risk and greatly influences the clinical pattern of the disease. There may be several mechanisms behind this, including decreased immune surveillance and enhanced production of KS-inducing cytokines and growth factors. The KS spindle cells secrete paracrine factors that appear to mediate angiogenesis and the mononuclear cell infiltrate. The mononuclear cells, in turn, may secrete cytokines that stimulate growth of KS cells, setting up an autocrine-paracrine loop.

CLINICAL FINDINGS

The initial evaluation of the patient with KS includes a complete history with a focus on the rate of progression of new KS lesions, HIV-related opportunistic infections, overall immune status, and treatment history. The clinical features of epidemic KS differ markedly from those of classic, iatrogenic, and endemic forms of the disease. In patients with AIDS, KS tends to be multicentric. It may appear as a single, seemingly innocuous skin blemish that is easily overlooked. Alternatively, larger confluent skin lesions, manifested as red, purple, or brown patches, plaques, or nodules, may spread randomly over the body surface. In some patients, only a few lesions are apparent, and they remain unchanged for years; in others, lesions proliferate rapidly. In most patients, new lesions develop gradually over several weeks to months.

Kaposi's sarcoma lesions of the head, the neck, and the tip of the nose are often disfiguring. Lymphatic involvement may produce debilitating and cosmetically unacceptable edema, particularly when the periorbital area, genitalia, and lower extremities are involved. About 30% of patients with cutaneous KS have gastrointestinal involvement. Examination of the oropharynx may uncover asymptomatic lesions on the palate, pharynx, or tongue; if allowed to grow, these lesions can interfere with eating or breathing. Fortunately, KS rarely causes gastrointestinal hemorrhage or obstruction. KS involvement of the tracheobronchial tree, pulmonary parenchyma and pleura may cause dyspnea, chest pain, pleural effusions, and fevers.

LABORATORY EVALUATION

Essential laboratory tests include a baseline CD4⁺ count and HIV viral load. The diagnosis of KS is relatively straightforward in HIV-infected individuals presenting with numerous erythematous or violaceous cutaneous or mucosal lesions. However, bacillary angiomatosis caused by *Rochalimaea* species and other conditions may mimic the appearance of KS. This latter condition is treatable with antibiotics and should be excluded by Warthin-Starry stain of biopsied material. A chest radiograph is useful when screening for asymptomatic pulmonary disease. Suspicious pulmonary lesions should be further evaluated by bronchoscopy. Symptomatic gastrointestinal involvement is best evaluated by endoscopy with biopsy of mucosal lesions.

OPTIMAL MANAGEMENT

Immediate therapeutic intervention is rarely necessary at the time of KS diagnosis, although many patients require some form of palliative treatment during the course of their disease. Small, localized lesions of limited number may be observed or treated with regional therapy, including intralesional vinblastine, topical liquid nitrogen, and 9-*cis*-retinoic acid gel. Radiation therapy is especially useful in treating tumors that are complicated by edema involving the extremities and periorbital areas. Painful lesions on the soles of the feet and those on the conjunctivae, nose, and ears can also be palliated with this modality. However, HIV-infected patients have heightened susceptibility to radiation-induced mucositis. Oral and genitoretal lesions probably are managed best by other modalities.

Extensive or rapidly progressive KS, particularly involving visceral organs, requires a more aggressive systemic approach. Single and combination chemotherapy consisting of *Vinca* alkaloids, etoposide, anthracyclines, and bleomycin are active against KS and produce response rates varying from 25% to 80%. Interferon- α in conjunction with HAART produces objective response rates of 30% to 60% when used in patients with CD4⁺ counts greater than 100 per cubic millimeter. Because liposomal anthracyclines are rarely associated with mucositis or alopecia, they have become a first-line treatment for patients who have progressive or symptomatic disease. Paclitaxel is another active agent that is often used when tumors progress following initial therapies. Important in all approaches to the treatment of patients with AIDS-associated KS is an effective antiretroviral regimen that limits HIV replication. When HIV viral loads are reduced, lesions will occasionally regress, and KS therapy can sometimes be scaled back without recrudescence of tumors.

NON-HODGKIN'S LYMPHOMA

DEFINITION

About 90% of AIDS-related NHLs are of B-cell origin. The histologic patterns are representative of aggressive lymphomas and fall into two groups: large-cell lymphomas, which include intermediate-grade large-cell and high-grade immunoblastic lymphomas, and high-grade, small, noncleaved lymphomas (often classified as Burkitt's or Burkitt-like lymphomas). Low-grade NHL and T-cell phenotypes rarely are seen in patients with HIV disease and are not considered to be AIDS-defining illnesses.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The risk for development of NHL appears to be constant over time and is not confined primarily to a single group, as is the case with KS. NHL may occur at any level of immune function. The median CD4⁺ count is approximately 100 per cubic millimeter. In contrast, primary CNS lymphoma occurs almost exclusively in severely immunocompromised individuals. The median CD4⁺ cell count is 30 per cubic millimeter.

ETIOLOGIC FACTORS AND PATHOGENESIS

The reason for the high incidence of NHL in patients with AIDS remains poorly understood. In one model, severe immunodeficiency leads to the reactivation of latent Epstein–Barr virus (EBV) infection. Chronic antigenic stimulation of B lymphocytes and macrophages by EBV and other pathogens elicits the release of various growth factors and cytokines, promoting B-cell growth and activation and facilitating malignant transformation of these cells. The usual T-cell suppressive factors called into play to limit B-cell proliferation are ineffective and, by a multistep process, in 25% to 50% of cases, proto-oncogenes such as *c-myc* are activated following specific chromosomal translocations.

CLINICAL FINDINGS

Sixty percent to 95% of AIDS-related NHL patients present with extranodal involvement. Common extranodal sites include the bone marrow in 33% of patients, the leptomeninges in 20%, the gastrointestinal tract in 17%, and the oral and anorectal mucosa in 7%. Patients with primary CNS involvement may appear confused, lethargic, or complain of headache. Such tumors almost always are composed of immunoblastic or large-cell lymphocytes and invariably are associated with EBV.

More than 80% of patients with AIDS-related NHL have significant fever, weight loss, and night sweats. Yet the diagnosis of NHL is often obscured by the presence of constitutional symptoms related to other non-neoplastic causes.

LABORATORY FINDINGS

HIV viral load and CD4⁺ T-cell count are routinely obtained in conjunction with a complete blood count, sedimentation rate, chemistry panel (including lactate dehydrogenase), and bilateral bone marrow aspirate and biopsy. Various cultures, stains, and additional radiographic studies may be required to evaluate the extent of disease and complicating infections. Unusual or suspicious growths mandate additional evaluation, often culminating in tissue biopsy. In the absence of a space-occupying CNS lesion, a spinal puncture is performed and fluid is collected for cytologic analysis. Patients with primary CNS lymphomas may have single or multiple contrast-enhancing and hypodense lesions on computed tomography and magnetic resonance imaging. For patients with focal neurologic defects and normal computed tomographic scans, magnetic resonance imaging may be more sensitive in the detection of occult disease. Although solitary lesions are more likely to be lymphoma, imaging alone cannot reliably distinguish between tumor and cerebral toxoplasmosis. The presence of polymerase chain reaction–amplified EBV DNA in spinal fluid appears to be a sensitive and specific test for primary CNS lymphoma.

OPTIMAL MANAGEMENT

Despite intensive chemotherapy, the median survival for HIV-infected patients with NHL and low CD4⁺ counts is only 4 to 6 months. However, patients with CD4⁺ counts greater than 100 cells per cubic millimeter may achieve response rates as high as 72% and disease-free intervals exceeding 15 months. Treatment strategies usually incorporate several paradigms: the use of systemic chemotherapy, even in patients with apparently localized disease on staging evaluation; the use of low-dose chemotherapy with or without hematopoietic growth factors in patients with lymphomatous bone marrow involvement, CD4⁺ T-cell counts less than 100 cells per cubic millimeter, or constitutional symptoms; the early use of prophylactic intrathecal methotrexate or cytarabine to prevent CNS relapse; the use of prophylactic antibiotics and antifungal agents to reduce the occurrence of opportunistic infections; and the use of non-myelosuppressive antiretroviral drugs to reduce HIV viral burden during periods of heightened immunosuppression.

Because toxoplasmosis is the cause of 90% of focal cerebral lesions, patients with focal neurologic defects or abnormal brain scans often are treated empirically with antitoxoplasmosis regimens while undergoing close observation. Failure to improve radiographically or clinically within 7 to 10 days mandates reconsideration of the diagnosis. Patients diagnosed with primary CNS lymphoma are most often treated with whole-brain radiation. Patients may achieve short-term palliation, but survival rarely exceeds 4 months.

MISCELLANEOUS CANCERS

In the setting of HIV infection, Hodgkin's disease is more commonly associated with advanced stage at diagnosis, lymphocyte depleted or mixed cellularity, and a propensity to involve extranodal locations. Patients respond to conventional chemotherapy, but tumors often recur. Consequently, patients have a median survival of only 12 to 16 months.

Anal cancer and cervical cancer, neoplasms associated with human papillomavirus infection, may occur with higher incidence in HIV-infected patients. This is due to the high prevalence of human papillomavirus infection in groups at risk for HIV and the high frequency of the premalignant condition, intraepithelial neoplasia in HIV-infected women. While the incidence of an abnormal Pap smear of the cervix is only 5% in otherwise healthy women, the incidence of abnormal cervical smears in women with HIV infection is 60%. Ongoing studies of infected individuals using Pap smears on cells obtained from the transitional zone of the anus and cervix should provide more data regarding the increasing incidence and optimum surveillance programs for these cancers in this population.

Although anecdotal reports of other malignancies reported in HIV-infected individuals abound, it is unclear as to whether these occur above the background prevalence in the general population. These malignancies include tumors of the skin, lung, brain, testes, and, in children, the mesenchyma.

CHAPTER 348: PRINCIPLES OF ANTIRETROVIRAL TREATMENT AND VACCINES

CHRISTOPHER J. LAHART

[General Principles in the Therapeutic Approach](#)
[Use of Plasma HIV RNA Levels: Viral Load Testing](#)
[Initiation of Antiretroviral Therapy](#)
[Therapeutic Agents](#)
[Choice of Antiretroviral Regimen](#)
[Changing Therapy](#)
[Vaccines](#)

During the late 1990s, HIV-infected patients have benefited from a propitious confluence of events. Based on years of research into the pathogenesis of HIV infection, therapeutic and diagnostic approaches representing dramatic improvements over previous methods have come into general use. Development of the non-nucleoside reverse transcriptase inhibitors and the protease inhibitors heralded a new era in the treatment of HIV infection. Broad use of plasma HIV RNA levels allowed further fine tuning of therapeutic interventions prior to clinical progression or loss of CD4⁺ lymphocytes. As a result, in the United States the mortality attributed to HIV infection and AIDS decreased by over 60% during 1996–1998. Despite these tremendous changes in our approach to antiretroviral therapy, the optimal timing of therapy initiation and the preferred agents with which to start therapy are still unknown. Additionally, even in the setting of perfect adherence to the therapeutic regimen, the ultimate durability of these new therapies is unknown at this time. There are also multiple barriers to perfect adherence with the need for multiple medications, difficult dosing schedules, varying dietary restrictions for some medications, and, for many persons living with HIV, lack of ready access to medications and physicians with the expertise necessary to properly prescribe the medications. The decrease in mortality seen in the most recent years may represent merely a delay in progression of disease rather than true disease containment.

GENERAL PRINCIPLES IN THE THERAPEUTIC APPROACH

As outlined in [Table 348.1](#), the harm to an individual with HIV infection stems from the continual replication of HIV and the resultant immune system dysfunction. Many pharmaceutical agents have been developed for use in antiretroviral therapy based on their ability to impair viral replication ([Table 348.2](#)). Unfortunately, no single agent with the ability to completely suppress viral replication has been found. Thus, the use of a single agent, or even most combinations of two agents, is associated with impaired, but still active, viral replication. In this setting there is transient benefit reflected in laboratory measures or actual clinical outcomes; however, this benefit is not durable. The transient nature of this benefit is due to the development and selection of resistant HIV viral mutants that then return viral replication to its previous level despite continued therapy. The end result is continued high-level viral replication and further immunologic decline.

TABLE 348.1. PRINCIPLES OF THERAPY OF HIV INFECTION (NIH PANEL)

Generic Name	Brand Name	Key Clinical Use	FDA Approval Date	Comments
Nucleoside analog reverse transcriptase inhibitors				
zalcitabine	Retron	ZDV, AZT	March 1987	
didanosine	ddi	ddI	October 1991	
zalcitabine	ddC	ddC	June 1992	
abacavir	Doril	ABC	June 1998

TABLE 348.2. APPROVED ANTIRETROVIRAL AGENTS AND INVESTIGATIONAL AGENTS IN ADVANCED PHASES OF DEVELOPMENT

The recent development and use of combinations of three or more effective antiretroviral medications has accomplished what was not possible before: the suppression of HIV viral replication as evidenced by plasma HIV RNA levels falling below the level of detection using highly sensitive assays. This approach has come to be known as “highly active antiretroviral therapy (HAART).” However, this is not to say that viral replication has been halted in all body compartments, particularly the lymphatic tissues. Indeed, there is evidence that a residual amount of replication does take place, although the clinical repercussions are not yet known. Even in the most successful trials, 20% to 40% of patients do not attain the goal of undetectable viral load. The reasons for such a high failure rate are not clear but should give pause to a practitioner recommending therapy in a more reluctant patient. Success is far from certain with these therapies, and failure implies resistant virus and limited future options. However, the rational use of these multidrug combinations has been demonstrated to suppress the plasma HIV RNA levels to below attainable levels of detection for over 3 years in over half of patients. These patients appear to continue to accumulate clinical and immunologic benefit. Even in those patients experiencing a treatment failure from the virologic standpoint, clear clinical benefit is seen in most. Studies designed to examine the approach of more intensive induction therapy with less intensive maintenance therapy have recently been presented. In the case of using three- or four-drug combination therapy as induction and then dropping medications to move into a maintenance mode, the maintenance therapy did not continue viral suppression for a large minority of the study participants. For the time being, it would appear that treatment must be continued on a life-long basis at the more intensive level. Studies of the utility of viral resistance testing to assess the baseline resistance profile of a particular patient's virus prior to the initiation of any therapy are under way. Perhaps this possibility of baseline resistance will help explain the relatively high rate of virologic failure.

USE OF PLASMA HIV RNA LEVELS: VIRAL LOAD TESTING

The level of plasma HIV RNA detected by specific assays directly correlates with the total viral burden in the infected individual. The pretreatment, or baseline, measurement of this level is the single best prognostic indicator in HIV infection. Higher levels are associated with more rapid disease progression, more rapid CD4⁺ lymphocyte decline, and the development of AIDS or death. Following an acute elevation during initial HIV infection, the plasma HIV RNA level usually decreases to a plateau, or set point, within 6 months. This level remains fairly constant over months to years and is the prognostically significant value. Although the range of values for the commercially available viral load tests generally extends up to 750,000 or 1 million copies of viral RNA per milliliter, prognostic studies in large cohorts of

patients have shown that the highest risk quintile contains those individuals with values greater than 30,000 to 55,000, depending on the type of assay used. Thus, the groups with the best prognoses are concentrated in the lower end of the viral load spectrum. With the initiation of effective antiretroviral therapy, this viral load measurement shows a rapid decline. This initial decline is used to assess the efficacy of the newly administered therapy. When repeated 3 to 6 weeks after the initiation of therapy, a three- to tenfold (0.5 to 1.0 log) decrease in the viral load should be seen. The plasma HIV RNA assay is then repeated on a regular basis to confirm continued efficacy of the therapeutic regimen. The durability of the response to treatment is directly related to the viral load nadir that is achieved. The most durable responses are in those individuals in whom the viral load has declined to below the limit of detection, which has been under 400 to 500 copies per milliliter in standard testing and under 50 copies per milliliter in highly sensitive assays.

INITIATION OF ANTIRETROVIRAL THERAPY

Since the approval of the first antiretroviral agent (zidovudine in 1987) there has been continual debate over the optimal time to initiate antiretroviral therapy. At this time there is general consensus that any patient with an AIDS diagnosis has endured too much immune system damage and is at too high a risk for progression to more advanced disease, hospitalization, or death for any further delay in therapy. There is also consensus, with minimal dissension, that any symptomatic HIV infection should be treated, regardless of CD4⁺ lymphocyte count and plasma HIV RNA level. Where substantial debate continues is in the patient who is free of any symptoms of HIV infection. Two sets of recommendations have recently been put forward; one by the International AIDS Society–USA and the other by the U.S. Department of Health and Human Services (DHHS). Although these recommendations do not totally agree on a level of plasma HIV RNA at which therapy should be started, the difference is inconsequential. A plasma HIV RNA level of greater than 5,000 to 20,000 copies per milliliter is deemed to be associated with a high enough risk of progression to AIDS (6% to 9% within 3 years) to warrant therapy, regardless of CD4⁺ lymphocyte count. For those individuals with a plasma HIV RNA level below this range, treatment is advised if the CD4⁺ lymphocyte count is less than 500 cells per cubic millimeter. Thus, a practitioner may consider delaying or withholding therapy in those individuals with both a CD4⁺ lymphocyte count above 500 cells per cubic millimeter and a plasma HIV RNA level below 5,000 copies per milliliter. In most clinical practices this is a small minority of patients.

In individuals with symptomatic HIV infection, an examination of the risk/benefit ratio clearly favors the use of antiretroviral therapy due to the advanced state of infection indicated by the presence of symptoms and the likelihood that the symptoms will be addressed by enhanced viral control and immunologic improvement. In the asymptomatic patient, the risk/benefit analysis can be more difficult to perform, particularly if there is a higher CD4⁺ lymphocyte count or a lower viral load. Potential benefits include the control of viral replication and thus decreased viral mutation and less selection of resistant virus, immune system maintenance or improvement, delayed disease progression, prolonged survival, lower risk of drug toxicity when used in less advanced infection, and possibly a decreased risk of viral transmission to contacts. Potential risks to the asymptomatic patient considering therapy include adverse drug reactions, decline in quality of life due to pill taking and scheduling, development of resistant virus, transmission of resistant virus, decreased options for future therapy and the unknown durability of current therapy, as well as the development of currently unknown long-term toxicity.

Due to the rather complicated nature of the combination therapies and the potential for side effects in someone previously asymptomatic, both physician and patient need to consider the difficulties of long-term adherence to the treatment regimen prior to the initiation of such a regimen. Incomplete adherence is associated with incomplete viral suppression and the development of resistance. Significant cross-resistance in both the non-nucleoside agents and the protease inhibitors can then develop, creating a severe limitation in any future therapies. This point cannot be emphasized enough. Clinical studies performed thus far indicate a need for 90% to 95% adherence to the dosing schedule to maintain viral suppression. This implies the need for an ongoing clinical relationship and a mechanism to ensure continued access to medication—two difficult propositions in today's health care environment ([Table 348.3](#)).

Class	Drug	Dosing	Toxicity	Comments
Nucleoside analogues	Zidovudine	300 mg b.i.d.	GI upset, headache, anemia, leukopenia	Maximum response more common in advanced disease
	Stavudine	300 mg b.i.d.	Peripheral neuropathy, myopathy, myalgia	Interaction of d,l-form with other drugs such as d,l-form of levodopa
	Lamivudine	150 mg b.i.d.	Peripheral neuropathy, myopathy	
Non-nucleoside reverse transcriptase inhibitors	Nevirapine	200 mg b.i.d.	Headache, rash, pruritus, dizziness, blurred vision, taste paresthesia	May have hepatotoxicity and associated to other nucleosides
	Didanosine	750 mg b.i.d.	Peripheral neuropathy, myopathy, myalgia	Interaction of d,l-form with other drugs such as d,l-form of levodopa
	Delamanvir	300 mg b.i.d.	Headache, dizziness, blurred vision, taste paresthesia	Interaction of d,l-form with other drugs such as d,l-form of levodopa
Protease inhibitors	Saquinavir	1,200 mg b.i.d.	GI upset, headache, rash, pruritus, dizziness, blurred vision, taste paresthesia	Strongly associated with resistance to other nucleosides
	Zalcitabine	375 mg b.i.d.	Peripheral neuropathy, myopathy, myalgia	Interaction of d,l-form with other drugs such as d,l-form of levodopa
	Didanosine	750 mg b.i.d.	Peripheral neuropathy, myopathy, myalgia	Interaction of d,l-form with other drugs such as d,l-form of levodopa

TABLE 348.3. DOSING RECOMMENDATIONS AND TOXICITIES

THERAPEUTIC AGENTS

Currently available antiretroviral therapies can be divided into two broad categories: inhibitors of HIV reverse transcriptase and inhibitors of HIV protease. Although other aspects of the viral life cycle are amenable to therapeutic attack, these two areas are the sole targets exploited thus far. Within the category of reverse transcriptase inhibitors (RTIs) there are two subcategories: the nucleoside analogue reverse transcriptase inhibitors (nRTIs), and the non-nucleoside reverse transcriptase inhibitors (NNRTIs). Clinical experience with nRTIs dates back to 1987, whereas with NNRTIs there is only 3 years' experience, and less than 4 years' with protease inhibitors (PIs). There remains much to be learned about the use of each category of antiretroviral agents as well as how to best combine them in effective therapy. Since the release of zidovudine and didanosine in early 1987, most antiretroviral treatment recommendations have utilized a combination of two nucleoside analogue reverse transcriptase inhibitors and one protease inhibitor as the starting point from which all therapy goes forward. The recent recognition of several adverse reactions that if not actually caused by protease inhibitors are at least more prevalent in patients on protease inhibitors has caused some rethinking about these treatment recommendations.

NUCLEOSIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

The six agents in this class of antiretrovirals are all nucleoside derivatives that act on HIV reverse transcriptase through competitive binding to reverse transcriptase in place of endogenous nucleosides and by inducing the termination of the elongating viral DNA. They all require phosphorylation to attain the active triphosphate form and are thus dependent on intracellular metabolic pathways. In planning therapy with nRTIs, it is important to consider combining a thymidine analogue (zidovudine or stavudine) with a non-thymidine analogue (didanosine, zalcitabine, lamivudine, or abacavir). Thymidine analogues are most active in virally activated cells, whereas nonthymidine analogues are active in resting cells.

Zidovudine

Zidovudine, a thymidine analogue, was the first antiretroviral agent approved for use against HIV. It was quickly demonstrated to have dramatic effects when compared to placebo in persons with advanced stage disease. Clinical and survival benefits were shown in multiple clinical trials. It remains a mainstay in combination therapy. Zidovudine is rapidly absorbed from the gastrointestinal tract and crosses the blood–brain barrier. No dietary restrictions complicate zidovudine use. The most common side effects are headache, fatigue, malaise, nausea, anemia, and leukopenia. The constitutional symptoms are greatest during the initial 2 to 4 weeks of therapy and generally improve afterward, although they may not resolve completely. Symptomatic therapy can be directed at these side effects. Side effects are also more common in those patients whose disease is more advanced at the time of drug initiation.

When initially approved for use, zidovudine was prescribed at a dose of 200 mg every 4 hours around the clock. The current recommended dose is 300 mg twice daily. The older dose was associated with much greater toxicity, particularly since it was being prescribed for prolonged periods of time in advanced infection. Since it was the only antiretroviral available for approximately 4 years, many patients took no other antiretroviral and progressed through their illness to death, despite zidovudine use. This issue is still raised by many patients presenting for initial care in this era. It should be addressed directly to facilitate patient adherence to an important component of many regimens.

Zidovudine used in the perinatal period has shown a significant decrease in the perinatal, or vertical, transmission of HIV infection. In the major controlled trial,

transmission in the zidovudine-treated group was 8.3%, whereas the placebo group had a transmission rate of 25.5%. In this trial zidovudine was prescribed after the first trimester, given intravenously intrapartum, and then administered to the newborn for the first 6 weeks of life. Shorter course studies have confirmed benefit with decreased transmission.

Didanosine

Didanosine, an adenosine analogue, was initially made available for compassionate use in those patients failing zidovudine therapy. So the initial experiences with the drug were in advanced, treatment-exposed patients. Clinically, it was shown to be more effective than continuing zidovudine in those patients who had already received more than 16 weeks of zidovudine. The drug is acid-labile and is packaged with buffers to prevent degradation in the stomach. For the best effect of these buffers, didanosine should be taken at least 30 minutes before a meal or 2 hours after a meal. Since didanosine is a twice-daily medication, this can often be handled by taking the medication prior to the first meal of the day and after the last. This dietary restriction offers a hurdle to be addressed when planning combination therapy. It would not be advisable to combine didanosine with a drug whose absorption is increased with food or a drug that requires the normally acidic stomach, thereby increasing the number of drug-taking episodes per day. For many patients the poor palatability of the buffered tablets is reason enough to stop the medication. This can often be avoided by dissolving the tablets in water and drinking the suspension. The main side effects of didanosine are a distal symmetrical polyneuropathy, pancreatitis, and diarrhea. Neuropathic symptoms generally improve over a period of weeks following discontinuation of the drug. Pancreatitis necessitates drug withdrawal, although asymptomatic elevations of amylase, lipase, and triglycerides are seen and can be followed. Once amylase levels surpass two times the upper limit of normal, the drug should be stopped. The diarrhea is thought to be related to the buffers and can be treated symptomatically.

Zalcitabine

Zalcitabine, a cytidine analogue, was initially approved as the first combination therapy. Clinical benefit was seen for patients in whom zalcitabine was added to ongoing zidovudine therapy. It was later demonstrated that this benefit was due to zalcitabine and not to the continued zidovudine, so that zalcitabine was given an indication outside of this combination therapy. Zalcitabine is administered every 8 hours and has no dietary restrictions, although when taken with food the maximum plasma concentration is reduced by a third. A dose-related distal symmetrical polyneuropathy is the most common side effect seen with zalcitabine use. This makes therapy combining didanosine and zalcitabine inadvisable from a tolerance standpoint. As with didanosine, the neuropathic symptoms are addressed by drug withdrawal and symptomatic medications. Stomatitis with ulcerations of the buccal mucosa, soft palate, pharynx, and tongue can occur. These are usually self-limited and treatment need not be interrupted. Pancreatitis is also listed as a side effect of zalcitabine, but this is unusual.

Stavudine

Stavudine, another thymidine analogue, was quickly adopted for general use due to its relatively easy dosing schedule and light toxicity profile. Although peripheral neuropathy is its main adverse effect, stavudine is less neurotoxic than zalcitabine and didanosine. Stavudine and zidovudine should not be administered together because of possible antagonism. This may be due to competition for activation by thymidine kinase since these are the two thymidine analogues. Zidovudine-resistant mutants are susceptible to stavudine. Extensive studies have demonstrated the effectiveness of stavudine in combination with didanosine or lamivudine. Stavudine resistance is seen clinically, but the exact mechanism of this resistance has not been fully elucidated. It appears that an insertion mutation rather than substitution may be responsible.

Lamivudine

Lamivudine is the second cytidine analogue approved for use against HIV. Lamivudine is very well tolerated and has no major toxicity. Resistance to lamivudine develops rapidly, although the development of this resistance seems to delay the development of resistance to zidovudine. Also, in zidovudine-resistant virus, the administration of lamivudine seems to resensitize the virus to zidovudine. Lamivudine is also available as a fixed-dose combination tablet with zidovudine, allowing combination nucleoside therapy with the convenience of a single tablet twice daily.

Abacavir

Abacavir is the first guanosine analogue and received FDA approval in late 1998. At this time there is limited information on its use in the general HIV-infected population. Abacavir has the highest anti-viral potency of any of the nucleoside analogues when examined as monotherapy for short durations. Studies examining its use in highly treatment-experienced patients are under way to determine its efficacy in various resistance situations. This drug is generally well tolerated, with gastrointestinal upset and headache being the most common side effects. A clinically important adverse reaction despite its occurrence in less than 5% of patients studied thus far is a hypersensitivity reaction. Characterized by fever, nausea, malaise, and with or without a rash, the severity of this symptom complex increases with continued dosing. Drug discontinuation is necessary. There should be no effort at rechallenge with this drug since a fatal reaction has been reported in that setting.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

This group of medications is related by their antiretroviral activity and not by chemical structure. These drugs bind to reverse transcriptase near the enzyme's catalytic site, leading to a conformational change that inactivates the enzyme. The NNRTIs are not dependent on intracellular mechanisms for any phosphorylation. Resistance to this class of antiretrovirals develops quickly and easily when they are used in suboptimal treatment regimens. The resistance that develops is usually class-wide, causing the loss of this whole class of drugs if virologic failure occurs while taking one. For this reason, extra care must be taken when incorporating NNRTIs into the treatment plan. At least one, if not two, new agents should be used in addition to the NNRTI. Rash is also a class-wide phenomenon as the most common adverse event.

The non-nucleoside reverse transcriptase inhibitors were overshadowed by the release of the protease inhibitors and the accompanying revolution in treatment. At the time of the release of nevirapine and delavirdine, these drugs were not properly appreciated for what they could offer in terms of therapeutic options. It is only now, in the face of possible long-term toxicity due to protease inhibitors and the recent approval of efavirenz, that they are being reevaluated as a group.

Nevirapine

Nevirapine is currently recommended in a twice-daily dosing schedule but has a pharmacokinetic profile that lends it to once-daily dosing. Such clinical trials are under way. Nevirapine is generally well tolerated, with rash being the primary treatment-limiting reaction. Nevirapine induces its own metabolism and is begun at a half-dose initially in an attempt to minimize the occurrence of rash. Some clinicians have prescribed a short course of steroids to further minimize the chance of rash. If treatment is continued despite the onset of rash, the reaction may progress to Stevens–Johnson syndrome. However, the majority of rashes remain mild to moderate and do not necessitate drug withdrawal. Resolution of the rash is rapid after drug discontinuation. In many clinics, nevirapine has been a part of the so-called salvage treatment of patients failing prior therapy. In combination with ritonavir and saquinavir, nevirapine can help achieve strong antiretroviral effect.

Delavirdine

Like nevirapine, delavirdine is generally well tolerated with rash as the primary adverse event. The rash seen with delavirdine seems to be milder than that sometimes observed with nevirapine. Unlike nevirapine, which is an inducer of the cytochrome P450 system, delavirdine is an inhibitor of this metabolic pathway. Delavirdine should not be taken shortly after antacids or didanosine since this will impair its absorption. Dosing of delavirdine is three times daily and each dose is four tablets. For persons having difficulty swallowing four tablets, they are readily dissolved in 3 or more ounces of water. Like the other NNRTIs, the place of delavirdine in treatment plans is undergoing reevaluation. Combined with nucleoside analogues, it offers potent antiretroviral activity. Head-to-head trials comparing the antiviral effect with that of protease inhibitors have not been completed; thus, neither delavirdine nor nevirapine is listed as a preferred initial regimen in the DHHS recommendations ([Table 348.4](#)).

Preferred Regimens	One Choice Each from Column A and Column B	
	Column A	Column B
	Indinavir	ZDV + ddI
	Nelfinavir	d4T + ddI
	Ritonavir	ZDV + ddC
	Saquinavir-SGC	ZDV + 3TC
	Ritonavir + saquinavir-SGC or HGC	d4T + 3TC
	Efavirenz	
Alternative regimens	Less likely to provide sustained viral suppression, or data inadequate	
	Nevirapine or delavirdine + one choice from column B	

* Department of Health and Human Services.

TABLE 348.4. DHHS^a RECOMMENDATIONS FOR INITIAL TREATMENT OF HIV INFECTION

Efavirenz

Efavirenz is the newest member of the NNRTI class, receiving FDA approval in late 1998. Efavirenz offers the attraction of once-per-day dosing. In addition to rash, patients taking efavirenz can experience a variety of central nervous system effects: dizziness, somnolence, confusion, impaired concentration. To help avoid these symptoms, most patients are advised to take efavirenz at bedtime. These symptoms will wane over the course of the first 2 weeks of therapy. Clinical data have shown that efavirenz compares favorably with protease inhibitor therapy when combined with nucleoside analogues. Additionally, a trial of efavirenz with indinavir alone demonstrated strong and durable anti-HIV effect without the use of nucleoside analogues.

PROTEASE INHIBITORS

The protease inhibitors burst onto the scene of HIV therapy in late 1995 and early 1996 with impressive clinical data, including dramatic clinical outcomes and large decreases in mortality in advanced patients when a single protease inhibitor was added to ongoing therapy. This occurred just as combination therapy with nucleoside analogues was gaining general acceptance. Protease inhibitors also represented the first opportunity to attack the productive aspect of the HIV viral life cycle. By initiating triple therapy instead of monotherapy or dual therapy, patients experienced remarkable turnarounds. Some of the luster has come off the protease inhibitors as metabolic complications have developed during their use. Initially seen in early clinical trials as many patients experiencing an elevation of serum triglycerides and/or cholesterol, the spectrum of alterations has grown. Following the release of the protease inhibitors, the FDA began to receive reports of glucose intolerance and frank diabetes mellitus related to protease inhibitor use. Subsequently, there has been much debate about the relationship of protease inhibitors to body habitus changes, including facial and extremity wasting, abdominal fat accumulation or truncal obesity, breast enlargement, and the development of fat pads over the lower neck/upper shoulders ("buffalo hump"). These developments have moderated the early enthusiasm for protease inhibitor use and, as noted above, have brought about a reexamination of the place for non-nucleoside combination therapy or other "protease-sparing" regimens.

Saquinavir

Saquinavir was first released in a hard-gel formulation that suffered from very poor bioavailability. This formulation is known as Invirase and has generally been replaced by a soft-gel formulation known as Fortovase. Both are well tolerated with gastrointestinal upset as the primary side effect. Due to its poor bioavailability, Invirase was not listed as a preferred agent in the DHHS recommendations ([Table 348.4](#)). Subsequent studies of the ritonavir/saquinavir combination have elevated Invirase to this list as part of the combination. There is little reason, however, to continue to use Invirase since the release of Fortovase. Fortovase is a preferred agent, although it does require three-times-a-day dosing with six capsules each time.

Ritonavir

Ritonavir is probably the most potent antiretroviral agent yet released, but it is also the least well tolerated. Many individuals can tolerate ritonavir with no problem at all, and for them it is an extremely effective part of their regimen. However, a large minority are unable to continue therapy due to gastrointestinal upset and circumoral paresthesias. Some of this intolerance can be addressed by a dose escalation strategy during the first 2 weeks of therapy as the cytochrome P450 system compensates for ritonavir's strong inhibition of this metabolic pathway. This inhibition can also be utilized in combination therapy, as has been done with the ritonavir/saquinavir combination. Taking advantage of this pharmacologic interaction allows for twice-daily dosing of saquinavir at a much lower total-milligram dose. During 1998 and 1999, the capsule formulation of ritonavir has been unavailable. Ritonavir has been distributed in a solution that has been unpalatable for many patients. This difficulty is being addressed with the development of a new capsule.

Indinavir

The release of indinavir marked a turning point in the presentation and reception of antiretroviral data. Since then discussion has focused on what percentage of persons on a particular regimen have obtained plasma HIV RNA levels below the level of detection. The data show a potent and very durable suppression of viral replication. Indinavir use is limited by a dosing schedule required to be every 8 hours with attention to avoiding meals. Attempts to modify the dose and the frequency to accommodate twice-daily administration have been unsuccessful. The tolerance of indinavir is quite good with some gastrointestinal upset. Nephrolithiasis and renal colic are the main adverse events of real clinical significance. This can be minimized through adequate hydration but does require about a half liter with each dose.

Nelfinavir

Nelfinavir use has progressively increased due to both its own characteristics and those of the other protease inhibitors. It has a more flexible three-times-a-day dosing recommendation and can be taken with food. Studies of twice-a-day dosing are very advanced and promising. It is well tolerated, with the main side effect being diarrhea. For most persons this is a dose initiation phenomenon with improvement following the first 2 weeks of treatment. Symptomatic treatment is usually effective.

CHOICE OF ANTIRETROVIRAL REGIMEN

Current published guidelines ([Table 348.4](#)) suggest only two approaches to antiretroviral therapy for initial consideration: two nucleosides with a protease inhibitor (or the ritonavir/saquinavir protease inhibitor combination), or two nucleosides with efavirenz (preferred list) or nevirapine or delavirdine (alternative list). Several recent studies may make a practitioner also consider the options of triple-nucleoside combination therapy using abacavir, or a non-nucleoside (efavirenz) with a protease inhibitor (indinavir or nelfinavir). Ultimately, the prescribing practitioner must take into account the very real possibility that the patient will need to alter therapy in the future due to toxicity or treatment failure. Because successful trials still show 20% to 40% of participants not obtaining an undetectable viral load, possible cross-resistance must be taken into consideration when planning the initial regimen. Beyond the purely pharmacologic considerations, care must be taken to consider the real-life scenario in which the medications will be taken. The patient's lifestyle must be part of the equation up front. Is there a rigid or flexible work schedule? Is food available at medication dosing intervals? How about refrigeration? What about hydration and the resultant urination? Is there a problem with pill swallowing, or is a solution or slurry preferred? Because adherence to the regimen is a most important factor, all of these issues need assessment.

CHANGING THERAPY

Once therapy has been initiated there may be a need to change it later in the course of care. A Change in therapy due to toxicity related to a particular drug can be accomplished by switching out the toxic drug for an alternate. There is no need to change the other components of the regimen. In the face of treatment failure, however, a single drug should never be switched or added. Much like the lessons learned over years of antituberculosis treatments, the entire failing regimen must be addressed. In HIV care it is not clear how helpful some of the available resistance testing may be. Results of such tests may help the practitioner know which drugs are more likely to *not* work but cannot assure the practitioner that any particular drug will be effective. To change a failing regimen, the entire past treatment history

should be investigated. An effort must be made to avoid new drugs with significant potential for cross-resistance. Information about optimal combinations and the sequence of a particular regimen is changing rapidly and would be out of date prior to the publication of this text. Patients failing their initial regimen should be cared for by practitioners highly experienced in the delivery of HIV care.

VACCINES

It appears that the development of a preventive vaccine for HIV is still little more than a hope. There are multiple obstacles to overcome, although some progress has been made. The virus itself offers many challenges with its multiple subtypes and high mutability. Examination of the host response to infection has not yielded clear indications to the immune responses that correlate to control of infection. Animal models of HIV infection are few and complicated by cost or scarcity of the animals themselves. Despite these problems, several vaccine candidates have made it into clinical trials. In general, the subunit vaccines have demonstrated the ability to generate neutralizing antibodies to the vaccine strain of the virus. Primary isolates of HIV, however, have not been neutralized.

Immune-based therapy of established HIV infection using so-called therapeutic vaccines is also in development. The idea here is to stimulate better immunologic control of the virus in an infected individual rather than attempting to prevent infection in the first place. This approach has gotten increased attention with the development of drug therapies able to bring the plasma HIV RNA levels to the undetectable range. In trials performed thus far, it has been difficult to demonstrate any clinical benefit to the use of this type of agent.

CHAPTER 349: HIV/AIDS: EPIDEMIOLOGY, PREVENTION, AND CONTROL

SUBHASH K. HIRA

Epidemiology
Prevention and Control

EPIDEMIOLOGY

AIDS was recognized as a clinical entity in 1981, and within the next few years important advances were made in the understanding of its epidemiology, cause, and natural history. HIV-1 is responsible for most of the AIDS cases reported throughout the world; HIV-2 is prevalent in western Africa and parts of Asia, including India, and is reported to be less pathogenic. HIV-1 is broken down to ten subtypes: A–J and O. The latter (the “O” stands for “outlier” and is considered to be the primitive form of HIV-1) is reported to be responsible for nine cases of AIDS that occurred in Cameroon in 1993 (P. Zekeng, personal communication, 1994). These subtypes are unevenly distributed throughout the world. For instance, subtype B is mostly found in the Americas, Japan, Australia, the Caribbean, and Europe; subtypes A and D predominate in sub-Saharan Africa; subtype C in South Africa and India; and subtype E in Central African Republic, Thailand, and other countries of Southeast Asia (Fig. 349.1). Laboratory studies have demonstrated that subtypes C and E infect and replicate more efficiently than subtype B in Langerhans’ cells present in the vaginal mucosa, cervix, and the foreskin of the penis but not on the wall of the rectum. It is likely that HIV subtypes C and E have a higher potential for heterosexual transmission than subtype B. However, other variables that affect the risk of transmission, such as the stage of HIV disease, the frequency of exposure, condom use, and the presence of other sexually transmitted diseases (STDs), are equally important.

FIGURE 349.1. Global distribution of HIV-1 subtypes. A–I, HIV genetic subtypes of high prevalence in a region; a–i, HIV genetic subtypes of low prevalence in a region.

HIV is transmitted in three ways: sexually, by anal or vaginal intercourse; parenterally, by transfusion with contaminated blood or injection with contaminated needles; and perinatally, by passage of infection from mothers to their infants (Fig. 349.2). However, these modes of transmission are not equally efficient. Transfusion with contaminated blood is a highly efficient means of transmission; about 95% of those who receive infected blood become infected. A study conducted by the U.S. Centers for Disease Control and Prevention showed that seroconversion occurred in 4 of every 1,000 health care workers who were inadvertently inoculated by contaminated hollow needles used on patients with HIV infection. No health care workers who were pricked by solid (suture) needles used in HIV-infected patients became infected. Male homosexual (anal) intercourse is an efficient means of virus transmission, as shown by the epidemiologic pattern observed in the United States and Western Europe. The efficiency of transmission in heterosexual (vaginal) intercourse is reported to range from 0.1% to 1%. However, this rate may be augmented four to eight times by the presence of a cofactor, such as genital ulcer disease, to 0.4% to 8%. This mechanism of heterosexual transmission accounts for the 1:1 ratio of AIDS cases among men and women in Africa and Asia, in contrast to the predominance of the disease in men in industrialized Western countries. Perinatal transmission is the third mechanism of virus spread. About 25% to 45% of children born to infected mothers are actively infected with HIV, and AIDS develops in most of them within the first 2 years of life. The virus transmission through infected breast milk has been attributed in 10% to 33% of mother–baby transmission.

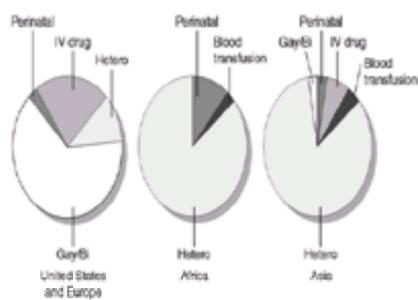

FIGURE 349.2. Modes of HIV transmission. Hetero, heterosexual; gay/bi, homosexual/bisexual; IV drug, intravenous drug use; blood trans, blood transfusion.

HIV transmission has not been documented to occur with any other type of exposure. Intensive studies of household contacts of HIV-infected patients have demonstrated virus transmission only to sexual partners. There is no public health concern regarding possible HIV transmission in the usual school, community, or employment settings.

As of December 1998, the Joint United Nations Program on HIV/AIDS estimated that, since the start of the epidemic two decades ago, at least 47 million individuals were infected with HIV worldwide. Of these, 13.9 million have died of AIDS, including 4.7 million women and 3.2 million children. Presently, there are 33.4 million individuals living with HIV/AIDS across the world; more than 95% of them live in developing countries (Table 349.1). Each day, about 7,000 young adults aged 15 to 24 get infected with HIV, mostly in developing countries of Africa and Asia.

Region	Epidemiologic Scenario	Adults and Children Living with HIV/AIDS	Adults and Children Newly Infected with HIV	% Prevalence Ratio	% HIV Positive Adults Who Are Women	Main Mode(s) of Transmission for Adults Living with HIV/AIDS
Sub-Saharan Africa	Low- to early 90s	22.0 million	6.0 million	0.8	50	Hetero
South and Southeast Asia	Low- to early 90s	210,000	70,000	0.1	20	Gay/bi, Hetero
South and Southeast Asia	Low- to early 90s	6.7 million	1.2 million	0.17	20	Hetero
East Asia and Pacific	Low- to early 90s	360,000	200,000	0.07	11	Gay/bi, Hetero, IV drug
Latin America and Caribbean	Low- to early 90s	1.4 million	50,000	0.4	20	Hetero, Gay/bi, Hetero
Caribbean	Low- to early 90s	100,000	40,000	0.3	30	Hetero, IV drug
Eastern Europe and Central Asia	Low- to early 90s	170,000	80,000	0.1	20	Gay/bi, Hetero
Western Europe	Low- to early 90s	360,000	60,000	0.1	20	Hetero, Gay/bi
North America	Low- to early 90s	800,000	40,000	0.4	20	Hetero, Gay/bi, Hetero
Australia and New Zealand	Low- to early 90s	12,000	600	0.1	1	Hetero, Gay/bi
Total		33.4 million	5.8 million	1.1	40	

***This proportion of adults (70% are men) of age being with infection is based on data from the 1998 WHO survey of HIV prevalence in 1998.

TABLE 349.1. REGIONAL HIV/AIDS STATISTICS AND FEATURES, DECEMBER 1998

At least 1 million individuals are infected in the United States, and AIDS has developed in half of them. African Americans bear a disproportionate burden of this epidemic. They are eight times more likely than whites to have HIV. Among black men, the national HIV prevalence is estimated to have reached 2%, and AIDS has become the leading killer in the 25–44 age group. For black women in the same age group, AIDS takes second place as cause of death. Since the widespread introduction of new combinations of antiretroviral drugs 2 years ago, the death rate for persons with AIDS continues to decrease to almost two-thirds below rates recorded in 1996. India has an estimated 4 million HIV-infected individuals. The seroprevalence of HIV in major Indian cities is rising steadily. In Mumbai, which has a population of 12 million, the seroprevalence among antenatal clinic attendants increased from 0.8% in 1992 and 2.4% in 1994 to 4.2% in 1998. It is estimated that by the year 2000 at least 46 million individuals will be living with HIV/AIDS worldwide and that more than 95% of these individuals will be living in developing countries.

Tuberculosis, the second biggest infectious killer, is on the increase, partially driven by the HIV epidemic. Individuals with dual HIV/tuberculosis infections are at greater risk of activation of tuberculosis and consequent death. About 30% of all AIDS deaths are attributable to tuberculosis.

The HIV epidemic has visible and less visible consequences. In several countries of sub-Saharan Africa, AIDS is causing highly visible damage. For example, the Rakai district of Uganda has lost a significant number of adults to AIDS. This has led to scores of AIDS orphans being cared for by aging grandparents while loss of productive work force has deepened poverty. Families struggle to find money to pay for funerals, and employers struggle to train new staff to replace the sick. The less visible consequences show that AIDS has reduced average life expectancy by 17 years and wiped out gains in child survival rates.

PREVENTION AND CONTROL

Because there is no known cure or vaccine for HIV infection, prevention and control strategies are extremely important. The early dramatic rise in HIV in the United States was reversed by the late 1980s due to prevention campaigns that increased condom use among gay men. However, during the last decade the rate of new infections has remained stable instead of continuing to decrease. In 1998, an estimated 75,000 persons became infected in the United States. Hence, prevention challenges are greater than before. The main approaches are as follows:

1. *Promotion of safer sexual behaviors.* Since the onset of the pandemic, information, education, and communication campaigns have been vital in reducing behaviors that put individuals at high risk for infection. These campaigns are of two types: broad mass communication for the general public, and targeted, more intensive behavioral change communication strategies aimed at vulnerable groups. Person-to-person education programs are important for certain vulnerable groups because such programs increase the level of knowledge about AIDS and high-risk behaviors.
2. *Promotion of condom use.* The promotion of safer sexual behaviors, including the use of condoms, is an integral part of prevention and control strategies. Condom use is encouraged through programs that involve market research, product importation, brand name packaging, advertising, media promotion, distribution, and management.
3. *Prevention and treatment of STDs.* Conventional STDs facilitate the transmission of HIV. Because of its adverse effect on the immune system, HIV infection can alter the incidence, natural history, and response to treatment of other STDs. In addition, these diseases rank among the top ten most important health problems in nonindustrialized countries in terms of years of healthy life lost (Over and Piot, personal communication, 1990). The early diagnosis and treatment of sexually transmitted diseases combined with behavioral intervention is recommended.
4. *Prevention of unsafe drug use behavior.* Prevention strategies for injected drug users in drug abuse treatment programs are successful but expensive. Community-based outreach programs that include education regarding the need to eliminate needle sharing, instruction in the disinfection of contaminated injection equipment, bleach distribution, and needle exchange are less expensive and equally successful. Each interaction with a client provides an opportunity for risk reduction education.
5. *Provision of a safe blood supply.* Transfusion-induced HIV infection can be prevented by safe blood initiatives, including rational use of blood. Yet as many as 3% to 5% of HIV-infected individuals in sub-Saharan Africa and parts of Asia become infected by contaminated blood. This is attributed to the low effectiveness of safe-blood programs in these countries.
6. *Targeted interventions.* For individuals at high risk of HIV infection, an epidemiologically sound set of preventive activities (interventions) are put together as a package. These interventions not only are easy to implement but they are cost-efficient and their impact is measurable.

CHAPTER 350: APPROACH TO THE PATIENT WITH HYPOXEMIA

DAVID H. INGBAR

[Clinical Signs and Consequences](#)
[Diagnosis](#)
[Pathophysiologic Factors](#)
[Approach to the Patient](#)

Hypoxemia is a common sign of pulmonary or cardiac disease. It may be suspected from clinical symptoms or physical examination, but laboratory testing is required to confirm its presence. The identification and differential diagnosis of hypoxemia are considered in this chapter.

Hypoxemia is defined as decreased arterial partial pressure of oxygen (P_{aO_2}) that decreases the oxygen saturation of hemoglobin; consequently, hypoxemia is defined as a P_{aO_2} of less than 60 mm Hg. When the P_{aO_2} is less than 50 to 55 mm Hg, hypoxemia is life threatening because the oxygen content of hemoglobin drops rapidly with even small decreases in oxygen partial pressure. Some experts use the term “relative hypoxemia” to indicate that the P_{aO_2} is lower than normal but not low enough to decrease the hemoglobin oxygen saturation.

Oxygenation normally decreases somewhat with increasing age. The efficacy of oxygen transfer from the alveolus to the pulmonary capillaries can be expressed as the gradient or difference between the alveolar and arterial oxygen partial pressures ($P_{AO_2} - P_{aO_2}$). The normal gradient is less than 10 mm Hg but rises slightly with age.

The normal levels of P_{AO_2} and P_{aO_2} are determined in part by the amount of alveolar ventilation. Changes in the alveolar ventilation alter the alveolar P_{O_2} and PCO_2 , thereby changing the end-pulmonary capillary gas pressures. The alveolar CO_2 partial pressure (P_{ACO_2}) directly relates to the rate of CO_2 production (V_{CO_2}) and the alveolar ventilation per minute (VA), as determined by the formula $P_{ACO_2} = (V_{CO_2}/VA)/(P_b - 47)$, where P_b is the barometric pressure and 47 is the water vapor pressure. The extent of change in the alveolar P_{O_2} , and consequently the arterial P_{O_2} , is predicted by the alveolar gas equation: $P_{AO_2} = F_{IO_2}(P_{atm} - P_b) - (P_{ACO_2}/0.8)$, where P_{atm} is the atmospheric pressure. The first term— $F_{IO_2}(P_{atm} - P_b)$ —represents the inspired oxygen partial pressure (P_{IO_2}). For patients breathing room air at sea level, the $P_{IO_2} = 150$ mm Hg and the alveolar gas equation simplifies to $P_{AO_2} = 150 - (P_{ACO_2}/0.8)$. The inspired P_{O_2} falls with altitude: in Denver, it is about 120 mm Hg; in high mountain villages in the Andes and Himalayas, it is about 100 mm Hg; and on the summit of Mount Everest, it is about 38 mm Hg.

Alveolar hypoventilation, as evidenced by hypercapnia, decreases the P_{aO_2} even when lung function is completely normal. For example, a patient who overdoses on narcotics with normal lungs might hypoventilate with a P_{aCO_2} level rising to 80 mm Hg. The predicted P_{AO_2} then would be 50 mm Hg. With an alveolar–arterial O_2 gradient of 8, the P_{aO_2} would be 42 mm Hg. Similarly, hyperventilation increases the P_{aO_2} in normal persons. Hyperventilation to a P_{aCO_2} of 24 mm Hg would lead to a P_{AO_2} of 120 mm Hg and a P_{aO_2} of 112 mm Hg.

CLINICAL SIGNS AND CONSEQUENCES

Hypoxemia sometimes is obvious, as in the patient who is cyanotic, tachypneic, and tachycardic, is audibly wheezing, and is using accessory muscles of respiration. The physiologic consequences and the associated signs and symptoms of different degrees of hypoxemia are outlined in [Table 350.1](#). However, some patients who seem comfortable and not in distress may still have life-threatening hypoxemia.

P_{aO_2} (mm Hg)	Abnormality in Function	Sign or Symptom
<60	Heart rate	Increased tachycardia
	Respiratory rate	Increased tachypnea
	\dot{V}_E and \dot{V}_D excretion	Decreased volume
<55	Cardiac output	Increased bounding pulse
	Dysrhythmias	Tachyarrhythmias Bradycardias
	Mentation	Increased somnolence Confusion
	Red blood cell mass	Increased erythropoiesis Erythrocytosis Neutrophilia
	Pulmonary arterial pressure	Increased jugular venous pressure Edema Right ventricular S_1 rightward shift in ventricular or aortic vectors
<30	Cardiac output	Shock
	Mentation	Decreased pulse pressure Increased lactic acidosis

*Right atrial enlargement, right ventricular enlargement, rightward shift in ventricular or aortic vectors.

TABLE 350.1. PHYSIOLOGIC EFFECTS OF HYPOXEMIA

Respiratory distress often is indicated by tachypnea, cyanosis, or use of the intercostal, sternocleidomastoid, and scaleni muscles. However, not all patients with these findings are hypoxemic. Some patients may be able to compensate for their lung problems and maintain a P_{aO_2} of more than 60 mm Hg due to their rapid ventilation. For example, many patients with interstitial lung disease or restrictive lung disease adopt a rapid, shallow breathing pattern, expending high energy in their work of breathing. Their arterial blood gases often show relative hypoxemia with a P_{aO_2} of 60 to 75 mm Hg and hypocapnia (e.g., P_{aCO_2} 30 to 36 mm Hg).

Cyanosis may be detectable when there is more than 5 g % of deoxygenated hemoglobin in the blood. Central cyanosis is detected in the perioral area and is most common in patients with cyanotic congenital heart disease. Peripheral cyanosis is detected in the nail beds. It is a much more subjective physical finding, and there often is interobserver disagreement. In addition, many seriously ill hypoxemic patients do not have cyanosis because they have anemia. Tachycardia may be the sole manifestation of hypoxemia. The increased catecholamines released in response to tissue hypoxia increase cardiac output and systemic oxygen delivery through increased heart rate and stroke volume. In addition, peripheral tissues vasodilate, increasing the number of open capillaries in response to local tissue hypoxia. Although this does not increase the oxygen content of blood, it decreases the diffusion distance for oxygen and increases tissue P_{O_2} . The decreased systemic vascular resistance also promotes tachycardia.

Tachypnea commonly occurs with hypoxemia. Patients may increase both their respiratory rate and their tidal volume. However, even experienced physicians cannot reliably estimate minute ventilation at the bedside.

The brain is very sensitive to decreased oxygen delivery. Consequently, agitation, seizures, or changes in mental status should raise the question of hypoxemia.

Cardiac consequences of hypoxemia are a major concern because they include myocardial ischemia, dysrhythmias, and decreased cardiac output.

Hypoxemia per se may indicate patients at risk for increased mortality. One study of inpatients at a tertiary care center who underwent continuous oximetry monitoring demonstrated increased postdischarge mortality in patients with episodic hypoxemia.

In summary the signs and symptoms of hypoxemia are very non-specific and easily attributed to other causes. Some patients may have essentially none of the above manifestations, and thus hypoxemia must be suspected and sought in patients at risk.

DIAGNOSIS

Hypoxemia may be diagnosed directly through arterial blood gas measurement of PaO₂ or oximetry measurement of percentage of hemoglobin saturated with oxygen. Arterial blood samples must be rapidly placed on ice or analyzed immediately; otherwise, cells in the sample may metabolize oxygen, yielding falsely low PaO₂ measurements. For example, patients with leukemia and circulating white blood cell counts above 60,000 cells per microliter may have falsely low measurements if they are not analyzed immediately or if cell metabolism is not abolished. Samples are placed in heparinized syringes, but the amount of residual heparin should be minimized because its volume dilutes the gas partial pressure and it is acidic. The patient's temperature and, if used, supplemental oxygen always should be noted on the laboratory request. The former is important in calculating the percentage of hemoglobin saturated with oxygen since it shifts the position of the hemoglobin–oxygen dissociation curve. Some laboratories calculate the percentage of hemoglobin that is saturated with oxygen based on a normal hemoglobin–oxygen dissociation curve, whereas others measure this directly with a cooximeter. Hyperlipidemia also may interfere with accurate measurement.

There is significant variability in arterial blood gas (ABG) results in clinically stable intensive care unit patients. In multiple studies, PaO₂ had a mean coefficient of variation of 5% to 6% over 1 hour. Therefore, clinical decision making should be based on trends and on large changes in arterial blood gas values.

Technology for continuous measurement of arterial PO₂, PCO₂, and pH has been developed, but the clinical value of these continuous measurements is not well established. They may be useful for earlier detection of desaturation, but they may alert caregivers too frequently, leading to time and dollars spent investigating brief desaturations without clinical significance.

Oximetry, a noninvasive method for assessing hypoxemia, uses the spectrophotometric changes in hemoglobin absorption of ultraviolet light upon oxygenation and deoxygenation. This measurement can be performed on arterialized blood in the heated ear lobe or through pulse oximetry. In pulse oximetry, the background absorption present during the nonfilling phase of blood flow is subtracted from the absorption during arterial pulsations to determine the absorption from arterial blood. It may be performed on the finger, toe, ear lobe, or bridge of the nose. Oximetry directly measures the percentage of hemoglobin saturated with oxygen. Above 85% saturation, most oximeters are accurate within 3%, but for oxygen saturations below 85% they are less accurate. Consequently, for oxygen saturations above 90% where the hemoglobin–oxygen dissociation curve flattens, a given oximetry measurement may correspond with a relatively wide range of PaO₂ values. Thus, oximetry is not a sensitive method to detect changes in PaO₂ for patients with a PaO₂ of more than 65 to 70 mm Hg.

Oximetry also may be inaccurate when there are high levels of bilirubin or other ultraviolet light–absorbing compounds in the bloodstream. Different oximeters measure absorption with different numbers of simultaneous wavelengths of light. Therefore, measurements by some, but not all, oximeters are inaccurate in the presence of methemoglobin or carboxyhemoglobin. Poor perfusion of the tissue measurement site also promotes inaccuracy and may require use of well-perfused sites such as the bridge of the nose.

Most oximeters average the percentage of oxygen saturation over multiple cardiac cycles. This gives more accurate and stable measurements; however, in patients with rapid or transient oxygen desaturation, this may delay or blunt the machine's readout indication that the patient has become hypoxemic. Many oximeters permit adjustment of the window of time averaging for the values reported, and it may be important to adjust this based on the patient's instability. This also is important to accurately assess hypoxemia in patients with apneic episodes.

PATHOPHYSIOLOGIC FACTORS

Hypoxemia can arise from multiple pathophysiologic mechanisms, but the four standard mechanisms are hypoventilation, shunt, ventilation–perfusion mismatch, and diffusion block or limitation. An additional rare mechanism is a low FIO₂, but this is relevant only in unusual environments, such as at very high altitude. Finally, a low mixed venous PO₂ can contribute to arterial hypoxemia when other significant abnormalities, such as shunt, are present. This is discussed further after consideration of shunt physiology.

HYPOVENTILATION

Alveolar hypoventilation lowers PAO₂ and raises PaCO₂ due to decreased minute ventilation. Because with pure hypoventilation the lung parenchyma is normal, the alveolar–arterial oxygen gradient remains normal. Hypoventilation commonly occurs when ventilatory drive is decreased by drugs, endocrine abnormalities, central nervous system disorders, or diseases of the neuromuscular system or chest wall. Narcotics, benzodiazepines, and other sedatives are common drug-related causes. Severe hypothyroidism or hypopituitarism can decrease ventilatory drive and cause hypoventilation. Diaphragm paralysis, muscular dystrophy, Guillain–Barre(c) syndrome, fibrothorax, and kyphoscoliosis are examples of restrictive abnormalities that may result in hypoventilation. Essentially, the normal closely coupled relation between PaCO₂ and minute ventilation is disrupted in either the sensing or effector limbs. Supplemental oxygen improves the hypoxemia of alveolar hypoventilation but does not decrease the hypercapnia.

SHUNT

Peripheral vascular shunts have little effect on oxygenation, but may increase venous PO₂. Intracardiac shunts can cause severe hypoxemia if there is right-to-left shunting, as may occur when pulmonary hypertension with the Eisenmenger complex is combined with an atrial or ventricular septal defect. Intrapulmonary shunts may be macroscopic (vascular) or microscopic (parenchymal). Arteriovenous malformations within the pulmonary arterial circulation are an example of the former that can cause hypoxemia. Finally, microscopic parenchymal shunts occur when blood flows through the capillaries of nonventilated alveoli; examples are flooded or atelectatic alveoli. When shunt is discussed as the physiologic cause of hypoxemia, microscopic parenchymal shunts usually are assumed to be the cause.

Hypoxemia due to shunt does not respond significantly to high-level supplemental oxygen because the alveolar PO₂ does not affect the oxygenation of blood flowing through the shunted alveolar capillary units. Shunt pathophysiologic processes commonly occur in pulmonary edema, acute lung injury (acute respiratory distress syndrome), pneumonia, or atelectasis. It also can occur in patients with sepsis or in association with hepatic cirrhosis. Therapy for the hypoxemia must be directed at the underlying cause of the shunt. When shunts are more than 30%, even 100% oxygen usually has relatively little benefit on oxygenation. In patients with hypoxemia from shunt physiologic factors, increasing cardiac output may worsen hypoxemia.

Normal persons have 1% to 3% of blood flow shunted past the lungs through the thesbian and bronchial circulations. Many clinicians calculate shunt at the bedside in the intensive care unit from ABG results obtained on supplemental oxygen. These calculations attribute all the hypoxemia to shunt physiologic factors and then yield a percentage shunt that would cause the observed hypoxemia. Strictly speaking, this is a calculation of venous admixture rather than a true measurement of shunt. To measure shunt, the patient should be breathing 100% oxygen so that all contributions of hypoventilation, diffusion block, and ventilation–perfusion mismatch are eliminated.

Hypercapnia is uncommon with shunt physiology, provided that minute ventilation increases in compensation for the hypoxemia. Hypercapnia sometimes occurs clinically in shunt from acute lung injury or severe pneumonia, but often it is multifactorial and CO₂ production is also increased.

VENTILATION–PERFUSION MISMATCHING

Ventilation–perfusion (V/Q) mismatch, the most common cause of hypoxemia, often confuses physicians and students. The normal lung has alveolar–capillary units with a broad range of V/Q ratios. The bases of the lungs receive more ventilation and more perfusion than the apices. The perfusion gradient results from gravity and is pronounced, whereas the ventilation gradient is less significant. Consequently, basal alveoli tend to have low V/Q ratios, whereas apical alveoli usually have relatively high V/Q ratios. The dispersion of V/Q ratios in the normal lung increases with age, leading to the slight increases in P_AO₂ - PaO₂.

Patients with hypoxemia from V/Q mismatching usually have more of both low- and high-V/Q units than normal. Alveolar capillary units with low V/Q ratios are well perfused but relatively underventilated; consequently, the venous blood leaving them still is partially deoxygenated. Low-V/Q units usually result from underventilation, as occurs in both obstructive and restrictive lung disease. Less commonly, these units result from overperfusion, as occurs when massive pulmonary emboli shunt high blood flow through small amounts of remaining normal pulmonary vascular bed. The extreme form of low-V/Q unit is shunt alveoli that are perfused but not ventilated. In contrast, units with high V/Q are relatively overventilated and their venous effluent is fully saturated. High-V/Q units may result from

overventilation or underperfusion. These units waste alveolar ventilation and work of breathing but do not make patients hypoxemic. High-V/Q units are common in patients with emphysema and in those receiving positive-pressure mechanical ventilation. The extreme form of high-V/Q unit is dead-space alveoli that are ventilated but not perfused. The systemic arterial P_{O_2} is determined by the relative numbers and distribution of high- and low-V/Q units and by the absolute blood flows to them.

V/Q mismatch often causes hypoxemia and less often causes hypercapnia. Hypoxemia results from increasing numbers of low-V/Q units. This form of hypoxemia corrects easily with small amounts of supplemental oxygen because a small increase in F_{IO_2} significantly increases the inspired P_{O_2} and hence the PAO_2 in the low-V/Q units. In turn, this increases the venous P_{O_2} in the blood exiting these units. There is no significant effect on the high-V/Q units.

V/Q mismatch also interferes with CO_2 excretion. Low-V/Q units have relatively high alveolar P_{CO_2} , but high-V/Q units have low P_{ACO_2} . Thus, once again, the low-V/Q units lead to blood gas abnormalities, in this case hypercapnia. However, two factors combine to make hypercapnia less common than hypoxemia. First, even a small increase in Pa_{CO_2} often triggers increased minute ventilation, which diminishes the tendency toward hypercapnia. Second, the carboxyhemoglobin dissociation curve is relatively linear and does not plateau in a fashion similar to the oxyhemoglobin dissociation curve. This allows red blood cells to load large amounts of CO_2 . The red blood cells that perfuse the high-V/Q units can transfer large amounts of CO_2 to the alveolus but can pick up only a limited quantity of oxygen. Thus, V/Q mismatch causes hypoxemia more readily than hypercapnia.

A clinical measure of the impact of low-V/Q units is the physiologic dead space or the ratio of dead space to tidal volume (V_{DS} or V_{DS}/V_T). Normal persons have about 150 mL of anatomic dead space obligated by the conducting airways. By measuring the end-expiratory P_{CO_2} ($PECO_2$) and assuming that the arterial P_{CO_2} accurately reflects the end-capillary P_{CO_2} in the perfused alveoli, one can calculate the V_{DS}/V_T ratio by the Bohr equation:

$$V_{DS}/V_T = (P_{ACO_2} - P_{ECO_2})/P_{ACO_2}$$

This equation attributes all the hypercapnia to dead space but in reality includes the contribution of low-V/Q alveolar–capillary units.

Patients with asthma and chronic obstructive pulmonary disease (COPD) typically have hypoxemia due to V/Q mismatch. When these patients have a high Pa_{CO_2} , usually there is a combination of severe V/Q mismatch and a diminished increase in minute ventilation to compensate for the respiratory acidemia. Supplemental oxygen readily corrects hypoxemia in patients with COPD, but some COPD patients given supplemental oxygen have significant increases in Pa_{CO_2} . The mechanism of the rise in CO_2 is controversial; two alternatives are suppression of hypoxic ventilatory drive in patients with blunted hypercapnic ventilatory drive; or alveolar oxygen increasing perfusion to poorly ventilated alveoli with high P_{ACO_2} .

From a practical standpoint, patients with acute exacerbations of COPD need to be given enough oxygen to get their Pa_{O_2} above 50 mm Hg, even if they are at risk for CO_2 retention. This should be done by starting with low levels of supplemental oxygen and increasing it in small increments to avoid preventable hypercapnia and acidosis. Even so, some patients require intubation and mechanical ventilation.

DIFFUSION BLOCK

Oxygen and carbon dioxide move passively between the alveolus and the capillary blood. The amount of diffusive gas transfer is determined by Fick's law: gas transfer = $D(P_A - P_c)$, where P_c is the capillary gas partial pressure and the diffusing capacity, D , is a combined coefficient determined by the thickness and properties of the intermediate structures (endothelial and epithelial cells and their basement membranes) and the gas exchange surface area. It is difficult to measure D for O_2 or CO_2 . As a clinical approximation, the diffusing capacity for carbon monoxide (CO) is measured; the oxygen diffusing capacity normally is 20% to 25% greater than for CO.

Gas diffusion usually does not limit gas exchange and hence diffusion block is an unusual sole cause of hypoxemia. The red blood cell normally spends 0.75 second traversing the pulmonary capillary and alveolar gas pressures are completely equilibrated after 0.25 second. Thus, there is a large reserve that can accommodate increased blood flow or greater barriers to diffusion. For example, even a threefold increase in cardiac output does not lead to desaturation from diffusion abnormality. Pulmonary fibrosis previously was believed to cause diffusion block. Most authorities now believe that there is a loss of alveolar capillary gas exchange surface but that diffusion block does not contribute significantly to hypoxemia at rest.

Occasionally gas transfer becomes limiting, usually when there is a combination of decreased transit time, abnormal thickening of the alveolar wall, and decreased PAO_2 as a driving force. Clinically this most commonly occurs when patients with interstitial lung disease exercise; it also may occur at high altitude. Hypoxemia from diffusion abnormality is corrected relatively easily with supplemental oxygen.

MIXED VENOUS HYPOXIA

In patients with underlying shunt pathophysiologic states, much of the blood flowing out of the lungs still is at mixed venous P_{O_2} . When this blood combines with better oxygenated blood from other units, the oxyhemoglobin dissociation curve requires that the oxygen content of the arterial blood be significantly decreased. Thus, when shunt physiology is present, the mixed venous PO_2 significantly affects the arterial P_{O_2} . Similar effects occur in low-V/Q units of the lung, but to a lesser degree. One clinical situation where this is relevant is exercise in patients with cardiac or lung disease. Some cardiac patients may be at risk because of low mixed venous P_{O_2} from poor tissue perfusion, combined with a tendency to develop pulmonary edema.

The mixed venous PO_2 is a function of tissue oxygen delivery, the distribution between organ beds, and the peripheral oxygen utilization. Because oxygen delivery is determined by the cardiac output and the oxygen content of the arterial blood, the arterial and mixed venous P_{O_2} measurements are closely linked.

There are several therapeutic implications of these relations. First, changes in Pa_{O_2} may due not to altered lung function but to changes in cardiac output or tissue oxygen use. For example, decreased cardiac output might lower Pa_{O_2} by lowering mixed venous PO_2 . Second, increasing the mixed venous PO_2 may increase the Pa_{O_2} in some clinical situations, such as severe acute lung injury. For example, transfusing acute respiratory distress syndrome patients to increase the oxygen-carrying capacity of the blood may increase the mixed venous, and hence the arterial, P_{O_2} .

APPROACH TO THE PATIENT

The two most important steps are to suspect that a patient may be hypoxemic and to assess oxygenation, preferably with an ABG measurement. Oximetry is rapid and inexpensive but can be misleading. First, as long as the patient's Pa_{O_2} is above 60 mm Hg, the oxygen saturation will be adequate and may be falsely reassuring. For example, if the patient is hyperventilating to a Pa_{CO_2} of 25 to 30 mm Hg, a Pa_{O_2} of even 65 may indicate severe difficulty with oxygenation. Also, supplemental oxygenation often already has been started as symptomatic treatment for respiratory distress, making oximetry more misleading. Second, hypercapnia and acid–base disorders will be missed if oximetry alone is performed.

Once hypoxemia is determined to be present, then the clinical cause must be ascertained. A rapid approach to the differential diagnosis of common clinical entities is presented in [Table 350.2](#); the specific entities are discussed elsewhere.

Normal Chest Radiograph	Abnormal Chest Radiograph
<p>Increased PaCO₂ Severe asthma Neuromuscular disease Ventilatory drive problem</p>	<p>Severe COPD Diaphragm impairment Thorax abnormality</p>
<p>Normal or Low PaCO₂ Pulmonary embolus Sepsis Moderate COPD Moderate asthma</p>	<p>Heart failure Pneumonia ARDS Interstitial fibrosis</p>

COPD, chronic obstructive pulmonary disease; ARDS, acute respiratory distress syndrome.

TABLE 350.2. RAPID DIFFERENTIAL DIAGNOSTIC APPROACH TO THE HYPOXEMIC PATIENT

Finally, when the PaO₂ is less than 60 mm Hg and the patient is in respiratory distress, or if myocardial ischemia may be present, then supplemental oxygen should be initiated. Oximetry may be useful to assess the response while the amount of supplemental oxygen is increased. Care must be taken when treating COPD patients to avoid worsening hypercapnia and respiratory acidemia. In this particular setting, it is essential to obtain repeat arterial blood gas measurements.

CHAPTER 351: APPROACH TO THE PATIENT WITH DYSPNEA

KATHY E. SIETSEMA

[Pathophysiologic Factors](#)
[Sensory Perceptions Related to Ventilation](#)
[Spectrum of Clinical Conditions Presenting with Dyspnea](#)
[Clinical Evaluation](#)
[Strategies for Optimal Care](#)

The term *dyspnea* is used to describe perceptions of difficulty or distress related to breathing. Some degree of dyspnea is considered normal in the appropriate context of activities or environment, such as during vigorous exercise or on ascent to higher altitude. However, dyspnea is recognized as symptomatic of disease when it occurs under inappropriate circumstances. Dyspnea is a presenting complaint of patients with a wide variety of medical diseases and undoubtedly arises by multiple mechanisms.

PATHOPHYSIOLOGIC FACTORS

Experimental models of dyspnea have demonstrated that the intensity of this symptom correlates with the ratio of *ventilatory requirement* at a given time to the *ventilatory capacity* of the individual. Ventilatory requirement is closely tied to the rate of CO₂ production and so is dictated by metabolic rate and activity level. The ventilation required for a given rate of CO₂ production is determined by the efficiency of ventilation, which reflects how well regional ventilation and perfusion are matched in the lung, and by the level of arterial CO₂. Ventilatory capacity is a function of the mechanical and neuromuscular properties of the thorax as well as the lungs, and may be therefore be reduced by extrapulmonary processes as well as by intrinsic lung disease. Even when ventilatory requirements are within an individual's capacity, the sense of *ventilatory effort* needed to meet those requirements may be increased by such factors as abnormal lung mechanics or respiratory muscle fatigue. For any condition to cause dyspnea there must be *sensory perceptions* related to breathing and ventilatory stimuli. To appreciate the range of conditions that can cause dyspnea, it is valuable to review the physiologic stimuli that give rise to respiratory sensations.

SENSORY PERCEPTIONS RELATED TO VENTILATION

Sensory perception involves a series of processes: activation of sensory receptors, transmission of information to the central nervous system (CNS), integration and processing of these inputs, and, finally, perception at higher brain levels. No discrete area of the cortex appears responsible for dyspnea perception, however, nor are there unique sensory receptors producing dyspnea when stimulated. Thus, although considerable insight has been gained into the stimuli that cause respiratory sensations and the conditions that modulate these sensations, the mechanisms responsible for dyspnea in many disease states remain incompletely understood.

RESPIRATORY CHEMORECEPTORS

Chemoreceptors provide feedback to brain stem respiratory centers for the control of ventilation. The carotid bodies, the principal peripheral chemoreceptors in humans, respond primarily to reductions in arterial PO₂, whereas central chemoreceptors are sensitive to PCO₂ and pH. There is controversy as to whether dyspnea can result solely from stimulation of chemoreceptors, or whether it depends instead on the resulting reflex increases in CNS ventilatory effort or ventilatory motor activity. Despite intersubject variability in chemoreceptor responsiveness, increases in chemoreceptor stimulation increase the level of dyspnea experienced at a given level of ventilation.

LUNG AND THORACIC CAGE SENSORY RECEPTORS

Afferent inputs from the airways and lung parenchyma are carried by the vagus nerve and include signals from irritant receptors, pulmonary stretch receptors, and J receptors. These pathways may be activated by lung inflammation, edema, or changes in lung volume. The diaphragm and intercostals are skeletal muscles and are the source of a rich array of sensory information. Muscle spindles respond to changes in muscle length or displacement, and tendon organs respond to tension developed within the muscle. These respiratory muscle mechanoreceptors appear to be important in the perception of dyspnea related to respiratory pattern or mechanics. Reflex increases in ventilation occur in response to pressure or stretch stimulation in the heart or pulmonary arteries. These observations provide circumstantial evidence to support a role for vascular mechanoreceptors in the pathogenesis of dyspnea, particularly in pulmonary hypertension and other cardiovascular disorders.

CENTRAL MOTOR COMMAND

Efferent output from the CNS to the respiratory apparatus has been termed "motor command." There is evidence that the magnitude of motor command can be sensed. This has led to the concept that brain stem respiratory centers send a copy of their efferent traffic to the cortex as well as to the respiratory apparatus.

INTEGRATION OF SENSORY INPUT

The sensory signals described above are part of a complex, redundant system that provides feedback for perceiving and controlling ventilation. Like many sensations, the severity of dyspnea is quantitatively related to the stimulus inducing it. In addition, the multiplicity of potential combinations of input from differential stimulation of each sensory receptor provides a mechanism for producing qualitative as well as quantitative differences in respiratory sensation.

It is likely that lung volume is sensed principally through muscle spindle and joint proprioceptors, and respiratory muscle tension through tendon organs. Many abnormalities of lung mechanics (e.g., lung compliance, impedance, or volume) resulting from cardiorespiratory disease can thus be derived from the relations between factors, or their time integrals, to which these receptors are sensitive. The sensation of ventilatory effort is proposed to be related to motor command, i.e., the efferent output of the respiratory center. A major postulate arising from research of dyspnea is that dyspnea results from consciousness of discrepancies between sensory input from the lungs and chest wall related to respiratory activity, and the expected perceptions based on motor command.

SPECTRUM OF CLINICAL CONDITIONS PRESENTING WITH DYSPNEA

Acute dyspnea, developing over minutes to days, most often reflects an acute cardiac or pulmonary process requiring urgent evaluation and treatment. Pulmonary processes in this context include diffuse airflow obstruction, pneumonia, upper airway obstruction, compression of the lung by chest trauma or pleural processes, rapidly progressive inflammatory disease, or diffuse lung injury with noncardiogenic pulmonary edema. Cardiovascular diseases causing acute dyspnea include pulmonary edema due to myocardial or valve dysfunction, thromboembolism, or pericardial disease. Chronic dyspnea, which is more likely to present diagnostic difficulty than acute dyspnea, is the focus of most of the following discussion. Disease categories to be considered in patients with chronic dyspnea, along with disease examples, are summarized in [Table 351.1](#).

Category	Examples
Impaired Pulmonary Function	
Airway obstruction	Asthma Chronic obstructive pulmonary disease Cystic fibrosis Tracheobronchomalacia
Fluid	Pulmonary edema Pleural effusion Hemothorax Empyema
Restriction of lung expansion	Interstitial lung disease Pulmonary fibrosis Sarcoidosis Hypertension Pneumoconiosis Scleroderma Radiation pneumonitis
Extrathoracic obstruction	Tracheal stenosis Tracheomalacia Tracheobronchomalacia Vocal cord dysfunction Diaphragmatic paralysis
Impaired Cardiovascular Function	
Heart failure	Left ventricular failure Right ventricular failure Congestive heart failure
Pulmonary vascular disease	Pulmonary hypertension Pulmonary embolism Pulmonary vasculopathy
Coronary artery disease	Myocardial infarction Angina pectoris Coronary artery disease
Altered Central Ventilatory Drive or Perception	
Systemic or metabolic disorders	Hypercapnia Hypoxemia Acidosis Anemia Hypothyroidism Hypoglycemia Hypocalcemia Hypomagnesemia Hypokalemia Hypophosphatemia Hypocalcemia Hypomagnesemia Hypokalemia Hypophosphatemia
Central nervous system disorders	Brainstem dysfunction Cerebral dysfunction Cerebellar dysfunction Cerebral dysfunction Cerebellar dysfunction Cerebral dysfunction Cerebellar dysfunction
Psychiatric disorders	Anxiety Depression Hyperventilation syndrome Panic disorder Somatoform disorder
Drugs	Opioids Sedatives Alcohol Cocaine Amphetamines Caffeine Nicotine Cocaine Amphetamines Caffeine Nicotine
Physiological responses during exercise	Exercise-induced asthma Exercise-induced laryngospasm Exercise-induced bronchoconstriction Exercise-induced pulmonary edema Exercise-induced pulmonary hypertension Exercise-induced pulmonary vascular disease Exercise-induced pulmonary vascular disease
Drugs	Opioids Sedatives Alcohol Cocaine Amphetamines Caffeine Nicotine

TABLE 351.1. SOME DISORDERS PRESENTING WITH CHRONIC DYSPNEA

OBSTRUCTIVE AIRFLOW DISEASES

Obstructive airflow diseases are characterized by a reduction in expiratory flow rates for a given lung volume. A common consequence is end-expiratory hyperinflation, resulting in alteration of the position of the respiratory muscles (principally foreshortening of the diaphragm, which decreases muscle efficiency, increases respiratory work, and can lead to muscle fatigue). Regional mismatching of pulmonary ventilation to perfusion due to heterogeneity of airflow obstruction increases ventilatory requirements and may result in arterial hypoxemia. Total ventilatory capacity is usually reduced. Thus, decreased capacity and increased requirements and effort may all contribute to dyspnea in patients with airflow obstruction.

Episodic worsening of dyspnea results from worsened airflow obstruction due to airway inflammation or bronchoconstriction. Temporal variability of airflow obstruction is particularly characteristic of asthmatics, whose lung mechanics may be entirely normal between exacerbations. Diurnal variation of airway tone is exaggerated in asthmatics and may be manifest as nocturnal dyspnea or cough. Dyspnea due to bronchospasm may follow exercise or exposure to irritants or allergens. Chest tightness is a common complaint in asthma and has been attributed to stimulation of irritant receptors in the lung.

Although much less common than diffuse airway disease, focal lesions such as tumor, stricture, or aspirated foreign body may cause obstruction of large airways. In the larynx or trachea, obstructing lesions may present with inspiratory stridor. An increasingly recognized cause of variable airflow obstruction is vocal cord dysfunction consisting of inappropriate adduction of the vocal cords during inspiration. This condition is often mistaken for asthma due to the intermittent nature of the symptoms.

INTERSTITIAL LUNG DISEASES

Progressive dyspnea on exertion is the most common presentation of interstitial lung diseases of any cause, and may sometimes begin before abnormalities are detectable on chest radiograph and before lung volumes are measurably reduced. Alterations in lung mechanics, sensed through either vagal or respiratory muscle afferents, are probably responsible for dyspnea early in the course of disease. Inflammation or fibrosis due to interstitial disease affecting the pulmonary capillaries can reduce the total alveolar–capillary interface and result in hypoxemia and, ultimately, pulmonary hypertension. As is true for obstructive diseases, with increasing severity of disease total ventilatory capacity decreases, while ventilatory requirements increase due to progressive ventilation to perfusion mismatching.

CARDIOVASCULAR DISEASES

Left ventricular dysfunction results in increased pulmonary venous pressure and vascular congestion, with attendant reduction in lung and pulmonary vascular compliance. With overt pulmonary edema, there is compromised gas exchange and arterial hypoxemia. In addition, reduction of maximal cardiac output reduces O_2 delivery and results in an earlier onset of lactic acidosis during exercise. This increases ventilatory requirements due to the need to compensate for metabolic acidosis and can cause dyspnea even in the absence of pulmonary congestion. Bronchial hyperreactivity or “cardiac asthma” may further contribute to dyspnea in heart failure. The mechanisms of dyspnea in pericardial disease and pulmonary vascular disease are not clear: dyspnea can occur even in the absence of hypoxemia or altered lung mechanics, thus suggesting a role for mechanical receptors (stretch receptors and/or baroreceptors) in the central circulation.

Many cardiovascular diseases, including cardiomyopathy, valvular disease, and pulmonary hypertension, present first with exertional dyspnea. Although coronary ischemia is typically manifest as angina, exertional breathlessness may be predominant, presumably due to ischemic ventricular dysfunction. Orthopnea and paroxysmal nocturnal dyspnea are additional manifestations of elevated pulmonary venous pressure. Pulmonary vascular diseases may be particularly difficult to diagnose. With acute pulmonary embolism, the onset of dyspnea is usually acute and unrelated to exertion; there is frequently associated anxiety, sometimes described as a sense of impending doom. Chronic forms of pulmonary hypertension are first manifest by exertional dyspnea and often are not diagnosed until secondary right ventricular hypertrophy or failure has developed. Exertional light-headedness or syncope, due to limited cardiac output, are ominous signs in this setting.

NEUROMUSCULAR WEAKNESS

Neurologic or myopathic diseases affecting the muscles of respiration can lead to respiratory insufficiency. The occurrence of dyspnea in these conditions depends primarily on the relation between ventilatory requirement and capacity, although there may be a heightened sense of respiratory effort, even when breathing capacity is adequate. Because the underlying neuromuscular disease may restrict the patient's activity, dyspnea is often not noted until ventilatory capacity is severely reduced. Phrenic nerve paralysis, either unilateral or bilateral, is a focal neurologic defect that can cause distressing dyspnea, typically worsened with recumbency as the weight of the abdominal contents displaces the diaphragm cephalad.

HYPERVENTILATION SYNDROMES

Hyperventilation, with no apparent cause, is a relatively common condition. It is frequently attributed to, but is not invariably associated with, anxiety or other psychological symptom. When idiopathic hyperventilation is the cause of dyspnea, it may be described as “air hunger” or inability to take a deep breath. The dyspnea is usually episodic; it often occurs at rest and may not worsen with exercise. As the basis for this condition is unclear, the diagnosis of psychogenic hyperventilation as the cause of unexplained dyspnea should be made with caution, and only after other potential causes have been considered.

METABOLIC AND OTHER CONDITIONS

Anemia reduces the blood's O_2 -carrying capacity, so that a greater proportion of the cardiac reserve is needed for a given metabolic rate. Lactic acidosis is incurred at a lower level of exertion, thereby increasing ventilatory requirements. Other, poorly understood mechanisms may also contribute to dyspnea caused by anemia. Metabolic acidosis from renal insufficiency, myopathy, or other causes can similarly lead to dyspnea due to increased ventilatory requirements. Progesterone, a ventilatory stimulant, is responsible for chronic respiratory alkalosis and exertional dyspnea associated with pregnancy. Obesity causes increased ventilatory requirements because of the added metabolic work of supporting excess weight during ambulatory activity; it can lead to exertional dyspnea on this basis. Dyspnea may be a symptom of hypo- or hyperthyroidism, which in either case may be due to respiratory muscle weakness or cardiovascular impairment, and in the latter also to increased metabolic rate or respiratory drive.

PREVALENCE OF CONDITIONS CAUSING DYSPNEA IN MEDICAL PRACTICE

The prevalence of the above diagnoses in patients presenting with chronic dyspnea depends on the patient population and practice setting. Two published reports tabulated diagnoses for a total of 162 patients referred to pulmonary specialists for evaluation of dyspnea. Combining results of these two studies, 48% of patients were found to have diseases of the lungs or airways, including (in order of frequency) asthma, chronic obstructive airway diseases, interstitial diseases, upper-airway obstruction, and lung cancer. Cardiovascular diseases accounted for 15%, including cardiomyopathy, coronary artery disease, pulmonary vascular disease, dysrhythmia, valvular and pericardial diseases. In 11% of patients, hyperventilation syndrome or psychogenic dyspnea was diagnosed. In 8%, dyspnea improved after treatment of gastroesophageal reflux or postnasal drip. Neuromuscular or extrapulmonary restriction of lung mechanics was identified in 4%, deconditioning in 4%, and metabolic diseases in 2%. Nine percent remained undiagnosed despite extensive evaluation. Despite the selection biases and the limited number of patients represented by these studies, this is probably a reasonable estimate of the distribution of causes of chronic dyspnea for which a diagnosis is not immediately apparent.

CLINICAL EVALUATION

HISTORY AND PHYSICAL EXAMINATION

Because a careful history and physical examination often identifies the cause of dyspnea, this is the essential starting point for clinical evaluations.

It is important to establish the acuity of symptoms, as this bears on the differential diagnosis and dictates how rapidly a diagnosis must be established and therapy instituted. Normally, the ventilatory system has a large functional reserve, and resting ventilation requires only a small percentage of the maximum capacity. Increases in ventilatory requirements and effort may not be noticed by the patient at rest. Therefore, in addition to the onset, character, and severity of dyspnea, information regarding current and past activity levels are needed to establish the context of the symptoms. Questioning should be specific, as patients may have difficulty quantifying their activity levels or may have unconsciously reduced activity levels over time to avoid symptoms of breathlessness. Because the magnitude of dyspnea associated with a particular physiologic stimulus is reproducible for a given person, a recent change in dyspnea during a particular activity is meaningful and an important part of the history.

Most patients do not complain of “dyspnea”, but use a variety of descriptors for discomfort or difficulty with breathing. Different descriptors are used with varying frequency among patients with different underlying diseases, supporting the concept that the perception of dyspnea results from a variety of sensations arising from multiple mechanisms. Although distinct clusterings of respiratory symptoms characterize different diseases, most descriptors are not unique to a particular condition. Personal, cultural, and linguistic factors can also affect how symptoms are described, limiting the utility of these distinctions in the evaluation of individual patients.

The differential diagnosis for chronic dyspnea is broad, and the physical examination needs to be similarly comprehensive. Careful attention should be directed to cardiorespiratory findings. Observation of the patient’s appearance and respiratory rate while walking or moving about the room is of particular value. Signs of systemic conditions, such as collagen vascular disorders, thyroid disease, or neurologic deficits, can also provide important direction to subsequent testing and should be sought systematically.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Acute Dyspnea

For acutely ill patients, a chest radiograph to evaluate for lung infiltrates or edema and arterial blood gas analysis to assess the adequacy of gas exchange are almost always indicated (Table 351.2). Peak expiratory flow rates are readily measured and provide an objective measure of the severity of obstruction in airway disease. An electrocardiogram (ECG) is indicated whenever cardiac disease is known or suspected. Additional studies that might be indicated on the basis of the initial evaluation include perfusion lung scanning to evaluate for thromboembolism, echocardiography to assess valvular or ventricular dysfunction, and analysis of respiratory secretions or lung tissue to identify infectious agents or noninfectious inflammatory processes.

Acute Dyspnea
Indicated initially in nearly all patients
Chest radiograph
Arterial blood gas analysis
ECG
Commonly indicated
Measurement of peak flow or spirometry
Indicated for selected patients (based on clinical suspicion and initial findings)
Perfusion lung scanning
Echocardiogram
Respiratory secretion analysis
Chronic Dyspnea
Indicated initially in acute patients
Pulmonary function tests (spirometry, with or without addi- tional measures of lung volumes, diffusing capacity, and ar- terial blood gases)
Chest radiograph
Blood hemoglobin concentration and chemistries
Consider if initial evaluation is abnormal
Bronchoprovocation testing
Exercise testing
Indicated for selected patients (based on clinical suspicion and initial findings)
Chest CT scanning
Schilling test
Other cardiac imaging procedures
Laryngoscopy or bronchoscopy
Transbronchial and mucosal biopsy
Thyroid function tests
Biopsy of lung tissue

TABLE 351.2. COMMON DIAGNOSTIC STUDIES USED IN EVALUATION OF DYSPNEA

Chronic Dyspnea

The cause of chronic dyspnea is often evident from the history, examination, and basic screening studies, such as hematocrit and blood chemistries. Additional tests should be selected with specific goals: to confirm the clinical impression, follow up abnormal findings, investigate cases of uncertain cause, or quantify impairment.

No set sequence of diagnostic studies can be recommended in all cases, as the selection of tests is guided by the clinical presentation and diagnostic probabilities. However, given the high prevalence of pulmonary conditions among dyspneic patients, the most useful tests for initial evaluation are usually measures of pulmonary function. Simple spirometry can demonstrate airflow obstruction, which characterizes the most common diseases presenting with dyspnea. The flow volume loop may further distinguish extrathoracic from intrathoracic obstruction. Restrictive processes can be suspected from spirometry and confirmed with measurement of lung volumes. The diffusing capacity is often reduced in interstitial or pulmonary vascular diseases. Chest radiographs are usually indicated to identify focal or diffuse disease of lung parenchyma and to assess cardiac size. The ECG may reflect chamber enlargement or evidence of prior infarction. Evaluation of serum thyroid-stimulating hormone is helpful to screen for thyroid disorders.

If the initial evaluation does not point definitively to a diagnosis, exercise testing often helps direct the workup further. The rationale is straightforward: Most dyspnea is worsened by exercise because of the increased requirements for cardiac and ventilatory outputs to support an increased metabolic rate. Therefore, exercise may uncover impairment in an organ system that had been adequately compensated at rest. Measurements of respiratory gas exchange, ventilation, heart rate, blood pressure, ECG, and, where appropriate, arterial blood gases during a graded exercise stress allow identification of limitations in the O₂ transport system and its components. At the same time, functional capacity or impairment can be quantified.

Other specific tests may be indicated by the initial evaluation. Bronchoprovocation testing is highly sensitive for reactive airway disease and should be performed if asthma is suspected despite normal pulmonary function tests. While pulse oximetry may detect overt arterial desaturation, blood gas analysis provides more precise assessment of oxygenation and is essential for characterization of acid–base disturbances. Echocardiography is a valuable starting point for suspected cardiac causes of dyspnea and is particularly sensitive for identifying valvular lesions. The presence of resting or exercise ventricular dysfunction can also be assessed in most subjects by echocardiography. Esophageal pH monitoring to identify gastroesophageal reflux, or radiography to identify sinus disease, may be obtained when occult upper-airway causes of dyspnea are suspected. Laryngoscopy is the diagnostic procedure of choice when vocal cord dysfunction is suspected. High-resolution computed tomography may be useful to establish the presence of interstitial diseases, especially if findings are equivocal on plain radiograph. Histologic examination of lung tissue is sometimes ultimately required for diagnosis of specific interstitial diseases.

STRATEGIES FOR OPTIMAL CARE

Treatment of dyspnea is directed at the underlying condition and is detailed in the relevant chapters of this text. For many conditions, however, treatment may be unable to reverse the disease or fully relieve dyspnea. This is particularly true in cases of lung involvement by malignancy, but it also applies to some patients with chronic obstructive pulmonary disease, interstitial lung disease, and pulmonary hypertension. Thus, palliative relief of dyspnea may be needed.

PHARMACOLOGIC APPROACHES

Increasing arterial PO₂ specifically suppresses carotid body output. Because the carotid bodies sense P O₂ over a wide range, extending well above the normal level of around 100 mm Hg, supplemental O₂ may reduce dyspnea for some patients, even if the arterial PO₂ is normal. Narcotic analgesics and anxiolytics can also suppress ventilatory drive, by altering the sensitivity of the chemoreceptors or through central mechanisms. Anecdotal success has been reported with the use of these agents in conjunction with appropriate O₂ therapy for treatment of patients with intolerable dyspnea due to chronic lung disease, but chronic use of these is usually limited by the undesirable side effects. Fear of narcotic side effects should not dissuade clinicians from their use for palliating dyspnea in patients with end-stage untreatable

malignant or nonmalignant disease.

PULMONARY REHABILITATION

An integrated approach to coping with chronic lung disease, particularly obstructive disease, is found in pulmonary rehabilitation programs that combine education, optimal medication and oxygen therapy, exercise conditioning, and psychological support. Such programs cannot reverse abnormalities of lung mechanics but are successful in reducing dyspnea. These effects are achieved in part by behavior modification, such as learning to pace activities so as to work within the range of ventilatory capacity, or altering breathing patterns to minimize dead-space ventilation. Physiologic effects of exercise conditioning allow some patients to do ambulatory activities with less lactic acidosis, thereby reducing ventilatory requirements. Educational and psychological aspects of rehabilitation also appear beneficial. Understanding the disease and its treatment offers patients more personal control over its impact on their lives. Becoming familiar with the bounds of exertional dyspnea and reassurance that dyspnea is predictable and not intrinsically dangerous may help patients desensitize themselves to this symptom when other treatments are exhausted.

EFFERENT LIMB

Cough usually starts with a deep inspiration, followed by a forced expiration against a closed glottis. Following this compressive phase, the glottis opens allowing an expulsive phase (Fig. 352.1). Cough initiated in the tracheobronchial tree is accompanied by a large inflation, while initiation in the larynx may not be accompanied by any inflation. During the compressive phase, the expiratory muscles contract against a closed glottis, allowing intrapleural and intra-alveolar pressures to rise to levels as high as 40 kPa for about 200 milliseconds. The expiratory phase occurs as the glottis opens and this expulsive phase may be long-lasting, with a large expiratory tidal volume or by a series of short expiratory efforts. Dynamic compression of the airways occurs downstream of the “equal pressure point” where intraluminal and extraluminal pressures across the bronchial wall are equal. Starting at high lung volumes, the equal pressure point is near the trachea, but it moves toward the smaller airways as the lung empties and the elastic lung recoil is diminished. As this occurs, the airflow velocity and kinetic energy of the air passing through the proximal airways increase, thereby improving the clearance of the airways. This may be further improved by a series of short expiratory efforts. Coughing at large lung volumes causes dynamic compression of larger airways, while coughing at low lung volumes induces dynamic compression of the lower airways. This may allow secretions to be moved from the smaller airways into the larger airways, and finally cleared from the tracheobronchial tree.

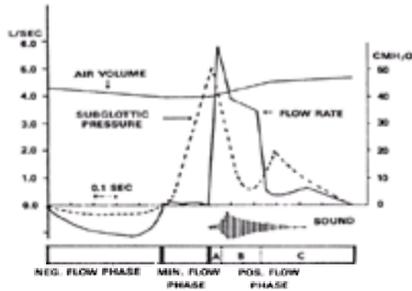

FIGURE 352.1. Changes in flow rate, volume, subglottic pressure, and sound level during a representative cough. During inspiration, the flow rate is negative; at the glottic closure, the flow rate is zero; and during the expiration phase, the flow rate is positive. (From Yanagihara N, von Leden H, Werner-Kukuk E. The physical parameters of cough: the larynx in a normal single cough. *Acta Oto-laryngol* 1996;61:495–502, with permission.)

Coughing may be accompanied by bronchoconstriction since the stimuli that cause cough, such as chemical irritants and inflammatory mediators, can also induce reflex bronchoconstriction. Afferent receptors for cough also cause reflex secretion of mucus from airway submucosal glands. Both bronchoconstriction and intraluminal mucus would narrow the luminal diameter and increase the linear velocity of airflow, resulting in more turbulence and central impaction of inhaled particles. Mucus also may trap inhaled particles and irritant chemicals.

INEFFECTIVE COUGH

Because cough is important in preventing foreign inhaled materials to enter the lower respiratory tract and in clearing lower respiratory tract secretions, an ineffective cough may lead to lower respiratory tract infections with pneumonia or bronchiectasis and lung collapse. This usually results from any condition associated with diminished expiratory flow rates or reduced ability to compress airways. These pathologic conditions may interfere with either the inspiratory or expiratory phases of cough or both, and include extrapulmonary causes such as rib fractures, disorders of respiratory muscles such as myasthenia gravis, depression of the cough reflex such as during postoperative anesthesia, and a variety of pulmonary causes such as asthma and bronchiectasis. Closure of the glottis is not essential for the production of an effective cough, but the muscles of expiration are the most important determinant of the production of elevated intrathoracic pressures.

MEASURING COUGH SEVERITY

Assessment of cough severity traditionally rests on asking the patient for his or her perception of the symptom. Measurement of the cough reflex can be done by counting the cough responses to inhalation of tussive agents such as capsaicin, the hot extract of peppers, and low-chloride solutions. Although cough can be induced directly by airway secretions and irritants, persistent cough may also result from an increase in the sensitivity of the cough receptor. Most patients with a nonproductive persistent cough due to a range of causes have an enhanced cough reflex to capsaicin when compared to healthy non-coughing subjects. Successful treatment of the primary condition underlying the chronic cough often leads to a normalization of the cough reflex. In contrast, patients with a productive cough, such as that associated with bronchiectasis and chronic bronchitis, do not usually demonstrate an enhanced cough reflex. The degree of the cough responsiveness to inhaled capsaicin may be a reflection of the severity of the cough, but this has yet to be examined. Of relevance to the evaluation and treatment strategies for persistent dry cough is the fact that the cough response can be augmented by various mediators of inflammation such as the prostaglandins PGE₂ and PGF_{2α}, and bradykinin through a process of sensitization.

Direct measurement of the number of coughs as a measure of severity has not been extensively assessed. A significant correlation between daytime cough numbers and daytime cough symptom scores has been shown for a group of chronic dry coughers. In both patients with cough of unknown cause or associated with asthma, the number of coughs counted were highest during the daytime, and very few coughs were observed at night during sleep. Both ambulatory monitoring of cough and measurement of the cough reflex are not routinely used in the clinical setting.

CAUSES OF COUGH: ACUTE AND CHRONIC

A useful clinical classification is to consider whether the cough is acute or chronic. Acute cough is usually due to a viral or bacterial upper respiratory tract infection. The cough of the common cold is usually self-limiting and accompanies the cold in 83% of sufferers within the first 48 hours. Other symptoms of postnasal drip—throat clearing, nasal obstruction, and nasal discharge—also accompany the cough, which usually resolves within 2 weeks, sometimes longer. Bronchial epithelial inflammation and damage is present in children with chronic cough following lower respiratory tract illness. Irritants may penetrate more readily through the damaged epithelium.

Acute onset of cough can also be the presenting symptom of more life-threatening respiratory conditions, such as acute bacterial pneumonia, congestive cardiac failure, pulmonary embolism or aspiration. These conditions are usually accompanied by other symptoms, such as shortness of breath and fever, but cough may be the predominant or, rarely, the only symptom.

Chronic cough (cough that persists for more than a month) can be caused by many diseases, but it is most commonly due to asthma, gastroesophageal reflux, postnasal drip, chronic bronchitis, and bronchiectasis. Smoking is a common independent determinant of cough with or without mucus hypersecretion. A smoker may also develop a chronic cough due to other causes that may or may not directly relate to cigarette smoke, such as an endobronchial tumor or the development of asthma. The definitive diagnosis of cough can be established if the specific treatment aimed at the condition is successful.

CONDITIONS ASSOCIATED WITH CHRONIC COUGH

POSTNASAL DRIP (RHINOSINUSITIS)

The strong association between postnasal drip (rhinosinusitis) and chronic persistent cough is based on epidemiologic evidence and on a prospective study in adults. Postnasal drip (“nasal catarrh”) is characterized by a sensation of nasal secretions or of a “drip” at the back of the throat, often accompanied by frequent throat clearing. There may be a nasal quality to the voice due to concomitant nasal blockage and congestion. Physical examination of the pharynx is often unremarkable, although infrequently a “cobblestoning” appearance of the mucosa and draining secretions are observed. Computed tomography (CT) of the sinuses may reveal mucosal thickening or sinus opacification and air–fluid levels. There may be an extrathoracic variable upper-airway obstruction presumably arising from upper-airway

inflammation.

Topical administration of corticosteroid drops in the head-down position is the best treatment, sometimes with the concomitant use of antihistamines. Topical decongestant vasoconstrictor sprays may be useful adjunct therapy for a few days, but rebound nasal obstruction may occur after prolonged use. Antibiotic therapy is advisable when mucopurulent secretions are present. Postnasal drip is a very common cause of cough, and empirical therapy is justified in the presence of suggestive symptoms.

ASTHMA

Chronic dry cough may occur in asthma under different clinical settings. Asthma may present predominantly with cough, often nocturnal, and the diagnosis is supported by reversible airflow limitation and bronchial hyper-responsiveness. This condition of “cough-variant” asthma is a common type of asthma in children. Elderly asthmatics may give a history of clinic cough prior to a diagnosis of asthma made on the basis of episodic wheeze. Cough may also occur as a sign of worsening of asthma, usually presenting first at night, associated with other symptoms such as wheeze and shortness of breath with falls in early morning peak flows. On the other hand, some patients with asthma develop a persistent dry cough despite good control of their asthma with antiasthma therapy.

Patients with asthma usually do not have an enhanced cough reflex, although a subgroup with persistent cough may. In these patients, cough receptors may be sensitized by inflammatory mediators such as bradykinin, tachykinins, and prostaglandins. Induction of sputum by inhalation of hypertonic saline often reveals a predominance of eosinophils, and bronchial hyper-responsiveness is invariably present.

Cough associated with asthma should be treated with antiasthma medication, including inhaled corticosteroid therapy and bronchodilators such as β_2 -adrenergic agonists. Often a trial of oral corticosteroids (e.g., prednisolone 40 mg per day for 2 weeks) is recommended. Treatment with nedocromil sodium can be a useful addition.

CHRONIC BRONCHITIS

Most patients with cough due to chronic bronchitis from cigarette smoking do not usually seek medical attention. Chronic bronchitis should be considered in a patient who produces phlegm on most days over at least three consecutive months, particularly during the winter months over at least 2 consecutive years. Often, the productive cough is exacerbated by upper respiratory infections with common viruses or by exposure to irritating dusts. Other causes of productive cough should be excluded, such as bronchiectasis or postnasal drip. Cessation of cigarette smoking is usually successful in reducing the cough. Treatment of any associated chronic obstructive pulmonary disease with β_2 -adrenergic agonists and anticholinergic agents may be indicated.

BRONCHIECTASIS

The cough of bronchiectasis is associated with excessive secretions from overproduction together with reduced clearance of airway secretions. Usually, the patient produces 30 mL or more of purulent sputum per day, sometimes accompanied by fever, hemoptysis, and weight loss. In early bronchiectasis, the condition may only present with a persistent productive cough. The chest roentgenogram may show increased bronchial wall thickening, particularly in the lower lobes in advanced cases, but thin-section CT of the chest can reveal early changes of intrapulmonary airway wall thickening, dilatation, and distortion.

The cough due to bronchiectasis may be successfully controlled with inhaled β_2 -agonist, which improves mucociliary clearance and reverses any associated bronchoconstriction, postural drainage of airway secretions, and use of intermittent antibiotic therapy.

GASTROESOPHAGEAL REFLUX

Patients with symptoms of gastroesophageal reflux, such as heartburn, chest pain, a sour taste, or regurgitation, may also complain of a chronic persistent cough. Not infrequently, there may be no symptoms of gastroesophageal reflux or impaired clearance of esophageal acid. An esophageal–tracheobronchial cough reflex mechanism has been proposed on the basis of studies in which distal esophageal acid perfusion induced coughing episodes in such patients. Local distal esophageal perfusion of lidocaine suppressed the acid-induced cough in patients with chronic cough, and the inhaled anticholinergic agent ipratropium bromide was also effective. Over 90% of the cough episodes are temporally related to reflux episodes. Significant reflux occurs in both supine and upright positions. A high proportion of patients with gastroesophageal reflux also appear to have gastrohypopharyngeal reflux, and there may be a direct effect of acid reflux on cough receptors in the larynx and trachea. Continuous monitoring of tracheal and esophageal pH in patients with symptomatic gastroesophageal reflux has demonstrated significant increases in tracheal acidity, with pH values falling to 4.10 during episodes of reflux. Other components of the refluxate apart from acid may also contribute to stimulating cough.

Evidence for gastroesophageal reflux can be obtained by upper gastrointestinal contrast series that show reflux of barium into the esophagus, or by esophageal pH monitoring revealing pH values in the lower esophagus outside normal values. Sometimes cough may coincide with the presence of reflux episodes. Treatment of gastroesophageal reflux consists of using either H_2 -histamine blockers or proton pump inhibitors, together with advice about elevation of the head of bed.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR COUGH

Angiotensin-converting enzyme (ACE) inhibitors are often prescribed for the treatment of hypertension and heart failure, and cough has been observed in 2% to 33% of patients. The cough is typically described as dry, associated with a tickling, irritating sensation in the throat. It may appear within a few hours of taking the drug but may also only become apparent after weeks or even months. The cough disappears within days or weeks following withdrawal of drug. Patients with ACE inhibitor cough demonstrate an enhanced response to capsaicin inhalation challenge. The mechanisms underlying ACE inhibitor cough are not clear, but accumulation of bradykinin and prostaglandins, which sensitize cough receptors directly, has been implicated. The best treatment for ACE inhibitor cough is to discontinue the treatment and to replace it with alternative therapies (such as an angiotensin II receptor antagonist, which does not cause cough).

CHRONIC PERSISTENT COUGH OF UNKNOWN CAUSE

Identification of a potential cause of cough has been reported in 78% to 99% of patients presenting at a specialized cough clinic. Treatment of identifiable causes may also not be successful. These patients present in a way similar to that of others in whom a cause has been identified. An enhanced cough reflex is found. Patients often complain of a persistent tickling sensation in the throat that often leads to paroxysms of coughing. This sensation can be triggered by factors such as a change in ambient temperature, the taking of a deep breath, and the presence of cigarette smoke or other irritants such as aerosol sprays or perfumes. These symptoms are typical of a sensitized cough reflex. Mucosal biopsies taken from a group of nonasthmatic patients with chronic dry cough showed evidence of epithelial desquamation and inflammatory cells, particularly mononuclear cells. These changes could represent the sequelae of chronic trauma to the airway wall following intractable cough and lead to sensitization of the cough reflex. Because no clear effective and safe antitussives are available, the control of persistent cough without associated cause remains difficult. Antitussive therapy may be instituted.

OTHER CONDITIONS

Other conditions causing cough include bronchogenic carcinoma, metastatic carcinoma, sarcoidosis, chronic aspiration, or left ventricular failure. These conditions can be excluded by chest roentgenogram. Psychogenic or habit cough is not uncommon, particularly in children, and is usually a diagnosis arrived at after exclusion of other causes. Habit cough is a throat-clearing noise made by a person who is nervous and self-conscious. Cough may be associated with a depressive illness.

PRACTICAL APPROACH TO CHRONIC PERSISTENT COUGH

The clinical approach to cough is first to identify and then to treat the cause(s) ([Table 352.3](#) and [Table 352.4](#)). The history and examination will often indicate likely associated diagnosis or diagnoses, and the timing of various investigations may vary according to presentation. Initial investigation may be limited to a chest roentgenogram, particularly if there is a high suspicion of a tumor, particularly in a smoker. A period of observation of 3 to 4 weeks in a patient who provides a good history of an upper respiratory tract infection prior to further investigation or therapeutic trial is adequate, although institution of an anti-inflammatory therapy such as

inhaled corticosteroids can be useful in controlling this type of cough.

1. History and physical examination
2. Chest roentgenogram for all patients
3. Initial evaluation leads to diagnosis of chronic bronchitis in cigarette smokers and of ACE inhibitor cough. Discontinue cigarette smoking and offending drug.
4. Further diagnostic evaluation on basis of initial evaluation:
 - (i) If suggestive of postnasal drip, order a CT scan of sinuses, and allergy tests.
 - (ii) If suggestive of asthma, request a record of peak expiratory flow measurements at home for 2 weeks and a bronchoprovocation test with histamine/methacholine, and/or a trial of antihistamine treatment.
 - (iii) If suggestive of gastroesophageal reflux disease, request 24-hour pH monitoring, and if necessary, an endoscopic examination of the esophagus, or a barium swallow series.
 - (iv) If the chest roentgenogram is abnormal, consider examination of sputum and a fiberoptic bronchoscopy. In some cases, a CT scan of the thorax and further lung function evaluation may be necessary.
5. Treat specifically for associated conditions. The cause(s) of cough (are) determined when specific therapies eliminate or improve the cough.

ACE, angiotensin-converting enzyme; CT, computed tomography.

TABLE 352.3. DIAGNOSTIC EVALUATION OF CHRONIC COUGH

1. Treatment of specific underlying cause(s)	
Asthma	Bronchodilators and inhaled corticosteroids
Allergic rhinitis and postnasal drip	Topical nasal steroids and antihistamines (with antibiotics, if indicated)
Esophageal reflux	H ₂ -histamine antagonist or proton pump inhibitor
Angiotensin-converting enzyme inhibitor	Alternative drug such as angiotensin II receptor antagonist
Chronic bronchitis	Smoking cessation
Bronchiectasis	Postural drainage; treat infective exacerbation and airway obstruction
Infective tracheobronchitis	Appropriate antibiotic therapy
2. Symptomatic treatment (only after consideration of cause of cough)	
Acute cough likely to be transient, e.g., upper respiratory viral infection	Simple linctus
Persistent cough (particular nocturnal)	Opiates (codeine or pholcodeine)
Persistent intractable cough due to terminal incurable disease	Opiates (morphine or diamorphine), local anesthetic aerosol
Cough in children	Simple linctus (pediatric)

TABLE 352.4. TREATMENTS FOR COUGH

Postnasal drip, asthma, and gastroesophageal reflux are the three most common conditions associated with a chronic dry cough. It would be sensible in the diagnostic approach to exclude these conditions first. Direct inspection of the nasal passages and throat together with a CT scan of the sinuses may be indicated, and ambulatory pH monitoring, with possible fiberoptic esophageal–gastroscopic examination. The diagnosis of asthma is supported by the presence of diurnal variation in peak flow measurements, bronchial hyper-responsiveness to histamine or methacholine challenge, and the presence of eosinophils in sputum. However, a therapeutic trial may be the best initial approach, particularly when the history and examination provide supportive clues. It is important that effective doses of medication over a sufficient period of time be given. Sometimes a longer-than-usual period of treatment is necessary to control the cough. Postnasal drip is an often overlooked condition, and aggressive treatment should consist of corticosteroid nasal drops with an antihistamine, with the possibility of adding antibiotic therapy and a short period of treatment with a nasal decongestant. Often more than one of these conditions may coexist, and cough may only respond with concomitant treatment of these. For example, inhaled steroid therapy and acid suppression with H₂-histamine blockers or a proton pump inhibitor would be indicated for the coexistence of asthma and gastroesophageal reflux.

Bearing in mind that there are a myriad of other, less common causes of a chronic cough, investigations must proceed further if the above causes are excluded. Full lung function tests to include lung volumes and gas transfer factor, along with a CT scan of the lungs, should be considered in case of bronchiolar or parenchymal disease or unsuspected bronchiectasis. Fiberoptic bronchoscopy should be considered and apart from excluding small central tumors provides mucosal biopsies for histologic examination.

THERAPIES AIMED SPECIFICALLY TOWARDS COUGH SUPPRESSION

When the treatment of the cause of cough is unavailable or ineffective, therapies specifically directed at eliminating the symptom of cough should be tried. Drugs that affect the complex mechanism of the cough reflex may act in several ways (Fig. 352.2). They may act by inhibition of central mechanisms within the cough center or by reducing the response of cough receptors in the airways. Opiates, demulcents, expectorants, local anesthetics, and antiasthma drugs have been used as antitussive agents with varying degrees of success.

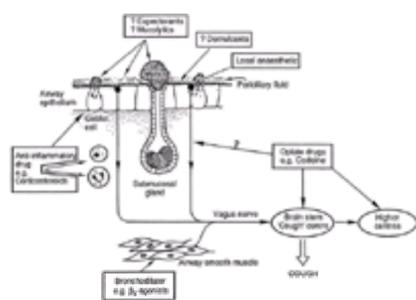

FIGURE 352.2. Afferent pathways of the cough reflex and some potential sites of action of antitussive drugs

NARCOTIC AND NON-NARCOTIC ANTITUSSIVES

Opiates, including morphine, diamorphine, and codeine, are the most effective antitussive agents. At their effective doses they cause physical dependence, respiratory depression, and gastrointestinal colic. Morphine and diamorphine are reserved for the control of cough and pain of terminal bronchial cancer patients, but codeine, dihydrocodeine, and pholcodeine can be tried in other cases of chronic cough. These drugs may cause some physical dependence and drowsiness; nausea, vomiting, and constipation may be important side effects.

Non-narcotic antitussives include dextromethorphan, which is a synthetic derivative of morphine with no analgesic or sedative properties and which is usually included as a constituent of many compound cough preparations sold over the counter. Other non-narcotic preparations include noscapine and levopropoxyphene, although their antitussive efficacy has not been proven.

EXPECTORANTS AND MUCOLYTICS

The basis for using these agents as antitussives lies in the belief that altering the volume of secretions or their composition leads to suppression of the cough reflex. Despite the lack of proof, mucolytic agents, such as acetylcysteine, carbocysteine, bromhexine, and methylcysteine, are often used to facilitate expectoration by reducing sputum viscosity in patients with chronic bronchitis. Aromatic agents, such as eucalyptus and menthol, have decongestant effects in the nose and can be

useful in short-term relief of cough. Demulcents also form an important component of many proprietary cough preparations and may be useful because the thick sugary preparation may act as a protective layer on the mucosal surface.

LOCAL ANESTHETICS

Lidocaine aerosol has been administered to patients with intractable cough with variable results and should be reserved for such patients. They work by inhibiting sensory neural activity but also remove reflexes that protect the lung from noxious substances. Their effects are transient, and they should be avoided in patients with asthma or a past history of asthma because they can induce severe bronchoconstriction.

ANTIASTHMA THERAPY

Often antiasthma therapy (β_2 -agonist and anticholinergic therapy or corticosteroid therapy) may be tried even in the absence of symptoms or tests supporting asthma. Cough may be accompanied by bronchoconstriction, which in turn can worsen cough—an effect that can be prevented by an inhaled β_2 -agonist. In addition, airway inflammation may be present in the airways as a contributory factor and could be controlled by an inhaled corticosteroid. Such treatment should be instituted as a trial after diagnostic evaluation has excluded most causes associated with the cough.

CHAPTER 353: APPROACH TO THE PATIENT WITH HEMOPTYSIS

EDWARD F. HAPONIK

[Pathophysiologic Factors, Causes, and Classifications](#)
[Diagnostic Approach](#)
[Life-Threatening Hemoptysis](#)

Hemoptysis is a common sign and symptom of respiratory and systemic disease, although its precise incidence is unknown. Expectoration of blood usually signals a condition that requires recognition and treatment, but the bleeding itself is self-limited. At the other extreme, severe pulmonary hemorrhage is a medical and surgical emergency. Thus, clinical challenges range from the reassurance of an ambulatory patient with an alarming but innocuous problem to the resuscitation of a drowning person. Judgments about the extent, pace, and priorities of the evaluation are highly individualized ([Table 353.1](#)); the pattern and degree of bleeding and its physiologic impact influence the clinical presentation and determine the approach to diagnosis and therapy.

- Respiratory
 - Pneumothorax
 - Subcutaneous emphysema
 - Pneumomediastinum
 - Pneumoperitoneum
 - Laryngeal damage
- Cardiovascular
 - Cardiac dysrhythmias
 - Loss of consciousness
 - Subconjunctival hemorrhage
- Central nervous system
 - Syncope
 - Headaches
 - Cerebral air embolism
- Musculoskeletal
 - Intercostal muscle pain
 - Rupture of rectus abdominis muscle
 - Increase in serum creatine phosphokinase
 - Cervical disc prolapse
- Gastrointestinal
 - Esophageal perforation
- Other
 - Social embarrassment
 - Depression
 - Urinary incontinence
 - Disruption of surgical wounds
 - Periculis
 - Purpura

TABLE 353.1. SOME MAJOR CLINICAL DISTINCTIONS BETWEEN MILD AND MASSIVE HEMOPTYSIS

PATHOPHYSIOLOGIC FACTORS, CAUSES, AND CLASSIFICATIONS

Although there are more than 100 causes of hemoptysis, the most commonly encountered problems and their presentations are summarized in [Fig. 353.1](#). Causes of bronchoscopically confirmed bleeding have changed during the past three decades; the likelihood of tuberculosis has decreased and that of lung cancer has increased. This shift reflects changes in the prevalence of these conditions and refinements of fiberoptic bronchoscopy, radiologic imaging, and other diagnostic tools.

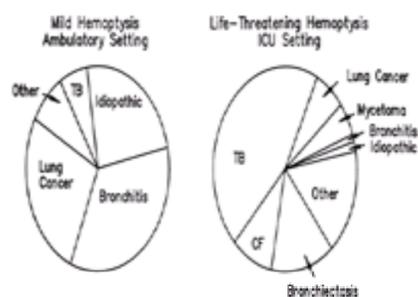

FIGURE 353.1. Relative frequencies of conditions associated with hemoptysis vary with the clinical settings in which bleeding occurs. Life-threatening hemorrhage more often complicates diseases, producing major lung parenchymal destruction or vascular disruption

The dual blood supply to the lung from the pulmonary and bronchial arterial systems, the proximity of all airways to vessels, and the diversity of conditions affecting the respiratory tract can lead to hemoptysis in various ways. Bleeding can originate from vascular disruption at any anatomical level, but the bronchial arterial system is the predominant source in most patients. Acute inflammatory disease (e.g., bronchitis) commonly causes mucosal hyperemia associated with superficial bleeding; blood-streaked sputum may worsen after coughing paroxysms. Chronic inflammation (e.g., bronchiectasis) and neoplasms may result in extensive, friable neovascular networks, often with systemic collateral communications. Bleeding occurs in the lower pressure pulmonary circulation less often (e.g., Rasmussen's aneurysm with tuberculosis, mycotic aneurysm with lung abscess, or endocarditis) and may worsen with pulmonary arterial hypertension. Acute and chronic destructive processes may erode large central vessels (e.g., bronchogenic carcinoma, cavitary tuberculosis, lung abscess, necrotizing pneumonia). Less often, congenital and acquired arteriovenous communications are the cause. Vessels may be lacerated by chest trauma and complicate increasingly performed invasive diagnostic procedures such as lung biopsy or Swan–Ganz catheterization.

Because the lung is, in effect, a sheet of blood, numerous injuries to either side of the alveolar–capillary membrane can cause varying degrees of hemoptysis. Capillary hemorrhage associated with pulmonary venous hypertension commonly results in bloody pulmonary edema fluid in patients with congestive heart failure. Alternatively, microvascular oozing might reflect diffuse immunologically mediated injury (e.g., vasculitis, pulmonary–renal syndromes), inhalation or aspiration of irritants (e.g., trimellitic anhydride), drugs (e.g., D-penicillamine), or infectious agents, or may represent diffuse alveolar damage following organ transplantation (e.g., cardiac or bone marrow transplants). Pulmonary capillaritis ([Table 353.2](#)) has been caused by various potentially treatable systemic diseases, and its incidence may be increasing. In immunocompromised patients, alveolar hemorrhage has been associated with thrombocytopenia, other coagulation abnormalities, and renal insufficiency, and is usually associated with infectious pneumonias. Cigarette smoking appears to predispose to alveolar hemorrhage.

- Common
 - Wegener's granulomatosis
 - Microscopic polyangitis
 - Systemic lupus erythematosus
- Uncommon
 - Primary capillaritis without systemic disease
 - Capillaritis associated with idiopathic pulmonary fibrosis
 - Rheumatoid arthritis
 - Scleroderma
 - Mixed connective tissue disease
 - Primary antiphospholipid syndrome
 - Henoch–Schönlein purpura
 - Mixed cryoglobulinemia
 - Behçet's syndrome
 - Pauci-immune glomerulonephritis
 - Autologous bone marrow transplantation

TABLE 353.2. CAUSES OF PULMONARY CAPILLARITIS

Bleeding rates in the range of 400 to 600 mL expectorated during a 16- to 24-hour period have arbitrarily defined “massive” hemoptysis, but considerably less hemorrhage presents a major threat to the patient whose ability to clear the airway effectively is compromised. Patients with altered mental status, severe preexisting lung disease, or ineffective cough are especially vulnerable, and the term “life-threatening” rather than “massive” applies. Severe hemorrhage has profound physiologic sequelae: alveolar filling or atelectasis due to aspirated blood causes hypoxemia due to ventilation–perfusion mismatch (and, with severe bleeding, physiologic shunt). Proximal airway obstruction by clot causes alveolar hypoventilation; with massive bleeding, death is usually caused by asphyxiation rather than by exsanguination, although the latter can occur in patients who survive the immediate respiratory collapse or after great vessel injuries.

DIAGNOSTIC APPROACH

Knowledge of the setting and patient population in which bleeding occurs (i.e., the pretest probabilities of disease) influences the differential diagnostic considerations (see [Table 353.1](#) and [Fig. 353.1](#)). The signs and symptoms of diverse pulmonary diseases are detailed elsewhere. Despite the nonspecificity of many of these manifestations, they help to assess the likelihood of particular pulmonary or systemic causes of hemoptysis and the patient’s overall physiologic reserve. Generally, clinical manifestations of the primary disease causing hemoptysis dominate the clinical presentation. Coagulopathies further predispose to bleeding, and coexisting nonpulmonary illnesses compromise the patient’s ability to tolerate it. In most patients, a carefully performed history, physical examination, chest roentgenogram, selectively used laboratory tests, and diagnostic bronchoscopy prove sufficient to guide management.

Evaluation begins with the detailed medical history and physical examination. The subglottic origin of expectorated blood is usually obvious, but bleeding from the upper airway (e.g., sinusitis, nasal polyps, nasopharyngeal and laryngeal neoplasms) or aspirated from the gastrointestinal tract must be considered. The latter might be suggested by associated nausea and vomiting or by the dark color and acidic character of blood. Less often, “pseudohemoptysis” due to foods, pigment-producing microbes (e.g., *Serratia marcescens*), or medications (oxidized Bronkosol) mimic bloody sputum. Historical and bedside clues might strongly suggest the cause of bleeding, but usually further objective information is necessary to localize the source of bleeding and to identify its specific cause, or at least to exclude serious treatable disease.

RADIOLOGIC STUDIES

The chest roentgenogram is a basic component of evaluation and often directs the highest-yield diagnostic approach. Characteristic apical cavitory disease might strongly suggest tuberculosis or central mass lesions bronchogenic carcinoma; focal consolidation might suggest bacterial pneumonia; diffuse radiographic infiltration should suggest widespread aspiration of blood or microvascular bleeding. Readily appreciated findings include broncholiths; “middle-lobe” syndrome; extensive cystic bronchiectasis; “crescent” signs of intracavitary mycetomas, clot, or necrosing lung or tumor; and vascular malformations. Abnormal roentgenograms are more often found in patients with severe, protracted bleeding. Especially when previous films are available for comparison, the extent of radiographic abnormalities also helps assess chronic anatomical abnormalities that might predict limited physiologic reserve. Serial chest films help to monitor the course or identify new hazards; for example, the abrupt opacification of a preexisting cavity is an ominous radiographic sign.

For carefully selected patients with unexplained hemoptysis or particular predispositions to disease, other imaging procedures have complementary applications. Their optimal, integrated roles continue to evolve. Historically, bronchography has helped document bronchiectasis, which when localized might benefit from surgical resection. Fewer than 10% of patients carefully evaluated in this manner have bronchiectasis, perhaps reflecting increased use of empirical antimicrobials in patients with bacterial infection and the decreased prevalence of tuberculosis.

Chest computed tomography (CT), which has supplanted bronchography at most centers, may also reveal occult masses or cavities, mycetomas, arteriovenous malformations, or parenchymal bleeding sites. Because of the high prevalence of self-limited, benign causes of bleeding, chest CT is not routinely indicated in all patients with hemoptysis. CT is most useful in patients at risk for lung cancer, in whom it may identify the neoplasm and assist in its staging.

Magnetic resonance imaging has documented bronchogenic cysts or vascular causes of bleeding (e.g., pulmonary arterial aneurysms) but is used less often than CT or chest x-rays. Defining the precise vascular source of bleeding by bronchial or pulmonary arteriographic examination may have major therapeutic implications in selected patients with chronic, recurrent, or life-threatening hemoptysis. Infrequently, use of radionuclides or radiolabeled autologous erythrocytes helps in the localization of occult chronic bleeding.

LABORATORY TESTS

Several laboratory studies may contribute to patient evaluation and are used selectively, according to clinical suspicions. Examination of expectorated sputum may identify infectious causes of hemoptysis (e.g., Gram stain, smears for mycobacteria and fungi) but usually is nondefinitive. Sputum cytopathologic evaluation is valuable in patients at risk for cancer, especially in the presence of suggestive central radiographic abnormalities. Hemosiderin-laden alveolar macrophages have been associated with chronic or occult pulmonary hemorrhage (e.g., in immunocompromised hosts with coagulopathies or fungal infections) but are not routinely useful. Serologic studies (e.g., collagen vascular disease profiles, anti–glomerular basement membrane or antineutrophil cytoplasmic antibodies) may help clarify systemic diseases and direct subsequent diagnostic and therapeutic procedures. Coagulation tests are often obtained in search of correctable abnormalities but usually have a low yield in the absence of a clinically obvious propensity for bleeding. Spirometry and arterial blood measurements provide useful estimates of pulmonary reserve and the physiologic impact of bleeding. An elevated carbon monoxide diffusion capacity may suggest pulmonary hemorrhage but does not define the cause of bleeding, and the procedure has limited value in the acute setting. Other tests (e.g., pulmonary ventilation–perfusion scanning to assess pulmonary embolism with infarction, hemodynamic measurements, echocardiography to exclude mitral stenosis) are useful when clinical findings suggest particular conditions. Routine otolaryngologic evaluations of all patients with hemoptysis has been advocated, but the yield is low in the absence of other signs or symptoms of upper-airway disease.

BRONCHOSCOPY

Careful upper- and lower-airway examination by fiberoptic bronchoscopy is indicated when hemoptysis is clinically significant, the simple database is nondiagnostic, and the test results will influence management. This relatively noninvasive outpatient procedure helps to localize bleeding and can identify a spectrum of conditions with specific (e.g., bronchial adenoma, bronchogenic carcinoma) and nonspecific (e.g., bronchitis) manifestations. Often, only focal or diffuse blood or even a normal tracheobronchial tree is seen; the precise cause of bleeding is unknown and is often considered to be occult bronchitis or bronchiectasis. Such patients are more properly regarded as having hemoptysis of unknown cause (e.g., essential or cryptogenic bleeding). Even such nondiagnostic bronchoscopy is clinically useful, however: few such patients subsequently are found to have lung cancer. Hemoptysis spontaneously abates by 1 month in about 75% of patients with nonlocalizing x-rays and nondiagnostic bronchoscopy and in over 90% of patients over the following year.

Repeat bronchoscopy is generally well tolerated and is indicated if the initial endobronchial examination was incomplete, if bleeding persists, or when follow-up radiographic studies or clinical risk factors suggest treatable disease (e.g., lung cancer, granulomatous infection).

Patient selection for fiberoptic bronchoscopy varies among institutions, but retrospective investigations suggest several useful criteria: bleeding that exceeds 1 to 2 weeks’ duration, expectoration of more than 30 mL of blood daily, older age (more than 40 years), abnormal chest roentgenograms (especially with central abnormalities), smoking history, chronic cough, and anemia all suggest lung cancer. Lung cancer occurs in about 5% to 8% of patients with normal or nonlocalizing chest x-rays and unexplained, significant hemoptysis. The high clinical benefit of detecting resectable lung cancer and the low risk of fiberoptic bronchoscopy generally favor the procedure in patients at risk. In contrast, young persons (under 35 years) with brief (less than 1 week), mild (less than 30 mL) bleeding are less likely to have lung cancer. Combinations of these negative findings have a high negative predictive value. Bronchoscopy is also deferred when the patient’s clinical status is prohibitively fragile, when bleeding originates from extrapulmonary sites or obvious non-neoplastic disease (e.g., pneumonia, pulmonary infarction), or with systemic etiologies.

The optimum timing of bronchoscopy for nonmassive hemoptysis is unclear. A bleeding site is identified bronchoscopically more often during the first 24 hours of presentation, but it has not been shown that outcomes are compromised when bronchoscopy is delayed for several days as bleeding abates.

Some patients with extensive airspace filling by blood (e.g., due to thrombocytopenia, diffuse alveolar damage, lung contusion) have had minimal hemoptysis; in these instances, bronchoalveolar lavage has helped clarify the nature of bleeding. In general, the diagnostic yield is lower and the risk higher in patients with diffuse

disease. Although transbronchial forceps biopsy has been diagnostic in this setting (e.g., with Wegener's granulomatosis, Goodpasture's syndrome), open or thoracoscopic lung biopsy or sampling of an extrapulmonary site of systemic involvement is more often helpful when definitive histologic diagnosis is essential to management.

LIFE-THREATENING HEMOPTYSIS

In fewer than 5% of patients with hemoptysis, pulmonary hemorrhage is life threatening and requires the diagnostic approach to be merged with therapy ([Fig. 353.2](#)). The clinician must simultaneously recognize the conditions associated with massive bleeding, protect the airway to maintain alveolar ventilation and preserve function of the nonhemorrhaging lung, and determine whether the patient is a candidate for urgent definitive treatment. Tuberculosis, lung cancer, bronchiectasis (including cystic fibrosis), and mycetomas are the leading causes of life-threatening bleeding ([Fig. 353.1](#)).

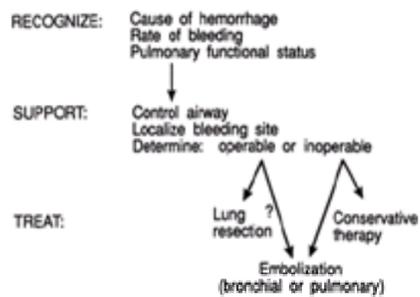

FIGURE 353.2. Effective management of patients with life-threatening hemoptysis requires the timely integration of diagnostic and therapeutic approaches

While oxygenation and general support are provided, airway maintenance is a focus of acute management. In most instances, insertion of a large, single-lumen tube is the initial approach. Placement of a double-lumen endotracheal tube permits selective lung ventilation and suctioning but requires considerable technical expertise. The patient is positioned with the bleeding side dependent in efforts to minimize aspiration into the more functional, nonhemorrhaging lung. Because accurate localization of the bleeding site determines subsequent therapy, bronchoscopy is usually performed urgently but carries increased risk. Rigid bronchoscopy is preferred because the open-tube instrument ensures an airway and permits several temporizing interventions: the insertion of large suction catheters; tamponade of bleeding or occlusion of the bronchus of the hemorrhaging lung by balloon catheters or blockers; and endobronchial instillation of iced saline, topical vasoconstrictors (e.g., vasopressin, epinephrine), or clot-promoting agents (e.g., thrombin).

Prospective comparisons of the outcomes of surgically and nonsurgically managed patients are unavailable. Controversies about the prognoses of patients with massive bleeding relate to institutional selection factors and the heterogeneity of patients reported in retrospective studies. Conditions associated with extensive lung necrosis and erosion of major vessels (e.g., lung cancer, lung abscess, cavitary tuberculosis, mycotic aneurysms) consistently have exceedingly high mortality (30% to 80%); patients with self-limited, superficial mucosal disease, such as bronchitis, have a good outcome with conservative management ([Fig. 353.3](#)). The overall mortality of life-threatening hemoptysis is about 10% in large, surgically treated populations; 30% in operable, medically supported patients; and 50% in inoperable patients treated medically.

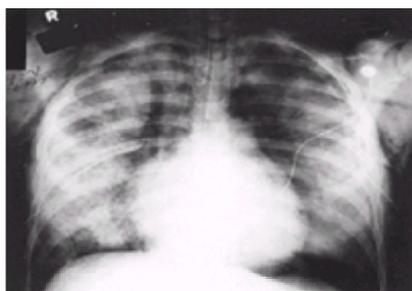

FIGURE 353.3. Diffuse air space filling due to Goodpasture's syndrome in a patient with hemoptysis. (Note the coexisting bilateral pneumothoraces and extensive subcutaneous emphysema due to barotrauma.)

Recurrent bleeding of unpredictable onset is the natural history of massive hemoptysis complicating destructive parenchymal disease. Accordingly, surgical resection of the bleeding site remains the established, definitive approach for operable patients. Estimates of the patient's functional status before the onset of bleeding and, when available, objective pulmonary function measurements are key components of the acute assessment. Once the decision for operative treatment has been made, it is advisable to proceed directly to surgery rather than to risk massive rebleeding.

Surgery is contraindicated when the patient's pulmonary reserve is marginal, when coexisting illness makes operative risks prohibitively high, when the bleeding site is diffuse or unidentified, in the presence of uncontrollable coagulopathy, or when bleeding is caused by unresectable cancer or systemic disease.

Angiographic identification of the vascular source of bleeding provides more active intervention for inoperable patients and is a temporizing option for surgical candidates ([Fig. 353.4](#)). Bleeding vessels may be occluded therapeutically by autologous clot, balloons, or synthetic agents. Cessation of bleeding is often immediate and in up to 75% of patients is definitive. The long-term efficacy of this procedure suggests that interventional angiography has a role as first-line therapy even in operable patients, but more data are needed.

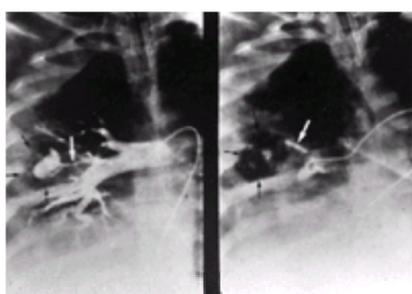

FIGURE 353.4. The pulmonary arteriogram in a patient with life-threatening hemoptysis due to lung abscess demonstrated a mycotic aneurysm (*left*). Bleeding abated after occlusion of the feeding vessel with a silicone balloon (*right*)

Massive bleeding due to systemic or diffuse microvascular disease ([Table 353.1](#)) is approached by treating the primary disorder, rather than by surgery or embolization. Corticosteroids for systemic lupus erythematosus, cyclophosphamide and corticosteroids for Wegener's granulomatosis, and plasmapheresis for Goodpasture's syndrome have successfully controlled bleeding. Emergency mitral valve replacement in patients with mitral stenosis is a classic disease-specific therapy. Pulmonary embolism with infarction or parenchymal hemorrhage may cause hemoptysis but seldom precludes anticoagulation. For severe bleeding in this setting, temporary discontinuation of anticoagulation and insertion of a caval interruption device may be necessary. Development of hemoptysis, pleurisy, and pulmonary infiltrates in leukopenic leukemia patients represents invasive aspergillosis until proven otherwise; the outcome depends on effective antifungal therapy and, even more importantly, on restoration of host defenses by treatment of the primary neoplasm. When hemoptysis complicates penetrating or blunt chest trauma, diagnostic procedures such as percutaneous needle or transbronchial lung biopsies, Swan–Ganz catheterization, or intraoperative accidents, the cause and high risk of bleeding are usually obvious and the management approach is directed by the primary clinical condition.

Several adjunctive measures have been used in patients with hemoptysis, but their efficacy has not been documented. Antitussives and sedatives may diminish cough, but they also compromise airway clearance and must be used cautiously. Empirical antimicrobials are often prescribed for tracheobronchial inflammation, but their benefits are unknown. Radiation therapy has palliated hemorrhage due to unresectable lung cancer and occasionally in patients with mycetomas. Less often, laser photocoagulation has been used to control bleeding from endobronchial tumors.

CHAPTER 354: APPROACH TO THE CRITICALLY ILL PATIENT

LEONARD D. HUDSON AND KENNETH P. STEINBERG

[History of Critical Care Medicine](#)
[Approach to the Critically Ill Patient](#)
[Elements of Critical Care Medicine](#)

Critical care medicine is a relatively new discipline of medicine. The name is self-explanatory: a field of medicine and surgery devoted to care of the critically ill patient—that is, the patient with any illness or injury the nature and severity of which either (a) pose a direct threat to life or (b) place the patient at high risk for complications that are life threatening. This life-threatening nature implies either the high risk or actual presence of single or multiple organ failure. Whether critical care medicine is a distinct discipline has been debated, but the debate is largely a semantic one. Critical care medicine actually involves multiple disciplines, not only in medicine and many of its various subspecialties, surgery, anesthesiology, and pediatrics, but also in nursing and other health care disciplines such as respiratory care, social work, and nutrition. In addition, a body of knowledge in critical care medicine has developed that includes management approaches to the critically ill patient, increased knowledge of particular disease processes that either cause a threat to life or are common complications in the critically ill patient, and specific therapies frequently applied to the critically ill patient (particularly life support measures such as mechanical ventilation and pharmacologic hemodynamic support).

The philosophy of the approach to management of the critically ill patient is similar to that applied to other patients with less severe illnesses, but the circumstances of the critically ill patient dictate certain changes in the way this philosophy is carried out and particularly affect the time frame of diagnosis and therapy. Several implications are discussed here and summarized in [Table 354.1](#).

TABLE 354.1. APPROACH TO THE CRITICALLY ILL PATIENT

Rapid Assessment of Life-Threatening Problems Requiring Immediate Attention and Initiation of Therapy
Rapid directed history, physical examination, and focused laboratory and imaging studies
Full history and physical examination repeated after immediate therapy to life-threatening problems

Therapeutic Decisions and Plans
Definite and clear therapeutic decisions (may be not treat and plan necessary)
Dynamic database (critical database usually incomplete)
Rapidly obtain, repeat, and update laboratory studies
Plan includes specific monitoring
Directed goals for early therapy
Possible adverse effects
Monitor for early and late effects that would lead to changes in therapy
Methods of monitoring and assessing end points and frequency of assessment

Dynamic Management Process
Each treatment decision regarded as a therapeutic trial
Frequent assessment of decisions made in the plan

Approaches of Multiple Problems
Recognize that multiple problems (e.g., multiple organ failure, multiple diseases) are common
Prioritization of treatment of multiple problems or diseases
Assessment of, and adjustment to, plan made accordingly

Prevention of Complications
Prevent complications of the disease process
Recognize complications of the therapy
Apply appropriate procedural complications
Minimize drug interactions
Recognize features of toxicity and factors of sensitive monitoring techniques and antibiotic therapy

TABLE 354.1. APPROACH TO THE CRITICALLY ILL PATIENT

One concept that has developed from the field of critical care medicine is that of multiple organ dysfunction syndrome (MODS), also known as multiple organ system failure. MODS is often a result of a systemic inflammatory process. The severity of the threat to life posed by MODS appears to be greater than the sum of any of its parts; that is, even though each individual organ failure may be potentially reversible, there appears to be a threshold of total number of failing organs (at least in certain clinical settings) beyond which survival is unprecedented. The approach to the critically ill patient with MODS is discussed in detail in [Chapter 355](#).

HISTORY OF CRITICAL CARE MEDICINE

The practice of medicine has always included care of the critically ill patient. However, a body of knowledge dealing specifically with care of critically ill patients evolved since the mid-1960s as critical care units or intensive care units (ICUs) developed across North America. Development of these units paralleled or lagged slightly behind the proliferation of coronary care units, which were devoted to a single-organ problem and especially treatment of a single disease manifestation (acute myocardial infarction). Significant development of early ICUs occurred in the 1960s, and ICUs became commonplace in the 1970s. Currently, 90% of hospitals have an ICU and almost all hospitals with more than 200 beds have at least one ICU. (Whether this high prevalence of ICUs in hospitals of all sizes is justified in this era of managed care and medical cost containment is debatable. Certainly, a case can be made on the basis of cost-effectiveness that fully equipped and staffed ICUs may be warranted only in tertiary referral centers; smaller hospitals may require only the ability and facilities to stabilize and support a patient who is expected to be unstable for a short and finite period or to support a critically ill patient until transfer to a tertiary center can be arranged.)

Growth in the field of critical care medicine paralleled the development of both practical life support systems and procedures and systems for monitoring the function of critical organs. Experience during wartime in the management of military casualties and experience in the management of critically ill civilians were both important factors in the growth of critical care medicine. Experience in caring for critically injured patients in the Vietnam War provided information on managing patients with severe trauma.

Training in critical care medicine developed in several specialties, especially medicine, surgery, anesthesiology, and pediatrics. Means of certifying for special clinical competence in critical care medicine were developed during the 1980s. An attempt was made to form a joint board or certifying test committee, with representatives from the primary boards of those specialties plus representatives from the Society of Critical Care Medicine. The goal of this joint committee was to develop a common procedure and test to certify, for expertise in critical care medicine, all critical care specialists regardless of their primary discipline. Members of this committee could not agree on training eligibility criteria, however, and the committee was disbanded. Subsequently, critical care medicine subspecialty boards or test committees were formed within the American boards of internal medicine, surgery, anesthesiology, and pediatrics. Eligibility criteria have been established for each primary discipline, and each of these primary boards awards certificates for special competence in critical care.

The American Board of Internal Medicine has established two training pathways, following general internal medicine training, that enable the trainee to sit for the examination for critical care medicine: (a) 3 years of combined training in an established subspecialty (usually pulmonary diseases) plus critical care medicine; or (b) 2 years in a critical care medicine training program within a department of medicine. Experience from the early examinations indicates that the most frequently chosen pathway is a combination of pulmonary and critical care medicine training. Two years of critical care medicine fellowship training is the next most common pathway, followed by a relatively small number of applicants with combined training in critical care medicine and a subspecialty other than pulmonary (e.g., cardiology or nephrology).

APPROACH TO THE CRITICALLY ILL PATIENT

Acuity and severity of illness and the potential threat to life markedly affect the approach to management of the critically ill patient compared with the approach to patients with less severe illness. The major effects are on the time frame within which steps in management must occur and the dynamic nature of the management process. Other characteristics exist, including the likelihood of multiple disease or organ problems, but time sequence and the need for frequent reassessment are the major distinguishing characteristics of critical care medicine ([Table 354.1](#)). The common need to institute nearly immediate therapy after rapid assessment of life-threatening problems means that the database on which actions are taken is incomplete. That database is also dynamic; not only is additional information becoming available, but changes are occurring in previously acquired data. After institution of therapy for acute life-threatening problems, the next assessment step, a directed history and physical examination, should be carried out rapidly. This step requires the physician to remember to repeat a full history and physical examination when the immediate dangers to life have been treated.

The approach to the critically ill patient requires that definite therapeutic decisions and plans be made. The therapeutic decision may be to do nothing (other than to carry out certain common supportive measures), but even this decision should be a firm one with a plan for evaluation. The patient's situation and the resulting database are dynamic; therefore, the plan must be flexible. The plan must include elucidation of end points (the desired beneficial effects of therapy as well as

possible adverse effects). Limits for these end points, which would lead to a change in therapy, must be determined, as must means of monitoring the end points. In this way, the monitoring or assessment of the patient is individualized to the patient's specific situation. The dynamic process also requires that reassessment be performed frequently. Again, the frequency of reassessment or monitoring should be tailored to the patient's specific situation. Management of the critically ill patient requires that each treatment decision be thought of as a true therapeutic trial, with frequent reassessment to determine whether the goals of therapy are being achieved or whether adverse effects have occurred. In some cases, lack of change in the patient should be considered an adverse outcome. A critically ill patient who fails to improve over time may be at increasing risk for development of complications and, thus, for higher morbidity and mortality. Even such standard decisions as fluid therapy must be individually tailored and frequently reassessed. For example, fluid orders should not be written for the standard 24-hour period but rather for 4 or 8 hours initially, with reassessment and new orders at the end of those time periods.

Although current practice of critical care medicine involves an understanding of cellular biology (particularly with regard to the systemic inflammation involved in MODS) and molecular biology (especially with certain proposed therapies), evaluation of the patient and of the effects of therapy continues to be based primarily on an understanding of normal physiologic and pathophysiologic processes. The process of monitoring organ function in the critically ill patient is essentially an exercise in practical clinical application of the principles of physiology and pathophysiology. Although many monitoring elements are performed in nearly every case, none of these should be considered routine but rather should be designed to provide information relevant to understanding the physiologic factors specific to the individual patient.

Finally, it must be recognized that the critically ill patient frequently has multiple problems that interact. This interaction may take the form of multiple organ failure, such as acute respiratory distress syndrome coupled with acute renal failure, with the resulting changes in intravascular fluid volume status related to the renal failure having significant effects on the pulmonary condition. Interaction may take the form of more than one disease. For example, many medical ICU patients have a chronic illness with a superimposed acute illness, which leads to worsening organ failure in organs affected by the chronic disease. The more aggressive treatments required may have more profound systemic effects or effects on multiple organs compared with most treatments for less severely ill patients. Finally, drug interactions, both known and unsuspected, are more likely to occur by abnormal drug metabolism related to organ dysfunctions (which also contributes to increased risk).

ELEMENTS OF CRITICAL CARE MEDICINE

Not only does the management of the critically ill patient necessitate a different approach; it also requires that several elements be in place. These elements are listed in [Table 354.2](#). The multidisciplinary nature of the team of caregivers and a functioning system for good communication between the caregivers are perhaps the most essential of these elements. The multidisciplinary approach, with specific roles for each type of health care provider but with a collegial working relationship and interchange between caregivers, must be emphasized. A recent study compares several critical care units and shows that improved patient outcome is related to the relationship between the physicians and nurses. The physician has the responsibility of determining the initial therapy and plan, and synthesizing the dynamic database, as well as the ultimate responsibility for ordering therapy and its evaluation. However, the wise physician includes the nurse's assessment of the patient's condition as one of the most important, perhaps the dominant, element in reassessment and listens carefully to any suggestions from the nurse. The nurse has the professional responsibility of converting many of the therapeutic goals to specific action plans and then implementing those plans. Optimal nursing care includes understanding the physiologic principles of the therapy, as well as the pathophysiology of the disease process, and appropriately questioning the therapeutic plan when the rationale is not clear or understood. Fostering clear communication between the various health care givers as well as between the health care team and the patient or patient's family and friends is extremely important. This includes creating an appropriate environment to encourage free communication, as well as establishing certain times and settings at which communication affecting management decisions is expected. The physical plant is secondary to the knowledge and skill of the critical care health providers but is still important to optimal management.

- Physician specialists in critical care and appropriate consultants available
- Nurse specialists in critical care
- Health care professionals with expertise in critical care, including respiratory care practitioners, social workers, physical therapists, nutritionists, and spiritual and emotional support staff
- Physical plant
- Monitoring Systems: necessary knowledge, equipment, and experience to obtain and interpret monitoring data on hemodynamic, respiratory, central nervous, and other systems
- Life Support Systems: ventilatory and oxygenation support; dialysis and hemofiltration; cardiovascular support, including pacemaking, cardiopulmonary resuscitation, and pharmacologic and mechanical hemodynamic support; and nutritional support
- Systems for Effective Communication: Communication among all health care providers, especially between physicians and nurses, and between critical care teams and patient and patient surrogates
- Means of resolving conflicts: medical issues and medical/ethical dilemmas

TABLE 354.2. ELEMENTS OF CRITICAL CARE MEDICINE

Bioethical dilemmas or problems appear to be more common, or at least more dramatic, in the management of the critically ill patient, probably because of the life-or-death nature of many of the decisions involved. It is important that the entire critical care team be alert to these issues and that a consistent approach to identification of problems and to possible resolution be maintained. If there is a willingness to understand various viewpoints, clear communication, and sufficient time, most problems can be managed to the satisfaction of all parties involved. Occasionally, however, ethical dilemmas arise involving conflicts of values that cannot be resolved in this manner. When conflicts arise, either between health care providers or between the critical care team and the patient or—more often—the patient's surrogate, a means of resolution (or frequently several alternative means) should be available. An approach to medical ethical issues is discussed further in [Chapter 2](#).

CHAPTER 355: MANAGEMENT OF THE CRITICALLY ILL PATIENT WITH MULTIPLE ORGAN DYSFUNCTION

PAUL M. DORINSKY AND MICHAEL A. MATTHAY

[Definition and Epidemiology](#)
[Pathogenesis](#)
[Management of the Patient with Multiple Organ Failure](#)
[Early Recognition and Prevention of Multiple Organ Failure](#)

One of the earliest descriptions of multiple organ failure, now referred to as the multiple organ dysfunction syndrome (MODS), has been credited to Baue in an editorial that he wrote in 1975:

The sequence of events often begins with a period of shock or circulatory failure at some point during the initial injury, accompanied sooner or later by failure of ventilation and the need for ventilatory support. This may be followed by renal failure, hepatic failure (jaundice and decreasing albumin levels), gastrointestinal (GI) failure (stress ulcers and GI bleeding), and metabolic failure (decrease in lean body mass and weakness due to progressive catabolism). Our ability to support a single system that has failed, transiently at least, is reasonably good. The support of two or more failed units, however, stresses our knowledge and capability. Survivors of multiple systems failure are infrequent.

Since this description was published, a number of medical and surgical studies have reported a high mortality rate associated with MODS in critically ill patients. Sepsis syndrome is clearly the most frequently encountered clinical problem associated with the development of MODS. Some patients, however, develop MODS and do not seem to have a clear-cut infectious cause. The best support for this possibility comes from data in studies of patients treated with interleukin-2 for malignant disorders. These patients frequently develop renal failure, GI failure, neurologic disturbances, and sometimes even acute respiratory failure. These observations suggest that release of potent endogenous humoral factors during noninfectious disorders (e.g., severe hypovolemic shock) may produce the clinical manifestations of the sepsis syndrome without necessarily being related to infection. Finally, primary lung injury itself can lead to the development of MODS. In any case, sepsis often complicates MODS even if sepsis is not the initial clinical disorder.

In the first part of this chapter, the definition and epidemiology of MODS are discussed with an emphasis on specific guidelines for defining the failure or dysfunction of the respiratory, cardiovascular, renal, hepatic, central nervous, and hematologic systems. In the second part, the pathogenesis of MODS is considered. In the third part, guidelines are provided for the management of patients with MODS, with an emphasis on practical issues related to therapy with fluids, colloid, blood, and vasoactive agents as well as anti-inflammatory agents. In the final section, the prevention and early recognition of MODS and sepsis syndrome are discussed.

DEFINITION AND EPIDEMIOLOGY

Multiple organ dysfunction syndrome refers to the pattern of altered organ function that occurs in acutely ill patients, especially patients with shock from sepsis, major trauma, severe pancreatitis, drug overdose, or thermal injury. The extent to which an individual organ is likely to be damaged in these clinical settings depends on numerous factors, including age, preexisting medical illnesses, severity of illness on admission to the intensive care unit (ICU), and the specific precipitating event. However, it is clear that organ dysfunction affects overall mortality, especially when the organ dysfunction is present before the patient is admitted to the intensive care unit. In fact, one recent study demonstrated that the presence of systemic organ dysfunction before ICU admission was one of the most significant predictors of nonsurvival for acute lung injury (ALI) patients.

The clinical manifestations of organ dysfunction in this patient group are also variable and have been defined by different criteria. Specifically, organ dysfunction in acutely ill patients ranges from minor biochemical abnormalities to irreversible organ failure. Nonetheless, the incidence of cardiac, renal, GI, hepatic, central nervous, and hematologic system failure has been studied especially in patients with acute respiratory failure. The definition and incidence of acute respiratory failure are discussed later in this chapter, after the criteria for failure of the nonpulmonary organ systems have been considered.

CARDIOVASCULAR DYSFUNCTION

The incidence of cardiovascular failure among critically ill patients varies from approximately 10% to 23%. Although a uniform definition in critically ill patients has not been established, most clinicians agree that cardiovascular failure exists when one or more of the following factors are present: (a) mean arterial pressure of 60 mm Hg or less; (b) cardiac index of 2.0 L per minute per square meter or less; or (c) reversible ventricular fibrillation or asystole. This definition could include a patient with an acute myocardial infarction and severe pump failure. However, it could also include a patient with septic shock who has high cardiac output, low systemic vascular resistance, and low mean arterial blood pressure. Cardiovascular failure therefore includes those disturbances that cause a major decrease in myocardial function as well as those clinical disorders associated primarily with abnormalities in the peripheral circulation.

Among the various critical illnesses that may present clinically with cardiovascular failure, the myocardial dysfunction that occurs with sepsis has been the most thoroughly investigated. Although human septic shock is usually characterized by elevated cardiac output and reduced systemic vascular resistance, it is also associated with a decrease in the left ventricular ejection fraction. In addition, recent studies have shown that septic patients have increased left ventricular end-systolic and end-diastolic volumes, normal or decreased stroke work, and decreased right ventricular ejection fraction. Among patients who survive, these cardiovascular parameters normalize.

The mechanism of myocardial dysfunction during sepsis is not entirely known. Nonetheless, serum obtained from patients with septic shock has been shown to depress myocardial cell contractility in vitro. Moreover, evidence suggests that tumor necrosis factor (TNF), an important humoral mediator of sepsis, is capable of depressing myocardial cell contractility. It is likely that one or more of these myocardial depressant substances is responsible for the reduction in ejection fraction and the ventricular volume changes that occur during sepsis.

Given the complexities associated with the diagnosis and management of cardiovascular dysfunction in acutely ill patients, the use of right heart catheterization has become routine for many physicians caring for ICU patients. However, a recent prospective study suggested that the use of right heart catheters was associated with both an increase in 30-day mortality (odds ratio = 1.24; 95% confidence interval = 1.03 to 1.49) and resource utilization. Although this study has been widely criticized on the basis of its design and conclusions, it has stimulated an intense dialogue on the role of these catheters in acutely ill patients. In addition, it has served as a catalyst for an upcoming, prospective, National Institutes of Health (NIH)-sponsored study on the role of right heart catheterization in the management of critically ill patients.

RENAL DYSFUNCTION

Renal dysfunction is a common complication in critically ill patients (40% to 55% incidence) and is manifested by reductions in urine output or a rise in the serum blood urea nitrogen and creatinine. Specifically, renal failure may be defined in this patient group as a serum creatinine in excess of 2 mg per deciliter, a urine output below 600 mL per 24 hours, or both.

The three most important risk factors for the development of renal failure in critically ill patients are hypotension, sepsis, and nephrotoxic drugs. Acute nonoliguric renal failure associated primarily with nephrotoxic drugs has a better prognosis than acute oliguric renal failure that occurs with septic shock or following major cardiovascular surgery.

GASTROINTESTINAL DYSFUNCTION

Alterations in GI tract function are estimated to occur in 7% to 30% of critically ill patients. The pathologic basis for GI dysfunction appears to be both an alteration in microvascular permeability and mucosal ischemia. For example, TNF causes necrosis of intestinal villi when infused into experimental animals. These morphologic

observations suggest a pathologic basis for the functional abnormalities of the GI tract that occur in critically ill patients.

The clinical manifestations of GI tract dysfunction are variable and include hemorrhage, ileus, malabsorption (e.g., inability to tolerate enteral feedings), and, occasionally, acalculous cholecystitis or pancreatitis. Among these complications, GI blood loss in excess of 1 g per deciliter of hemoglobin per 24 hours is generally accepted as clinically significant.

An intact GI tract mucosa provides an essential barrier to the entry of bacteria into the systemic circulation. Because GI mucosal integrity is frequently impaired in critically ill patients, bacterial growth may be increased in areas of bowel that are normally sterile. In addition, bacteria may translocate or migrate from the bowel lumen into the peritoneal cavity, regional lymph nodes, and the portosystemic circulation. To the extent that this migration occurs, the process of bacterial translocation may propagate septic shock and result in further lung and systemic organ injury.

Clinical data in support of a central role for the GI tract in the pathogenesis of MODS in acutely ill patients is increasing. In this regard, marked alterations in GI permeability were demonstrated to occur in a prospectively studied group of ICU patients using monosaccharide and disaccharide probes. Perhaps even more significant, however, was the observation that the patients who developed MODS had significantly greater alterations in intestinal permeability upon ICU admission than those who did not ultimately develop MODS. Taken together, these observations suggest that altered GI tract function plays an important if not a central role in the pathogenesis of MODS in critically ill patients.

HEPATIC DYSFUNCTION

Fulminant hepatic failure is uncommon in critically ill patients and occurs in less than 10% of these patients. By contrast, reversible elevations in serum transaminases or elevations in serum bilirubin or clotting parameters are common and may be found in as many as 95% of critically ill patients. Criteria for hepatic dysfunction in critically ill patients are in a state of evolution. Nonetheless, elevation in serum bilirubin that exceeds 4 to 5 mg per deciliter, a prothrombin time that is greater than 1.5 times control, or a serum albumin that is below 2.0 g per deciliter is indicative of significant hepatic dysfunction.

As a complication of septic shock or other critical illnesses, hepatic dysfunction is of more than academic interest. The liver is an important reticuloendothelial organ, the function of which is also altered when the liver is damaged. In this context, there is compelling clinical evidence in support of the notion that liver dysfunction is a major determinant of survival in patients with ALI. For example, it has been shown that mortality from septic shock approaches 100% in patients with severe hepatic damage. Likewise, when hepatic failure occurs in the setting of acute respiratory failure, the prognosis for recovery from the ALI is exceedingly poor. Thus, evidence is accumulating to suggest the various systemic organs are not merely targets of damage during critical illnesses. Rather, once these organs are damaged, they have a substantial impact on host defense, the propagation of injury to other organs, and survival.

CENTRAL NERVOUS SYSTEM DYSFUNCTION

Abnormalities of central nervous system (CNS) function are frequently described in critically ill patients. For example, CNS dysfunction, including disorientation, confusion, agitation, obtundation, and seizures, occurs commonly in septic patients. One study reports a 9% incidence of CNS dysfunction, defined as an inability to follow simple commands, in 106 patients with intra-abdominal sepsis. By contrast, another recent study, using an altered sensorium as the criteria for CNS dysfunction, reports a 33% incidence of CNS abnormalities in sepsis.

Use of the Glasgow Coma Scale helps to provide a more uniform, standard approach to defining CNS function. The scale provides a measurement of visual, motor, and verbal (e.g., orientation) responsiveness ([Table 355.1](#)). The Glasgow Coma Scale can be used in intubated patients; the CNS function is considered abnormal in critically ill patients with a score of less than 6 to 8 (maximal score = 15). Using these criteria, abnormalities of CNS function have been found to occur in 7% to 30% of critically ill patients. The factors that underlie CNS dysfunction in this patient population are unclear but may include the production of false neurotransmitters, direct microvascular injury, or brain ischemia from global or regional reductions in cerebral blood flow.

Parameter	Score
Eye Opening	
Spontaneous	4
To speech	3
To pain	2
None	1
Motor Response	
Obeys verbal commands	6
Responds appropriately to painful stimuli (localizes pain)	5
Withdraws to pain (e.g., flexion withdrawal)	4
Decorticate posturing	3
Decerebrate posturing	2
No response	1
Verbal Responses	
Oriented and conversant	5
Disoriented but conversant	4
Inappropriate response	3
Incomprehensible sounds	2
No response	1

TABLE 355.1. GLASGOW COMA SCALE

HEMATOLOGIC DYSFUNCTION

The frequency of hematologic abnormalities among critically ill patients ranges from approximately 0% to 26%. There is little clinical consensus, however, regarding the definition of hematologic failure in this patient group. A number of parameters, including platelet count, white blood cell count, fibrinogen levels, and coagulation parameters, have been used to assess the adequacy of the hematologic system in these patients. Despite some differences, most clinical studies employ criteria that include a platelet count of 50,000 per cubic millimeter or fewer, a white blood cell count of 1,000 per cubic millimeter or fewer, or a fibrinogen level below 100 mg per deciliter to define hematologic failure. Obviously, the presence of severe neutropenia decreases host resistance to infection, whereas thrombocytopenia increases the risk of bleeding and the need for transfusion of blood products.

ACUTE RESPIRATORY FAILURE

The incidence of acute respiratory failure in critically ill patients varies considerably depending on the criteria used to define failure of the respiratory system. Although the term *acute respiratory disease syndrome* (ARDS) has been very useful for designating the clinical syndrome, a more quantitative definition has been needed. A recent North American–European consensus conference proposed a simplified, uniform definition of ALI and ARDS. Acute lung injury is defined as that existing in a patient with a $\text{PaO}_2/\text{FIO}_2$ less than 300 with chest radiographic evidence of bilateral pulmonary infiltrates. Exclusion criteria include the presence of interstitial lung disease or left ventricular failure assessed by history, physical examination, or laboratory criteria. As previously noted, the role of right heart catheterization in the management of patients with ARDS is controversial and will be the subject of an upcoming, NIH-sponsored clinical trial. However, at the present time it appears prudent to recommend that a pulmonary arterial catheter be inserted only when it is clinically necessary to determine if the patient has a pulmonary arterial wedge pressure less than 18 mm Hg.

ARDS is defined with the same criteria as ALI except the $\text{PaO}_2/\text{FIO}_2$ ratio is less than 200. As such, the distinction between ALI and ARDS is based entirely on the severity of the gas exchange alterations. The clinical relevance of this distinction remains to be proven. Nonetheless, the notion that the distinction between ALI and ARDS may not be relevant was underscored by a recent study in which the overall mortality in medical patients with ALI was 58% and was identical to the mortality in the subset of these patients who had ARDS.

A quantitative scoring system for assessing ALI has also been used to evaluate the severity of lung injury ([Table 355.2](#)). This system is based on the severity of hypoxemia and the extent of infiltrates on the chest radiograph. If the patient is mechanically ventilated, abnormalities in the compliance of the lungs and the level of positive end-expiratory pressure are also scored. Using these criteria, patients can be classified as having mild, moderate, or severe lung injury.

System	Component	Points
Cerebral Dysfunction	PaCO ₂ > 50 mmHg	4
	PaO ₂ < 60 mmHg	4
	PaO ₂ < 80 mmHg	2
	PaO ₂ < 100 mmHg	1
Respiratory Dysfunction	PaO ₂ /FiO ₂ < 300	4
	PaO ₂ /FiO ₂ < 400	2
	PaO ₂ /FiO ₂ < 500	1
	PaO ₂ /FiO ₂ < 600	0
Cardiac Dysfunction	MAP < 65 mmHg	4
	MAP < 75 mmHg	2
	MAP < 85 mmHg	1
	MAP < 95 mmHg	0
Renal Dysfunction	Cr > 2.0 mg/dL	4
	Cr > 3.0 mg/dL	2
	Cr > 4.0 mg/dL	1
	Cr > 5.0 mg/dL	0
Hematologic Dysfunction	Hb < 7 g/dL	4
	Hb < 8 g/dL	2
	Hb < 9 g/dL	1
	Hb < 10 g/dL	0
Gastric Dysfunction	pH < 7.35	4
	pH < 7.45	2
	pH < 7.55	1
	pH < 7.65	0
CNS Dysfunction	PaO ₂ < 60 mmHg	4
	PaO ₂ < 80 mmHg	2
	PaO ₂ < 100 mmHg	1
	PaO ₂ < 120 mmHg	0

TABLE 355.2. COMPONENTS OF THE ACUTE LUNG INJURY SCORE^a

SPECIAL CONSIDERATIONS

Although not unique to any particular organ system, a number of serious problems exist with respect to MODS. Because there is a general lack of consensus regarding the criteria for individual organ system failure, the incidence of organ failure is variable among different study centers and contributes to the general confusion in this area. Until more uniform criteria are established, the true incidence and natural history of MODS remains unclear. The new criteria for ALI and ARDS, discussed previously, are a good example of progress in this area. Prospective studies of these criteria and definitions of liver, renal, gastric, hematologic, cardiac, and CNS dysfunction are needed.

Despite the current uncertainties, a number of important issues regarding MODS in critically ill patients have been resolved. First, the number of involved organ systems impacts significantly on patient mortality. Mortality for a single-organ failure ranges from 15% to 30% and for two-organ failure from 45% to 55%. By contrast, mortality exceeds 80% when three or more organ systems fail and reaches 100% if the MODS persists beyond four hospital days. Second, certain organ systems (e.g., heart, kidney, lung, and liver) are involved more frequently than other organ systems. Third, the presence of organ dysfunction before a patient is admitted to the ICU is a major predictive factor for nonsurvival in patients with ALI. Finally, early detection and treatment of the underlying cause of the MODS may offer the best hope for treatment of this potentially fatal disorder.

PATHOGENESIS

Multiple organ dysfunction syndrome occurs in a variety of clinical settings, including infection, severe hypotension, and multiple trauma. Prototypic among the risk factors for MODS is septic shock. Moreover, evidence is accumulating to suggest that MODS during sepsis and other critical illnesses is caused by widespread organ injury that in turn is caused by activated inflammatory cells and a variety of humoral mediators. However, any theory regarding the pathogenesis of MODS during sepsis or other acute, catastrophic illnesses must take into account the abnormalities in systemic gas exchange that occur in these disorders and manifest as an abnormal relation between oxygen uptake (VO₂) and oxygen delivery (DO₂).

As illustrated in Fig. 355.1, whole-body oxygen uptake is normally maintained at a constant level over wide ranges of oxygen delivery. This is accomplished by means of local compensatory mechanisms, which include increases in oxygen extraction and increases in recruitable capillary reserves (the cross-sectional area of perfused capillaries within an individual organ). Once these mechanisms for the preservation of oxygen uptake are exhausted, V O₂ falls in a manner that is directly related to the reductions in oxygen delivery. The level of oxygen delivery below which oxygen uptake begins to fall is termed D O_{2c} (critical threshold for oxygen delivery), and it signifies the level of DO₂ below which oxygen supply–demand imbalances exist.

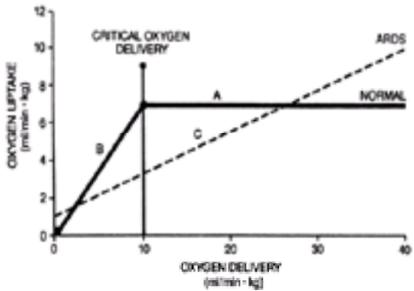

FIGURE 355.1. Oxygen uptake–oxygen delivery (VO₂–QO₂) relation in normal subjects and in patients with ARDS. V O₂ is regulated by whole-body metabolic demand and is normally constant over a wide range of Q O₂ values (line A). Constancy is accomplished by local compensatory mechanisms, including increases in oxygen extraction and increases in the cross-sectional density of perfused capillaries. Once these compensatory mechanisms are exhausted, further reductions in Q O₂ are accompanied by reductions in VO₂ (line B). The QO₂ below which VO₂ begins to decrease is termed the critical threshold for Q O₂ (QO_{2c}). In contrast to the normal situation, VO₂ is dependent on QO₂ at nearly all levels of QO₂ in ARDS. This finding indicates that an oxygen supply–demand imbalance exists at all levels of Q O₂ in ARDS patients. ARDS, acute respiratory distress syndrome. (From Dorinsky PM, Gadek JE. Mechanisms of multiple nonpulmonary organ failure in ARDS. *Chest* 1989;96:885–892, with permission.)

In contrast to the situation described for the normal VO₂–DO₂ relationship, the relation between VO₂ and DO₂ in critically ill patients is often markedly altered. For example, in many critically ill patients, VO₂ is dependent on DO₂ at nearly all levels of oxygen delivery, including levels that would normally be more than adequate to meet tissue metabolic demands. These abnormalities indicate that oxygen supply–demand imbalances may exist at all levels of D O₂ in these patients.

In recent years, the concept that the VO₂–DO₂ relationship is altered in the critically ill patient has been challenged. In particular, whether V O₂ is calculated using the Fick equation [VO₂ = cardiac output × (A – VO₂ content difference)] or measured using a metabolic cart may affect whether or not an abnormal VO₂–DO₂ relationship is observed in these patients. The explanation for differences in measured versus calculated V O₂–DO₂ is not intuitively obvious. However, when both VO₂ and DO₂ are calculated, it is believed that an artifactual mathematical coupling occurs because both V O₂ and DO₂ share the variables of cardiac output and arterial oxygen content. This problem may be avoided by measuring VO₂ directly, using a metabolic cart. However, in some studies, an abnormal relationship between V O₂ and DO₂ was observed whether or not VO₂ was measured using a metabolic cart or calculated using the Fick equation. As such, criticisms of the method by which V O₂ was determined do not negate the concept that VO₂–DO₂ relationships can be altered in the setting of sepsis or ALI—a fact that has been well established experimentally. Rather, these observations underscore the notion that whole-body VO₂–DO₂ relations in humans may be unreliable and that a better method for assessing oxygenation in individual tissues needs to be established.

Despite remaining uncertainties, a number of mechanisms exist that may explain both the nonpulmonary organ failure and the V O₂–DO₂ abnormalities that occur in this patient population. These mechanisms may be divided into two broad categories: (a) altered blood flow distribution and (b) endothelial or parenchymal injury.

ALTERED BLOOD FLOW DISTRIBUTION

Oxygenated blood that bypasses nutrient capillary beds could alter V_{O_2} - DO_2 relationships and cause organ damage. This sequence of events may result from (a) a redistribution of cardiac output to organs with inherently low O_2 extraction fractions (e.g., skeletal muscle), (b) an increase in the fraction of cardiac output that bypasses nutrient capillaries through anatomical, precapillary arteriovenous channels (e.g., shunt flow), (c) local blood flow heterogeneities such that tissue oxygen supply and demand are unbalanced, or (d) a reduction in recruitable capillary reserves that would prevent effective compensation for reductions in oxygen supply.

ENDOTHELIAL OR PARENCHYMAL INJURY

Endothelial injury may be accompanied by local edema formation, with subsequent increases in diffusion distances for oxygen or reductions in capillary surface area (e.g., reduced recruitable capillary reserves), or both. Alternatively, direct parenchymal cell injury may impair O_2 use at any level of oxygen delivery by impairing cellular oxidative metabolism.

POSSIBLE MECHANISMS OF INJURY

Little direct experimental evidence supports the hypothesis that either MODS or the systemic V_{O_2} - DO_2 abnormalities in ARDS, septic shock, and other critical illnesses are caused by primary alterations in the distribution of cardiac output (e.g., increased anatomical shunt flow or increased blood flow to organs with low O_2 extraction). By contrast, evidence indicates that nonpulmonary organs sustain significant structural and functional damage in these disorders, including alterations in individual organ V_{O_2} - DO_2 matching.

The best studied experimental model for MODS has been septic shock, produced either by live bacterial organisms or by endotoxin. Bacteria or bacterial products have a variety of direct effects on endothelial cells. For example, structural studies of endothelial monolayers exposed to endotoxin show that these cells undergo contraction, become pyknotic, and finally die.

Endotoxin or live bacteria can also induce the release of a variety of mediators that can cause cell injury. Considerable experimental evidence indicates that both cyclooxygenase and lipoxygenase products of arachidonic acid metabolism participate in the hemodynamic, pathologic, and metabolic derangements that occur during sepsis. Also, complement is activated in sepsis. In one study, the elevated levels of a C5a derivative correlated with the severity of hypotension and metabolic acidosis. There has also been considerable recent interest in the possible role of cytokines (e.g., TNF) in mediating systemic organ injury. In one recent study, anti-TNF antibodies prevented in rabbits the development of endotoxin-mediated hypotension, fibrin deposition, and death. In addition, anti-TNF antibody prevented shock and death in baboons given live *Escherichia coli* organisms, but only when given 2 hours before the bacteremia.

Many studies (but not all) report a central role for neutrophils in mediating both the systemic and pulmonary injury from bacteria or endotoxin. In recent animal studies, a monoclonal antibody to the adherence-promoting leukocyte glycoprotein CD18 prevented systemic organ injury after acid-induced ALI and reduced systemic organ injury from hemorrhagic shock and improved survival. Although many schemes have been proposed to explain the mechanism by which neutrophils cause tissue injury, recent work suggests that there may be important interactions between elastases and toxic oxygen radicals elaborated by neutrophils.

Finally, evidence from several sources suggest that there is a link between the organ injury that occurs during sepsis and other critical illnesses and the V_{O_2} - DO_2 alterations that occur in these settings. It has generally been presumed that the mechanism for the altered V_{O_2} - DO_2 relationships in these disorders is insufficient delivery of oxygen to metabolically active tissues. However, altered oxygen metabolism, especially during sepsis, cannot be totally accounted for by this proposed mechanism. This may explain the fact that several clinical trials have shown that augmentation of oxygen delivery in the setting of established sepsis or ALI failed to reduce mortality and in some studies actually increased mortality. This apparent clinical paradox may be reconciled by a hypothesis that proposes that both organ injury and VO_2 - DO_2 alterations during sepsis and other critical illnesses are the result of mitochondrial injury. Experimental data in support of this notion is increasing. However, future studies are needed to more definitively address the validity of this compelling hypothesis.

MANAGEMENT OF THE PATIENT WITH MULTIPLE ORGAN FAILURE

Critically ill patients at risk for developing MODS generally present with one or more of the following clinical signs: shock (hypovolemic, cardiac, or septic), acute respiratory failure, or a major alteration in mental status. These clinical problems initially require a prompt therapeutic response to stabilize the patient. In general, initial management is directed to maintaining an adequate blood pressure and supporting gas exchange. For example, patients who present with hypovolemic shock, either from trauma or from GI bleeding, require rapid intravascular volume expansion with blood and crystalloid or colloid. Likewise, patients who have severe alterations in mental status with failure to protect the airway or progressive respiratory failure require prompt endotracheal intubation and mechanical ventilation. It is very important that the physician caring for critically ill patients recognize that the initial priority must be to stabilize the patient's circulatory and respiratory status. For example, the decision to insert a pulmonary arterial catheter should not take precedence over initial management of hypotension and respiratory failure. Once the patient is stabilized and appropriate support given to the circulatory and respiratory systems, careful assessment of the likely cause of the patient's condition should then be undertaken.

A logical starting point in evaluating critically ill patients is a search for the usual causes of shock, which include sepsis, cardiac failure (especially acute myocardial infarction), GI bleeding, acute pancreatitis, drug overdose, and occult bleeding from recent trauma. The physician, however, must always maintain a high index of suspicion for the presence of septicemia and should have a low threshold for obtaining blood cultures and appropriate cultures of other possible sources of infection. In addition, patients with even presumptive evidence for infection should be promptly placed on broad-spectrum antibiotics. General supportive measures have been discussed; the remainder of this section addresses specific issues related to support of the circulatory system and the respiratory system, as well as longer term measures, including appropriate support of the patient's nutritional status. The primary emphasis is on patients with sepsis and acute respiratory failure. Management of shock associated with acute myocardial infarction is covered in [Chapter 73](#).

GUIDELINES FOR FLUID THERAPY

Except for patients with acute blood loss, who need blood transfusion to maintain the hematocrit between 25% and 35%, most patients need crystalloid or colloid therapy. At the present time, most medical and surgical centers favor the use of crystalloid over colloid for volume expansion. This preference is based in part on the ability of crystalloid (unlike colloid) to restore both the intravascular and the interstitial component of the extracellular fluid space. Some physicians do administer colloid in an attempt to maintain circulating plasma protein osmotic pressure; however, large volumes of colloid are often needed to achieve this objective, and the clearance of an infused protein from the intravascular space is usually quite rapid. Despite the advantages of crystalloid versus colloid, red blood cells remain the ideal volume expander because they both increase oxygen transport to the tissues and maintain intravascular volume.

The timing of fluid resuscitation in hypotensive patients with acute blood loss has been examined recently. One study concluded that a delay of aggressive fluid resuscitation until surgical intervention improves outcome in patients with shock from penetrating injuries to the torso. These results, however, need to be confirmed in other medical centers before they can be accepted as optimal guidelines for the timing of fluid resuscitation.

In general, the appropriate fluid therapy depends on the cause of the patient's shock. For the patient with an acute myocardial infarction, fluid replacement should be titrated to maintain the pulmonary arterial wedge pressure between 15 and 20 mm Hg. By contrast, for patients with hypovolemic shock, traumatic shock, or septic shock, an increase in the central venous pressure or pulmonary arterial wedge pressure to 15 to 20 mm Hg may not be optimal. For example, in one study that examined volume resuscitation in patients with septic shock, the investigators found that increases in pulmonary arterial wedge pressure beyond 11 to 12 mm Hg did not result in a higher cardiac output.

Ideally, optimal fluid resuscitation in any form of shock should include the restoration of euvolemia; however, euvolemia is often difficult to define in critically ill patients. In addition, the adjustment of fluid therapy depends on the use of vasoactive agents, a topic discussed in the next section. Finally, although invasive hemodynamic monitoring with a pulmonary arterial catheter is frequently used to assist in the management of patients with septic shock, there is no evidence that this kind of monitoring changes outcome. Given these uncertainties, the best indexes for evaluating fluid replacement therapy are the patient's acid-base status, mental status, skin perfusion, and, perhaps most importantly, urine flow and renal function.

VASOACTIVE AGENTS

The most useful vasopressor for treating patients with septic shock is dopamine. Dopamine improves cardiac output via a positive chronotropic effect, an increase in preload to the heart, and an increase in contractility. This agent is particularly efficacious in septic shock because it both increases cardiac output and improves blood flow to the kidneys when given at doses below 10 µg per kilogram per minute. Moreover, dopamine, in contrast to fluid replacement therapy, has the additional advantage of increasing the cardiac output without increasing the pulmonary arterial wedge pressure. Finally, dopamine, unlike dobutamine, does not cause vasodilatation, thus making it preferable in shock caused by factors other than primary cardiac failure.

In some patients, septic shock will be unresponsive to even high doses of dopamine. In these patients, norepinephrine can be added to provide an increase in systemic arterial pressure. Epinephrine is another catecholamine that can be used for blood pressure support in severe septic shock. In doses greater than 10 µg per minute, epinephrine causes primarily a stimulation. High doses of any of these potent vasopressors cause vasoconstriction that may maintain systemic blood pressure, but blood flow to the kidneys, the splanchnic bed, muscles, and skin may be markedly reduced.

It is often difficult to determine the level of mean arterial pressure or cardiac output that is optimal in septic shock. In general, our recommendation is to try to adjust the mean arterial pressure and cardiac output to a level that stabilizes the metabolic acidosis associated with sepsis and improves tissue perfusion, particularly as indicated by urine flow. However, some patients with severe septic shock will require very high doses of dopamine, norepinephrine, or epinephrine to maintain even a barely adequate blood pressure.

In most patients, vasodilator therapy is not appropriate in the setting of septic shock. In a minority of cases, patients with primary cardiac disease may present with hypotension and an elevation of systemic vascular resistance associated with septicemia. These patients may benefit from dobutamine and, occasionally, from low doses of afterload reduction with a vasodilator, such as nitroprusside or nitroglycerin. With the exception of these patients, the use of vasodilators in the setting of multiple organ dysfunction and septic shock remains experimental.

ANTI-INFLAMMATORY AGENTS

A large number of animal model studies have demonstrated the potential value of various anti-inflammatory agents for the treatment of septic shock. In many of these studies, however, the pharmacologic agents were effective only for prevention, not as treatment. A recent multicenter trial of the prostaglandin inhibitor ibuprofen showed no benefit on reducing mortality in patients with sepsis. Also, ibuprofen treatment had no effect on the incidence of ARDS from sepsis. Thus, there are no clinically proven anti-inflammatory agents that decrease morbidity or improve mortality in patients with ARDS, septicemia, or MODS.

Corticosteroids had been used for a number of years in the management of patients with septicemia and ARDS, based largely on the unproven clinical impression that they might be beneficial. In the last few years, however, a number of prospective, well-controlled studies have demonstrated that corticosteroids are of no therapeutic value in patients with either septic shock or ARDS. Specifically, these clinical studies demonstrate that corticosteroids do not prevent the development of ARDS in patients with sepsis, nor do they prevent MODS, and they have no favorable effect on mortality.

IMMUNOTHERAPY

The most promising new therapeutic approach for the treatment of sepsis derives from recent studies using immunotherapy plus antibiotics. In two clinical trials, administration of hyperimmune sera to *E. coli* was given to patients with gram-negative bacteremia or to patients at risk for gram-negative bacteremia. In both studies there was a substantial decrease in morbidity and mortality. These two studies marked the beginning of an era of immunotherapy for ARDS, sepsis, and MODS. Since that time, numerous immunotherapeutic agents have been developed, synthesized, and tested in large, multicenter clinical trials ([Table 355.3](#)). The results of most studies that involve these agents have been reviewed. Unfortunately, none of these agents have been shown to prevent MODS or to improve outcome in patients with ARDS or sepsis. Perhaps as our ability to identify patients with ARDS or sepsis earlier in their clinical course improves, so too will the efficacy of these innovative immunotherapeutic agents.

Immunotherapeutic Agent	Site of Action	Outcome in Animals	Status and Outcome of Clinical Trials
HA-III	LPS	Efficacious in most	Completed
ES	LPS	Efficacious	Completed, No benefit
TNF mAb	TNF	Efficacious	Completed, No benefit
I-1 RA	I-1 receptor	Efficacious	Completed, No benefit
I-6 mAb	I-6	Efficacious	Completed, No benefit
I-8 mAb	I-8	Efficacious	Pending
mAb 62.3	CD11c/CD18	Efficacious	Planned
BP	LPS	Efficacious	Pending
TF mAb	TF	Efficacious	Planned

LPS, lipopolysaccharide; TNF, tumor necrosis factor; mAb, monoclonal antibody; I-1, RA, interleukin-1 receptor antagonist; I-1, interleukin-1; I-6, interleukin-6; I-8, interleukin-8; BP, bactericidal permeability increasing factor; TF, tissue factor.

TABLE 355.3. IMMUNOLOGIC THERAPY FOR MODS

ANTIBIOTICS

Selection of appropriate antibiotics for patients with septic shock and MODS is very important. In general, a careful search for the likely source of sepsis should be undertaken and then appropriate broad-spectrum antibiotics instituted. Although antibiotic therapy is an important part of the treatment of patients with confirmed or suspected septic shock, the guidelines for specific selection of antibiotics are covered in [Chapter 335](#).

NUTRITIONAL SUPPORT

Nutritional and metabolic support is an essential part of the management of patients with MODS. Hypermetabolism develops early in the syndrome, and severe malnutrition can become a prominent feature within days after the onset of illness. The characteristics of the hypermetabolic state include (a) increased resting energy expenditure and oxygen consumption, (b) increased use of carbohydrate, fat, and amino acids as energy substrates, and (c) increased loss of nitrogen in the urine. The hypermetabolic state results in profound protein catabolism, which is associated with a decrease in total body protein synthesis. The mechanism for the alteration of metabolism observed in patients with multiple organ failure appears to be related to the inflammatory mediators and the hormonal response to injury. Unfortunately, these fundamental alterations in metabolism do not appear to be readily altered by therapy. If adequate nutritional support is not provided, however, it is likely that organ dysfunction will be accelerated.

The goal of nutritional support in patients with, or at risk for, MODS is to prevent substrate-limited metabolism and to support, rather than attempt to alter, the hypermetabolism (see [Chapter 130](#) for a detailed discussion of nutritional support).

In general, nutrition should be provided by the enteral route whenever possible. Enteral feedings eliminate cholestasis and reduce the risk of acalculous cholecystitis. Enteral alimentation may also offer some protection against GI hemorrhage in mechanically ventilated patients.

For patients who cannot tolerate enteral feeding, parenteral nutrition is a viable therapeutic alternative. The standard regimens of hyperalimentation, however, may not meet metabolic needs and can actually be harmful. Improved support can usually be achieved by decreasing the caloric and glucose load and by increasing the load of protein. For example, a regimen of 35 to 40 nonprotein calories per kilogram per day with 2 to 3 g per kilograms per day of amino acids has been described as an initial starting point. The regimen is then adjusted by determination of resting energy expenditures or the respiratory quotient. Intravenous fat emulsions can also be included to reduce the problems of excess glucose administration and to prevent essential fatty acid deficiency. Fatty emulsions can be used to provide 30% to

40% of the nonprotein calories.

In some patients, the amino acid load associated with hyperalimentation may worsen renal failure and accelerate the need for dialysis. Clinical judgment must be exercised to determine the potential benefits of initiating early hyperalimentation versus delaying dialysis in patients with MODS and renal failure. In general, we recommend providing adequate alimentation and dialysis, as needed.

ETHICAL SUPPORT

It is very important for physicians to assess carefully the likelihood of meaningful recovery in each critically ill patient with MODS. This assessment will depend on the natural history of the patient's underlying disease, as well as the extent and severity of organ failure. There is a growing awareness among the medical community that reasonable limits should be exercised by physicians and patients' families in supporting patients with critical illnesses and MODS. Recent studies demonstrate that some patient groups have a particularly poor prognosis for recovery. For example, bone marrow transplantation patients and those with ARDS have a less than 5% chance for recovery, whereas patients with a combination of hepatic failure and ALI have nearly 100% mortality. In addition, one study in two ICUs at the University of California Medical Center showed that withdrawal of life support was the mechanism for death in approximately 80% of patients in the ICU setting. As more information becomes available regarding prognostic indexes for specific disease processes, it may help guide decisions to discontinue life support in patients who do not have a reasonable chance for meaningful recovery.

EARLY RECOGNITION AND PREVENTION OF MULTIPLE ORGAN FAILURE

EARLY RECOGNITION

A number of studies have been published that identify patients who are at the highest risk for developing MODS. Patients with multiple trauma and hypotension who require emergency surgery and multiple transfusions are one common group of patients at high risk. Other patients considered to be at high risk for the development of MODS include patients with septic shock, patients with advanced chronic diseases (e.g., chronic liver disease or chronic renal failure) who are hospitalized for cardiac failure or a primary infection, and patients with AIDS. Finally, patients who are immunosuppressed because of an underlying malignancy or its treatment may be at particularly high risk for MODS, from both the toxic effects of the chemotherapy and the increased susceptibility to septicemia.

Some investigators have evaluated clinical factors as well as easily measurable plasma factors that might predict which patients with nonpulmonary sepsis syndrome would progress to develop ALI. One study focused on the possible value of a product of endothelial cells for predicting ALI. This study was based on the premise that endothelial cell injury is a ubiquitous, early event in the pathogenesis of sepsis. A variety of in vitro and in vivo studies have shown that both pulmonary and systemic endothelial cell injury occur during endotoxemia and septicemia. The investigators measured plasma levels of von Willebrand's factor-antigen (vWf-Ag) because vWf-Ag has been shown to be released from endothelial cells in vitro when they are injured and because two prior clinical studies demonstrated that plasma vWf-Ag levels are markedly elevated in patients with established acute respiratory failure. Plasma vWf-Ag levels were increased twofold in patients with nonpulmonary sepsis who subsequently developed ALI, compared with those in patients with nonpulmonary sepsis who did not progress to ALI. Moreover, of the 15 patients who developed ALI from sepsis, 14 patients died (93% mortality). An elevated vWf-Ag level above 450 (% of control) was predictive of the development of ALI (87% sensitivity, 77% specificity) and had a positive predictive value of 80% for identifying septic patients who were not likely to survive. In a subsequent study, plasma vWf-Ag was elevated in most patients at risk for ALI from both sepsis and nonseptic causes but did not have a significant predictive value for identifying which patients would develop ARDS. This study differed from the previous study cited in the heterogeneity of patient risks included. Thus, plasma vWf-Ag has some predictive value for identifying risk of developing ARDS and MODS in the more homogeneous risk group of patients with sepsis. Other studies have indicated that elevation of plasma ICAM-1, an endothelial and epithelial adhesion molecule, also has predictive value for identifying sepsis patients who will have the highest mortality.

More studies are needed to combine clinical factors and readily measurable plasma factors to identify those patients with sepsis syndrome at the greatest risk of developing ALI. These patients would be reasonable candidates for early treatment with immunotherapy, anti-inflammatory agents, and other new treatments that may become available in the near future.

PREVENTION OF MULTIPLE ORGAN DYSFUNCTION

Interest has grown in various approaches to reducing the risk of MODS, particularly because outcome is so poor once a patient develops MODS. Although specific treatment approaches have yet to be established, a number of general supportive measures are available. Perhaps the most important supportive measure is prevention of infection. Nosocomial infection can be reduced by good hand washing, removal of unnecessary intravascular and urinary catheters, and prevention of skin ulcers. Moreover, it is important to change central venous catheters in a timely manner (e.g., every 3 to 4 days) and to remain diligent to the possibility of surgically treatable infections.

Some studies suggest that an additional approach to preventing nosocomial infections in critically ill patients may be the use of selective decontamination. This approach involves the use of nonabsorbable antibiotics (orally or topically) to the oral pharynx as well as the administration of intravenous antibiotics. Although mortality has not been significantly reduced in the studies published to date, the incidence of late nosocomial infections was decreased in the patients who receive selective decontamination.

Finally, it may be important that some patients receive prophylaxis for upper GI bleeding (see [Chapter 107](#)). Prophylaxis can be provided with enteral feedings, antacids, sucralfate, or histamine blockers. Sucralfate may have an additional advantage over antacids in its being associated with a lower incidence of nosocomial pneumonia. One study indicated that respiratory failure and coagulopathy were the two most important independent risk factors for GI bleeding in critically ill patients.

CHAPTER 356: APPROACH TO THE PATIENT WITH ACUTE RESPIRATORY FAILURE

THOMAS CORBRIDGE

[Presentation](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care Management](#)
[Prognosis and Outcome](#)

Acute respiratory failure (ARF) is defined as a sudden deterioration in the ability of the respiratory system to maintain adequate gas exchange. It may occur in the previously healthy (e.g., pneumonia), or in the setting of chronic respiratory failure (e.g., acute exacerbation of chronic obstructive pulmonary disease)—a state commonly referred to as acute-on-chronic respiratory failure. A primary disturbance of oxygenation is called acute hypoxemic respiratory failure; a sudden rise in carbon dioxide tension defines acute hypercapnic respiratory failure. Implicit in all of these terms is the fact that there has been an acute decline in the patient's usual condition.

PRESENTATION

Respiratory distress is the hallmark of ARF. However, hypoxemia may present solely as an alteration in mental status or tachycardia; and in some cases hypercapnia may present only as a change in mental status, tachycardia, hypertension, or papilledema.

There are no clear cutoff values for PaO₂ or PaCO₂ that define ARF. Commonly accepted values are PaO₂ below 60 mm Hg and PaCO₂ above 50 mm Hg while breathing room air. However, these values are influenced by age, altitude, preexisting lung disease, and other nonrespiratory factors. For example, consider that an 80-year-old person living in Denver, Colorado normally has a PaO₂ of 60 mm Hg, and that a 60-year-old with chronic obstructive pulmonary disease (COPD) at sea level may have a baseline PaO₂ of 60 mm Hg and a PaCO₂ of 50 mm Hg. Conversely, a PaO₂ of 70 mm Hg in a 20-year-old hypocapnic patient is distinctly abnormal (see below). Therefore, to be consistent with ARF, hypoxemia or hypercapnia must be significant and acutely different from baseline.

Acute respiratory insufficiency (ARI) is distinguished from ARF by the lack of significant blood gas deterioration. These terms are descriptors of common pathophysiologic processes, with ARI referring to illness of lesser severity or better physiologic compensation. Serial blood gas measurements help discern the transition from ARI to ARF.

PATHOPHYSIOLOGIC FACTORS

Although oxygenation and ventilation are unavoidably linked, it is helpful to consider the determinates of each separately and to establish whether the problem is primarily one of oxygenation or ventilation.

DETERMINATES OF OXYGENATION

An understanding of the alveolar gas equation is mandatory for understanding hypoxemic states. A simplified and commonly used version of this equation is as follows:

$$PAO_2 = (P_b - PAH_2O)FIO_2 - PACO_2/RQ$$

where PAO₂ is alveolar oxygen tension; P_b, barometric pressure; PAH₂O, alveolar water vapor pressure; FIO₂, fraction of inspired oxygen; RQ, respiratory quotient (ratio of CO₂ production to O₂ consumption); and PACO₂ is alveolar CO₂ (assumed to equal PaCO₂). In a normal subject breathing room air at sea level, P_b is 760 mm Hg, PAH₂O is 47 mm Hg, FIO₂ is 0.21, PaCO₂ is 40 mm Hg, and RQ is assumed to be 0.8 (although it can be measured by inspiratory and expiratory gas analysis). Under these conditions, the predicted PAO₂ is 100 mm Hg.

In health, PaO₂ approaches PAO₂, so that the difference between the two, P(A-a)O₂, is small (less than 10 mm Hg in a young adult). Calculation of P(A-a)O₂ helps prevent misinterpretations of PaO₂. For example, a room air, sea level PaO₂ of 90 mm Hg is too low in a 20-year-old with a PaCO₂ of 20 mm Hg because P(A-a)O₂ is 25 mm Hg.

PaO₂ increases normally with age according to the formula: P(A-a)O₂ = 2.5 + 0.25(age). P(A-a)O₂ also increases as FIO₂ increases, complicating its use in patients on supplemental oxygen. In such cases, an estimate of gas exchange may be obtained by relating the arterial to the alveolar oxygen tension (PaO₂/PAO₂). A ratio of 0.8 or greater indicates adequate gas exchange. An even simpler estimate can be obtained by dividing PaO₂ by FIO₂. This ratio is normally greater than 400.

The alveolar gas equation predicts four causes for a low PAO₂ (and thereby a low PaO₂) that do not elevate P(A-a)O₂: low barometric pressure, low FIO₂, high PaCO₂, and low RQ ([Table 356.1](#)). Only high altitude and hypercapnia are important in common clinical practice. Consider, for example, the effects of a PaCO₂ of 60 mm Hg in a patient with heroin overdose and a room air PaO₂ of 60 mm Hg. In this case, hypoxemia occurs because alveolar CO₂ displaces oxygen and the rate of oxygen removal from alveoli may exceed its resupply. The P(A-a)O₂ is normal so hypoxemia is entirely explained by the elevated PaCO₂.

Conditions with Normal P(A-a)O ₂	Conditions Elevating P(A-a)O ₂	Conditions Associated with Low Pvo ₂
High altitude	Intrapulmonary shunt (pneumonia, pulmonary edema, alveolar hemorrhage, lobar atelectasis)	Low cardiac output
Hypercapnia	Low V/Q states (asthma, COPD, PE)	High oxygen consumption
Low respiratory quotient	Diffusion limitation	Anemia
Low FIO ₂		Low P _b

COPD, chronic obstructive pulmonary disease; PE, pulmonary embolism.

TABLE 356.1. COMMON CAUSES OF HYPOXEMIA

States that elevate P(A-a)O₂ include disorders that lower ventilation (V) to perfusion (Q) ratios, or impair diffusion. Under normal conditions, ventilation and perfusion are closely matched (i.e., V/Q approaches 1). A V/Q of zero defines shunt. In the lung, alveolar filling processes (such as pneumonia, pulmonary edema, and alveolar hemorrhage), and acute lobar atelectasis cause shunt ([Fig. 356.1](#)). Right-to-left intracardiac shunt similarly isolates venous blood from inspired oxygen. Indeed oxygen supplementation may have minimal effects in a patient with significant shunt physiology.

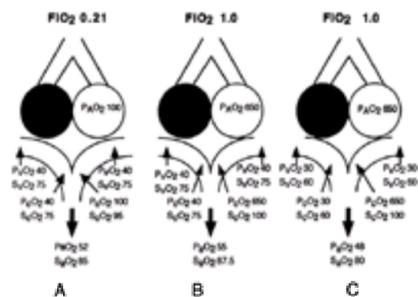

FIGURE 356.1. Effects of 50% intrapulmonary shunt on PaO₂ in a two-lung-unit model, each receiving 50% of the cardiac output, during three experimental conditions: on room air with a normal PvO₂ (A), on 100% oxygen with a normal PvO₂ (B), and on 100% oxygen with a low PvO₂ (C). Three points along the transit of blood are noted: the mixed venous entry point, the end-capillary point and the arterial blood. For simplicity, effects of dissolved oxygen have been ignored. Sa O₂ is determined by averaging S_cO₂, not P_cO₂, from each lung unit. Note how little PaO₂ increases despite 100% oxygen. Note also how lowering PvO₂ affects PaO₂. PvO₂, partial pressure of oxygen, mixed venous blood; SvO₂, oxygen saturation, mixed venous blood; P_cO₂, partial pressure of oxygen, end-capillary blood; S_cO₂, oxygen saturation, end-capillary; PaO₂, partial pressure, arterial blood; Sa O₂, oxygen saturation, arterial blood

Disorders lowering V/Q (but not to zero) include asthma and COPD, diseases of the airways that lower ventilation to perfused lung units. Low V/Q is also important in the hypoxemia of pulmonary embolism (PE), in part because nonobstructed vessels receive more blood flow. PE occasionally causes shunt when a foramen ovale opens in the setting of acute right heart strain. Unlike shunt, low V/Q states respond well to supplemental oxygen because poorly ventilated lung units still supply oxygen to passing blood.

Diffusion limitation refers to pathologic processes that increase the distance between a functional alveolus and the pulmonary capillary bed (as in pulmonary fibrosis), or to processes that decrease the oxygen diffusion gradient (as in carbon monoxide intoxication, hemoglobinopathy, and anemia). The importance of diffusion limitation in routine clinical practice is debated.

Perfusing low-V/Q units with a low PvO₂ (the PO₂ of venous blood in the precapillary bed) also causes hypoxemia (Fig. 356.1). Causes of low PvO₂ are listed in Table 356.1. Low PvO₂ does not affect PaO₂ in the normal lung, which can adequately oxygenate even severely desaturated venous blood.

DETERMINATES OF HYPERCAPNIA

PaCO₂ is set by the ratio of carbon dioxide production (VCO₂) to carbon dioxide elimination, modified by a constant (K). CO₂ elimination is determined by alveolar ventilation (VA), where VA is the portion of minute ventilation (Ve = respiratory rate x tidal volume) that participates in gas exchange. In other words, V A equals Ve times a fraction that accounts for dead-space ventilation (1 - Vd/Vt), where Vd is the volume of dead space and Vt is tidal volume. Dead space (defined as V/Q of infinity) does not participate in gas exchange and consists mainly of large airways. Normally, Vd/Vt is less than 0.25. If Vd/Vt is 0.25, then 1 - Vd/Vt is 0.75 and 75% of Ve eliminates CO₂. The constant K (0.863) is necessary to convert CO₂ elimination in the gas phase, measured in BTPS, to STPD, and to convert fractional concentration to partial pressure. Thus:

$$PaCO_2 = VCO_2(0.863)/[Ve(1 - Vd/Vt)]$$

PaCO₂ is about 40 mm Hg under normal conditions of VCO₂, 220 mL per minute; Ve, 7 L per minute; Vd, 125 mL; and Vt, 500 mL.

This formula predicts three causes for hypercapnia: low Ve, high VCO₂, and high Vd/Vt. Disorders that lower Ve may be understood by considering the relationship between respiratory muscle strength and respiratory system load (Fig. 356.2). The neuromuscular apparatus must generate enough negative intrathoracic pressure to overcome two major obstacles: the resistance to airflow in the conducting airways, and the elastance of the lungs and chest wall (which includes the abdomen). As long as the pressure generated is able to overcome these two mechanical loads, adequate alveolar ventilation will be sustained. If not, CO₂ accumulates.

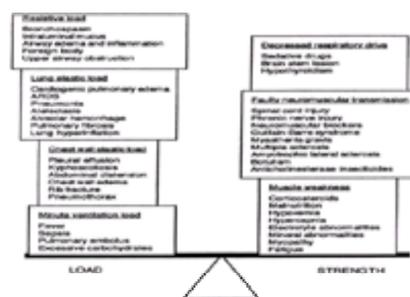

FIGURE 356.2. Conditions associated with hypercapnic respiratory failure may be divided into conditions affecting neuromuscular strength and conditions affecting respiratory system load. In order to maintain minute ventilation, adequate strength must be present to handle the given load. (Adapted from Schmidt GA, Hall JB. Acute-on-chronic-respiratory-failure. In: Hall JB, Schmidt GA, Wood LDH, eds. Principles of critical care, second ed. New York: McGraw-Hill, 1998:565–594.)

Patients with normal neuromuscular function may develop hypercapnic respiratory failure in the face of markedly altered lung mechanics (e.g., a young patient with acute asthma). Alternatively, hypercapnia may develop in a patient with normal lung mechanics when neuromuscular strength is markedly decreased (e.g., drug overdose or amyotrophic lateral sclerosis). Often both strength and load are affected. In an exacerbation of COPD, resistive load is increased by secretions and bronchospasm and elastic load is increased by auto-PEEP and lung hyperinflation. Auto-PEEP (auto-positive end-expiratory pressure) occurs when expiratory airflow limitation prevents complete emptying of alveolar gas. Auto-PEEP represents a threshold pressure that must be overcome before inspiratory airflow can occur. Auto-PEEP thus increases inspiratory work of breathing. The hyperinflated lung is also harder to inflate if it is operating at a flatter portion of its pressure-volume relationship (i.e., it has a lower compliance). At the same time, diaphragm force generation is decreased by hyperinflation (which places the diaphragm in a mechanically disadvantageous position), acute respiratory acidosis, and a lack of substrate delivery to the diaphragm due to hypoxemia, abnormalities of electrolytes and minerals, or shock. Malnutrition and corticosteroid therapy may also decrease diaphragm function.

As Vd/Vt increases, so will PaCO₂ for a given Ve and VCO₂. In some conditions, such as emphysema or PE, dead space is high because of obliteration or obstruction of blood vessels continuing to receive ventilation. In other cases, dead space increases because high alveolar pressure decreases adjacent blood flow, a state aggravated by low intravascular hydrostatic pressure. Examples include a severely hyperinflated asthmatic and a patient with the acute respiratory distress syndrome (ARDS) requiring high levels of PEEP.

Carbon dioxide production is increased in patients who are working excessively to breathe and in patients who are febrile, septic, or receiving carbohydrate-rich diets. High CO₂ production contributes to hypercapnia when a compensatory increase in Ve does not occur (as in a mechanically ventilated patient receiving a fixed Ve or in

a patient with severe COPD).

HISTORY AND PHYSICAL EXAMINATION

The general appearance of the patient (posture, speech, diaphoresis, alertness) provides a quick guide to disease severity and need for intubation. In severely ill patients, stabilizing measures may be required before a history can be taken or a detailed examination performed. Still, the history and physical examination invariably helps establish the cause of ARF in most cases. Fever, dyspnea, and cough with lateralizing signs of consolidation is suggestive of pneumonia. A history of preexisting cardiac disease combined with dyspnea, bilateral inspiratory crackles, distended neck veins, a third heart sound, or a pathologic murmur suggests cardiogenic pulmonary edema. Acute breathlessness in a patient with an abnormal mental status or a history of neuromuscular weakness suggests the possibility of aspiration. Respiratory failure in a patient with connective tissue disease, such as systemic lupus erythematosus, raises the possibility of alveolar hemorrhage, as well as that of infectious and noninfectious pneumonitis.

A history of atopy or asthma and exam findings of wheeze, diminished air entry, and expiratory phase prolongation are consistent with acute severe asthma. It is important to keep in mind that severely obstructed patients have a silent chest. That is, they may not wheeze at all because there is insufficient flow for wheeze to occur. Accessory muscle use and pulsus paradoxus indicate severe airflow obstruction, but the absence of these findings does not exclude a severe attack. A “mediastinal crunch” or subcutaneous emphysema (crepitus) suggests pneumomediastinum or pneumothorax and a potentially worse clinical course.

It is important to keep in mind that “all that wheezes is not asthma.” An extensive smoking history suggests COPD, which may be associated with variable degrees of fixed and reversible airflow obstruction, pulmonary hypertension, and chronic respiratory acidosis. Cardiac asthma refers to airway hyperreactivity stemming from congestive heart failure. Heart failure is usually discernible on examination, but the distinction between heart failure and primary airway disease can be difficult, particularly in the elderly. The presence of a foreign body must be considered in children and in adults with poor swallowing, altered mental status, or recent dental work. Foreign body obstruction may cause atelectasis with or without ipsilateral tracheal deviation. Tracheal deviation is also caused by contralateral volume expanding lesions such as pneumothorax or pleural effusion. Upper airway obstruction from granulation tissue, tumor, infection, laryngeal edema, or vocal cord dysfunction may also be mistaken for acute asthma. Stridor is not always distinguishable from wheeze, and wheezes may be heard best over the trachea. Inspiratory phase prolongation is a useful sign of upper airway obstruction.

Pulmonary embolism should be considered in all breathless patients, unless there is another convincing cause of ARF. Historical features worrisome for PE include recent surgery, malignancy, prior thromboembolic disease, a family history of thromboembolic disease, pregnancy, the use of oral contraceptives in a smoker, right heart failure, and prolonged immobility (including recent long travel). Dyspnea is invariably present. Hemoptysis, pleuritic chest pain, syncope, and shock also occur. Examination classically reveals tachypnea and tachycardia. The lungs may be clear or there may be basilar crackles. Wheezes are rare. Significant pulmonary hypertension is signaled by accentuation of the pulmonic component of the second heart sound or a third heart sound. The finding of a swollen or erythematous extremity is suspicious but not diagnostic of thromboembolic disease. Likewise, normal extremities do not exclude clot.

Assessment of neuromuscular function is important in patients with ARF, keeping in mind that it is the imbalance between strength and load that leads to hypercapnic respiratory failure. The examiner should seek evidence for an underlying neuromuscular disease and for other factors associated with weakness, such as fatigue, malnutrition, electrolyte disorders, and chronic use of corticosteroids.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

If circumstances permit, the initial blood gas should be obtained on room air to allow for determination of $P(A-a)O_2$. If the patient is receiving supplemental oxygen by nasal cannula or face mask, $P(A-a)O_2$ cannot be measured accurately because FIO_2 is not precisely known. A rough calculation, however, still suggests whether $P(A-a)O_2$ is normal or not. In intubated patients, the FIO_2 is known and $P(A-a)O_2$ can be measured, but because $P(A-a)O_2$ varies with FIO_2 , it is less useful than PaO_2/PAO_2 or PaO_2/FIO_2 . Whenever possible, comparison with a baseline blood gas is helpful. It is also important to measure hemoglobin (which is important for oxygen delivery) and white cell count (which helps assess the possibility of infection).

Pulse oximetry allows for continuous, noninvasive readings of arterial saturation. However, it has several limitations. First, the 95% confidence interval for measurements is $\pm 4\%$ for SaO_2 greater than 70%. Pulse oximetry is even less accurate in severe hypoxemia. Thus, a value of 92% could correspond to a SaO_2 by blood gas between 88% and 96% (roughly corresponding to a PaO_2 between 55 mm Hg and 95 mm Hg). Second, accuracy is affected by a number of factors that overestimate (carboxyhemoglobinemia, methemoglobinemia), underestimate (methylene blue, jaundice, dark nail polish), and have variable effects (patient temperature, hypoperfusion, skin pigmentation) on measured values. Third, $PaCO_2$ and pH are not measured by pulse oximetry.

The relationship between serum pH and $PaCO_2$ is crucial in the evaluation of patients with hypercapnic respiratory failure. For every 10 mm Hg rise in $PaCO_2$ acutely, pH falls by 0.08 unit. Thus, an acute increase in $PaCO_2$ from 40 to 60 mm Hg should drop the arterial pH from 7.40 to 7.24. If this is not the case, additional factors should be considered including compensation and other primary acid–base disturbances. Accurate interpretation of the acid–base status requires simultaneous measurement of electrolytes and calculation of the anion gap.

A chest radiograph should be obtained and compared (if possible) with previous films for the detection of infiltrates, pneumothorax, hyperinflation, atelectasis, pleural effusion, and change in heart size. Radiographic patterns associated with ARF are listed in [Table 356.2](#). Measurement of expiratory airflow by a peak flowmeter or spirometer helps assess the severity of obstruction in patients with acute asthma; and a normal peak flow helps direct the clinician away from an obstructive process. Echocardiography helps to delineate right- and left-sided ventricular function, valvular integrity, and the presence of pericardial disease. Noninvasive tests for deep venous thrombosis, such as duplex ultrasonography, are useful in evaluating patients with suspected thromboembolic disease. These studies are helpful when positive, but 30% to 40% of patients with acute PE have negative studies. Ventilation–perfusion scans are useful in some cases, but the majority of studies are indeterminate. In selected patients, spiral CT scanning with a PE protocol or pulmonary angiography is required to establish a diagnosis of PE.

Lucent	Diffuse	Focal
Intracardiac shunt	Diffuse pneumonia	Pulmonary infarction
Arteriovenous malformation	Bronchopulmonary dysplasia	Lung mass
Cirrhosis	Alveolar hemorrhage	Pneumonia
Asthma	Acute respiratory distress syndrome	Aspiration
Pulmonary embolism	Cardiogenic pulmonary edema	Mucus plug
Pneumothorax	Aspiration pneumonia	Contusion
	Lymphangitic spread of cancer	Reexpansion or dependent pulmonary edema
Microatelectasis	Drug reaction	Atelectasis
	Interstitial lung disease	

TABLE 356.2. SELECTED DISORDERS AND RADIOGRAPHIC PATTERNS ASSOCIATED WITH HYPOXEMIA

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

The primary responsibility of the treating clinician is to identify and treat life-threatening conditions, beginning with sequential assessment of the ABCs (airway, breathing, and circulation). The foremost goal is immediate correction of arterial hypoxemia. In nonintubated patients, the fraction of inspired oxygen should be increased until an oxygen saturation of 90% to 92% is achieved. A pulse oximeter allows for initial rapid titration of oxygen, but the adequacy of oxygenation should be confirmed by blood gas. Supplemental oxygen can be delivered by nasal cannula or face mask with the highest FiO_2 achieved by delivering 100% oxygen through a tight-fitting, non-rebreathing face mask. Refractory hypoxemia identifies patients with shunt physiology. When this is caused by cardiogenic pulmonary edema, continuous positive airway pressure (CPAP) by nasal or full-face mask is particularly effective because it reduces venous return to the right-sided heart, decreases left

ventricular afterload, and redistributes alveolar fluid. CPAP is less reliable in patients with ARDS and pneumonia, but it still works in selected patients.

If adequate oxygenation cannot be achieved quickly by non-invasive means, intubation and mechanical ventilation are indicated. During the peri-intubation period, FiO_2 should be 1.0, though it should be decreased as soon as possible to no greater than 0.6 to avoid oxygen toxicity. Strategies that allow for a nontoxic FiO_2 in most cases include (a) the use of PEEP, (b) therapies that increase PvO_2 , and (c) positional changes. Other strategies (most often considered in ARDS) include the use of nitric oxide, partial-liquid ventilation, and surfactant. Discussion of these therapies is beyond the scope of this chapter.

PEEP is synonymous with CPAP in a mechanically ventilated patient. In diffuse lung disorders (such as cardiogenic pulmonary edema and ARDS), PEEP lowers shunt by the mechanisms specified above. By maintaining a higher end-exhalation lung volume, PEEP may also prevent the closing and opening of lung units with each tidal breath, a situation that generates significant shear forces and may contribute to ventilator-induced lung injury. When using PEEP, care must be taken to limit V_t excursions above the set PEEP to avoid lung over-distention. In focal lung disease (such as pneumonia), PEEP may preferentially distend normal lung units, thereby diverting blood flow from them to diseased areas and worsening V/Q inequality. PEEP is also detrimental to gas exchange when it decreases cardiac output and PvO_2 by decreasing venous return or when it increases dead-space ventilation.

Strategies that elevate PvO_2 may improve PaO_2 . These include (a) the use of sedatives and/or paralytics to decrease oxygen consumption, (b) fluid resuscitation and/or use of inotropes and vasodilators to increase cardiac output, and (c) blood transfusion.

The purpose of positional maneuvers is to improve V/Q inequality by increasing blood flow to healthier lung units. In lobar pneumonia, this goal may be achieved by placing the "good lung down". In ARDS, prone positioning improves oxygenation two-thirds of the time, but it has not yet been shown to affect outcome.

Concurrent with supportive measures, it is necessary to treat the underlying disorder responsible for ARF. Examples include the use of antibiotics for pneumonia, diuretics and afterload reducers for congestive heart failure, and immunosuppressants for some cases of alveolar hemorrhage. It is beyond the scope of this chapter to discuss all of these therapies in detail.

Successful treatment of acute hypercapnic respiratory failure requires restoration of the balance between the neuromuscular strength and respiratory system load. When the problem is strictly one of decreased neuromuscular function (e.g., drug overdose), restoring neuromuscular competence is all that is required (e.g., naloxone infusion). When hypercapnia results primarily from abnormal lung mechanics (e.g., acute severe asthma in an otherwise healthy person), the primary strategy should be to decrease respiratory system load (see [bibliography](#) for suggested readings on the management of acute severe asthma). Often both strength and load must be addressed, as in the case of acute exacerbations of COPD. An expanded discussion of the care of patients with COPD exacerbation is included because this condition is a common cause of respiratory failure.

In COPD, hypercapnic respiratory failure results when the precarious balance between decreased patient strength and increased load on the respiratory system is tipped in the wrong direction, often by a relatively trivial insult. To restore this balance, the treating clinician should first achieve 90% saturation of arterial blood. Adequate oxygen saturation is important for respiratory muscle function and to further decrease the risk of myocardial ischemia, arrhythmia, cerebral injury, and respiratory arrest. Clinicians are often hesitant to supply oxygen, fearing that patients will stop breathing. It is now known, however, that supplemental oxygen does not stop patients from breathing; rather, oxygen elevates PaCO_2 by increasing V_d/V_t and the haldane effect. Oxygen causes a small and insignificant fall in V_e , and respiratory drive remains supranormal despite oxygen. Substrates other than oxygen are important for adequate muscle function. Electrolytes and minerals should be corrected and nutritional supplementation provided early in the course of acute illness. CPAP decreases the inspiratory work of breathing in patients with air trapping by decreasing the pressure gradient required for inspiratory gas flow. Additional support can be achieved by adding pressure support to CPAP (commonly referred to as noninvasive positive pressure ventilation, or NPPV). Considerable data support the use of NPPV in acute COPD exacerbations.

Several pharmacologic agents are available to lower respiratory system load. Bronchodilators are used to decrease airway resistance. While much of the airflow obstruction of COPD is fixed, many patients have a reversible component that responds to bronchodilators. Available data demonstrate that the combination of a β -agonist and ipratropium bromide is better than either drug used alone. Bronchodilators may also decrease lung inflation by improving expiratory airflow. This places the diaphragm in a better position and may improve lung compliance. The available data do not support the use of theophylline in the initial management of exacerbations of COPD. Systemic corticosteroids are beneficial, and antibiotics should be used whenever there is an increase in sputum amount or purulence.

Patients failing pharmacotherapy and NPPV should be intubated and mechanically ventilated. During mechanical ventilation, it is important to avoid excessive lung hyperinflation and high levels of auto-PEEP. Setting a short inspiratory time and low V_e extends exhalation time and achieves this goal. It is also important to ensure patient-ventilator synchrony and adequate rest of fatigued respiratory muscles. The goal of ventilatory support is to return the arterial pH to normal, not to return the PaCO_2 to normal. In a patient with compensated respiratory acidosis, returning PaCO_2 to normal levels could result in deleterious lung hyperinflation and significant metabolic alkalosis.

PROGNOSIS AND OUTCOME

The outcome of ARF is frequently good, but it depends on multiple host and disease factors, including age, presence of comorbid conditions, and severity and nature of the acute insult. For instance, asthmatics who develop ARF and arrest out of hospital have a poor prognosis for meaningful recovery if they arrive with anoxic brain injury. On the other hand, asthmatics who are intubated in hospital rarely die if a ventilator strategy is used that limits lung hyperinflation. Patients with acute exacerbations of COPD similarly do well, although intubated patients do have a 20% to 30% mortality rate. In ARDS, mortality is approximately 40%. Preliminary data suggest that mortality in ARDS is less if a small tidal volume is used during mechanical ventilation. If ARDS is associated with other organ dysfunction, mortality increases, so that by the time three major organs have failed for three consecutive days, mortality exceeds 90%.

Because the prognosis of ARF is generally good, an initial plan to deliver critical care, including intubation, is appropriate unless the patient had previously decided to forego life-sustaining therapies. It is important to monitor patient progress (or lack thereof) and maintain open communication with the patient and/or surrogate so that good decisions can be made regarding the utility of critical care. Finally, for patients who recover, it is important to consider whether measures can be taken to prevent a recurrent episode of ARF.

CHAPTER 357: APPROACH TO THE PATIENT WITH ACUTE RESPIRATORY DISTRESS SYNDROME

KENNETH P. STEINBERG AND LEONARD D. HUDSON

[Etiologic Factors](#)
[Clinical Presentation and Diagnosis](#)
[Pathophysiologic Factors](#)
[Therapy](#)
[Course, Outcome, and Complications](#)

Acute respiratory distress syndrome (ARDS) (previously called adult respiratory distress syndrome) represents the abrupt onset of diffuse lung injury characterized by severe hypoxemia and generalized pulmonary infiltrates in the absence of cardiac failure. Although the syndrome may be initiated by a wide variety of illnesses or injuries, the clinical picture and histopathologic factors are remarkably uniform. The incidence of ARDS has been variably estimated at 15,000 to 150,000 cases per year in the United States. Despite the sophisticated monitoring and support systems available in intensive care units, progress has been slow. However, the survival rates do appear to have improved from about 40% in the 1970s and 1980s to about 60% in the 1990s. Most recently, a large clinical trial of mechanical ventilation demonstrated further improvement in survival from 60% to 70% with the use of small tidal volumes. Nevertheless, even with this improvement the death rate remains regrettably high and, because a large proportion of ARDS victims are relatively young previously healthy adults, the effect in terms of productive life lost is immense.

ETIOLOGIC FACTORS

Acute respiratory distress syndrome has been associated with a diversity of precipitating clinical events, the most common of which are listed in [Table 357.1](#). Infectious causes appear to be the most common, with sepsis syndrome and bacterial or viral pneumonia leading the list. Approximately 40% of patients with sepsis syndrome or severe sepsis will develop ARDS. Major traumatic injury, often involving extensive soft-tissue damage, is also a common cause with approximately 25% of victims developing ARDS. Aspiration of gastric contents is an etiologic picture frequently seen in patients with an altered level of consciousness. Other risk factors include massive transfusion, inhalation injury, pancreatitis, near-drowning, and drug overdose. Many other causes of ARDS have been described in case reports and small series.

Disorder	Estimated Incidence (%)
Direct or primary causes:	
Aspiration of gastric contents	22–36*
Diffuse pneumonia	*
Pulmonary contusion	17–22*
Inhalation injury	*
Near-drowning	*
Indirect or secondary causes:	
Sepsis	
Bacteremia without sepsis	4
Severe sepsis/sepsis syndrome	35–45
Major trauma	25
Hypertransfusion	5–36
Drug overdose	5–8
Pancreatitis	*

* Incident not known.

TABLE 357.1. CLINICAL DISORDERS ASSOCIATED WITH ARDS^a

CLINICAL PRESENTATION AND DIAGNOSIS

Acute respiratory distress syndrome usually develops rapidly, occurring most often within 12 to 72 hours of the predisposing event. Respiratory distress, severe hypoxemia, and generalized pulmonary infiltrates are all necessary for the diagnosis of ARDS ([Fig. 357.1](#)). Because the arterial partial pressure of oxygen (PaO_2) is influenced by the fraction of inspired oxygen (FIO_2), most ARDS definitions have defined hypoxemia in terms of a $\text{PaO}_2/\text{FIO}_2$ ratio or ratio between arterial and alveolar oxygen tensions ($\text{PaO}_2/\text{PAO}_2$ ratio). The specific definition of ARDS varies depending on the author and the attempt to describe the severity of the disease. The most widely accepted definition was developed by a joint American–European consensus committee in 1994. The concept of acute lung injury (ALI) as a spectrum of severity, with ARDS as the most severe end of the spectrum, was formulated by this group ([Table 357.2](#)). Bilateral pulmonary infiltrates must be present on chest radiographs, although correlation between the roentgenographic abnormalities and the degree of hypoxemia varies widely. Hypoxemia with a $\text{PaO}_2/\text{FIO}_2$ ratio less than 300 defines ALI; a ratio of less than 200 describes ARDS. Congestive heart failure as a possible explanation of the pulmonary findings should be excluded either by a pulmonary artery occlusion pressure measurement of less than 18 mm Hg or clinically. Total respiratory compliance is usually reduced, but this is generally not required for the diagnosis.

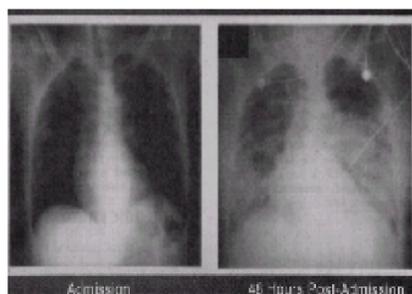

FIGURE 357.1. The presence of bilateral pulmonary infiltrates in a patient with sepsis is consistent with the development of acute respiratory distress syndrome within 48 hours of admission to the intensive care unit (*right*).

	Onset	Oxygenation	Chest Radiograph	PAOP
ALI criteria	Acute	$\text{PaO}_2/\text{FIO}_2 < 300$ mm Hg	Bilateral interstitial or alveolar infiltrates	< 18 mm Hg if measured or no clinical evidence of left atrial hypertension
ARDS criteria	Acute	$\text{PaO}_2/\text{FIO}_2 < 200$ mm Hg	Bilateral interstitial or alveolar infiltrates	< 18 mm Hg if measured or no clinical evidence of left atrial hypertension

TABLE 357.2. CRITERIA FOR ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

To date, no specific laboratory findings of ARDS have been described other than those necessary to meet the criteria of the syndrome. Although certain blood and bronchoalveolar lavage (BAL) fluid abnormalities are common or universal in ARDS, such as evidence of activation of inflammatory pathways with elevation of multiple cytokines or reduction in plasma fibronectin levels, these findings are not specific to ARDS. Patients with similar underlying illnesses or injuries who do not develop ARDS may also have the same findings. Although they may be pathogenetically important, these findings are not yet helpful clinically in predicting the course or outcome of ARDS.

ARDS may develop as a part of the fat embolism syndrome after long-bone fractures. Fat embolism syndrome is characterized by mental status changes, conjunctival and axillary petechiae, anemia, thrombocytopenia, and diffuse lung injury with hypoxemia occurring 24 to 72 hours after injury. The pathogenesis has not been clearly elucidated but is believed to involve the release of toxic free fatty acids from bone marrow fat after trauma. ALI follows long-bone fractures in 5% to 10% of patients. The incidence of full-blown fat embolism syndrome has declined dramatically in recent years, however, presumably because of earlier stabilization of fractures.

Occasionally, a patient develops ARDS without recognition of any of the processes known to be associated with the syndrome. This occurs in 5% to 10% of the ARDS patients we see. If other processes in the differential diagnosis have been excluded, the patient still should be considered to have ARDS. In such patients, a careful search for precipitating causes of the syndrome should be undertaken. This especially includes ruling out occult sources of sepsis such as intra-abdominal abscess. BAL may be helpful as well to rule out unusual pathogens, acute eosinophilic pneumonia, and other intrinsic pulmonary processes such as severe hypersensitivity pneumonitis, bronchiolitis obliterans-organizing pneumonia, and diffuse pulmonary hemorrhage syndromes.

The term ARDS is used because it denotes a common syndrome despite multiple etiologic factors or associated illnesses. It implies similar if not identical pathophysiologic processes. Whether or not this is true is unclear. The etiologies of ARDS can be grouped into direct (primary) and indirect (secondary) causes of lung injury ([Table 357.1](#)). Indirect lung injury is believed to develop after an extrapulmonary process leads to systemic inflammation and blood-borne inflammatory mediators that secondarily cause injury to pulmonary capillary endothelial cells. This vascular injury then leads to interstitial and alveolar epithelial injury. Primary or direct lung injury develops in the opposite sequence, with alveolar inflammation and injury progressing to capillary injury. There is some evidence that primary and secondary lung injury respond differently to clinical interventions such as administration of positive end-expiratory pressure (PEEP) and prone positioning. More work needs to be done, however, before different strategies of care for ARDS of different causes can be recommended. Moreover, it may be difficult to distinguish between diffuse lung inflammation due to diffuse pneumonia with generalized involvement of the lung by microorganisms (direct injury) and a localized pneumonia that leads to sepsis with resultant widespread intravascular (indirect) injury.

Hantavirus pulmonary syndrome (HPS), a viral disease first described in 1993, is a unique cause of severe acute respiratory failure. The virus is thought to be transmitted by aerosols of the infected feces and urine of the deer mouse. This syndrome is discussed in [Chapter 308](#). Signs and symptoms of HPS include fever, hypotension secondary to profound volume depletion from increased vascular permeability and third-spacing of fluids, thrombocytopenia, neutrophilia, and increased hematocrit (secondary to volume depletion). As the illness progresses, dyspnea, pleuritic chest pain, hemoptysis, and diffuse rales develop rapidly. Respiratory failure results from the accumulation of highly proteinaceous noncardiogenic edema in the lungs. The chest radiograph reveals diffuse alveolar infiltrates. The reported case fatality rate is approximately 60%. Autopsy studies have revealed diffuse alveolar damage with edema, hyaline membranes, and a marked, mononuclear, interstitial inflammatory infiltrate. Unlike ARDS, polymorphonuclear leukocytes are generally not seen.

Because of the unique clinical syndrome, viral cause and pathologic picture (lack of polymorphonuclear leukocytes), it is not clear as to whether HPS should be considered to be ARDS. However, HPS is a cause of ALI with noncardiogenic pulmonary edema secondary to epithelial and endothelial lung injury and is associated with a high mortality. Treatment consists of aggressive supportive care. For these reasons, as with diffuse infection, HPS is similar to ARDS, hence its inclusion in this chapter.

High-altitude pulmonary edema (HAPE) has been established as an increased permeability form of pulmonary edema, but the constituents of alveolar fluid obtained by BAL and the pathologic factors differ from those of other forms of ARDS. The time course after therapy also varies. Therefore, HAPE is not considered a classic form of ARDS. One possible difference is that HAPE is associated with less surfactant abnormality and thus with less extensive diffuse microatelectasis.

PATHOPHYSIOLOGIC FACTORS

PHYSIOLOGIC CHANGES

The physiologic abnormalities associated with ARDS include impaired gas exchange, altered lung mechanics, and pulmonary vascular changes. Hypoxemia is seen early in the course and is believed to be caused by intrapulmonary venoarterial shunting due to alveolar flooding and collapse. These phenomena, along with septal edema and fibrosis, lead to a reduction in lung compliance, low functional residual capacity, and increased work of breathing. The loss of microvasculature in the later stages of ARDS leads to pulmonary hypertension and increased dead space with impaired carbon dioxide elimination, even while oxygenation may be improving.

STRUCTURAL CHANGES

The histologic changes in the lung that characterize ARDS represent a relatively nonspecific response to injury and have been termed *diffuse alveolar damage* by pathologists. These changes are found in other disease processes, such as fibrosing alveolitis or drug-induced pulmonary disease, and the pattern shows little variability, even among cases of ARDS associated with widely divergent causes. Inflammatory cells, especially neutrophils, accumulate within the alveolar space and are believed to contribute to the lung injury by releasing of granular enzymes and oxidants. Type I alveolar epithelial cells appear to be the most susceptible to injury, undergoing cytopathic changes extremely early, with resultant damage to the alveolar basement membrane. Pulmonary vascular endothelial cells are also affected, although the histologic changes are less striking and occur more slowly. Endothelial and epithelial cells undergo changes in permeability, allowing interstitial and alveolar edema to develop. Hyaline membranes, identical to those seen in premature infants with respiratory distress syndrome, are caused by the aggregation of fibrin and other proteins in the alveolar space. Alveolar flooding occurs, accompanied by distortion of the alveoli by septal edema and impairment of surfactant function with the loss of functional lung units through microatelectasis. These phenomena lead to hypoxemia as well as to abnormalities in lung mechanics (low lung compliance and reduced functional residual capacity).

As the process continues, there is loss of pulmonary microvasculature, intravascular thrombosis, and distortion of septal architecture due to fibrosis. Vascular damage is believed to be responsible for pulmonary hypertension, increased dead-space ventilation, and a reduction in carbon monoxide diffusing capacity.

Lung scarring is well documented in patients with ARDS and appears to be associated with both fibroblast proliferation and increased collagen synthesis. Increased amounts of lung collagen have been documented as early as a few days after the onset of ARDS. The regulation of collagen deposition appears to be a dynamic process, as evidenced by a shift from predominantly type III collagen in the earlier stages to type I collagen in the later stages of ARDS. The recovery of normal lung function in many survivors of ARDS has been taken as evidence that pulmonary fibrosis complicating ARDS is not necessarily permanent. Studies have correlated the degree of the fibrotic response in the lung with mortality.

PATHOGENESIS OF LUNG INJURY

Pulmonary inflammation is a prominent feature of ARDS, and inflammatory cells and biochemical markers have been implicated in the lung injury process, much as they have in arthritis and other diseases. Neutrophils are found in the lungs of ARDS patients, and investigators have also found evidence that toxic neutrophil products have been released into the alveolar space. Although prior depletion of neutrophils in experimental animals has led to amelioration of the lung injury induced by certain stimuli, there are many clinical reports of patients with profound neutropenia who have developed ARDS. Neutrophils may not be required for the development of lung injury, but they appear to represent at least one major mechanism by which tissue damage is initiated or amplified during ARDS.

Although attention has been focused on neutrophil-derived oxygen radicals and proteolytic enzymes, other inflammatory pathways and other cell types may also be involved. Proteins in the complement cascade, kinin system, and coagulation system are susceptible to the action of proteases, generating products with proinflammatory activity. Phospholipase products, including platelet-activating factor, prostaglandins, and lipoxygenase products of arachidonic acid, have also been studied as potential mediators of lung inflammation. The potential role of free fatty acids in the pathogenesis of lung injury after long-bone fractures has been

mentioned previously. Tumor necrosis factor and other cytokines (e.g., interleukins 1 and 8) may be important intermediates, particularly in cases of ARDS associated with sepsis. In addition, the lipopolysaccharide molecule itself appears to have direct cytotoxic effects, along with a multitude of actions mediated indirectly through the activation or priming of inflammatory cells.

THERAPY

GOALS

The therapy for ARDS is primarily supportive. However, there is strong evidence that traditional approaches to mechanical ventilation may contribute to and propagate both pulmonary and systemic inflammation. Therefore, therapy is directed at the correction of physiologic abnormalities presenting a threat to life or organ function while simultaneously minimizing the risk of ventilator-associated lung injury (VALI). Although some patients respond to oxygen therapy alone, mechanical ventilation is usually required, along with PEEP. Newer modes of mechanical ventilation offer an alternative when conventional therapy is inadequate or associated with complications. Fluid management must balance the need for adequate cardiac output and prevention of renal failure against the potential for exacerbation of pulmonary edema.

Therapeutic controversies include the following:

- The level of F_{IO_2} that is nontoxic to the lung
- The risk/benefit ratio of higher PEEP and lower F_{IO_2} versus lower PEEP and higher F_{IO_2}
- The risk/benefit ratio of high PEEP with maintenance of cardiac output by volume administration or vasoactive agents
- The preferred mode of mechanical ventilation
- The philosophy of fluid management (whether to “dry out” the patient and run the risk of increased lung water)
- The use of colloid versus crystalloid solutions in fluid management

VENTILATORY MANAGEMENT

Oxygen Therapy and Mechanical Ventilation

The major physiologic abnormality in ARDS is hypoxemia due to intrapulmonary shunt. The work of breathing is increased by reduced lung compliance and by the increased minute ventilation requirement imposed by the associated hypermetabolic state and increase in physiologic dead space. These factors contribute to patient discomfort and may further impair oxygenation by increasing oxygen consumption. The majority of patients with ARDS require tracheal intubation and mechanical ventilation either to overcome hypoxemia or to alleviate ventilatory failure due to excessive work of breathing. Although supplemental oxygen therapy alone is rarely adequate, the application of continuous positive airway pressure (CPAP) through a tight-fitting mask is sometimes sufficient to improve both oxygenation and comfort.

High concentrations of oxygen can be injurious to the lung, potentially intensifying ARDS. Although an F_{IO_2} of 0.8 or higher has been demonstrated to cause direct injury to lung tissue, there is no clear agreement as to what level of F_{IO_2} is nontoxic. In general, the lowest F_{IO_2} achieving adequate oxygenation (generally, an arterial oxygen saturation less than or equal to 88% to 90%), should be used. Administration of PEEP can improve arterial oxygenation and allow a reduction in F_{IO_2} . PEEP may also play a role in protecting against VALI, as discussed below.

Until recently it was conventional to use tidal volumes of 10 to 15 mL per kilogram in persons with ARDS. A body of evidence now strongly suggests that conventional ventilatory techniques can worsen lung injury in previously injured lungs. Two mechanisms have been identified as the cause of VALI: (a) overdistention of alveoli from the use of high V_T ; and (b) cyclical opening and closure of alveoli with each breath that creates shear forces on alveolar epithelium. This theory arose from animal model studies in the 1970s and 1980s but the evidence was largely ignored as irrelevant by clinicians. Recent human studies now suggest that VALI is a clinically relevant process that can contribute to lung and systemic inflammation and patient mortality.

The clinical evidence began with uncontrolled reports of small V_T ventilation (5 to 6 mL per kilogram) with permissive hypercapnia. These case series reported remarkable survival rates and were followed by a relatively small randomized controlled trial in which reducing V_T as part of a “lung-protective” mechanical ventilation strategy decreased 28-day mortality but not hospital discharge mortality. Other studies in which the V_T was limited were disappointingly negative.

The recently completed large randomized controlled trial conducted by the NIH/NHLBI ARDS Clinical Trials Network now provides strong evidence that VALI is likely to occur in humans. That study compared 6 mL per kilogram tidal volume to 12 mL per kilogram and was stopped early for efficacy with a significant survival benefit in the low tidal volume group. Patients enrolled in the study were placed on volume-controlled ventilation in the assist/control (A/C) mode (Table 357.3). Their ideal body weights (IBWs) were calculated and their tidal volumes were set at either 12 mL per kilogram IBW or 8 mL per kilogram IBW. The V_T was then reduced in the small- V_T group by 1 mL per kilogram increments over 4 hours to 6 mL per kilogram IBW. If the plateau pressure (inspiratory hold pressure) exceeded 30 cm H_2O in the 6 mL per kilogram group, the V_T could be reduced further to a minimum of 4 mL per kilogram IBW. Hypercapnia and respiratory acidosis were tolerated, but if the pH dropped to less than 7.15 despite sodium bicarbonate infusion, the V_T could be increased. The mortality in the 12 mL per kilogram group was 40%, and this was reduced to 30% in the 6 mL per kilogram group—a difference that is both clinically and statistically significant.

```
Calculate ideal body weight (IBW)
• Male IBW = 50 + 2.3 (height (in.) - 60)
• Female IBW = 45.5 + 2.3 (height (in.) - 60)
Select assist-control mode
Set initial  $V_T$  to 8 mL/kg IBW
Reduce  $V_T$  by 1 mL/kg at intervals  $\approx$  2 hours until  $V_T$  = 6 mL/kg
IBW
Set initial respiratory rate to approximate baseline minute ventilation
(maximum rate  $\leq$  35 breaths/min)
Set inspiratory flow rate above patient demand (usually  $>$  80 L/min)
Adjust respiratory rate and  $V_T$  to achieve pH and plateau pressure ( $P_{plateau}$ ) goals
• If  $P_{plateau} >$  30 cm  $H_2O$ : decrease  $V_T$  by 1 mL/kg (minimum = 4 mL/kg)
• pH goal: 7.30–7.45
• If pH 7.15–7.30, increase RR
• If pH  $<$  7.15, consider  $NaHCO_3$  or increase  $V_T$  in 1 mL/kg increments until pH  $>$  7.15
```

(Adapted from the NIH/NHLBI ARDS Clinical Trials Network Respiratory Management of ARDS Study protocol.)

TABLE 357.3. INITIAL VENTILATOR SETUP AND ADJUSTMENT

In addition to V_T , another major clinical decision includes the mode of ventilation to be used. The conventional approach has been to use volume-controlled ventilation in either the A/C mode, as in the NIH trial, or the intermittent mandatory ventilation (IMV) mode. One advantage of the A/C mode is that if minute ventilation requirements increase (e.g., due to fever, sepsis, or changes in dead-space ventilation), the patient will be able to meet them by triggering the machine at a higher rate. The A/C mode is theoretically associated with a lower work of breathing, although some patients continue to perform inspiratory work even during ventilator-assisted breathing. The A/C mode, though, can lead to air trapping and auto-PEEP, and on some ventilators the inspiratory flow rate can be slow at low respiratory rates. In these instances, other modes of ventilation, such as IMV, may be advantageous. Some authors and clinicians recommend the use of pressure-controlled ventilation (PC) in ARDS patients, but no mode of mechanical ventilation when used properly has been proven to decrease mortality in ARDS. Given the data provided by the NIH trial, we recommend A/C as the mode of choice and only use another mode if there are strong specific indications in an individual case. Because of potential adverse effects, other modes, such as inverse ratio ventilation (IRV) or airway pressure release ventilation (APRV), should be applied only with careful monitoring by experienced personnel.

Positive End-Expiratory Pressure

PEEP remains a mainstay of ventilatory management in patients with ARDS. The beneficial effect of PEEP on arterial oxygenation in ARDS, allowing a reduction in the F_{IO_2} thus potentially reducing the risk of oxygen toxicity, was reported when the syndrome was first described clearly in 1967. The improvement in arterial Pa_{O_2}

with PEEP is associated with an increase in lung volume, measured as functional residual capacity, which results from either opening of previously collapsed lung units or increasing the size of some acini such that the volume of edema fluid present no longer totally fills the acinus, thus making some portion available for gas exchange. PEEP does not decrease extravascular lung water, in fact, total lung water may increase with PEEP.

Achieving the “optimal level of PEEP”—the level that best balances potential benefits with potential risks—has been an elusive goal. The major risk of PEEP is a reduction in cardiac output mediated primarily through a decrease in venous return related to the increase in intrathoracic pressure. It has not been clearly demonstrated that PEEP is associated with an increased risk of pneumothorax. Although improvement in oxygenation and reduction in the F_{IO_2} appears to be a desirable goal, choosing the best PEEP is limited by our incomplete knowledge on the risk of oxygen toxicity in patients with lung injury. Animal model studies suggest that prior lung injury may produce tolerance to the toxic tissue effects of high levels of inspired oxygen; whether this is true in humans with ARDS is unknown. Of course, the ultimate desired benefit is a reduction in mortality in these patients, a goal that has not yet been clearly demonstrated in a large controlled trial with any particular PEEP strategy.

Animal model studies have demonstrated that PEEP has a protective effect against VALI. The lungs of animals ventilated with high tidal volumes but with PEEP show considerably less injury than the lungs of animals given the same high tidal volumes but without PEEP. It is hypothesized that PEEP prevents the cyclical opening and closing of alveoli, which can lead to a stress injury of the alveolar wall and thus diffuse lung injury. A strategy for choosing a level of PEEP to prevent this cyclical opening and closing has been suggested—that of measuring a pressure–volume curve of the respiratory system in a patient with ARDS. As the lung volume is increased, a deflection is seen from a relatively flat slope where an increase in pressure results in very little change in volume to a much steeper slope where pressure and volume increase proportionally. One relatively small two-center study found that utilizing a PEEP level 2 cm H_2O above this so-called lower inflection point combined with limiting tidal volume (6 mL per kilogram) compared to much lower PEEP values and more traditional tidal volumes resulted in improved 28-day mortality. Although we find the theoretical basis for this strategy compelling, confirmation of a beneficial outcome in a large multicenter trial is needed before the results can be generalized to a wide variety of patients with ARDS and before we can recommend its routine use. In the meantime, we continue to favor selection of a PEEP level from data obtained in a PEEP trial. In such a trial, PEEP is increased in increments at relatively short (15 to 30 minutes) intervals with measurement of arterial blood gases and hemodynamics. A PEEP level is then selected that incorporates the bias of the clinician regarding available data, the severity of the ARDS, the F_{IO_2} required, and the hemodynamic status. The detrimental effect of PEEP on cardiac output is sensitive to the intravascular volume status. If blood pressure falls (or if cardiac output drops when a pulmonary artery catheter is in place) before a PEEP level is reached that achieves the oxygenation goals or would be likely to prevent considerable areas of lung from cyclical collapse and reopening, then intravascular volume can be increased and the PEEP trial repeated.

PHARMACOLOGIC THERAPY

Corticosteroid therapy has been widely used in the treatment of respiratory failure, but well-controlled clinical trials have failed to demonstrate any clear benefit either in the early treatment or in the prevention of ARDS. Randomized controlled trials have also failed to confirm a previous report suggesting a beneficial effect of large-dose corticosteroids in sepsis. Four small uncontrolled series and one small randomized trial of methylprednisolone therapy in nonresolving, late-phase (more than 7 days' duration) ARDS suggested possible benefit. This treatment carries with it potential harm with an increased risk of infection, hyperglycemia, and prolonged neuromuscular weakness. A large-scale, well-controlled clinical trial is now under way. Currently, the routine use of corticosteroids is not recommended in patients with ARDS. Recent randomized controlled trials of stress dose hydrocortisone (e.g., 100 mg t.i.d., a considerably lower dose than used in most previous sepsis trials) in patients with sepsis and hypotension requiring vasopressors have suggested a mortality benefit compared to placebo. These trials have been relatively small and require confirmation in a large multicenter trial.

Prostaglandin E_1 is a vasodilator with anti-inflammatory properties that lowers pulmonary artery pressures and increases cardiac output in ARDS. Because the drug is 95% metabolized during a single pass through the lung, vasodilatation of the systemic vasculature is usually minimal. Despite an earlier report of improved survival in ARDS patients treated with prostaglandin E_1 , a subsequent multicenter controlled trial showed no reduction in ARDS severity, duration, or mortality. Other modulators of the inflammatory response, including ketoconazole, lisophylline, pentoxifylline, ibuprofen, antioxidants, and antibodies directed against endotoxin, complement fragments, and tumor necrosis factor, have been studied without evidence of benefit. Surfactant replacement, so successful in infant respiratory distress syndrome, is also being evaluated in ARDS. Nitric oxide, an inhaled selective pulmonary vasodilator, is being studied as a means to improve gas exchange. It has been shown to improve oxygenation and reduce pulmonary artery pressures in ARDS, but no survival benefit has yet been demonstrated in a controlled clinical trial. So far, none of these therapies can be recommended for the routine treatment of ARDS.

COURSE, OUTCOME, AND COMPLICATIONS

Once a patient develops ARDS, the course is variable, lasting from a few days to several months. The average duration of mechanical ventilation is approximately 10 to 12 days, and about 10% to 20% of patients remain ventilator-dependent for longer than 3 weeks. Even in patients who resolve their underlying illness or injury and respond readily to supportive therapy, the course usually lasts several days, in contrast to patients with cardiogenic pulmonary edema, who typically respond to therapy much more rapidly, improving in a few hours or at most in 1 to 2 days. The primary determinants of outcome appear to be age, underlying disease process, degree of the fibrotic response, prevention of VALI by an appropriate ventilation strategy, and development of complications, especially infection and multiple organ dysfunction.

One-third of the deaths in ARDS patients are related to the underlying disease or injury; that is, death is caused by events occurring before the onset of ARDS. The remaining two-thirds of ARDS deaths are due to complications that have their onset either coincident with or after ARDS onset. Only about 15% of nonsurvivors die a respiratory death (i.e., due to hypoxemia or respiratory acidosis that is refractory to treatment).

Three-fourths of those who die of complications have clinical evidence of sepsis syndrome (septic shock) and associated multiple organ system failure. The specific cause of death may vary, but sepsis syndrome and extrapulmonary organ system failure seem to be the common link. Although these patients do not die a respiratory death, most of them still meet the criteria for respiratory failure at the time of death. The exact process leading to death in these patients is unknown.

Sepsis syndrome is much more common in patients with ARDS than in critically ill patients who do not have respiratory failure, even when differences in duration of endotracheal intubation and mechanical ventilation are considered. This may reflect a higher incidence of nosocomial lung infection due to disturbances in local defense mechanisms, or significant defects in systemic cellular and humoral immune function associated with the syndrome. Sepsis syndrome does not always have an infectious cause; the systemic manifestations of pulmonary inflammation can produce the sepsis syndrome. This may explain why, in one series, outcome in patients with ARDS with infectious complications was not influenced by whether appropriate antibiotic therapy had been administered. Nevertheless, a careful search for infectious foci is always warranted.

Another significant complication in patients with ARDS is pulmonary barotrauma with resultant pneumothorax. Although the term *barotrauma* implies that this complication is caused by high pressures in the lung, other factors are probably operative as well. The incidence of barotrauma has been correlated with the level of peak airway pressure and to the use of large V_T values in mechanically ventilated patients. The pathogenesis probably involves overdilatation of lung regions that have already been structurally weakened by alveolar inflammation. Subsequent alveolar rupture leads to the tracking of gas along bronchial and vascular bundles into the mediastinum. The continued air leakage may result in further soft-tissue dissection into retroperitoneal and subcutaneous tissues, or the accumulated mediastinal emphysema may rupture across the thin mediastinal pleura, causing pneumothorax. In patients on positive-pressure ventilation, immediate placement of a chest tube is essential to avoid the life-threatening complications of a tension pneumothorax.

Patients can and do survive prolonged courses of ARDS, even when complicated by sepsis, barotrauma, and pulmonary fibrosis. The recently described decline in mortality speaks to the importance of supportive care, including the use of lung-protective mechanical ventilation strategies, and prevention and treatment of complications. Advances in specific therapies may lead to a further decline in mortality.

CHAPTER 358: APPROACH TO THE PATIENT WITH PLEURAL DISEASE

STEVEN A. SAHN AND JOHN E. HEFFNER

Pleurisy
Pleural Effusions

PLEURISY

Pleurisy denotes inflammation of the pleura with or without pleural effusion. Pleurisy can result from direct trauma to the chest wall, but it most commonly occurs from extension of localized disease of the lung (pneumonia), mediastinum (esophageal rupture), pericardium (pericarditis), or abdomen (subphrenic abscess), or from systemic disease (lupus erythematosus). Patients who present with pleurisy usually have an associated pleural effusion; the presence or absence of pleural fluid may be a helpful differential finding. For example, viral pleurisy, rheumatoid pleurisy, and sarcoid involvement of the pleura often lack pleural effusions, whereas bacterial pneumonia, lupus pleuritis, and postcardiac injury syndrome usually have associated pleural fluid.

PATHOPHYSIOLOGY

A scant nerve supply exists in the lung distal to the bronchi, primarily composed of efferent twigs of sympathetic and vagal origin. Therefore, stimulation of the visceral pleura and lung usually does not produce pain. The parietal pleura, in contrast, is a highly sensitive surface, supplied extensively with sensory afferents from intercostal, sympathetic, phrenic, and vagus nerves.

Injury to the costal parietal pleura produces sharp, localized pain at the site of irritation. Inflammation of the peripheral diaphragmatic pleura also results in localized pain but tends to extend over a greater area of the chest wall, back, or abdomen. The area of perceived pain expands in relation to the intensity of the injury. Irritation of the central portion of the diaphragmatic pleura does not elicit pain in the immediate area but results in referred pain to the ipsilateral posterior neck, shoulder, and trapezius muscle. Stimulation of the mediastinal parietal pleura over the pericardium also may result in pain referred to the neck. This referred pain results because most of the sensory fibers of the phrenic nerve enter at the C4 level of the spinal cord, the usual entry point of sensation from the shoulder.

CLINICAL FEATURES

The patient with pleurisy complains of pain on breathing that may be minimal or severe, depending on the degree of inflammation. The patient may describe the chest pain as stabbing or shooting, or as a stitch in the side. It is exacerbated by deep breathing, coughing, sneezing, or even talking. Pleuritic pain may be relieved by manual pressure against the chest wall that causes splinting. However, this maneuver does not differentiate pleural inflammation from other causes of pleuritic-like pain caused by rib fractures, myositis, or neuritis, which also can respond to a diminution in chest wall motion.

The pain of costal pleural inflammation is located directly over the site of irritation, with associated tenderness to deep palpation. Cutaneous hypersensitivity and abdominal pain are notably absent. In contrast, irritation of the lateral anterior and portions of the posterior diaphragmatic pleura results in a more diffuse area of pain over the lower thorax, back, and abdomen, accompanied by cutaneous hyperesthesia, exacerbation by pressure, and muscle rigidity. The neck and shoulder pain from irritation of the central diaphragmatic pleura is associated with tenderness, hyperesthesia, hyperalgesia, and muscle spasm.

Dyspnea, a common complaint, results partially from the voluntary and involuntary restriction in respiration imposed by the pain. An accompanying large pleural effusion, pneumonia, or other underlying lung disease may aggravate shortness of breath. Other presenting symptoms depend on the cause of the pleurisy. For example, a shaking chill, fever, and purulent sputum suggest bacterial pneumonia as the cause of the pleurisy, whereas isolated acute pleuritic pain and dyspnea may indicate spontaneous pneumothorax.

The patient generally has shallow and rapid breathing and ipsilateral restriction of chest wall motion, and often lies on the affected side to limit chest expansion. Palpation verifies the limited ipsilateral movement of the hemithorax and rarely demonstrates a friction rub. The percussion note may be flat owing to underlying consolidation or pleural effusion; fremitus may be increased or diminished, depending on the presence or absence of consolidation.

A pleural friction rub confirms the diagnosis of pleurisy. The succinct description by Hippocrates that in pneumonia “the lung . . . squeaks like a leather strap” is difficult to improve on. A pleural friction rub, which is often evanescent, can vary in intensity from a faint scratchy sound to a loud creak that is appreciated close to the ear. The presence of pleural fluid may modify or abolish the pleural rub. A pleural friction rub usually is audible during both phases of respiration but is best heard at or near the end of inspiration; the rub disappears with breath holding, in contrast to a pericardial rub. The pleural friction rub may be localized or heard over a wide area, and is most frequently appreciated over the lateral and posterior regions of the inferior thorax. It is rarely heard over the upper thorax and apex because of limited movement of the lung in the apexes relative to the bases. In the patient with acute pleurisy, splinting diminishes the friction rub; only when the patient is encouraged to take a deep breath is the rub “discovered” by the clinician.

The clinician may hear a false friction rub if the stethoscope is allowed to slide over the skin; firm pressure eliminates this problem and increases the intensity of the rub. It is sometimes difficult to differentiate crackles from a friction rub; cough may diminish or ablate crackles but has no effect on the rub.

DIFFERENTIAL DIAGNOSIS

The symptoms associated with pleurisy are nonspecific, and the documentation of a pleural friction rub simply confirms pleural inflammation. The remaining history, physical findings, and pertinent laboratory tests enable the clinician to narrow the differential diagnosis of pleurisy ([Table 358.1](#)). The history may suggest empyema (alcoholism, loss of consciousness 10 days previously, fever), pulmonary embolism (recent leg fracture with cast, acute onset of dyspnea), postcardiac injury syndrome (myocardial infarction 2 weeks previously, fever, dyspnea), or asbestos pleurisy (shipyard worker for the past 15 years). A history of vomiting, retching, and chest or upper abdominal pain should raise the possibility of esophageal rupture. A known diagnosis of systemic lupus erythematosus or a history of taking drugs (procainamide, hydralazine, quinidine, phenytoin) associated with the lupus syndrome, sarcoidosis, rheumatoid disease, or uremia should alert the clinician to a potential cause of pleurisy. Drugs such as nitrofurantoin, methysergide, methotrexate, and procarbazine have been associated with pleurisy.

TABLE 358.1. CLINICAL FEATURES OF COMMON DISEASES THAT CAUSE PLEURISY

An elevated leukocyte count with a shift to the left suggests a bacterial infection such as pneumonia, subphrenic abscess, esophageal rupture (mediastinitis and

empyema), hepatic or splenic abscess, or severe inflammation (pancreatitis). Leukopenia may be seen with viral pleurisy or systemic lupus erythematosus.

The chest radiograph may establish the diagnosis of pneumothorax or suggest bacterial pneumonia (lobar consolidation with effusion), esophageal rupture (left hydropneumothorax with mediastinal and subcutaneous emphysema), or pathologic process originating below the diaphragm (subphrenic abscess: elevated hemidiaphragm, small effusion, air-fluid level below the diaphragm).

Pleural fluid analysis is the most helpful diagnostic test in establishing the presumptive or definitive diagnosis in most cases of pleurisy ([Table 358.2](#)). Thoracentesis should be performed as soon as the presence of a pleural effusion is documented by chest radiograph. Cell counts, protein/lactate dehydrogenase (LDH)/glucose/amylase concentrations, pH, and appropriate cultures should be obtained on most patients who present with pleuritic chest pain. Essentially all patients with pleurisy have exudative effusions. Bloody effusions are suggestive of pulmonary embolism, postcardiac injury syndrome, neoplasm involving the pleura, uremic pleural effusion, pleural endometriosis, or asbestos pleural effusion. Pus aspirated from the pleural space confirms the diagnosis of empyema, either related to pneumonia or from esophageal rupture (anaerobic empyema). An increased pleural fluid amylase (greater than serum amylase) level in the setting of pleurisy is found with acute pancreatitis and esophageal rupture; pleural fluid associated with esophageal rupture has a low pH (often 6.00 or less), whereas that associated with pancreatitis has a pH between 7.30 and 7.40. The pleural fluid nucleated cell count is increased (more than 10,000 per microliter) with a polymorphonuclear predominance in bacterial pneumonia, esophageal rupture, pancreatitis, and subphrenic abscess. A low (less than 5,000 per microliter) nucleated cell count with a lymphocyte predominance usually is observed in tuberculous pleurisy. Causes of pleurisy with pleural effusions of low pH (less than 7.30) and a glucose level below 60 mg per deciliter include empyema, esophageal rupture, rheumatoid pleurisy, lupus pleuritis, and tuberculous pleurisy.

Disease	Diagnostic Pleural Fluid Tests
Empyema	Observation (pus, putrid odor); culture
Malignancy	Positive cytology; LE cells present; AHA (pleural fluid/serum ratio) ≥ 1.00
Lupus pleuritis	Positive AFB stain, culture
Tuberculous pleurisy	High amylase, pleural fluid acidosis
Esophageal rupture	Coferin as low as 6,000
Fungal pleurisy	Positive KOH stain, culture
Chylothorax	Triglycerides (> 150 mg/dL); lipoprotein electrophoresis (chylomicrons)
Hemothorax	Hematocrit (pleural fluid/blood ratio) ≥ 0.50
Urothorax	Creatinine (pleural fluid/serum ratio) ≥ 1.00
Peritoneal dialysis	Protein (> 1 g/dL); glucose (300–400 mg/dL)
Extravascular migration of a central venous catheter	Observation (milky if lipid is infused); glucose (P/Serum) ≥ 1.0 if glucose is infused
Rheumatoid pleurisy	Characteristic cytologic findings (pH < 7.00 ; glucose < 10 mg/dL; LDH > 1000 IU/L)

AFB, acid-fast bacillus; AHA, anti-nuclear antibody; LE, lupus erythematosus; P/S, pleural fluid/serum.

TABLE 358.2. DIAGNOSES THAT CAN BE ESTABLISHED DEFINITELY BY PLEURAL FLUID ANALYSIS

If the cause of the pleurisy remains unclear after pleural fluid analysis, then other appropriate studies should be done. These include a ventilation–perfusion lung scan and possibly angiography if pulmonary embolism is a consideration, a pleural biopsy to diagnose suggested tuberculous pleurisy, a contrast study of the esophagus to confirm a suspected diagnosis of esophageal rupture, or an abdominal computed tomography (CT) scan if subphrenic abscess is a likely possibility.

The treatment and course of pleurisy vary with the underlying disease. Drainage of the pleural space is necessary in postpneumonic empyema and esophageal rupture, and in some patients with pneumothorax. Patients with lupus pleuritis and postcardiac injury syndrome respond rapidly to corticosteroids, whereas many patients with pleuritic pain obtain relief from the nonsteroidal anti-inflammatory drugs. With appropriate and prompt treatment, most patients with pleurisy have successful outcomes, as it is unusual for patients with malignant pleural effusions or mesothelioma to manifest pleuritic chest pain.

PLEURAL EFFUSIONS

The clinical recognition of a pleural effusion signifies that an abnormal physiologic state exists whereby there is a dysequilibrium in the formation and removal of pleural fluid. The pleural fluid commonly is the sequela of primary pulmonary disease, but it can also result from disease in an extrapulmonic focus, such as the heart (congestive heart failure), the kidneys (nephrotic syndrome), the liver (cirrhosis), and the pancreas (acute pancreatitis). Pleural effusions also can occur with systemic diseases (systemic lupus erythematosus, yellow-nail syndrome), metastatic malignancy, and iatrogenic causes such as drug therapy (nitrofurantoin) and extravascular migration of central venous catheters. Therefore, patients with pleural effusions may present not only to the pulmonologist but to the general internist, medical subspecialist, family physician, dermatologist, and surgeon.

VALUE OF PLEURAL FLUID ANALYSIS

The discovery of pleural fluid provides the opportunity to verify the disease, procedure, or drug that has caused the pleural effusion. With thoracentesis at the bedside, the fluid can be rapidly sampled and observed, its constituents examined microscopically, and its cells and biochemistry quantified. A comprehensive and systematic approach to analysis of the fluid in conjunction with the clinical presentation should allow the clinician to diagnose the cause of the pleural effusion in 75% of patients at the initial thoracentesis. A definitive diagnosis, such as finding malignant cells or specific organisms in pleural fluid, can be established only in about 25% of patients, but a presumptive diagnosis, based on the prethoracentesis clinical impression, can be substantiated by pleural fluid analysis in an additional 50% of patients. However, even with a nondiagnostic thoracentesis, pleural fluid analysis is useful in excluding other causes of the pleural effusion, such as infection. Therefore, in 75% of patients, the cause of the effusion can be “diagnosed,” and in over 90% of patients clinical decision making–related information can be gained by pleural fluid analysis.

DIAGNOSTIC THORACENTESIS: INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

When a pleural effusion is suspected on physical examination and confirmed radiographically, a diagnostic thoracentesis should be performed in an attempt to establish the cause of the effusion. Instances where observation is warranted, in lieu of thoracentesis, include uncomplicated congestive heart failure and viral pleurisy. In the former the clinical diagnosis is usually secure, and in the latter there is typically only a small amount of fluid. However, if the clinical situation is atypical or does not progress as anticipated, thoracentesis should be performed without delay. When the sampling of pleural fluid is indicated clinically but the volume of the pleural effusion is small on a standard chest radiograph, thoracentesis should be performed under ultrasonographic guidance.

There are no absolute contraindications to diagnostic thoracentesis. Relative contraindications include a bleeding diathesis, anticoagulation, small volume of pleural fluid, mechanical ventilation, and active skin infection. The patient on mechanical ventilation is not at increased risk of pneumothorax from thoracentesis but is more likely to develop tension pneumothorax if the lung is punctured.

Complications of diagnostic thoracentesis include pain at the needle insertion site, bleeding, pneumothorax, empyema, and spleen or liver puncture.

DIAGNOSES THAT CAN BE ESTABLISHED DEFINITELY BY PLEURAL FLUID ANALYSIS

The select number of diagnoses that can be established definitively by thoracentesis are shown in [Table 358.2](#). Confirming the diagnosis of chylothorax does not establish its cause but provides evidence that the thoracic duct has been violated; lymphoma is the cause of more than 50% of chylothoraxes. Esophageal rupture is one of two diagnoses (the other is malignancy) that causes a pleural effusion with a high amylase (salivary) concentration and pleural fluid acidosis (pH less than 7.30); the pleural fluid pH usually approaches 6.00 by 48 to 72 hours after rupture as a result of anaerobic empyema. Empyema, tuberculous pleurisy, rheumatoid disease, and lupus pleuritis all can be associated with a low pleural fluid pH (less than 7.30), but the pleural fluid amylase concentration is less than the concomitant serum amylase. In 10% to 14% of patients with malignant effusions, the fluid may be salivary amylase-rich; however, the pleural fluid pH is usually not below 7.05. With extravascular migration of a central venous catheter, the resultant pleural effusion can have characteristics similar to those of the infusate (milky if lipid is being given) and may be hemorrhagic and neutrophil-predominant due to trauma and inflammation. The ratio of pleural fluid to serum glucose exceeds 1.0 if glucose is being infused; however, the pleural fluid glucose level is usually lower than the infusate, as glucose is transported rapidly from the pleural space.

of the following criteria is present, the fluid has a high likelihood of being an exudate; if none is present, the fluid has a high likelihood of being a transudate.

Ratio of pleural fluid protein to serum protein more than 0.5

Pleural fluid protein greater than 2.9 g per deciliter

Ratio of pleural fluid LDH to serum LDH more than 0.6

Pleural fluid LDH more than 0.45 of the upper limits of normal of serum LDH

Ratio of pleural fluid cholesterol to serum cholesterol more than 0.3

Pleural fluid cholesterol greater than 45 mg per deciliter

Transudates have characteristic but nondiagnostic cellular and biochemical characteristics that support their noninflammatory pathogenesis. These effusions are usually straw-colored, nonviscous, and odorless. In about 80% of cases, the nucleated cell count is less than 1,000 per microliter; it is rare to find a transudative effusion with a nucleated cell count of above 10,000 per microliter. Eighty-five percent of transudative effusions have red blood cell counts up to 10,000 per microliter, so the clinician cannot exclude a serosanguinous effusion as a transudate.

Transudative effusions are composed primarily of lymphocytes, mesothelial cells, and macrophages. It is unusual for transudates to be neutrophil-predominant; if found, this should suggest a dual diagnosis. A low pleural fluid glucose level (less than 60 mg per deciliter) is not found in transudative effusions (with the exception of urinothorax), and the pleural fluid pH is alkaline and exceeds the simultaneously obtained arterial blood pH, usually in the range of 7.45 to 7.55.

PLEURAL FLUID PROTEINS

Although most transudates have absolute total protein concentrations below 2.9 g per deciliter, acute diuresis in congestive heart failure can elevate protein levels into the exudative range. Tuberculous pleural effusions virtually always have total protein concentrations above 4.0 g per deciliter, although protein concentrations vary widely in parapneumonic effusions and malignant effusions. However, the clinician should consider lymphoproliferative disorders such as Waldenström's macroglobulinemia and multiple myeloma when pleural fluid protein concentrations of 7.0 to 8.0 g per deciliter are discovered. When exudative criteria are met by LDH but not protein measurements, malignancy and parapneumonic effusions should be considered. Very high concentrations of pleural fluid LDH (more than 1,000 IU per liter) are characteristically found with empyema, rheumatoid pleurisy, and paragonimiasis; they are sometimes observed with malignancy and rarely with tuberculosis. Pleural effusions secondary to *Pneumocystis carini* pneumonia often have a pleural fluid/serum LDH ratio of more than 1.0 and a pleural fluid/serum protein ratio of less than 0.5.

NUCLEATED CELLS

The total pleural fluid nucleated cell count is virtually never diagnostic; however, counts above 50,000 per microliter are usually found only in complicated parapneumonic effusions, which are loculated effusions with positive bacteriology and a low pleural fluid pH (less than 7.30). When the pleural fluid is grossly purulent, the nucleated cell count may be less than anticipated because the neutrophils have undergone lysis; cellular debris, fibrin, and coagulated pleural fluid account for the purulence of the fluid. Exudative pleural effusions from bacterial pneumonia, acute pancreatitis, and lupus pleuritis usually have total nucleated cell counts of more than 10,000 per microliter. Chronic exudates, typified by tuberculous pleurisy and malignancy, usually have nucleated cell counts of below 5,000 per microliter.

The timing of thoracentesis in relation to the acute pleural injury determines the cellular predominance. The early cellular response to pleural injury is neutrophilic. As the time from the acute insult lengthens, the effusion evolves to a mononuclear predominance if pleural injury does not persist or recur. Therefore, in diseases in which the patient presents shortly after the onset of symptoms, such as bacterial pneumonia, pulmonary embolism with infarction, and acute pancreatitis, effusions are usually neutrophil-predominant. Diseases with an insidious onset, such as malignancy and tuberculous pleurisy, usually have lymphocyte-predominant effusions.

Pleural fluid lymphocytosis, particularly with lymphocyte counts of 85% to 95% of the total nucleated cells, suggests tuberculous pleurisy, lymphoma, sarcoidosis, chronic rheumatoid pleurisy, yellow-nail syndrome, chylothorax, or acute lung rejection. Carcinomatous pleural effusions are lymphocyte-predominant in over half of cases, usually in the range of 50% to 70%. As some lymphocytic effusions can be diagnosed by pleural biopsy, an undiagnosed lymphocytic exudate is the most appropriate indication for this procedure. However, the finding of a lymphocyte-predominant transudate is not such an indication.

Pleural fluid eosinophilia (ratio of pleural fluid eosinophils to total nucleated cells greater than 10%) is commonly associated with air or blood in the pleural space (Table 358.6). Pleural fluid eosinophilia is rare with tuberculous pleurisy. The prevalence of malignancy is similar in eosinophilic and noneosinophilic pleural effusions. About a third of patients with eosinophilic pleural effusions are considered "idiopathic"—many of these effusions are probably due to occult pulmonary embolism or benign asbestos pleural effusion. The mechanism for pleural fluid eosinophilia is unknown; however, a common finding in patients with spontaneous pneumothorax is reactive eosinophilic pleuritis. Patients with eosinophilic parapneumonic effusions usually do not become infected, do not develop complicated effusions, and do not require pleural space drainage for resolution. Pleural fluid basophilia (ratio of pleural fluid basophils to total nucleated cells greater than 10%) has been found only with leukemic involvement of the pleura.

Disease	Comment
Pneumothorax	Most common cause of PFE
Hemothorax	May take 1–2 wk for PFE to develop
Benign asbestos pleural effusion	Up to 50%; probably a common cause of idiopathic PFE
Pulmonary embolism	Associated with radiographic infarction and hemorrhagic effusion
Previous thoracentesis	Usually due to pneumothorax or bleeding
Parasitic disease	Paragonimiasis, hydatid disease, amebiasis, acariasis
Fungal disease	Histoplasmosis, coccidioidomycosis
Drug-induced	Dantrolene, bromocriptine, nitrofurantoin
Lymphoma	Hodgkin's disease
Carcinoma	Not excluded by PFE
Tuberculous pleurisy	Rare

PE, eosinophilic total nucleated PF cells > 10%.

PFE, pleural fluid eosinophilia.

TABLE 358.6. PLEURAL FLUID EOSINOPHILIA

Mesothelial cells are found in small numbers in normal pleural fluid. They are prominent in transudative pleural effusions and are variable in exudative effusions. The major clinical significance of mesothelial cells in exudates is that a finding of more than 5% mesothelial cells makes tuberculous pleurisy unlikely. Mesothelial cells may be confused with malignant cells. A paucity of mesothelial cells in pleural fluid is noted with diffuse pleural injury or fibrosis that inhibits exfoliation into the pleural space. In addition to tuberculous pleurisy, this finding is common with empyema, rheumatoid pleurisy, and chronic malignant pleural effusions, and after the use of sclerosing agents.

The pleural fluid macrophage has its origin in the circulating blood monocyte. Its importance in the pleural space may be as a modulator of pleural injury, being called to the pleural space by neutrophil-released chemotaxins. The presence of macrophages is not of diagnostic value, but differentiation from mesothelial cells is important, as the presence of macrophages does not exclude tuberculous pleurisy.

The presence of numerous plasma cells in pleural fluid is suggestive of multiple myeloma with pleural involvement. The presence of few plasma cells in serous fluid is

nondiagnostic and has been observed in several nonmalignant diseases.

PLEURAL FLUID GLUCOSE AND PH

A low pleural fluid glucose concentration, defined as a glucose concentration below 60 mg per deciliter or a pleural fluid/serum glucose ratio of below 0.5, narrows the differential diagnosis of the exudate to rheumatoid pleurisy, complicated parapneumonic effusion or empyema, malignant effusion, tuberculous pleurisy, lupus pleuritis, and esophageal rupture (Table 358.7). All transudates and most exudates have pleural fluid glucose concentrations similar to that of blood glucose. The mechanism responsible for a low pleural fluid glucose level depends on the underlying disease and includes decreased transport of glucose from blood to pleural fluid (rheumatoid pleurisy, malignancy) and increased use by constituents of pleural fluid, namely, neutrophils, bacteria (empyema), and malignant cells. The lowest glucose concentrations are found in rheumatoid pleurisy and empyema, with glucose being undetectable in some cases. When the glucose concentration is low in tuberculous pleurisy, lupus pleuritis, and malignancy, it usually falls in the range of 30 to 50 mg per deciliter.

Diagnosis	Usual pH (Incidence)	Usual Glucose Concentration (mg/dL)
Empyema	5.50-7.29 (~100%)	<40
Esophageal rupture	5.00 (~100% by 48 h)	<60
Rheumatoid pleurisy	7.00 (80%)	0-30
Malignancy	5.95-7.29 (33%)	30-59
Tuberculous pleurisy	7.00-7.29 (20%)	30-59
Lupus pleuritis	7.00-7.29 (20%)	30-59

TABLE 358.7. DIAGNOSIS ASSOCIATED WITH PLEURAL FLUID ACIDOSIS (pH <7.30) AND LOW GLUCOSE CONCENTRATION (PF/S <0.5)

Pleural fluid for glucose measurement should be placed immediately in a tube containing sodium fluoride to stop glycolysis; failing to do so may falsely decrease the glucose concentration, especially in fluids containing a large number of metabolically active granulocytes. A falsely low glucose effusion can lead the clinician down a confusing diagnostic pathway.

A pleural fluid pH below 7.30 with a normal blood pH is found with the same diagnoses associated with a low pleural fluid glucose concentration (Table 358.7). A pH below 7.30 represents a substantial accumulation of hydrogen ions, as pH in normal pleural fluid is about 7.60 due to a bicarbonate gradient between pleural fluid and blood. Transudates generally have a pleural fluid pH in the range of 7.40 to 7.55; most exudates range from 7.30 to 7.45. Pleural fluid acidosis (pH less than 7.30) has been found with esophageal rupture, empyema, rheumatoid pleurisy, malignancy, tuberculous pleurisy, and lupus pleuritis.

The mechanisms responsible for pleural fluid acidosis include increased acid production by pleural fluid cells and bacteria (empyema, esophageal rupture) and decreased hydrogen ion efflux from the pleural space due to pleuritis, tumor, or pleural fibrosis (malignancy, rheumatoid pleurisy, and tuberculous pleurisy). A low pleural fluid pH has diagnostic, prognostic, and therapeutic implications in parapneumonic and malignant effusions. In para-pneumonic effusions, a pH below 7.20, usually in association with a glucose level below 40 mg per deciliter and an LDH level above 1,000 IU per liter, indicates with a high likelihood that pleural space drainage will be necessary to resolve pleural sepsis and prevent pleural fibrosis. When the pleural fluid pH is 7.30 or higher, a parapneumonic effusion usually can be treated with antibiotics alone, directed at the pneumonia. With a malignant pleural effusion, a pH below 7.30 is associated with a poorer survival, a high yield on pleural biopsy and cytology, and less successful chemical pleurodesis. However, the pleural fluid pH should not be the sole criterion for a decision concerning pleurodesis. The general health, functional status, and extent of metastases should be considered. Furthermore, a high percentage of patients with a low pleural fluid pH will have successful pleurodesis.

PLEURAL FLUID AMYLASE

The finding of an amylase-rich pleural effusion, defined as a pleural fluid amylase level greater than the upper limits of normal for serum amylase or a pleural fluid/serum amylase ratio greater than 1.0, narrows the differential diagnosis of the exudative effusion to acute pancreatitis, chronic pancreatic pleural effusion (usually with pseudocyst formation), esophageal rupture, and malignancy. Mechanisms that may be operational in the pathogenesis of a pancreatic pleural effusion include direct contact of pancreatic enzymes with the diaphragm, transfer of ascitic fluid via transdiaphragmatic lymphatics or diaphragmatic defects, communication of a fistulous tract between a pseudocyst and the pleural space, and retroperitoneal movement of fluid into the mediastinum with mediastinitis or rupture into the pleural space. Of the possible factors involved in the increased pleural fluid amylase concentration, movement of the enzyme from the peritoneal to the pleural cavity by lymphatics appears to be of considerable importance. Furthermore, impaired lymphatic drainage from the pleural space, in combination with amylase clearance by the kidney, explains why the pleural fluid/serum amylase ratio is greater than unity.

The pleural fluid amylase concentration may be normal in early acute pancreatitis but it increases over time. In contrast to acute pancreatitis, the amylase concentration in chronic pancreatic effusions is always elevated and may reach levels above 100,000 IU per liter; the serum amylase level may be elevated due to back-effusion or may be normal.

Ten percent to 14 percent of patients with malignant pleural effusion have increased pleural fluid amylase concentrations. The most common malignancy causing amylase-rich effusions is adenocarcinoma of the lung, followed by adenocarcinoma of the ovary. However, other cell types of lung cancer as well as lymphoma and leukemia have been associated with amylase-rich effusions. Patients with malignant amylase-rich effusions have predominantly salivary-type isoamylase; thus, the finding of a salivary isoamylase-rich effusion is virtually diagnostic of malignancy in the absence of esophageal perforation. Furthermore, it is highly suggestive of adenocarcinoma of the pleura, as mesothelioma has not been reported to produce salivary amylase.

PLEURAL FLUID CYTOLOGIC EXAMINATION

Pleural fluid cytologic examination has a positive diagnostic yield in 40% to 90% of patients with malignancy. The most important reason for the variability in diagnostic yield is that the effusion is paramalignant. Paramalignant effusions are effusions associated with a known malignancy but are not due to pleural involvement with the tumor. These effusions are due to local effects of the tumor (obstructive atelectasis, obstructive pneumonia with parapneumonic effusion, and impaired lymphatic drainage of the pleural space), systemic effects (pulmonary embolism), and results of therapy (radiation). Additional reasons for the variability in cytologic diagnosis are the tumor type (high positivity with adenocarcinoma, low with Hodgkin's disease), the number of specimens submitted (yields tend to increase with additional specimens due to exfoliation of fresher cells), and the interest and expertise of the cytopathologist.

OTHER TESTS

Immunologic markers in pleural fluid are helpful in the diagnosis of rheumatoid pleurisy and lupus pleuritis but, except for the finding of lupus erythematosus (LE) cells, are nondiagnostic. A rheumatoid factor in pleural fluid of 1:320 or higher, or a measurement greater than the serum rheumatoid factor, is suggestive of rheumatoid pleurisy. A pleural fluid antinuclear antibody (ANA) level of 1:320 or higher, or a measurement greater than serum ANA with a homogenous staining pattern, is suggestive but not diagnostic of lupus pleuritis. The finding of LE cells in pleural fluid is specific for the diagnosis of lupus pleuritis, but the sensitivity of the test is unknown. The likelihood of finding pleural fluid LE cells appears to increase if the fluid is allowed to stand at room temperature for several hours before examination by Wright's stain. Pleural fluid complement levels are low in most patients with lupus pleuritis and rheumatoid pleurisy; this is true whether total hemolytic complement or complement components are measured. Some overlap exists in pleural fluid complement levels between lupus pleuritis and rheumatoid pleurisy and other exudative effusions; however, very low complement levels are found only in the two connective tissue diseases.

UNDIAGNOSED PLEURAL EFFUSION

An understanding of the pathogenesis of pleural fluid formation and knowledge of pleural fluid analysis in conjunction with the clinical presentation should allow the cause of the pleural effusion to be determined in most cases. Sometimes, however, the clinical presentation and stage of disease do not allow a diagnosis to be established. Observation of the patient and repeat pleural fluid analysis are often diagnostic. The decision to pursue more invasive procedures to establish the cause of the pleural effusion depends on the clinical course and the patient's urgency to have a diagnosis established. If symptoms are minimal or improving, a less aggressive approach is indicated, but if the patient has anxiety concerning the undiagnosed effusion, a more aggressive approach may be pursued.

Percutaneous needle biopsy of the pleura is of diagnostic value in tuberculous pleurisy and malignant involvement of the pleura. Suspicion of these diagnoses is the main indication for its use. Culture and histologic examination of the pleural tissue is positive in 50% to 80% of patients with tuberculous pleurisy; the yield in malignant pleural effusions is 40% to 50%. It may be helpful in the diagnosis of fungal pleurisy, particularly coccidioidomycosis, but it is rarely positive in rheumatoid pleurisy. In the patient with suspected malignancy, pleural fluid cytologic examination should be the initial diagnostic approach, as its sensitivity is greater than that of pleural biopsy. However, if the initial cytologic examination is negative, a repeat cytologic examination several days later in conjunction with percutaneous pleural biopsy provides an increased diagnostic yield.

The yield of fiberoptic bronchoscopy in the patient who has a pleural effusion as the only abnormality on chest radiograph and who does not have clinical symptoms of tracheobronchial disease (hemoptysis, cough) is exceedingly low. However, when there are clinical signs (hemoptysis) or radiographic evidence (mass lesion, atelectasis, mediastinal and hilar adenopathy) that suggest tracheobronchial or parenchymal abnormalities, the yield of bronchoscopy is considerably higher.

Thoracoscopy establishes the diagnosis in virtually all patients with malignant pleural effusions. It is of minimal value in the diagnosis of nonmalignant pleural effusions and is unnecessary for the diagnosis of tuberculous pleurisy, as percutaneous pleural biopsy has a high diagnostic yield. Pleural biopsy culture and histologic examination in conjunction with pleural fluid culture and sputum analysis will diagnose about 90% of patients with tuberculous pleural effusions. However, if the tuberculin skin test is positive in the patient with a lymphocyte-predominant exudative pleural effusion who has a negative histologic and bacteriologic evaluation, the patient still needs to be treated for tuberculous pleurisy. All tuberculous effusions resolve in 2 to 4 months with or without chemotherapy; however, there is a high risk (about 70%) that the patient will develop pulmonary or extrapulmonary tuberculosis within the next 5 years.

The value of chest CT is limited in establishing the cause of an undiagnosed pleural effusion. However, a CT scan may demonstrate abnormalities suggestive of asbestos-related pleural disease, empyema, mesothelioma, metastatic adenocarcinoma, or fibrothorax. Furthermore, finding mediastinal or hilar adenopathy and parenchymal lesions that are not clearly delineated by the standard chest radiograph can guide further diagnostic procedures.

With improved instrumentation, thoracoscopy has virtually replaced open pleural biopsy for the diagnosis of unknown pleural disease. One possible exception is mesothelioma, where a large amount of tissue may be necessary for diagnosis. However, many thoracoscopists have demonstrated a high yield in the diagnosis of mesothelioma.

CHAPTER 359: APPROACH TO THE PATIENT WITH A SOLITARY PULMONARY NODULE

JOSEPH P. LYNCH III AND ELLA A. KAZEROONI

[Factors that Predict a Benign \(Versus Malignant\) Source](#)
[Other Diagnostic Studies](#)
[Management](#)
[Several Pulmonary Nodules](#)

A solitary pulmonary nodule (SPN) is a single, circumscribed nodular opacity within the lung parenchyma that should be sufficiently discrete to allow measurement of the diameter in two planes. Because nodules larger than 3 cm almost invariably are malignant, they are excluded from this discussion. SPNs with specific patterns of calcification on plain chest radiographs virtually always are benign and do not require additional evaluation. An aggressive evaluation is warranted for all noncalcified SPNs, however, because an asymptomatic SPN may be the presenting feature of bronchogenic carcinoma, for which prompt surgical excision may be curative. Many of the same differential diagnostic considerations and tests used for SPN evaluation also may be applied to the evaluation of several pulmonary nodules, but there are significant differences in management. A thorough discussion of the approach to several nodules is beyond the scope of this chapter and is addressed only briefly.

Infectious granulomas and primary bronchogenic carcinomas each account for between 30% and 60% of SPNs in most series. Hamartomas constitute about 6% of SPNs; bronchial adenomas, 2%; metastatic malignancies, 3% to 5%; and miscellaneous causes, such as intrapulmonary lymph nodes, pulmonary infarction, and arteriovenous malformations, less than 5%. When bronchogenic carcinomas take the form of asymptomatic SPNs, complete surgical resection of the lesion can be achieved in up to 90% of cases, with the 5-year survival rate approaching 50%. Because a delay in resection of bronchogenic carcinoma may lessen or eliminate the chance for cure, an aggressive diagnostic approach—to include possible thoracotomy and SPN resection—is warranted unless specific contraindications to surgery exist. Nearly half of SPNs are benign, however, and would not require resection if a benign diagnosis could be established with less invasive or noninvasive techniques. In an attempt to limit the number of unnecessary thoracotomies, several criteria have been used to differentiate benign from malignant lesions more reliably. At least one center has reported an increase in the percentage of resected SPNs that are malignant, from 55% to 60% in the early 1980s to 90% to 100% in the early to mid-1990s. This is likely due to the advancement of imaging technologies, such as computed tomography (CT) and positron emission tomography (PET), that allow more benign nodules to be diagnosed without surgical intervention.

FACTORS THAT PREDICT A BENIGN (VERSUS MALIGNANT) SOURCE

CLINICAL FEATURES

The probability that a lesion is malignant increases progressively with advancing age. SPNs in patients less than 35 years old are malignant in fewer than 1% to 2% of cases. In contrast, SPNs are malignant in 15% to 30% of patients 35 to 45 years old and in more than 50% of patients over age 50. The presence or absence of symptoms cannot distinguish benign from malignant lesions. The history, physical examination, serologic tests, and skin tests for purified protein derivative and fungi are often appropriate in the evaluation of an SPN, but they do not reliably exclude malignancy. Smoking history has some predictive value, since the risk of carcinoma rises considerably with increasing number of pack-years. The risk of carcinoma in nonsmokers over age 35, however, is sufficiently high to justify an aggressive evaluation even in this group.

CHEST RADIOGRAPHY

Various radiographic criteria have been applied to differentiate benign and malignant SPNs. They include the size and growth rate of the lesion, the presence or absence of calcification within the lesion, satellite lesions, and the smoothness of the margin. Once an SPN is detected on plain chest radiographs, obtaining any previous chest radiographs is important, since the review of previous chest radiography reports alone may be misleading. The growth rate on serial radiographs may suggest the nature of the lesion. Lesions that are stable in size for 2 or more years are so rarely malignant that they may be followed with repeated radiographs at 6 and 12 months. New SPNs, lesions that have increased in size, or lesions in which stability can be documented for less than 2 years should be examined promptly by biopsy or resected to establish a specific diagnosis. Because doubling times for carcinomas vary widely (30 to 400 days), obtaining serial radiographs prospectively to assess the rate of growth before confirming the nature of the lesion is not recommended.

The likelihood of malignancy grows with increasing size of the lesion. SPNs smaller than 1 cm in diameter are benign in more than 90% of cases. Seventy percent of SPNs exceeding 2 cm in diameter and more than 90% of lesions larger than 3 cm are malignant. Overlap exists, however, and 5% to 10% of bronchogenic carcinomas are smaller than 1 cm when they first are identified.

Calcification within an SPN markedly lessens but does not exclude the chance of malignancy. The specific pattern of calcification is of critical importance. There are four benign patterns of calcification: dense and solid, central, popcorn or lobulated, and laminated. A clump of lobulated calcification within a nodule (a popcorn pattern) is essentially pathognomonic of hamartoma. Patterns of calcification that should be considered indeterminate of benignity or malignancy include eccentric, smudgy and stippled, or punctate. Eccentric calcification is sometimes seen with carcinomas, for instance, a carcinoma that surrounds a nearby calcified granuloma, and cannot be used to differentiate benign from malignant lesions. Satellite lesions, or several smaller radiopacities surrounding a central nodule, are more often associated with a benign origin, but because exceptions exist, this feature has marginal discriminatory value.

The smoothness or regularity of the SPN margins may provide a clue to the nature of the lesion. The margins of most carcinomas are irregular or spiculated, while most benign lesions have smooth or sharp, rounded margins. A smooth margin may be seen in more than 40% of carcinomas, however, so this is an unreliable single sign of benignity. Although assessment of size, growth rate, pattern of calcification, and margin characteristics may be useful in estimating the probability that a lesion is benign or malignant, these features can be misleading. The only chest radiographic criteria that are reliable in certifying that a lesion is benign are the four described patterns of calcification (dense and solid, central, popcorn or lobulated, and laminated) and lack of growth for at least 2 years ([Table 359.1](#)).

Almost Certainly Benign
Distinctive pattern of calcification (dense, central, popcorn or laminated)
Radiographic stability for at least 2 y
Very Likely Malignant
>2.5 cm in size
Grossly irregular or spiculated margin
Indeterminate
Eccentric, smudgy or punctate calcification
Smooth margins or sharp edge
Cavitation
Satellite lesions
<2.5 cm in size

TABLE 359.1. SOLITARY PULMONARY NODULE: CHEST RADIOGRAPHY OF PROGNOSTIC IMPORTANCE

COMPUTED TOMOGRAPHY

CT of the chest is far more sensitive than plain chest radiographs or standard tomography for detecting calcification and may provide additional information as to the benign or malignant nature of an SPN. When the specific benign features are not seen on chest radiographs, thin-section CT through the lesion is carried out. Thin-section CT scanning using 1- to 3-mm sections is superior to conventional CT scans, with sections at 8 to 10 mm thickness, for evaluating the attenuation (density) of nodules, since the partial volume-averaging effect that may be evident with larger sections is eliminated. The CT features of nodules are categorized in

Table 359.2. If one of the four benign patterns of calcification can be identified on thin-section CT, the nodule is considered benign, and the CT examination can be terminated without requiring intravenous contrast and the risk of contrast-related complications. Localized or eccentric foci of calcification have no discriminatory value, because localized calcification in an otherwise low-density lesion is evident on CT in 10% to 15% of carcinomas. An additional benign feature that can be seen on thin section is fat attenuation within a nodule, indicating a hamartoma. More than 50% of hamartomas can be diagnosed on CT by using the following criteria: diameter less than 2.5 cm, a smooth margin, and focal collections of fat or fat and calcification.

Almost Certainly Benign
 Distinctive pattern of calcification (dense, central, popcorn or laminated)
 Fat

Likely Benign if All the Following are Present:
 Diffuse calcification (attenuation >164 HU), calcification occupying $\geq 10\%$
 Smooth margin
 Diameter <2.5 cm

Likely a Hamartoma if All the Following are Present:
 Diameter <2.5 cm
 Smooth edge
 Focal collections of fat, or fat alternating with areas of calcification

HU, Hounsfield units.

TABLE 359.2. SOLITARY PULMONARY NODULE: CT FEATURES OF PROGNOSTIC OR DIAGNOSTIC IMPORTANCE

If a nodule does not meet the specific criteria for benign features on CT, it must be considered possibly malignant. Although the precise role of chest CT in the evaluation of SPN remains the subject of controversy, the next logical step is complete chest CT of the thorax and upper abdomen, including the adrenal glands, to search for suspected bronchogenic carcinoma. CT may detect additional nodules, enlarged lymph nodes, or liver, adrenal, or bone lesions suggestive of metastases, which subsequently can be sampled as part of lung cancer staging.

The characteristics used to evaluate nodules on chest radiographs, such as lesion size and margin, also are used for CT scans. Individually, these features lack sufficient sensitivity to exclude malignancy. The size of the lesion has predictive value, however. In one series, 35 of 36 lesions larger than 3 cm were malignant, whereas only 20% of benign SPNs were larger than 2 cm. In a separate study, only 16 of 279 benign SPNs (6%) exceeded 2.5 cm in diameter. The smoothness and sharpness of the edge of the margin of the lesion are also important prognostically. In a multicenter study of 384 SPNs, 97% of the 188 benign nodules had smooth or relatively smooth borders on CT scan, whereas 80 of 91 SPNs with an irregular or spiculated border were malignant. Accordingly, any SPN exhibiting an irregular margin on chest CT scan should not be characterized as benign, regardless of other CT characteristics. A smooth, sharp margin has no discriminatory value, since 60% of SPNs in one series with smooth margins were carcinomas.

Other techniques have been used to classify nodules on CT as benign or malignant, including CT nodule densitometry and CT nodule enhancement. With respect to the former method, tissue attenuation values on CT range from $-1,024$ Hounsfield units (HU) to $+1,024$ HU, with 0 HU representing water, $-1,024$ HU representing air, and $+1,024$ HU representing dense mineral. CT scanners must be calibrated regularly to ensure that these values do not drift. The higher the CT number of a nodule, the more likely that it contains calcification. CT nodule densitometry was first reported for the evaluation of SPNs by Siegelman et al. in 1980. CT numbers were measured for 91 noncalcified nodules seen on chest radiographs. The mean CT number of the 58 malignant lesions was 92 HU; none exceeded 147 HU. In contrast, the mean CT number exceeded 164 HU in 20 of 33, or 61%, of benign lesions. Calcified nodules seen on chest radiographs typically have CT numbers ranging from 600 to 1,200 HU. The authors suggested that SPNs with CT numbers exceeding 164 HU can be presumed to be benign, whereas lesions with CT numbers less than 164 HU should be classified as indeterminate. High attenuation values (calcification) distributed diffusely throughout a lesion and occupying at least 10% of the cross-sectional area strongly suggest a benign origin. In two large series encompassing more than 500 malignant lesions, no malignancy exhibited diffuse calcification or had representative CT numbers above 164. Among 166 SPNs categorized as benign by CT criteria, none proved to be malignant at operation or after prolonged follow-up. Lesions assessed by CT as indeterminate were malignant in 355 of 458 (78%) and 176 of 229 (77%) cases, respectively.

Several technical factors, including kilovoltage, slice thickness, size of the nodule, position of the nodule within the thorax, type of scanner, and the algorithm used to construct images, may influence quantitative CT densitometry measurements. Since quantitative CT data obtained from different centers may vary considerably, an absolute CT number (such as 164 HU) cannot be used to distinguish benign from malignant lesions reliably across different centers. In the mid-1980s, a technique was developed in which reference nodules of known density were inserted into a chest phantom to determine more accurately the density of nodules on CT. Lesions denser than the reference phantom were likely to be benign, and the remaining lesions were indeterminate. The use of the phantom was transient, and because of the technical factors previously discussed, most centers no longer use the reference phantom.

Lung nodule contrast enhancement on CT after intravenous contrast administration has been investigated in the evaluation of SPNs. In a series of 107 indeterminate SPNs measuring 7 to 30 mm in diameter (52 malignant, 55 benign), Swensen et al. (1996) found that a 20-HU increase in attenuation (or higher) from baseline was an indicator of malignancy; this technique was 98% sensitive and 73% specific for malignancy. Pathologic correlation showed that the degree of nodule enhancement was related to the amount of central vascular staining. More widespread application of this technique is necessary before conclusions can be drawn regarding the role of this technique in SPN evaluation.

POSITRON EMISSION TOMOGRAPHY

PET using fluorodeoxyglucose or [^{11}C]methionine has been investigated in the evaluation of SPNs. Increased tracer uptake is characteristic, but not pathognomonic, of malignant lesions, because some infectious and inflammatory lesions also evidence uptake. Absent tracer uptake is more useful and is a strong negative predictor of malignancy. A lesion without uptake is almost certainly benign, with one caveat. One limitation of PET scanning is the inability to evaluate consistently lesions less than 2 cm in size. While a lesion less than 2 cm with positive uptake may be malignant, lesions of this size without uptake are not consistently benign. Therefore, PET cannot be recommended for the evaluation of nodules less than 2 cm. In one series of 50 patients with nodules 3 cm or smaller in size, PET was 90% sensitive and 83% specific for malignancy; 10% of malignant lesions were incorrectly classified as benign, and 17% of benign lesions were erroneously categorized as malignant. In the same series, CT was 100% sensitive and 52% specific for malignancy. How PET fits into the algorithm for SPN evaluation is unclear, and PET scanners are not as widely available as the other technologies described here.

OTHER RADIOLOGIC IMAGING

Magnetic resonance imaging, digital or planar tomographic imaging, and single photon emission tomography have no advantage over CT scanning and are not recommended. Radioimmunoscinigraphy using technetium Tc 99m—or indium In 111—labeled monoclonal antibodies is an exciting area of research investigation, but this method is of unproven clinical value.

OTHER DIAGNOSTIC STUDIES

FIBEROPTIC BRONCHOSCOPY

Sputum smears and cultures for specific pathogens or sputum cytologic evaluations are diagnostic in only 1% to 3% of asymptomatic SPNs and have no role in routine management because of their expense. They may be indicated, however, for patients with serious underlying disease who are not candidates for thoracotomy and are marginal candidates for invasive diagnostic procedures. Flexible fiberoptic bronchoscopy (FFB) or percutaneous needle aspiration sometimes can be helpful in the evaluation of SPNs, because thoracotomy may be avoided if a specific benign source can be established by either of these techniques. A thoracotomy still is required, however, if the biopsy result is nonspecific or negative. FFB establishes the diagnosis in 40% to 80% of malignant SPNs but in only 5% to 20% of benign SPNs. Size and nodule location strongly influences the yield. Diagnostic accuracy is less than 30% for lesions smaller than 2 cm but exceeds 60% in lesions larger than 3 cm in diameter. Central lesions are diagnosed more accurately with FFB (more than 60%) than lesions within 2 cm of the peripheral pleural surface (20% to 30%). The diagnostic yield from bronchoscopy is greater when a positive bronchus sign is noted on CT, that is, when a bronchus can be identified extending into the

lesion to be sampled.

PERCUTANEOUS NEEDLE ASPIRATION

Percutaneous needle aspiration performed under fluoroscopic or CT guidance has a higher yield but a greater complication rate than FFB. Pneumothoraxes complicate needle aspiration in 10% to 20% of cases (compared with a 1% to 2% complication rate with FFB). Nodules clearly visible in two planes are usually approached with fluoroscopy, whereas CT is used for nodules not visible in two planes (usually smaller nodules) and for nodules in difficult locations (abutting the great vessels or aorta). The diagnostic accuracy of needle aspiration is especially high for malignant lesions, ranging from 85% to 97%. The diagnostic yield can be increased by the use of immediate cytologic study to determine the adequacy of the specimen, so that additional needle passes can be taken during the same procedure if further sampling is required.

As with FFB, the rate of positive diagnoses correlates with the size of the lesion, with a yield of 50% to 70% for lesions smaller than 1 cm but more than 90% for lesions exceeding 4 cm in diameter. There is no need to perform needle aspiration simply to corroborate the diagnosis of carcinoma in patients who are acceptable candidates for thoracotomy. Needle aspiration may be advantageous if a specific benign diagnosis is suspected, such as infection, but it is in this context that needle aspiration has shown the least impressive results. In most medical centers, fine-needle aspiration has had a high diagnostic accuracy in terms of malignant lesions, but it less frequently establishes a specific diagnosis in the context of benign lesions. Using a cutting needle to obtain a core of tissue may increase the yield for benign diagnoses. With percutaneous core-needle biopsies, specific diagnostic yields of 60% to 97% have been reported, even for benign lesions.

VIDEO-ASSISTED THORACOSCOPIC BIOPSY AND MINITHORACOTOMY

An SPN usually can be resected with video-assisted thoracoscopic (VATS) techniques or minithoracotomy. These techniques have lower rates of morbidity than standard posterolateral thoracotomy and are ideally suited to the identification and resection of SPNs suspected of being benign. For small nodules deep to the pleural surface, CT-guided methylene blue injection or hook-wire placement can be used during VATS to guide the surgeon to the lesion, because surgeons lose the tactile sensation of palpation of the lungs that accompanies thoracotomy. If the lesion proves to be malignant at the time of surgery, many surgeons extend the incision and perform standard thoracotomy with curative intent. Studies suggest that high rates of curative resections can be achieved with VATS. In one large series of 388 patients undergoing VATS, 217 nodules were diagnosed as malignant and 171 as benign. Methylene blue or hook-wire localization was used in 76 patients (20%) for guidance. In 67 patients (17%) the procedure was converted into a thoracotomy, primarily owing to an inability to resect the lesion completely (n = 33) or to carry out a lobectomy (n = 30). In this same series, 21 lobectomies were successfully carried out without requiring conversion to open thoracotomy.

MANAGEMENT

The decision to proceed with surgery (VATS or thoracotomy) for the diagnosis of SPNs depends on several factors, including the likelihood that a lesion is malignant, the patient's overall physical condition and ability to withstand surgery, and the patient's desires. Although the axiom When in Doubt, Take It Out generally applies, the physician should avoid being overly dogmatic and should assess the factors cited earlier before arriving at a treatment strategy. For example, for a patient with asymptomatic SPN but such severe pulmonary disease that thoracic resection would be impossible, one could justify following the lesion with serial chest radiographs as the initial step. In contrast, watching a noncalcified SPN of indeterminate cause in a healthy 50-year-old patient cannot be justified. In some cases, the appropriate management strategy may not be obvious. For a 30-year-old nonsmoker who has a 1-cm SPN with a smooth margin, in whom the risk of malignancy is less than 1%, the decision to repeat a chest roentgenogram at 3 months would be reasonable. This approach would be ill advised, however, if the same person had a strong smoking history, a larger nodule, or a lesion with irregular borders.

Lillington and colleagues pointed out that by applying Bayes theorem and analyzing multiple (presumably independent) variables, such as age, smoking history, and size of the lesion, one could arrive at a better estimate of likelihood of malignancy than by using any single variable. This approach is intriguing but still establishes only probabilities and not actual risk. Hence, in the final analysis, thoracotomy (or VATS) may be required to substantiate the diagnosis. Owing to the low risk of surgery for benign lesions and the potentially fatal outcome if malignant lesions should fail to be promptly resected, the prudent approach is to resect any SPNs that are not clearly calcified on chest radiographs (or CT) and when ancillary tests (e.g., FFB or needle aspiration) have failed to achieve a specific benign diagnosis.

SEVERAL PULMONARY NODULES

Several small parenchymal nodules (often less than 5 mm) may be evident on chest CT scan performed as part of the evaluation of an SPN. At least 30% to 50% of incidental nodules noted on CT are benign, even when the SPN is carcinoma. In patients who are otherwise able to undergo resection, we usually proceed with thoracotomy but look for and take biopsy specimens of any additional nodules noted at the time of operation. In patients who are marginal candidates for operation, needle aspiration biopsy of one or more of the nodules may be considered as an alternative to immediate thoracotomy. Additional nodules detected on CT scan should not be considered definitely malignant unless specific histologic confirmation has been obtained.

CHAPTER 360: APPROACH TO THE PATIENT WITH INTERSTITIAL LUNG DISEASE

KEVIN K. BROWN

[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care](#)

The clinician evaluating the patient with known or suspected interstitial lung disease (ILD) faces a diagnostic challenge, with a long and heterogeneous list of potential causes to consider ([Table 360.1](#)). To complicate the evaluation, the majority of these disorders have nonspecific initial pulmonary symptoms, noncharacteristic parenchymal shadowing on chest radiography, and a similar restrictive pulmonary physiologic picture. Moreover, the majority of the ILDs are of unknown origin, the most common causes being sarcoidosis, the idiopathic interstitial pneumonias (such as idiopathic pulmonary fibrosis, or IPF), and connective tissue disease–related ILD. Of the ILDs of known cause, those related to occupational and environmental exposures predominate. Despite these obstacles, almost every case of ILD can be confidently diagnosed with the appropriate combination of clinical, radiologic, physiologic, and histologic data.

Category	Sub-category	Specific Disease	
Idiopathic	Pneumonias	Idiopathic pulmonary fibrosis (IPF)	
		Cryptogenic organizing pneumonia (COP)	
	Interstitial pneumonias	Respiratory bronchiolitis (RB)	
		Hypersensitivity pneumonitis (HP)	
	Other	Eosinophilic granuloma (EG)	
		Pulmonary histiocytosis X	
	Occupational and Environmental	Coal dust	Coal workers' pneumoconiosis (CWP)
			Anthracosis
		Silica	Silicosis
			Caplan's syndrome
Asbestos		Asbestosis	
		Asbest-related pleural disease	
Other		Byssinosis	
		Farmer's lung	
Connective Tissue Disease-Related		Scleroderma	Progressive systemic sclerosis (PSS)
			Localized scleroderma (morphea)
	Sjögren's syndrome	Primary Sjögren's syndrome	
		Secondary Sjögren's syndrome	
	Rheumatoid arthritis	Rheumatoid lung disease	
		Caplan's syndrome	
	Other	Systemic lupus erythematosus (SLE)	
		Systemic sclerosis (SSc)	

TABLE 360.1. ETIOLOGIC CLASSIFICATION OF INTERSTITIAL LUNG DISEASE

PATHOPHYSIOLOGY

The underlying source for most of these disorders is unknown, and the mechanisms of action responsible for the transition from normal lung to fibrosis remain a focus of active ongoing investigation. In those diseases characterized by progressive fibrosis, however, a common pathogenetic sequence is proposed. Injury to the alveolar and/or endothelial cells may occur through inhalation or via the vasculature, with resultant recruitment of local and circulating inflammatory cells. T lymphocytes and macrophages appear to have a central role in the transition from acute injury to chronic inflammation; depending upon the type or stage of disease, excess numbers of neutrophils, plasma cells, or even eosinophils can be found. Why this inflammation persists is not known, though continued exposure to an inciting agent or antigen or failure of the lung's intrinsic anti-inflammatory mechanisms have both been hypothesized.

This chronic inflammation progresses to a fibrotic response characterized by fibroblast proliferation and excess production of collagen and extracellular matrix. This process leads to architectural distortion and disruption of gas-exchange units, with ensuing physiologic disturbance. While they are characterized as “interstitial,” these disorders also can involve the alveolar space, the vasculature, the small membranous airways, and even the pleura. Sometimes this process can be checked and even reversed (such as in cryptogenic organizing pneumonia) but in the majority of patients the process proceeds uninhibited. Ultimately, it results in the development of “honeycomb lung” or end-stage fibrosis, with large cystic spaces separated by thick bands of fibrous tissue.

For those ILDs that are not characterized by progressive irreversible fibrosis, different pathophysiologic events take place. An alveolar filling process with lipoproteinaceous material (alveolar proteinosis), blood (diffuse alveolar hemorrhage, or DAH), malignant cells (e.g., alveolar cell carcinoma or lymphoma), or eosinophils (eosinophilic pneumonia) develops in some of these disorders. The unexplained proliferation of local smooth-muscle cells is seen in lymphangioleiomyomatosis (LAM) and the genetically related tuberous sclerosis. As with other organs, amyloid protein can be deposited in many compartments, including the alveolus, the vessels, and the alveolar capillary membrane.

HISTORY AND PHYSICAL EXAMINATION

The importance of a detailed history in the evaluation of ILD cannot be overemphasized. The most common initial symptoms are slowly progressive (often over several months) exertional breathlessness and a chronic nonproductive cough. Often, the indolent development of exertional breathlessness is overlooked and is incorrectly attributed to the general aging process or lack of physical conditioning. Many patients will note that they have just “slowed down.” The cough is often attributed to recurrent upper respiratory tract infections, postnasal drip, or asthma. The breathlessness and cough sometimes develop so insidiously that the patient fails to notice until a spouse or friend points out the symptoms. The cough can be particularly troublesome in those ILDs that also affect the airways, including respiratory bronchiolitis (RB), cryptogenic organizing pneumonia, sarcoidosis, hypersensitivity pneumonitis (HP), eosinophilic granuloma (EG or pulmonary histiocytosis X), bronchiolitis, and lymphangitic carcinomatosis.

Wheezing is uncommon, but when it is present it can be an important clue to associated airways involvement, with such conditions as RB, HP, eosinophilic pneumonia, or the Churg–Strauss syndrome. Sputum production is unusual, though hemoptysis can be noted and may be an early feature of LAM, EG, vasculitis, or one of the DAH syndromes. Hemoptysis seen in the context of a known ILD can be due to a superimposed infection, pulmonary embolus, or malignancy. Chest pain is atypical, though pleurisy can accompany almost any of the connective tissue diseases, some drug-induced disorders, and the pneumothoraces that complicate LAM or EG. Atypical, nonpleuritic, midsternal chest pain occasionally is seen in sarcoidosis.

The symptoms in the majority of ILDs are chronic and progressive over months to years. Some take the form of acute illness that arises in just days (acute interstitial pneumonia, acute eosinophilic pneumonia); others progress as subacute illness over the course of weeks (cryptogenic organizing pneumonia, DAH, and some drug-induced ILDs). These acute forms of ILD must be differentiated from atypical respiratory infections, cardiac decompensation, and pulmonary emboli. Gender and age can be helpful in making a diagnosis. Most patients with IPF are older than 60, whereas patients with connective tissue diseases and sarcoidosis tend to be younger than 50. LAM develops only in premenopausal women, and the ILD that complicates connective tissue disease is more common in women—except for RA, which more commonly afflicts men.

A review of systems must be performed, with a particular focus on the systemic complaints seen in such autoimmune diseases as arthralgias or joint swelling, Raynaud's phenomena, dry eyes and dry mouth, myalgias, or exanthems. Even in the context of a previously diagnosed ILD, examination for these symptoms is useful, since lung disease can precede the development of a definable connective tissue disease by years. The medical history often gives clues to other pulmonary (such as lung cancer) or systemic illnesses (such as rheumatoid arthritis) or to therapies (such as chemotherapy or radiation) that could have resulted in lung injury. Information concerning current medications, including over-the-counter and nontraditional oral or inhaled therapies, vitamins, food supplements, and recreational drugs, should be solicited.

Previous medications (of any sort) taken for an appreciable length of time also should be reviewed, because the signs or symptoms of drug-induced lung disease may not appear for months or years after the exposure. The use of tobacco products should be explored, since some ILDs are seen primarily in smokers (desquamative interstitial pneumonia, RB, EG, pulmonary hemorrhage in Goodpasture's syndrome). Occasionally, a family history of similar chest or systemic illnesses will be found, because some ILDs have shown evidence of familial association either through genetic mechanisms of action (IPF, tuberous sclerosis, and perhaps sarcoidosis) or

common exposures (HP).

Among the most common causes of ILD are occupational and environmental exposures. Diagnosis requires an exhaustive review of current and previous occupations, an understanding of the actual job performed, the likely exposures encountered, and whether or not protective equipment was used. The same is true of the environmental history in terms of exposures in the home as well as potential exposures preceding the initial symptoms or radiographic abnormalities. The presence of hot tubs, swimming pools, humidifiers, water damage, or pets in the home should be examined. Exposures during the pursuit of hobbies or avocations, such as bird breeding, are of special importance for the diagnosis of HP. The development of symptoms in relation to particular exposures, such as the workplace or a home workshop, or the improvement in symptoms over the weekend or on vacation away from the home suggests a potential environmental exposure as the cause.

Physical findings of a skin rash, eye changes, adenopathy, salivary or lacrimal gland enlargement, hepatosplenomegaly, synovitis, or muscle tenderness can be useful hints to an underlying connective tissue disease, malignancy, vasculitis, or sarcoidosis ([Table 360.2](#)). Clubbing most often occurs in IPF. The chest auscultatory examination often shows fine, mid-to-end inspiratory crackles (dry rales) in IPF, asbestosis, CTD-related ILD, and the chronic form of HP, whereas fewer abnormal sounds are heard in other granulomatous and eosinophilic lung disease. Mid-inspiratory musical crackles are often noted in HP and other diseases that affect the small airways (bronchioles). Wheezing suggests an associated airway abnormality, such as eosinophilic pneumonia or RB-ILD. Pleural or pericardial rubs are occasionally noted in CTD-related disease. In the late stage of any ILD, there may be findings of right ventricular failure with increased intensity of the pulmonic component of the second heart sound, elevated jugulovenous pressure, and peripheral edema. Examination of the joints may show deformities or synovitis characteristic of a particular autoimmune disease.

Abnormality	Associated ILD
Systemic sclerosis	Interstitial lung disease, pulmonary hypertension
Myositis	Interstitial lung disease
Raynaud's phenomenon	Interstitial lung disease
Arthritis	Interstitial lung disease
... (many more rows)

TABLE 360.2. EXTRATHORACIC PHYSICAL FINDINGS IN THE INTERSTITIAL LUNG DISEASES

LABORATORY STUDIES AND DIAGNOSTIC TESTS

IMAGING STUDIES

Chest Radiography

Abnormal results on a chest radiograph (CXR) discovered during a routine physical exam, in preoperative evaluation, or in response to respiratory symptoms are the common initial finding that precipitates evaluation for ILD. The usefulness of the CXR is limited, however, because up to 10% of patients with symptomatic and histologically proven ILD are said to have normal results on CXR. While the CXR is only occasionally useful in making a specific diagnosis, recognition of a radiographic pattern narrows the differential diagnosis ([Table 360.3](#)). For example, the presence of bilateral basilar reticular markings and pleural plaque suggests asbestosis. Radiographic patterns in ILD traditionally have been divided into alveolar-filling and interstitial infiltrates. This approach is limited, since many ILDs have a pattern that combines both features. While the general availability of high-resolution computed tomography (HRCT) has diminished the importance of the CXR in defining ILD, the CXR is still a good starting point.

Patterns	Associated Diagnoses
Increased lung volumes	IPF, CTD-related, emphysema
Increased lung volumes	IPF, CTD-related, emphysema
Mid-upper zone predominance	Sarcoidosis, hypersensitivity pneumonitis, eosinophilic pneumonia
Lower zone predominance	IPF, CTD-related, asbestosis
Septal thickening	IPF, CTD-related, asbestosis
... (many more rows)

TABLE 360.3. USEFUL CHEST RADIOGRAPHIC PATTERNS

High-resolution Computed Tomography

HRCT should be considered a standard method for the initial evaluation of most patients with ILD. It is more sensitive than plain radiography in identifying ILD (particularly in those symptomatic patients with a normal or near-normal CXR), with a sensitivity greater than 90% in diffuse lung disease compared with 80% for the CXR. The radiographic pattern on HRCT often suggests a particular set of diagnostic possibilities ([Table 360.4](#)). HRCT also more easily identifies mixed patterns of disease (such as ILD plus emphysema) or additional pleural, hilar, or mediastinal abnormalities. It has a better correlation with physiologic impairment and can be used more easily as a road map for either transbronchial or open biopsy.

By Type of Radiographic Abnormality	Associated Diagnoses
Reticular lines	CTD-related, IPF, asbestosis
... (many more rows)

TABLE 360.4. USEFUL HRCT PATTERNS IN THE DIAGNOSIS OF ILD

Gallium Scanning

In general, gallium scanning is not useful in the diagnosis or management of ILD. From a diagnostic perspective, the abnormal lung accumulation of gallium citrate Ga 67 24 and 48 hours after intravenous injection will occur in a variety of ILDs. This finding is therefore nonspecific, since it is seen in infections, drug-induced lung disease, IPF, sarcoidosis, CTD-related ILD, and others. Whole-body scanning may be of use in the evaluation of some patients with suspected sarcoidosis, to confirm extrathoracic organ involvement.

PHYSIOLOGY

Pulmonary Function Testing

Pulmonary function testing is necessary for the evaluation of ILD. While ILD can be accompanied by a variety of physiologic abnormalities, including normal function, the classic separation of restrictive and obstructive disease helps categorize the patient's illness and narrows the differential diagnostic possibilities. The majority of ILDs have a restrictive ventilatory defect, though occasionally an obstructive (such as in LAM or EG) or a mixed restrictive–obstructive defect (as in HP, RB, or mixed IPF/emphysema) may be present.

Lung Volumes

Patients usually show symptoms of generally symmetric reduction in the total lung capacity, functional residual volume, and residual volume, which defines the restrictive ventilatory defect. Patients with LAM, EG, or bronchiolitis may have normal or even increased lung volumes, particularly the residual volume.

Spirometry

Airway function in ILD is typically well preserved. Both the forced expiratory volume in 1 second (FEV₁) and the forced vital capacity (FVC) are reduced in a restrictive defect, with the FEV₁/FVC ratio and the expiratory flow rates normal and often supranormal except in the context of concomitant small airway disease. Airflow limitation can be detected if diseases that affect the small airways, such as HP, bronchiolitis, LAM or EG, are present.

Diffusing Capacity of the Lung for Carbon Monoxide

The diffusing capacity of the lung for carbon monoxide (DLCO) is usually decreased, sometimes to very low values. This decrease is related primarily to ventilation-perfusion ratio mismatch, with a poorly ventilated fibrotic lung still being adequately perfused. Marked declines in oxygenation can occur even with a normal DLCO, and, for this reason, DLCO cannot substitute for an actual measure of arterial blood gases, particularly with exercise. Marked reduction of DLCO with relative maintenance of lung volumes suggests concomitant pulmonary vascular disease such as that seen in progressive systemic sclerosis, emphysema, or a cystic lung disease (LAM, EG). In DAH the DLCO may be normal or even elevated, since intra-alveolar hemoglobin absorbs the inhaled carbon monoxide.

Pressure-volume Curve

A reduction in lung compliance or an increase in the elastic recoil or stiffness of the lung is a common finding in those ILD patients with a restrictive ventilatory defect. The measurement of the lung's pressure-volume curve can be useful when radiographic or other physiologic information is difficult to interpret or shows conflicting evidence. Such testing is technically demanding, making it generally less practical except in specialized centers.

Gas Exchange

Gas exchange in an identified ILD is almost always abnormal, particularly with exercise. Pulse oximetry to identify the presence of oxygen desaturation either at rest or with exertion is a good screening method, but it is not as reliable or sensitive as direct measures of gas exchange. Hypoxemia with an elevated alveolar–arterial oxygen tension gradient is the rule. There is sometimes accompanying respiratory alkalosis, and in the late stages of any ILD increased carbon dioxide can be found. Measurements of gas exchange during walking or stationary bicycling are practical and helpful in assessing the severity of disease as well as defining the adequacy of supplemental oxygen replacement. Direct measures of gas exchange (arterial blood gases) are more sensitive, reliable, and reproducible than those relying on ear- or finger-probe oximetry, though the latter measures are less invasive and less expensive.

LABORATORY EVALUATION

Laboratory studies are generally nonspecific, though there are exceptions ([Table 360.5](#)). Serologic studies to detect autoimmune disease are often helpful, in particular, antinuclear antibody, rheumatoid factor, and, in the appropriate clinical context, antinuclear cytoplasmic antibody. While subtle elevations in both the antinuclear antibody and rheumatoid factor are seen in several ILDs, significant elevations, even in the absence of systemic disease, may suggest an evolving connective tissue disease. A complete blood count and biochemical evaluation of liver and renal function should be carried out to look for evidence of systemic disease. Elevated erythrocyte sedimentation rates, C-reactive protein titers, and hypergammaglobulinemia are relatively common nonspecific findings. Elevated lactic dehydrogenase can be present in a variety of ILDs (IPF, alveolar proteinosis, acute interstitial pneumonia).

Parameter	Interstitial Lung Disease
Complete blood count	Normal; anemia may be present in advanced disease
Erythrocyte sedimentation rate	Elevated in many cases, particularly in systemic disease
C-reactive protein	Elevated in many cases, particularly in systemic disease
Antinuclear antibody	Present in many cases, particularly in systemic disease
Rheumatoid factor	Present in many cases, particularly in systemic disease
Antinuclear cytoplasmic antibody	Present in many cases, particularly in systemic disease
Lactic dehydrogenase	Elevated in many cases, particularly in acute interstitial pneumonia
Gamma globulin	Elevated in many cases, particularly in systemic disease
Angiotensin-converting enzyme	Elevated in many cases, particularly in sarcoidosis
Serum precipitin testing	Useful in identifying hypersensitivity pneumonitis
Beryllium lymphocyte proliferation test	Useful in identifying chronic beryllium disease

TABLE 360.5. LABORATORY FINDINGS IN THE INTERSTITIAL LUNG DISEASES

An elevated angiotensin-converting enzyme level suggests sarcoidosis but is nonspecific, since it also is found in HP, silicosis, lymphocytic interstitial pneumonia, and the adult respiratory distress syndrome, among other disorders. Serum precipitin testing to antigens known to cause HP is useful but not diagnostic, and rarely does a random hypersensitivity panel provide insight in the absence of an identified antigen exposure. Identification of circulating serum precipitins to a known organic exposure in a patient with pathologically proven HP helps cement the relationship between the exposure and the disease. The identification of antibodies to organic antigens can merely mean exposure to the antigen, however, without indicating disease; the absence of antibodies does not exclude HP. The blood beryllium lymphocyte proliferation test has high specificity and sensitivity for chronic beryllium disease and can be used to distinguish this disorder from other granulomatous ILDs.

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage (BAL), used previously primarily for investigational purposes, appears to have a limited role in the initial evaluation and diagnosis of ILD. The ability to use the available data regarding BAL in ILD is limited by the lack of standardized techniques in both the performance of the procedure and the laboratory analysis of the lavagate. The primary clinical usefulness of BAL is to narrow the differential diagnosis, though it can provide a definitive diagnosis in rare cases.

Particular patterns of the cellular differential allow one to focus on a small group of potential diagnoses, while different lavage abnormalities may point to others ([Table 360.6](#)). Lavage is also helpful in excluding infectious diseases.

Findings	Potential or Real Diagnoses
Cellular differential Eosinophilia (>35%) Lymphocytosis (>35%)	Eosinophilic pneumonias Sarcoidosis, hypersensitivity pneumonitis, LIP Lymphoma, malignancy Drug-induced lung disease Diffuse alveolar hemorrhage
Bloody lavage with hemoglobin-laden macrophages	Infection
Organisms on stain or culture	Malignancy
Positive cytologic results	Lipoid pneumonia
Lipid-laden macrophages	Abundant proteinosis
PAS-positive hyaline/amorphous material	Pneumocystosis
Ferruginous bodies (Coccidioides), dust particles	Berylliosis
Lymphocyte transformation test	Eosinophilic granuloma
Sirbeck granules on electron microscopy of mononuclear cells	

LIP, lymphocytic interstitial pneumonia; PAS, periodic acid-Schiff.

TABLE 360.6. USEFUL BRONCHOALVEOLAR LAVAGE FINDINGS

A standard fiberoptic bronchoscope is passed through successive airways until its tip is wedged, usually in a third- or fourth-generation bronchus. In ILD the right-middle lobe or lingula typically is used. Once the bronchoscope is wedged, aliquots of saline (usually 20 to 60 ml) are infused and withdrawn individually, and the collected specimen is sent for evaluation. In normal subjects, about 60% of the infused saline will be retrieved and 10 to 15 × 10⁶ overall cells obtained, with a differential of 85% macrophages, 10% lymphocytes, 2% polymorphonuclear cells, and less than 1% eosinophils or basophils. Eosinophilia or lymphocytosis in lavage fluid can significantly narrow the differential diagnosis. Eosinophilia of more than 35% or lymphocytosis of more than 35% is generally helpful. In the idiopathic interstitial pneumonias the lavage findings are nondiagnostic, with generally greater overall numbers of cells and often a near normal differential.

LUNG BIOPSY

Given the number of potential diagnoses and the generally nonspecific nature of clinical, physiologic, radiographic, and laboratory findings, a lung biopsy is often necessary for definitive diagnosis. Histopathologic evaluation of lung tissue remains the most sensitive and specific test to determine accurately the diagnosis and prognosis of the underlying disease.

A transbronchial lung biopsy specimen often is obtained at the time BAL is performed. It is possible to make a histologic diagnosis with transbronchial biopsy, but it is not usual. The technique is helpful for the diagnosis of granulomatous diseases, in patients with peribronchovascular disease (such as lymphangitic spread of carcinoma), and in some airspace-filling diseases, such as eosinophilic pneumonia, bronchoalveolar carcinoma, or alveolar proteinosis. It is very unusual to establish a diagnosis of any of the idiopathic interstitial pneumonias (usual interstitial pneumonia, desquamative interstitial pneumonia, cryptogenic organizing pneumonia, acute interstitial pneumonia, nonspecific interstitial pneumonia) from a transbronchial biopsy specimen. If findings from a transbronchial biopsy specimen are nonspecific, an open or video-assisted thorascopic lung biopsy is indicated. This approach should be considered if diagnostic uncertainty persists after noninvasive evaluation and the patient is not at high risk for a surgical procedure or if therapeutic decisions would change given a particular histologic finding. While some ILDs have unique histologic findings (desquamative interstitial pneumonia or EG), others (rheumatoid arthritis) can produce a variety of abnormal pulmonary histologic patterns (UIP, honeycombing, BOOP, NSIP, bronchiolitis, vasculitis). Some histologic patterns (UIP) are seen in several ILDs (IPF, chronic HP, asbestosis, connective tissue disease–related ILD).

The appropriate management of ILD requires a specific diagnosis, which generally necessitates histologic information. While many of these disorders have poor prospects for long-term survival, there are important differences in prognosis and therapy. A firm diagnosis gives both the physician and the patient a sense of confidence when evaluating the available options based on the untreated natural history of the disease, the likelihood of response to therapy, and the risk of disease and therapy-related complications.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

Since the natural history of most untreated ILDs is progression of fibrosis with its attendant physiologic and lifestyle impairment, most clinicians feel that at least a time-limited trial of therapy is warranted even in the absence of well-designed controlled trials. End-stage lung disease or honeycomb lung can occur in the vast majority of the ILDs and is irreversible. The goal of therapy should be to prevent its development or progression. Lesser degrees of pathologic change usually include a combination of mature fibrosis, granulation tissue (organizing pneumonia), and chronic inflammation. It is the granulation tissue and chronic inflammation that are potentially reversible. A major goal of therapy is to suppress this chronic inflammatory response and reverse the deposition of granulation tissue. The earliest possible diagnosis and institution of therapy is likely to offer the best chance of a response.

The initial intervention should include a vigorous search to identify an etiologic agent and, if found, to avoid it. A patient with HP may need no more than removal from the pertinent exposure to recover completely, while failure to avoid the exposure will lead to recurrent or chronic progressive disease. The patient with RB-ILD may stabilize or improve with cessation of tobacco smoking, whereas one with drug-induced lung disease may respond to cessation of the medication and a short course of corticosteroids. In most of the ILDs, such as IPF, CTD-related ILD, and sarcoidosis, however, the source is unknown, and therapy is directed at the chronic inflammatory response presumed to be responsible for the progressive fibrosis.

Almost all ILD patients need treatment. Control of inflammation requires immunosuppressive medications. Corticosteroid therapy is still considered the standard approach. The response can vary widely, from near complete response (eosinophilic pneumonia) to limited or no response (asbestosis). Unfortunately, corticosteroids have significant side effects, particularly at the doses used in ILD. Even in responsive patients, side effects of therapy may warrant a decrease in dose or even cessation of therapy. Cytotoxic agents—cyclophosphamide and azathioprine—are common treatments for ILD. The beneficial effect noted in Wegener's granulomatosis is one example of how they can consolidate and amplify the benefits of corticosteroids. Many clinicians now add a cytotoxic drug after initial high-dose corticosteroid therapy as a steroid-sparing agent, to allow for maintenance of a response at a much lower steroid dose. Others may initiate therapy with lower doses (10 to 20 mg per day of prednisone) of corticosteroids and a cytotoxic agent simultaneously, taking advantage of their differing mechanisms of anti-inflammatory action. When immunosuppressive therapy is used, particularly combination therapy, *Pneumocystis carini* prophylaxis should be considered. Colchicine also has been proposed to offer modest therapeutic benefit in IPF.

Both the dose and length of therapy depend upon the specific ILD. While some may respond within days (eosinophilic pneumonia) and others within weeks (sarcoidosis and cryptogenic organizing pneumonia), disorders such as IPF require months (often 3 to 6 months) of therapy before a response can be detected. Response to therapy usually is defined by improvement of symptoms and stabilization or improvement in functional, gas exchange, and radiographic abnormalities. Objective evaluations should be carried out on a scheduled basis and as clinically indicated.

A major contributor to death in ILD is hypoxemia, which also can lead to secondary complications, such as pulmonary hypertension and right ventricular failure. Supplemental oxygen to help maintain normoxia at rest, exercise, and sleep can improve significantly a patient's sense of well-being and help prevent hypoxia-related complications. The use of supplemental oxygen also may be necessary to allow a patient to engage in exercise or a pulmonary rehabilitation program. A routine exercise program is important in maintaining aerobic cardiovascular fitness, weight control, bone mass on corticosteroid therapy, and an overall sense of well-being. Any patient with chronic lung disease should receive a pneumococcal vaccine and a yearly influenzae vaccine.

COMPLICATIONS AND PITFALLS

Clinical deterioration in patients with ILD is common and can be life-threatening. Deterioration generally is caused by progression of the primary disease, a disease-related complication, or a complication associated with therapy ([Table 360.7](#)). Disease progression usually takes the form of progressive respiratory

symptoms with increased dyspnea and cough. Radiologic and physiologic deterioration and worsening gas exchange accompany the symptoms. Worsening of symptoms does not in itself define progression of disease, however, since disease-related complications can be heralded in the same fashion. Right and/or left ventricular dysfunction, pulmonary embolism, respiratory infection, pulmonary malignancy, and pneumothorax all can mimic the progression of an underlying ILD. Complications of treatment include infection, respiratory and peripheral muscle weakness, and osteoporosis.

TABLE 360.7. CLINICAL DETERIORATION IN PATIENTS WITH ILD

The most common pitfall in the management of ILD is the failure to establish a diagnosis. At the first sign of disease, patients with IPF may have had abnormal CXR results for more than 5 years. It is not unusual to find that by the time the diagnosis is established, end-stage fibrosis is present. With the currently available therapies, initiation of treatment before development of end-stage fibrosis offers the only hope for response. In some patients a generic diagnosis of ILD is made on the basis of symptoms and a CXR. Corticosteroid therapy is instituted, and the patient responds—but the abnormalities recur after cessation of therapy, or significant complications arise. Without a fully characterized diagnosis, the appropriate dose and length of therapy, alternative medications, and risk of recurrence or complications cannot be intelligently considered.

Indications for REFERRAL

The initial evaluation of a patient with known or suspected ILD should include an exhaustive history and complete physical examination. A plain CXR, an HRCT scan, and pulmonary function testing with lung volumes, spirometry, and a DLCO should be obtained. Gas exchange should be assessed with a resting arterial blood gas analysis and exercise oximetry. A complete blood count, blood chemistry panel, urinalysis, and serologies are undertaken as dictated by the history (anti-nuclear antibody, rheumatoid factor, antineutrophil cytoplasmic antibodies, anti-basement membrane antibody, and so forth). It is important to review all available old CXRs and pulmonary function studies. The type and pace of change over time often provide insight into the diagnosis and activity of the disease. Common chest diseases (chronic obstructive pulmonary disease, heart failure, atypical pneumonia, asthma, mycobacterial or fungal disease) can mimic ILD, and it is important to consider them as the evaluation evolves. It is likely that most patients ultimately will require lung biopsy to characterize their disease fully, though this decision might be left for the consultant.

Almost all patients with a suspected or known diagnosis of ILD would benefit from referral to a pulmonologist, since pulmonologists are in the best position to combine the clinical, radiographic, physiologic, and pathologic findings of a particular case into a coherent diagnosis. This is particularly true if there are questions regarding the relationship of a lung disease to an occupational or environmental exposure or if a therapeutic immunosuppressive or cytotoxic drug trial is contemplated. Patients with a deteriorating clinical status after initiation of therapy also would benefit from referral, since progression of the underlying disease, complications of the primary disease, and complications of therapy can all manifest in a similar fashion.

A pulmonologist can perform and/or interpret specialized tests, such as open, thorascopic, or transbronchial lung biopsy; BAL; a pressure-volume curve; and cardiopulmonary testing (exercise testing with arterial blood gas analysis to determine if physiologic limitation exists, whether its cause is cardiac or pulmonary, and the degree of hypoxemia with exertion). They also can determine whether additional testing, such as radionuclide scans, right-sided heart catheterization, pulmonary angiography, or studies of respiratory drive would be useful.

CHAPTER 361: APPROACH TO THE PATIENT WITH SUSPECTED PNEUMONIA

GALEN B. TOEWS

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care](#)

PRESENTATION

Pneumonia is defined as an acute inflammatory process of the lung parenchyma. The inflammatory process is associated with symptoms of acute infection, auscultatory findings consistent with airspace filling and/or lobar consolidation, and an acute infiltrate visible on a chest radiograph. The goals of treating a patient with suspected pneumonia are to establish the presence of an intrapulmonary process, to determine that infection is present, to identify the causative agent, to assess the severity of illness, and to initiate appropriate therapy. Determining the exact causative agent of acute pneumonia is difficult. Therefore, the clinician must collect and correctly interpret various clinical, epidemiologic, and laboratory clues to make a presumptive initial diagnosis. The initial treatment usually is based on the clinical signs and symptoms, an estimate of the severity of illness, the need for hospitalization, evidence of coexisting disease, the patient's age, and the relative frequency of specific pathogens in the at-risk population. The clinical picture of pneumonia classically has been categorized into four syndromes: bacterial or typical, atypical, anaerobic/cavitary, and opportunistic. Nonetheless, some studies have found no convincing associations between symptoms, physical findings, or laboratory test results and specific etiologic factors.

Lower respiratory tract infections are the leading cause of death from infectious diseases in the United States. Community-acquired pneumonia affects three million patients and results in approximately ten million physician visits, 5,000 hospitalizations, and 45,000 deaths in the United States annually. Pneumonia is the sixth most common cause of death in the United States. Death rates associated with pneumonia and influenza increased by 59% between 1979 and 1994. The growing proportion of persons who are at least 65 years of age accounts for much of this increase. Age-adjusted rates also rose by 22%, suggesting the importance of comorbid conditions in a greater percentage of the population. Financial costs associated with pneumonia are estimated at \$14 million in direct costs and \$9 million in lost wages annually. Mortality rates are estimated to be less than 1% for patients who are not hospitalized, but they are approximately 14% for hospitalized patients. Thus, a sense of clinical urgency often exists in the early management of acute pneumonia because of the potential for a fatal outcome.

PATHOPHYSIOLOGY

The lungs are inoculated repeatedly with microorganisms from the upper airways and from inhaled aerosols. Inoculum size, bacterial virulence, and the state of host defenses determine the pathogenetic potential of a microbial challenge. The development of a clinical infectious disease of the lungs is determined largely by the success or failure of pulmonary defense mechanisms.

Several factors combine to protect the lower respiratory tract against infection that might result from inhalation or aspiration of infective organisms. The configuration of the upper airway passages ensures that a thin, laminar flow of air passes close to hairs and sticky surfaces that can trap potentially infectious particles. Secretory immunoglobulin A, which constitutes 10% of protein in nasal secretions, binds to and neutralizes certain viruses and may even protect against bacterial colonization by blocking the adherence of bacteria to mucosal surfaces. The epiglottis is the major organ that prevents particles from entering the trachea; its closure during swallowing ensures that mouth contents pass down the esophagus. Similarly, the larynx prevents the passage of secretions down into the trachea and allows the generation of the intrapulmonic pressure needed for an effective cough. If particles succeed in entering the trachea, ciliary action and coughing work together to clear them from the bronchi, the former by steadily moving particles toward the larynx and the latter by propelling them rapidly, bypassing ciliary action.

When bacteria bypass these mechanisms, noncellular and cellular host factors at the level of the alveolus provide further protection. Bacterial cell wall components, such as peptidoglycan in gram-positive bacteria, can activate the complement cascade and generate C3b on the bacterial surface. Three sets of reactions result. First, C3b is recognized by polymorphonuclear leukocytes (PMNs) and macrophages, thus serving as an opsonizing factor; second, C5a is generated, providing a potent chemotactic force for attracting PMNs into the area; and third, membrane attack complexes may be generated on the bacterial surfaces. In the absence of antibody that reacts with the bacterial surface, the alternative complement pathway, a relatively slow and inefficient process, is responsible. These reactions proceed far more vigorously through the classic complement pathway in the presence of immunoglobulin that reacts specifically with antigenic sites on the bacterial surfaces. Cellular defenses depend on alveolar macrophages and recruited PMNs, which can ingest infectious organisms. Inflammatory cell recruitment is dependent on chemokines, a supergene family of small, inducible, protein mediators. Immune and nonimmune cells (epithelial cells, fibroblasts, endothelial cells) generate chemokines in response to microbial products (lipopolysaccharides) or host-derived mediators, such as tumor necrosis factor α or interleukin-1. Virulent bacteria resist attempts at phagocytosis in the absence of relevant antibodies, usually because of the presence of an exopolysaccharide capsule or slime layer. Other microorganisms, such as mycobacteria and fungi, are eradicated only by activated macrophages and, therefore, require intact cell-mediated immunity.

HISTORY AND PHYSICAL EXAMINATION

COMMUNITY-ACQUIRED PNEUMONIA

Symptoms of acute lower respiratory tract infection include cough, with or without sputum production; change in the color of respiratory secretions; dyspnea; chest discomfort; fever or hypothermia; shaking chills; sweats; and pleuritic chest pain. Nonspecific symptoms of abdominal pain, anorexia, fatigue, myalgias, and headache also may be present.

Physical examination may document fever, tachycardia, and tachypnea. In advanced cases, confusion, cyanosis, splinting, and labored breathing may be noted. Localized, fine crepitant rales are noted initially over the involved portion of lung, and signs of lobar consolidation (bronchial breath sounds, whispered pectoriloquy, vocal fremitus, and dullness to percussion) may be found as the disease progresses. Extension of pneumonia to pleural surfaces is associated with pleuritic pain and signs suggestive of a pleural effusion. Lower-lobe pneumonias may cause referral of pain to the abdomen; the clinical symptoms of these patients can mimic those of an acute intra-abdominal process. The white blood cell count is elevated in most patients with bacterial pneumonia. Leukopenia, if present, is a poor prognostic sign.

A chest radiograph is critical to making the diagnosis of pneumonia; however, it is almost never diagnostic of the specific infectious agent causing pneumonia. A localized bronchopneumonia pattern is the most typical radiographic finding. Nevertheless, dense lobar or multilobar consolidation, cavitation, or large pleural effusions also are found in patients with bacterial pneumonia. Certain radiographic features may aid diagnosis. Several bilateral, cavitary infiltrates suggest infection caused by *Staphylococcus aureus*. Ill-defined, thin-walled cavities (pneumatoceles); bronchopleural fistulas; and empyema also develop in the context of *S. aureus* infections. Cavitation also indicates gram-negative infection, *Streptococcus pneumoniae* type 3, or anaerobic infection.

ANAEROBIC/CAVITARY PNEUMONIA SYNDROME

Anaerobic infections usually take the form of subacute or chronic constitutional and pulmonary symptoms. Symptoms often are present for 3 to 5 weeks. Chronic cough, usually productive or containing purulent sputum, is reported by virtually all patients. A putrid odor of the sputum is present in 33% to 60% of patients and is virtually diagnostic of anaerobic infection. Fever (about 102°F) and chest pain occur in half of patients. The chest pain may be pleuritic or a dull, aching pain. About one-third of patients experience hemoptysis and weight loss (about 20 pounds). About 75% of patients have a predisposition to aspiration of oropharyngeal secretions. Alcoholism is the most common predisposition; others include seizure disorders, dysphagia, cerebrovascular accidents, and general anesthesia. Poor dental hygiene and periodontal disease are often present. Patients who experience anaerobic infections stemming from aspiration almost always have some teeth. Physical examination of the chest usually is not helpful. Laboratory findings are nonspecific; leukocytosis and anemia are noted in most patients.

Lung abscesses are associated with bronchogenic carcinoma in 10% to 30% of cases. Certain signs and symptoms may be useful in differentiating patients who have carcinoma from those who have abscess alone. The presence of systemic symptoms (chills, sweats, general malaise), predisposition to aspiration, an initial oral

temperature above normal, and a white blood cell count greater than 10,900 per milliliter are associated with a high probability of no underlying malignancy.

Numerous organisms other than anaerobes can result in these symptoms. The possibility of involvement of extrapulmonary organs always should be explored, because it suggests a cause other than anaerobes and may even indicate a specific origin of infection. Several verrucous or ulcerative skin lesions frequently are seen in blastomycosis and coccidioidomycosis and may be the first complaint. Skin lesions also are seen with cryptococcosis and nocardiosis, but much less frequently. Oral ulcers (painful or painless) are a characteristic manifestation of histoplasmosis and also are noted in cases of blastomycosis, coccidioidomycosis, and tuberculosis. Headache or the presence of abnormal spinal fluid points to coccidioidomycosis, tuberculosis, or cryptococcosis. Focal neurologic symptoms or signs in a patient with a cavitary lung lesion suggest the possibility of brain abscess associated with anaerobic disease or nocardiosis. Bone involvement indicates tuberculosis, blastomycosis, or coccidioidomycosis; the spine is affected most often. Blastomycosis and tuberculosis can involve both the upper and the lower genitourinary tracts.

The chest radiograph provides important clues. Anaerobes typically cause cavitary lesions (lung abscess), necrotizing pneumonia, or empyema. Lesions usually are found in dependent segments, and the right lung is involved in 75% of cases. The posterior segment of the right-upper lobe often is affected. About two-thirds of lesions are found in the posterior segments of the upper lobes or the superior segments of the lower lobes. A prominent infiltrate frequently surrounds the cavity, and the wall of the cavity is thick (more than 4 mm) and ragged. An air-fluid level strongly suggests anaerobic disease. Although gram-negative bacilli and *S. aureus* produce similar radiographic manifestations, anaerobic infections can be pinpointed by their indolent clinical course and association with aspiration. Anaerobes also can cause acute pneumonitis that is clinically and radiographically indistinguishable from pneumococcal pneumonia.

Typical and atypical tuberculosis, histoplasmosis, coccidioidomycosis, sporotrichosis, and melioidosis all characteristically produce unilateral upper-lobe fibrocavitary disease that looks like tuberculosis. Prominent infiltrates often surround cavities in tuberculosis and melioidosis. A thin-walled cavity is suggestive of coccidioidomycosis or sporotrichosis. Cryptococcosis and actinomycosis take the initial form of masslike nodular infiltrates, whereas nocardiosis has manifestations that resemble consolidative segmental pneumonia. Lesions of nocardiosis and actinomycosis tend to cavitate eventually. Pleural effusions, chest wall abscesses, and osteomyelitis of an adjacent rib also suggest infection with *Nocardia* or *Actinomyces* organisms. Calcification commonly occurs in tuberculosis, histoplasmosis, and coccidioidomycosis, but it is rare in actinomycosis, blastomycosis, cryptococcosis, nocardiosis, or sporotrichosis.

OPPORTUNISTIC PNEUMONIA SYNDROME

For a discussion of opportunistic pneumonia syndrome, see [Chapter 362](#).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

GRAM'S STAIN OF SPUTUM

A Gram's stain of expectorated sputum is the only diagnostic tool available to all physicians at the outset of therapy. The value of examining expectorated sputum is the subject of debate, since no studies have correlated data from Gram's stains to cultures of alveolar secretions in large numbers of patients with community-acquired pneumonia.

If a Gram's stain is part of the clinical evaluation, the patient must be instructed properly regarding sample collection, and the sample collection should be supervised directly by a physician. If sputum is collected without supervision, there is a 75% chance that the specimen will be of poor quality. Gram-stained sputum should first be examined under low-power magnification (100 \times) and the number of epithelial cells and neutrophils determined. Large numbers of epithelial cells (more than 25 per low-power field) reflect contamination of the specimen with oral contents; in this case, another specimen should be collected, regardless of the number of visible neutrophils. Even if these criteria are applied, the usefulness of Gram's stain data is uncertain. No studies have demonstrated clearly the cost-effectiveness or other advantages of attempts to identify the etiologic pathogen.

In the appropriate clinical context, a predominance of gram-positive, lancet-shaped diplococci reflects *S. pneumoniae* infection. The presence of more than 10 diplococci per oil-immersion field (1,000 \times) reportedly predicts the isolation of pneumococci in sputum with a specificity of 85% and a sensitivity of 62%. Similarly, the presence of small, gram-negative coccobacillary organisms suggests *Haemophilus influenzae* infection, whereas the presence of gram-positive cocci in tetrads and grapelike clusters denotes *S. aureus* infection. The presence of more than 12 organisms resembling *H. influenzae* distinguishes patients with acute bacterial exacerbations from those who have recovered from pneumonia or are well.

Special stains or preparations of sputum frequently are required in the evaluation of cavitary pneumonias. An acid-fast smear should be carried out in all cases of subacute, chronic, or cavitary pneumonia, because it provides the first evidence of infection in about half of patients who show culture-positive results for *Mycobacterium tuberculosis*. A modified acid-fast stain (sulfuric rather than hydrochloric acid in the decolorizer) should be used if the partially acid-fast *Nocardia* species is sought. Examination of a potassium hydroxide wet-mount preparation may allow rapid diagnosis of blastomycosis, coccidioidomycosis, and cryptococcosis. A Gomori's methenamine-silver or periodic acid-Schiff stain may be useful for identifying fungal elements.

SPUTUM CULTURES

Culture of expectorated sputum is neither specific nor sensitive. If isolation of penicillin-resistant pneumococci is anticipated in light of local epidemiologic and sensitivity data, sputum culture and sensitivity data are useful. Half of patients with bacteremic pneumococcal pneumonia have negative results on sputum cultures, even when large numbers of organisms are present on Gram's stain. Furthermore, expectorated sputum is contaminated with oropharyngeal flora. Because organisms that produce pneumonia often colonize the oropharynx of the uninfected patient, sputum cultures may erroneously suggest pneumonia infection.

Sputum cultures are valuable in the diagnosis of certain subacute/cavitary pneumonias. Mycobacteria grow well on culture media, and it has been estimated that sputum cultures can detect as few as 10 acid-fast bacilli per milliliter of concentrated, digested sputum. A period of 4 to 8 weeks is required for growth. Interpretation of positive sputum cultures for *Mycobacterium avium* complex is difficult, because this organism can colonize patients without causing disease.

The yield of fungal cultures varies with the organism and the stage of disease. Chronic forms of coccidioidomycosis and blastomycosis yield positive culture results in 70% to 100% of cases if several specimens are collected. In histoplasmosis, the yield depends on the stage of illness. In the early stages, characterized by a clinical picture of nonbacterial pneumonia and an interstitial infiltrate, the yield is only 30%; in the chronic cavitary stage, the yield approaches 70%. In cryptococcosis, less than 50% of patients have positive results on sputum culture. Transtracheal aspirates or percutaneous aspirates are required as culture sources for *Actinomyces*, because this organism is part of the normal oral flora. Anaerobic culture conditions must be requested for this organism. Isolation of *Nocardia* organisms also requires special considerations. Although this organism can grow aerobically, it rarely is recovered from routine sputum cultures, because the cultures are discarded before the 3 to 5 days required for this organism's growth. The laboratory should be requested to hold cultures longer than usual if *Nocardia* is the suspected culprit. *Nocardia* organisms also may be isolated in fungal or tuberculosis cultures, because it grows well on the media used in these cultures.

BLOOD AND SEROLOGIC STUDIES

Blood cultures (two sets) should be obtained from all patients who require hospitalization for suspected bacterial pneumonia. A positive blood culture finding offers definitive proof of the cause of pneumonia. Blood culture results are positive in 20% to 30% of patients with pneumococcal pneumonia and gram-negative bacillary pneumonia.

DNA PROBES AND AMPLIFICATION

Rapid diagnostic tests that use nucleic acid amplification for detecting microbes that cause pneumonia are under development. The greatest potential usefulness for these tests will be in detection of *Mycoplasma pneumoniae*, *Legionella* species, and selected pathogens that infrequently colonize the upper airways in the absence of disease. Polymerase chain reaction for detection of *M. tuberculosis* is the only such assay for a respiratory pathogen approved by the Food and Drug Administration.

DIFFERENTIAL DIAGNOSIS

The clinical signs and symptoms, including history, physical examination, and routine laboratory tests and roentgenographic examination, do not allow the clinician to pinpoint a specific diagnosis and source of infection in patients with community-acquired pneumonia. *H. influenzae*, *S. aureus*, and *S. pneumoniae* produce indistinguishable clinical syndromes. Bacterial and viral agents bring about subacute illness indistinguishable from that caused by *M. pneumoniae*. *Legionella* species and influenza can provoke subacute pneumonia or even life-threatening pneumonia.

Certain pathogens cause pneumonia more often in patients with specific risk factors. Pneumococcal pneumonia develops more frequently in the elderly and in patients with a variety of comorbid conditions, including chronic obstructive pulmonary disease, cardiovascular disease, HIV infection, immunoglobulin deficiency, asplenia, and hematologic malignancy. *S. pneumoniae* is the second most common cause of acute pneumonia in patients with AIDS. *Legionella* is an opportunistic pathogen; it is an important cause of pneumonia in patients with chronic obstructive pulmonary disease who smoke, patients with renal failure, and organ transplant recipients.

Parenteral drug abusers often suffer pneumonia as a result of hematogenous dissemination of organisms from an infected injection site or from right-sided endocarditis. The onset of this form of pneumonia can mimic acute pulmonary embolism with pleuritic chest pain, dyspnea, and fever. Insufficiency murmurs of the tricuspid, aortic, and mitral valves may be present. *S. aureus* is the most common cause of pneumonia in these patients, but disease may stem from infection with *S. pneumoniae* and gram-negative bacilli, such as *Pseudomonas*, *Serratia*, and *Proteus*.

Bacterial pneumonia that arises in the convalescent phase of influenza deserves special attention. Symptoms of typical pneumonia (shaking, chills, pleuritic chest pain, cough productive of purulent sputum) appear in these patients 2 to 14 days after the onset of signs and symptoms of influenza. In many instances, the symptoms of the viral illness have nearly resolved, and the patient complains of a relapse. This type of pneumonia, which is sometimes life-threatening, most often is caused by *S. pneumoniae*, but *S. aureus* also is seen more commonly than in patients without influenza.

Seasonal differences exist in the incidence of community-acquired pneumonia. *S. pneumoniae* and *H. influenzae* infections and influenza occur predominantly in the winter. *Chlamydia pneumoniae* organisms cause pneumonia year round. The incidence of *Legionella* infections is highest in the summer. An increase in the incidence of *Mycoplasma* infection occurs every 3 to 6 years. Viral agents associated with pneumonia in adults include influenza A and B and adenovirus types 3, 4, and 7. Adenoviral infections are found primarily in military recruits, and outbreaks are most common between January and April. Influenza triggers disease in an epidemic pattern, though sporadic cases also occur. Respiratory syncytial virus, rhinovirus, enterovirus, and parainfluenza are unusual pathogens in adult patients.

Although it is ideal to make a specific diagnosis and pinpoint the source of disease in the management of community-acquired pneumonia, limitations in diagnostic testing usually make this goal impossible. The responsible microbe is not identified in about 50% of patients, even when extensive diagnostic tests are undertaken. Accordingly, an empiric approach to initial antibiotic therapy is often required.

Upper respiratory tract infections should be distinguished from lower respiratory tract infections; most upper respiratory tract infections are of viral origin and do not require antimicrobial therapy. Chest radiographs are particularly valuable for documenting the presence of lower respiratory tract infection, detecting alternative diagnoses or associated conditions, and assessing the severity of pneumonia; radiographs are occasionally useful in determining the origin of pneumonia. Pulmonary infections also must be differentiated from other pulmonary diseases. Pulmonary pathologic conditions have a limited number of signs and symptoms; accordingly, the majority are nonspecific ([Table 361.1](#)). This is a particularly important consideration in the evaluation of outpatients, for whom laboratory and radiographic investigations are limited.

Cough	Asthma Chronic bronchitis Upper respiratory tract infection Bronchogenic carcinoma Interstitial lung disease Drugs (captopril)
Dyspnea	Asthma Chronic bronchitis Emphysema Congestive heart failure Interstitial lung disease Pulmonary vascular disease Chronic bronchitis
Sputum production	Asthma Bronchiectasis
Fever	Upper respiratory tract infection Non-respiratory tract infection Rheumatic diseases
Pulmonary infiltrates	Congestive heart failure Bronchiolitis obliterans-organizing pneumonia Pulmonary carcinoma Pulmonary hemorrhage Pulmonary vasculitis Atelectasis

TABLE 361.1. DIFFERENTIAL DIAGNOSIS OF CLINICAL MANIFESTATIONS OF PNEUMONIA

STRATEGIES FOR OPTIMAL CARE

Indications for HOSPITALIZATION

The initial task in the treatment of patients with community-acquired pneumonia is to determine whether the patient can be treated as an outpatient or whether hospitalization is required. This decision has a significant impact on the cost and outcome of therapy. There are no firm guidelines concerning the time at which a patient should be admitted, but factors that raise the risk of death or the risk of a complicated course have been identified ([Table 361.2](#)). A prediction rule has been developed to predict the risk of dying within 30 days of presentation in patients with community-acquired pneumonia. This scoring system employs 19 variables that stratify patients into groups I to V according to risk of death ([Table 361.2](#)). While these groups were validated as predictors of death, they serve as a rational foundation for decision making regarding hospitalization. Prognosis is sufficiently good in categories I or II to consider outpatient care. Category III patients might be hospitalized briefly or treated as outpatients. Patients in categories IV or V require hospitalization. The availability and quality of home support and the probability of compliance are crucial variables. Prognostic scores are complex and should not supercede clinical judgment.

TABLE 361.2. A SCORING SYSTEM FOR PREDICTION OF MORTALITY

Patients with severe community-acquired pneumonia should be separated from those with pneumonia that is less severe but still requires hospitalization. Although no universally accepted definition of severe community-acquired pneumonia exists, the presence of one of the conditions shown in [Table 361.3](#) defines pneumonia as severe. These patients have a mortality rate of about 50% and must be identified immediately for intensive care. The most common pathogens associated with community-acquired pneumonia treated on an outpatient basis, community-acquired pneumonia treated on an inpatient basis, and severe community-acquired pneumonia are shown in [Table 361.4](#). An unusual cause of community-acquired pneumonia should be considered if the history provides epidemiologic clues (exposure, occupation, geography, travel) ([Table 361.5](#)).

- Respiratory rate >30 breaths/min
- Systolic BP <90 mm Hg or diastolic BP <60 mm Hg
- Bilateral or multilobe involvement
- Severe respiratory failure— P_{aO_2}/F_{iO_2} ratio <250 mm Hg
- Requirement for mechanical ventilation
- Requirement of vasopressors for >4 hr
- Urine output <20 mL/hr, acute renal failure requiring dialysis

BP, blood pressure.

TABLE 361.3. FINDINGS SUGGESTING SEVERE COMMUNITY-ACQUIRED PNEUMONIA

Common	Uncommon
Outpatient pneumonia <i>Streptococcus pneumoniae</i> <i>Aerobic gram-negative bacilli</i> Respiratory viruses <i>Chlamydia pneumoniae</i> <i>Haemophilus influenzae</i>	<i>Legionella</i> species <i>Staphylococcus aureus</i> <i>Mycobacterium tuberculosis</i> Fungi <i>Klebsiella pneumoniae</i>

TABLE 361.4. ORGANISMS THAT CAUSE PNEUMONIA

Type of Pneumonia	Exposure History	Occupational or Risk Population
Asthma	Cattle, horses, swine, veal, hams	Butchers, farmers, veal orders, agricultural workers
Breastitis	Cattle, swine, goats, raw milk products	Dairymen, workers, meat slicers, immigrants from Mexico, veterinarians, agricultural workers
Cardiomyopathy	Travel to San Joaquin Valley, eastern California, southwest Texas, New Mexico, Arizona	Agricultural workers, construction workers
Cryptosporidiosis	Spain, Iraq, Iraq	ADIs
Aspergillus pulmonary syndrome	Overcrowded conditions, institutional	Asbestosis, workers in flour, cement, lignite, silica, asbestos, talc, talc, talc
Histoplasmosis	Chicken or bird droppings, travel to Ohio or West Virginia	Agricultural workers, construction workers
Legionnaires' disease	Contaminated air system or hospital water supply	Office workers, maintenance workers, hospitalized patients, military personnel
Melioidosis	Travel to Southeast Asia, Australia, South and Central America, Guam	Workers, farmers, agricultural workers
Rhage	Ground squirrels, prairie dogs, rabbits, rats in endemic areas (western United States)	Butchers, carpenters, agricultural workers
Rift Valley fever	Subtropical, subtropical, semiarid, arid, semiarid, arid	Bird farmers, agricultural workers
Q fever	Cattle, sheep, or goat milk, placenta, or feces; raw cheese	Agricultural workers, butchers, farmers
Sarcoidosis	Travel to Middle East, Europe, Asia, Africa, or Oceania	Workers, farmers

TABLE 361.5. HISTORICAL CLUES TO UNUSUAL PNEUMONIAS

MANAGEMENT

Selection of antibiotics is straightforward if a causative agent has been pinpointed. Initial therapy for community-acquired pneumonia is necessarily empiric, however, because clinical and radiographic findings are nonspecific and diagnostic tests cannot identify the responsible microbe in most instances. Initial empiric therapy must be broad, so that several different possible microbes are inhibited. Antimicrobial treatment should be initiated promptly after the diagnosis of pneumonia is established; a delay from the time of admission to initiation of antibiotic therapy exceeding 8 hours is associated with rising death rates. Antimicrobial therapy can be adjusted to specific narrow-spectrum agents if an etiologic agent is identified and antimicrobial susceptibility tests are available.

COMMUNITY-ACQUIRED PNEUMONIA TREATED ON AN OUTPATIENT BASIS

A macrolide antibiotic is reasonable empiric therapy for outpatients. Erythromycin (250 mg taken orally every 6 hours for 14 days) provides excellent coverage for *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, and *Legionella pneumophila* but is relatively inactive against *H. influenzae*. Clarithromycin (500 mg taken orally every 12 hours for 14 days) or azithromycin (500 mg administered orally on day 1 and then 250 mg taken orally each day for 4 days) is an alternative for patients who experience unacceptable gastrointestinal symptoms with erythromycin. Clarithromycin and azithromycin have in vitro activity against *H. influenzae* as well as *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*; the latter agents could be considered for patients likely to be harboring *H. influenzae* (those with a history of smoking). Clarithromycin should not be given to pregnant women.

Doxycycline (100 mg taken orally twice daily for 14 days) is also acceptable therapy for these patients, because it is inexpensive, produces few side effects, and can be administered once or twice a day. Reluctance to use doxycycline is based on the concern that a substantial percentage of *S. pneumoniae* organisms are resistant; contemporary studies show that 5% to 8% of these organisms are resistant to doxycycline. Fluoroquinolones (which have enhanced activity against *S. pneumoniae*), such as levofloxacin (500 mg administered orally every 24 hours for 7 to 14 days), trovafloxacin (200 mg taken orally every 24 hours for 7 to 14 days), sparfloxacin (400 mg ingested orally as a loading dose followed by 200 mg every 24 hours for 7 to 14 days), or grepafloxacin (600 mg administered every 24 hours for 7 to 14 days), are also appropriate therapy. These drugs are active against most aerobic gram-positive cocci, gram-negative bacilli, *H. influenzae*, *Moraxella catarrhalis*, *Legionella* species, *M. pneumoniae*, and *C. pneumoniae*. Morbidity and mortality rates and the need for subsequent hospitalization are no higher among outpatients treated with less expensive agents.

COMMUNITY-ACQUIRED PNEUMONIA TREATED ON AN INPATIENT BASIS

Patients with community-acquired pneumonia who require hospitalization are usually treated with parenteral antibiotics. Intravenous b-lactam agents with activity against *S. pneumoniae*, such as cefuroxime (750 to 1,500 mg administered intravenously every 8 hours), ceftriaxone (1 g taken intravenously every 12 hours), or cefotaxime (1 g taken intravenously every 8 hours) plus erythromycin (1 g administered intravenously every 6 hours), are appropriate therapy for hospitalized patients. This regimen is effective antimicrobial treatment against *S. pneumoniae*, *H. influenzae*, anaerobes, gram-negative bacilli (*Klebsiella pneumoniae*,

non-pseudomonads), and *L. pneumophila*. Intravenous treatment with levofloxacin (500 mg daily) or trovafloxacin (200 mg daily) alone also is appropriate.

SEVERE COMMUNITY-ACQUIRED PNEUMONIA

Certain pathogens have a strong relationship to severe community-acquired pneumonia ([Table 361.4](#)), so antibiotic therapy must be tailored to inhibit these microbes. *S. pneumoniae* and *L. pneumophila* are the most common organisms responsible for these types of pneumonia. Gram-negative bacilli cause severe pneumonia almost exclusively in patients with chronic obstructive pulmonary disease, alcoholism, and diabetes mellitus. Ceftioxone (1 g taken intravenously every 12 hours), cefotaxime (1 g delivered intravenously every 8 hours), or piperacillin tazobactam (3.375 g dispensed intravenously every 6 hours) plus erythromycin (1 g taken intravenously every 6 hours) or azithromycin (500 mg administered intravenously daily) is appropriate therapy. Treatment with levofloxacin (500 mg administered intravenously daily) or trovafloxacin (200 mg dispensed intravenously daily) is also effective therapy.

P. aeruginosa is rare except in patients with bronchiectasis, patients who have received broad-spectrum antibiotics for 1 week or patients who have undergone phagocyte-suppressive therapy. Patients with risk factors for *P. aeruginosa* infection should be given piperacillin/tazobactam (3.375 g taken intravenously every 6 hours), imipenem (500 mg taken intravenously every 6 hours), meropenem (1.0 g dispensed intravenously every 6 hours), or cefepime (1.0 to 2.0 g administered intravenously every 6 hours) plus erythromycin (1 g delivered intravenously every 6 hours), azithromycin (500 mg given intravenously daily), levofloxacin (500 mg taken intravenously daily), or trovafloxacin (200 mg administered intravenously daily) plus gentamycin or tobramycin (1.7 mg per kilogram delivered intravenously every 8 hours).

The therapy for anaerobic/cavitary pneumonia depends on the pace of the illness and the degree of clinical toxicity. Clindamycin is effective for most patients with anaerobic pulmonary disease and is the drug of choice. If tuberculosis is a strong possibility in light of clinical symptoms, antituberculosis therapy should be initiated while waiting for culture results. Treatment of other causes of chronic cavitary pneumonia is postponed until a diagnosis is established.

COMPLICATIONS

Pleural fluid can be detected on radiography in 40% of patients hospitalized for pneumonia. In most cases, the amount is so small that needle aspiration is unsuccessful. When fluid can be obtained, in about 90% of cases, it is not purulent, microorganisms cannot be seen on Gram's stain, and the pH is above 7.2. In these patients, fluid removal (if enough is present) and implementation of appropriate antibiotics seem to be associated with uneventful recovery. This state is called uncomplicated parapneumonic effusion.

When radiography shows loculated fluid, or if the fluid is frankly purulent, gives a positive result on Gram's stain, or has a pH less than 7.1, the diagnosis of empyema or complicated parapneumonic effusion is made. This condition is associated with a substantially greater risk of serious morbidity. Pneumococcal and anaerobic pneumonias appear to cause most empyemas, though pneumonia due to *Streptococcus pyogenes* is associated with a disproportionately high incidence of empyema. The essence of therapy for complicated empyema is to remove the infected material from the pleural space by whatever means is required—needle aspiration, thoracentesis tube, or thoracotomy. Delay of this essential treatment is likely to lead to a prolonged hospital course and the eventual need for thoracotomy. See [Chapter 358](#) for further discussion of pleural effusions. Aside from empyema, other complications of bacterial pneumonia are rare. Metastatic infection may affect the meninges, heart valves, pericardium, bones, and joints. Cases of purulent pericarditis and vertebral osteomyelitis are seen infrequently.

COST-EFFECTIVENESS

The initial decision to hospitalize patients with pneumonia or to treat them as outpatients in the ambulatory care setting is the major determinant of cost of treatment. Judicious use of antibiotics can clearly lower costs, but these costs are trivial when compared with hospital costs. Average costs of treating community-acquired pneumonia in the hospital are 17 to 51 times higher than in the ambulatory setting. Thus, limiting the need for hospitalization or the length of stay offers the greatest opportunity to reduce health care costs.

No controlled trials have addressed specifically the question of length of therapy for pneumonia. It is reasonable to treat *S. pneumoniae* infections until a patient is afebrile for 72 hours. Pneumonia caused by *M. pneumoniae*, *C. pneumoniae*, and *Legionella* species should be treated for at least 2 weeks. Shorter courses of therapy should be used if azithromycin is given. Changing from intravenous to oral therapy is associated with economic and social benefits. This adjustment can be made if the patient's clinical symptoms are improving and if he or she is hemodynamically stable, able to swallow drugs, and has a functioning gastrointestinal tract. These conditions are usually met within 2 to 4 days. Broad-spectrum cephalosporins, newer macrolides, and fluoroquinolones have been used successfully as oral therapy. Patients failing to improve within this time frame should be evaluated for reasons for failure. Possible reasons include an incorrect diagnosis ([Table 361.1](#)), a resistant pathogen, host defense abnormalities, medication error, poor compliance, or an unusual pathogen ([Table 361.5](#)). Complications or extension of disease (empyema) should be considered. Radiographic signs of improvement may be delayed; follow-up radiographs should be obtained 7 to 12 weeks after initiation of treatment.

PREVENTION OF PNEUMONIA

Influenza vaccine should be given annually to persons at risk for complications and to health care workers. The currently available 23-valent pneumococcal vaccine should be administered, as suggested by the Centers for Disease Control Guidelines.

CHAPTER 362: EVALUATION OF PULMONARY DISEASE IN THE IMMUNOCOMPROMISED HOST

PHILIP C. HOPEWELL

[Factors Affecting Lung Defenses](#)
[Recognition and Quantification of Immunocompromise](#)
[Differential Diagnosis of Respiratory Disease in Immunocompromised Patients](#)
[Diagnostic Approach](#)
[An Integrated Diagnostic Strategy](#)

This chapter defines the diagnostic strategies applicable to patients with disorders that result in a reduction in the functional capabilities of the immune system in the broad sense. These disorders include abnormalities in polymorphonuclear leukocyte (PMN) number or function, dysfunction of the humoral immune system, and alterations in cell-mediated immunity. In many instances, defects may exist in more than one component of lung defenses, and nonimmunologic factors may compound these abnormalities further.

FACTORS AFFECTING LUNG DEFENSES

QUANTITATIVE OR QUALITATIVE NEUTROPHIL DEFECTS

A decline in the number of circulating PMNs is particularly common in patients undergoing chemotherapy for malignancies, in patients with acute leukemia, and in patients who have undergone bone marrow transplantation. If the cells function normally, serious infections generally are not seen until the absolute PMN count falls below 500 per microliter. The incidence of infection also seems to be directly related to the rate of reduction in PMN counts.

Qualitative defects in PMN function can occur as a result of abnormalities in any of the steps involved in the ingesting and killing of infecting organisms. Most of the primary disorders in which PMN function is impaired are congenital, recognized in childhood, and uncommon. They include chronic granulomatous disease, Chédiak-Higashi syndrome, and Job syndrome. Myeloperoxidase deficiency, though common, is not usually associated with an increased rate of infection unless another abnormality is present as well.

Of greater relevance to this discussion are the acquired disorders of neutrophil function. Corticosteroids, antineoplastic drugs, irradiation, and alcohol all can impair the effectiveness of PMNs by decreasing chemotaxis or adherence. In addition, alterations in neutrophil chemotaxis caused by a circulating inhibitor have been described in the context of cirrhosis, renal failure, and Hodgkin's disease. Various complement-deficiency states also are associated with reduction in chemotaxis.

Abnormalities in the number or function of PMNs are associated with pyogenic bacterial infections. The specific organisms encountered relate to the circumstances of the patient and his or her environment. Because granulocytopenia more commonly develops in hospitalized patients, who may have been receiving antimicrobial therapy and who may have cofactors predisposing to pulmonary infections, organisms such as *Staphylococcus aureus* and aerobic gram-negative bacteria tend to predominate. Much less often, neutropenic patients may experience respiratory tract infection caused by *Candida*, *Mucor*, and *Aspergillus* species.

HUMORAL IMMUNODEFICIENCY

Antibody production is a function of B lymphocytes; thus, decreased antibody production results when the number of B cells is critically reduced or when their ability to respond to specific antigens is impaired. The prototypic example is X-linked agammaglobulinemia, in which there is complete absence of B lymphocytes. Common variable immunodeficiency is not necessarily associated with an overall decline in B cells. In both of these situations, IgG is most affected, and sinopulmonary infections with both gram-positive and gram-negative encapsulated bacteria are commonplace.

Patients infected with the human immunodeficiency virus (HIV) are in many ways similar to patients with common variable immunodeficiency. Although B cells are present, they do not respond effectively to specific antigens. This presumably is the basis for the increased incidence of severe bacterial infections (particularly those caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*) in these patients. Other conditions associated with defective antibody production include multiple myeloma, chronic lymphocytic leukemia, and the splenectomized state. In each of these conditions, pneumococcal pneumonia, often with bacteremia, frequently develops, and infections with other encapsulated organisms have been reported.

CELLULAR IMMUNODEFICIENCY

Cell-mediated immunity is mainly responsible for fending off intracellular pathogens. Killing of these organisms within the lung is accomplished primarily by alveolar macrophages and secondarily by cytotoxic lymphocytes. Primary abnormalities of cell-mediated immunity are uncommon and become evident early in life. They include severe combined immunodeficiency, DiGeorge syndrome, ataxia telangiectasia, and Wiskott-Aldrich syndrome. Far more common are defects produced by various diseases and therapeutic interventions. Acquired immunodeficiency syndrome (AIDS) is characterized by a progressive and ultimately profound reduction in cell-mediated immunity produced by HIV infection. Untreated Hodgkin's disease also uniformly impairs cell-mediated responses. A large number of other disorders cause reductions in cell-mediated immunity but do not predictably predispose to infection. In addition to diseases, therapeutic agents, such as corticosteroids, azathioprine, cytotoxic drugs, and radiography, have a dose-related effect on cell-mediated immunity.

Because many of the infectious diseases that develop as a consequence of alterations in cell-mediated immunity are reactivations of latent infections, their incidence is determined by the prevalence of the underlying infection. This is especially true for tuberculosis, nontuberculous mycobacterial diseases, and fungal processes. In addition, infections with other bacteria, particularly *Listeria monocytogenes*, *Salmonella* species, and *Legionella* species, and with parasites, especially *Strongyloides stercoralis*, may develop in persons with deficient cell-mediated immunity.

RECOGNITION AND QUANTIFICATION OF IMMUNOCOMPROMISE

Initial recognition that a patient is immunocompromised generally results from a knowledge of the clinical conditions and therapies that interfere with host responsiveness. Neutropenia is identified easily and quantified simply by an accurate total white blood cell and differential count. As observed previously, the risk of infection is increased with counts of less than 500 per microliter when there has been a rapid decline in PMNs and when there are factors that interfere with PMN function. Although there are tests that measure different aspects of PMN function, they are of limited clinical relevance under usual circumstances. It can be assumed, however, that alcoholism, cirrhosis, diabetes, and treatment with corticosteroids, antineoplastic drugs, and radiography cause impairment of PMN function.

A reduction of immunoglobulin concentration should be suspected in patients who have recurrent sinopulmonary infections. The abnormality can be identified and quantified by measurement of serum immunoglobulins and immunoglobulin subsets using immunoelectrophoresis. Total B-cell counts also may quantify the defect. Cellular immunodeficiency can be assumed in patients who have conditions that are known to suppress cell-mediated immunity, as discussed previously. In patients with HIV infection, the best means of quantifying the degree of immunosuppression is the total CD4 lymphocyte count. The rate of opportunistic infections relates inversely to the total CD4 lymphocyte count, with a striking increase associated with CD4 lymphocyte counts less than 200 per microliter.

DIFFERENTIAL DIAGNOSIS OF RESPIRATORY DISEASE IN IMMUNOCOMPROMISED PATIENTS

As shown in [Table 362.1](#), several other categories of conditions, in addition to infections, should enter the differential diagnosis. Within the differential diagnosis, opportunistic infections are the most important disorders of which to be aware, because they often are treatable and, without treatment, may progress rapidly. As mentioned previously and as indicated in [Table 362.2](#), the pathogens can be predicted to a certain extent from a knowledge of the underlying disease and the abnormalities in host defenses that the disease or its treatment can produce. Knowledge of the likely organisms also allows for selection of appropriate diagnostic studies and rational empiric therapy. Respiratory disorders, either preexisting or new, that are unrelated to the underlying disorder or its treatment figure into the differential diagnosis. A variety of chronic lung diseases may worsen during the course of another illness. Asthma, which is common in the general population, is likely to develop in a population of immunocompromised patients. Because immunocompromised patients are often on bed rest and because some have neoplastic

conditions, they may be predisposed to pulmonary embolism. Left ventricular failure with cardiogenic pulmonary edema also may occur and is related to intrinsic heart disease and, occasionally, fluid overload or cardiotoxic drugs.

Opportunistic infections: all categories of pathogens
 Preexisting or new lung disease unrelated to immunosuppression: asthma, chronic obstructive pulmonary disease, pulmonary embolism, cardiogenic pulmonary edema
 Lung involvement by the primary disease process: leukemic infiltration, Hodgkin's disease with lymph node or parenchymal involvement, plasmacytoma, lymphangitic metastases
 Hematologic processes related to primary disease or its treatment: intrapulmonary hemorrhage, intrapulmonary leukostasis, leukemic cell lysis pneumonopathy
 Pulmonary reactions to agents used to treat the primary process: bleomycin, methotrexate, radiation
 Idiopathic processes presumably related to immunosuppression or to the immunosuppressive process: Kaposi's sarcoma, lymphoid interstitial pneumonia, nonspecific interstitial pneumonia
 Graft-versus-host disease

TABLE 362.1. DIFFERENTIAL DIAGNOSIS OF PULMONARY PROCESSES IN IMMUNOCOMPROMISED PATIENTS

Defect	Disease	Pulmonary infection
Neutropenia	Primary throm or cyclic neutropenia Acute leukemia and myelodysplastic disorders Bone marrow transplant	Community-acquired bacterial pneumonia, usually, atypical; gram-negative bacteria, especially <i>Pseudomonas aeruginosa</i> , <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> , <i>Candida</i> species, <i>Aspergillus</i> species, <i>Mucor</i>
Complement abnormalities	Primary (D or C3 deficiency) Side effect of disease (defect in alternate pathway)	<i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , atypical gram-negative bacteria
Leukocyte dysfunction	Primary immunoglobulin deficiencies	<i>Streptococcus pneumoniae</i>
Infection	Human immunodeficiency virus infection	<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Pneumocystis carinii</i> , <i>Aspergillus fumigatus</i> , <i>Coccidioides immitis</i> , <i>Histoplasma capsulatum</i> , <i>Aspergillus</i> species
Other immunodeficiency	Human immunodeficiency virus infection, Hodgkin's disease, immunosuppressive therapy, bone marrow transplantation	<i>Pneumocystis carinii</i> , <i>Aspergillus fumigatus</i> , <i>Coccidioides immitis</i> , <i>Legionella</i> species, <i>Listeria monocytogenes</i> , <i>Cryptosporidium</i> species, <i>Cytospora</i> species, <i>Coccidioides immitis</i> , <i>Histoplasma capsulatum</i> , <i>Aspergillus</i> species

TABLE 362.2. DEFECTS IN HOSTS DEFENCES, UNDERLYING ASSOCIATED DISEASES, AND LIKELY PULMONARY INFECTIONS

Many of the primary disorders can involve the lungs or intrathoracic lymph nodes directly, for example, leukemia, Hodgkin's disease, non-Hodgkin's lymphoma, and metastatic solid tumors. In addition to direct involvement by tumors, there may be secondary hematologic effects. In patients who have major coagulation defects, there may be spontaneous bleeding into the lung. Intrapulmonary leukostasis is believed to account for dyspnea and hypoxemia in patients with both acute and chronic nonlymphocytic leukemia. This condition usually has developed in patients with white blood cell counts of more than 200,000 per microliter. A syndrome suggestive of diffuse lung damage has been reported after administration of chemotherapy. This so-called leukemic cell lysis pneumonopathy is believed to result from destruction of white blood cells within the lungs, with subsequent liberation of white cell enzymes causing lung damage.

Lung disease caused by agents used to treat neoplastic processes can mimic many of the other conditions listed in the differential diagnosis. Confounding the problem is the fact that there is no test that can provide a positive diagnosis of drug-induced lung disease, though the histopathologic features may be highly suggestive in some instances. Bleomycin most often is associated with lung disease, probably followed in frequency by methotrexate.

Several idiopathic processes can affect the lungs in immunosuppressed patients. These disorders presumably are caused by immunosuppression itself or by the primary condition underlying immunosuppression. Kaposi's sarcoma is common in patients with AIDS, but it also may develop with other forms of immunosuppression. Nonspecific interstitial pneumonitis is seen in patients with HIV infection but is found in other immunocompromised patients as well. The condition is characterized by interstitial inflammatory changes without a specific histologic pattern. Lymphoid interstitial pneumonitis is a typical finding in children with HIV infection but also develops in both immunosuppressed and nonimmunosuppressed patients without HIV infection. The histopathologic picture shows interstitial infiltration with lymphocytes, peripheral lymphoid aggregates, and small amounts of fibrosis. Both nonspecific pneumonitis and lymphoid interstitial pneumonitis are diagnoses of exclusion, even when the histopathologic characteristics are consistent. Only after the other diseases, particularly opportunistic infections, have been ruled out can these idiopathic disorders be diagnosed. Graft-versus-host disease occurs only in patients who have had bone marrow transplantation. Pulmonary involvement is seen in the chronic form of the disease, which begins about 3 months after transplantation. The disease usually manifests as a nonproductive cough, dyspnea, and bronchospasm.

DIAGNOSTIC APPROACH

HISTORY, PHYSICAL EXAMINATION, AND INITIAL LABORATORY EVALUATION

The diagnostic evaluation for pulmonary disease in an immunosuppressed patient may be initiated by respiratory symptoms, fever, or the discovery of an abnormality on chest radiography. In patients who are capable of providing a history, this information can yield important clues with regard to the severity of the pulmonary process and the nature of the immunosuppression. Pertinent historical information includes a description of the kind of respiratory symptoms, usually cough and shortness of breath; their duration; and their functional effects. Whether or not the cough is productive of sputum, its amount, and its color should be determined. It is important to gauge the severity of shortness of breath. Obviously, shortness of breath that progresses rapidly and produces marked limitation in activity indicates that the evaluation must be pursued with some urgency, whereas a condition with a more indolent course can be evaluated at a more leisurely pace. Other important symptomatic manifestations of pulmonary conditions are chest pain and fever. In assessing any fever, one should determine its duration, magnitude (if known), and association with chills. The severity and nature of chest pain, especially whether it is pleuritic, should be ascertained.

In many instances, it is not known that the patient is immunosuppressed at the time of initial evaluation. Thus, pertinent historical information would include previously diagnosed diseases associated with immunosuppression; drug therapy that could impair immune responsiveness, especially glucocorticoids or cytotoxic agents; and membership in a recognized HIV transmission category. In addition, it is important to determine whether the patient was taking antimicrobial drug therapy before the evaluation.

The physical examination, like the history, can provide useful data concerning the presence and severity of lung disease as well as inferential evidence of an immunosuppressive disorder. In addition to the routine examination, particular attention should be paid to detecting oral lesions, such as thrush (oral candidiasis) or hairy leukoplakia; cutaneous findings, such as Kaposi's sarcoma or herpetic lesions; lymphadenopathy, as might be indicative of HIV infection or a hematologic or reticuloendothelial malignancy; and liver or splenic enlargement, which is also suggestive of a malignant process.

Routine laboratory studies, particularly a complete blood cell count and differential, can be extremely useful in suggesting the presence of an underlying immunosuppressive process and perhaps its cause, such as leukemia. Leukocytosis can reflect a standard bacterial infection. Tests of liver and kidney function are of value in identifying disorders that in themselves are associated with weakening of host defenses or can compound other immunosuppressive disorders.

As a general rule, serologic studies have not been found to be of much assistance in identifying infecting organisms. An exception to this rule, however, is the detection of circulating cryptococcal antigen, which provides strong evidence of cryptococcal infection. Likewise, detection of precipitating antibodies (IgM) to *Coccidioides immitis* or a high titer (more than 1:16) of complement-fixing antibody (IgG) is highly suggestive of infection with this organism.

ROENTGENOGRAPHIC STUDIES

Roentgenography of the chest should be carried out for all patients who are being evaluated for respiratory symptoms or physical findings. Although radiographic abnormalities can never establish etiologic sources, they can be extremely helpful in narrowing the differential diagnosis and providing guidance for subsequent diagnostic studies. A wide variety of radiographic patterns can be encountered in immunocompromised patients. Diffuse interstitial infiltration is the most common pattern produced by opportunistic lung infections. (The term *interstitia* is used to describe the roentgenographic pattern, not to indicate the anatomic location of the process within the lungs.) This pattern is particularly common in *Pneumocystis carini* pneumonia and also is seen with cytomegalovirus, *Mycobacterium tuberculosis*, and infection with nontuberculosis mycobacteria and with fungi, especially *Histoplasma capsulatum* and *C. immitis*. As any of these conditions becomes more severe, there may be diffuse airspace consolidation, occasionally with air bronchograms.

Diffuse infiltration is the rule in drug-related lung disease, leukemic infiltration, lymphangitic metastases, intrapulmonary hemorrhage, leukostasis, leukemic cell lysis pneumonopathy, lymphocytic interstitial pneumonia, and nonspecific interstitial pneumonia. Pulmonary edema, both cardiogenic and noncardiogenic, also must be included in the differential diagnosis. Localized infiltration is more consistent with pyogenic bacterial pneumonia, legionellosis, fungal infection (especially with *Cryptococcus neoformans* and *Aspergillus* species), lymphoma, and lung infarction. Virtually all of the conditions that cause diffuse infiltration can produce localized abnormalities, but they are less likely to do so.

Single or several nodular lesions most likely are caused by primary or metastatic neoplasms, including lymphoma, fungal infections (especially *C. neoformans*), and mycobacterial infections. Cavitation may occur in these lesions as well as in staphylococcal pneumonia and in pneumonia provoked by *Klebsiella*, anaerobic bacteria, and *Aspergillus*. *P. carini* has been reported to produce cavitory lesions and pneumatocele formation. Although *M. tuberculosis* frequently causes cavitory lesions in immunocompetent patients, it rarely does so in patients with advanced HIV infection.

Pleural effusion is not typically associated with opportunistic infections or drug-induced lung diseases. It may develop in the context of metastatic neoplasia, Kaposi's sarcoma, pyogenic bacterial pneumonias, and tuberculosis as well as heart failure and pulmonary infarction. Intrathoracic adenopathy usually is caused by lymphomas and by infectious processes, in particular, mycobacterial and fungal infections. Metastatic malignancies also can cause lymph node enlargement. The presence of adenopathy is strong evidence arguing against *P. carini* infection as the only pulmonary disease. In patients with respiratory symptoms and normal chest film results, high-resolution computed tomography scans may show evidence of lung disease. This is especially true for *P. carini* pneumonia.

PULMONARY FUNCTION STUDIES AND GALLIUM LUNG SCANS

Because the evaluation of respiratory symptoms in immunocompromised patients often requires invasive and expensive studies, there must be some objective indication that lung disease is present. In most patients, the chest film shows abnormal results and thus provides the objective evidence. In some patients who have subsequently been found to have lung disease, however, the chest film has shown normal findings. In these patients, measurements of pulmonary function, including arterial blood gas determination and calculation of the alveolar to arterial P O₂ difference (P[A - a]O₂), have been of value. Of the routine pulmonary function tests, the diffusing capacity of the lung for carbon monoxide (DLCO) is the most sensitive to the presence of opportunistic pulmonary disease. Many unrelated disorders can cause a reduced DLCO value (less than 80% of the predicted value), including emphysema, pulmonary vascular disease, pulmonary fibrosis, and intravenous drug abuse. Nevertheless, a decline in the DLCO in an immunocompromised patient with respiratory symptoms should be accepted as an objective indicator of lung disease, prompting further evaluation. Similar sensitivity has been noted for measurements of gas exchange with exercise. These measurements assess arterial blood gases at rest and with a standard level of exercise and then determine the difference in the P(A - a) O₂. Failure of the P(A - a)O₂ to decrease by at least 5 mm Hg with exercise is regarded as a positive test result, indicating the presence of lung disease.

Radionuclide imaging of the lungs by gallium citrate Ga 67 is also a sensitive means of detecting pulmonary inflammation. Lung scanning is performed 48 to 72 hours after injection of 5 to 7 mCi of gallium, and any pulmonary uptake is regarded as abnormal. Conditions such as *P. carini* pneumonia are generally associated with diffuse uptake. In addition to uptake in the pulmonary parenchyma, uptake may be noted in intrathoracic lymph nodes.

SPUTUM EXAMINATION

Examination of sputum, either spontaneously produced or induced by inhalation of hypertonic (3% to 5%) saline, is extremely valuable in identifying organisms in patients with opportunistic pulmonary infections. Most patients with pyogenic bacterial pneumonia have sputum production, as do some patients with other infectious diseases. Sputum specimens produced spontaneously should be smeared promptly and stained with Gram and acid-fast stains. A portion should be submitted for culture for pyogenic bacteria and mycobacteria. Definitive identification of the organisms present is not possible from examination of the smear, but there may be strong presumptive evidence of the organism.

In addition to bacteria, the presence and number of PMNs, alveolar macrophages, and squamous epithelial cells should be noted. Alveolar macrophages are indicative of a lower respiratory tract origin, and PMNs are associated with acute inflammation. Squamous epithelial cells indicate contamination with oropharyngeal contents. An obvious limitation is in the diagnosis of pyogenic bacterial infections in which contamination with oropharyngeal flora precludes interpretation of an organism as originating from the lungs. Even with regard to the potential for contamination, however, isolation of a bacterial pathogen in the sputum from a patient who has a pulmonary condition that could be caused by the organism is often sufficient information on which to base therapy. Sputum examination is of greater value when an organism that is not normally present in the oropharynx is seen or isolated in culture. Finding an acid-fast organism on smear is adequate evidence to prompt initiation of antimycobacterial therapy. In patients with AIDS, examination of induced sputum has a sensitivity for *P. carini* of about 70%. By using Giemsa stain or other rapid-staining techniques, a result can be obtained promptly, thus avoiding the need for more invasive procedures.

Culture of sputum often provides definitive identification of organisms seen on smear, though these organisms may still represent oropharyngeal flora. A routine culture can identify most pyogenic bacterial organisms within 48 hours. Mycobacterial cultures take considerably longer, but with the use of radiolabeled substrates, growth can be detected in 5 to 14 days. Standard culture media require 2 to 6 weeks for growth. Identification of species often requires another 2 weeks, but the use of specific DNA probes may shorten the process to a few hours. Identification and speciation of *M. tuberculosis* is now possible using rapid amplification techniques. At present, however, the approved use of such methods is limited to specimens in which acid-fast organisms have been seen on microscopic examination.

ROLE OF EMPIRIC TREATMENT

The evaluation described thus far is only minimally invasive; however, the next steps that can be undertaken to identify a specific condition require more invasive studies. An option that can be considered at this point is the use of an empiric treatment trial. This option is based on the assumption that the process is most likely an infection and that the infection is the most serious and most treatable of all of the possible diagnoses. Based on the nature of the defect in host defenses, the pathogens likely to cause infection in a particular context can be predicted and an antimicrobial regimen selected. If the patient is neutropenic, agents to cover aerobic gram-negative organisms, including *Pseudomonas aeruginosa* and also *S. aureus*, should be used. Patients with altered cell-mediated immunity are likely to be infected with *P. carini* as well as mycobacteria, fungi, and *Legionella* species.

Because of the long-term nature of antimycobacterial treatment and the toxicity of amphotericin B, empiric therapy for mycobacteria and fungi should not be started except while awaiting results of cultures. Empiric treatment of this group of patients with trimethoprim-sulfamethoxazole and perhaps erythromycin is a rational approach. If empiric therapy is undertaken, it is important to monitor the patient carefully for indications of improvement or deterioration. If there is no improvement or if the patient's condition worsens, more definitive studies should be done. How long the empiric trial should go on before moving ahead to more definitive procedures depends on a number of factors, including the severity of the condition, the rapidity of its progression, and the patient's wishes.

BRONCHOSCOPIC PROCEDURES

The flexible fiberoptic bronchoscope provides ready access to the lower respiratory tract for making visible the endobronchial anatomy and sampling material for histologic and microbiologic evaluations. The procedure itself is minimally invasive and can be performed in awake patients using conscious sedation and topical anesthesia. Any bronchoscopic procedure should begin with a careful examination of the airway. A variety of endobronchial lesions can be seen, including granulomas from mycobacterial or fungal diseases and tumors. In patients with AIDS, findings of typical hemorrhagic-appearing submucosal lesions of Kaposi's sarcoma is sufficiently definitive to establish a diagnosis.

The samples that should be obtained with the bronchoscope vary somewhat, depending on the underlying disorder and the pulmonary diseases that are believed to be present. In patients who likely have pyogenic bacterial pneumonia, the specimens should include a sampling of material from the involved area with the use of a

protected brush. The protected brush is contained within two catheters, the outer one sealed at its distal end by a small wax plug. The system enables uncontaminated specimens to be collected from lower airways. The diagnostic specificity of protected brush catheter specimens is increased by quantitative cultures of the material obtained. Colony counts of more than 10⁵ more likely indicate that the infection is caused by the isolated organism.

In patients thought to have HIV-related opportunistic infections, bronchoalveolar lavage is highly sensitive. This procedure samples material from a large number of alveoli; thus, it is likely to detect intra-alveolar infections. The lavage specimen should be centrifuged, smeared, and stained for *P. carinii* and acid-fast organisms. Immunofluorescent staining for *Legionella* species also can be carried out. The specimen should be cultured for mycobacteria and fungi and perhaps for viruses, *Legionella* species, and *Mycoplasma* organisms. In patients with HIV infection, the sensitivity of bronchoalveolar lavage for the common infecting organisms, especially *P. carinii*, approaches 100%. The sensitivity in other immunocompromised patients is not so high, but it is still good for the organisms described previously.

In patients in whom disorders other than infections rank high in the differential diagnosis, bronchoalveolar lavage should be supplemented by transbronchial biopsy. The biopsy adds considerably to the risk of the bronchoscopic procedure and cannot be performed in the context of an uncorrectable coagulation disorder. This limits the usefulness of the procedure in some immunosuppressed patients. Bleeding is also a risk for patients with pulmonary hypertension, and patients receiving mechanical ventilation have a risk of tension pneumothorax.

Tissue obtained by transbronchial biopsy should be subjected to histologic and microbiologic examinations. Touch imprints of fresh, moist tissue should be stained and examined for *P. carinii*. An unfixed portion of the tissue should be cultured for mycobacteria, fungi, and perhaps viruses. Fixed tissue sections should have standard hematoxylin-eosin staining as well as acid-fast and methenamine silver stains. Immunofluorescent stains and cultures for *Legionella* also should be undertaken if the epidemiologic and chemical features are consistent with legionellosis. Special stains may be necessary, depending on the findings on hematoxylin-eosin-stained sections.

When there is enlargement of the mediastinal or hilar lymph nodes with or without pulmonary parenchymal involvement, transtracheal needle aspiration may be used to sample material from the nodes. This is most easily accomplished when the subcarinal nodes are affected, but right-sided paratracheal and hilar nodes also can be aspirated. This technique can be used to aspirate mass lesions in the lungs. Specimens obtained by transbronchial aspiration should be examined as cytologic preparations. In addition, stains and cultures for mycobacteria and fungi should be carried out.

NEEDLE ASPIRATION LUNG BIOPSY

Needle aspiration of the lung has been used for many years, especially in children, to provide material for diagnosing infections. The technique also can be used in evaluating localized mass lesions that may be either infectious or neoplastic. The sensitivity of the procedure is fairly high for both infections and tumors. Unfortunately, the rate of complications is also high. Both pneumothorax and bleeding may occur, at an overall rate of about 40%.

OPEN LUNG BIOPSY

Open lung biopsy can be accomplished either via the traditional limited thoracotomy incision or using a thoracoscope. Because of its lesser degree of invasiveness, the thoracoscopic approach is favored in many centers. If it can be performed promptly, the major advantage offered by open lung biopsy is that it is the most expeditious means of arriving at a diagnosis without concern that a condition is being overlooked. A nondiagnostic open lung biopsy is accepted as being nondiagnostic, whereas failure to obtain a diagnosis using less invasive studies often leaves the physician with doubts about the validity of the negative result. Additional advantages of open lung biopsy are that the area to be sampled can be selected while it is directly visible and effective hemostasis can be achieved even in the presence of coagulopathy. The procedure can be undertaken in severely ill patients who require mechanical ventilation.

The disadvantages of open lung biopsy are several. It requires an operating room and, usually, general anesthesia; the potential exists for infection and for chronic air leak; and the patient is left with postoperative pain and a thoracostomy tube, which, in immunocompromised patients, can serve as a nidus for infection. For all of these reasons, the decision to perform an open lung biopsy should not be made lightly but only after the benefits and risks have been thoroughly assessed. These complications are substantially less likely with a thoracoscopy procedure. Tissue specimens obtained by open lung biopsy should be examined as described for tissue from transbronchial biopsy, including making touch imprints and culturing the tissue. For this reason, the tissue specimen should not be immersed immediately in fixative; instead, a portion should be placed on moistened sterile gauze in an airtight container for transport to the laboratory.

AN INTEGRATED DIAGNOSTIC STRATEGY

The first step in formulating an integrated diagnostic strategy for the immunocompromised patient with lung disease is to assess the immune defect and determine the differential diagnosis based on the underlying disease and the nature of the abnormality in host defenses. Routine diagnostic evaluation, including chest radiography, can assist in narrowing the differential diagnosis. The rapidity or urgency with which the evaluation proceeds should be determined by the overall assessment of the severity of the illness and the pace at which it is progressing. If infection is possible, a sputum specimen should be obtained using inhalation of hypertonic saline if necessary. In patients who have respiratory symptoms but normal results on chest radiograms, pulmonary function tests, especially measurement of the DLCO and gas exchange with exercise, may provide the necessary objective indication of lung disease. A high-resolution computed tomography scan can be useful in this situation. If these test results are normal, a gallium lung scan may be helpful.

At this point, if no specific diagnosis is established, the decision can be made to embark on an empiric course of antimicrobial treatment with close observation of the response. Alternatively, a specific diagnosis may be sought using a bronchoscopic technique. This course should be taken in patients who have failed to respond to empiric therapy as well. The particular bronchoscopic procedure should be determined by the differential diagnosis based on the underlying disorder and the immune defect. If a pyogenic bacterial infection is possible, a specimen should be obtained from the involved area by the protected brush technique. In the context of a defect in cell-mediated immunity, bronchoalveolar lavage should be conducted and transbronchial biopsy considered. If the lavage result is negative or if the differential diagnosis includes noninfectious disorders, a transbronchial biopsy should be carried out, unless there is a contraindication. When all studies are inconclusive or when transbronchial biopsy is contraindicated, a decision concerning open lung biopsy must be made. At this point, if the lung disease is not progressing rapidly, a second bronchoscopic procedure can be undertaken. The value of open lung biopsy in this context is not well established, and the risk may outweigh the gain.

CHAPTER 363: ASTHMA

SALLY E. WENZEL

[Definition](#)
[Natural History and Epidemiology](#)
[Environmental Risk Factors for the Development of Asthma](#)
[Physiology](#)
[Asthma Diagnosis](#)
[Approach to the Management of Asthma](#)

DEFINITION

Asthma is defined as intermittent, reversible airway obstruction in association with increased nonspecific bronchial reactivity. These physiologic changes are now known to exist in the context of airway inflammation. The addition of inflammation to the definition has shifted the understanding of asthma from a disease of airway nerves and smooth muscle to one that identifies inflammation as the driving force for the symptoms associated with the disease. This realization has led to a dramatic shift in the treatment of the disease in the past 10 years.

NATURAL HISTORY AND EPIDEMIOLOGY

Asthma is one of the most common and expensive chronic illnesses in the United States, affecting between 5% and 10% of the population. Annual health care costs were about six to seven billion dollars in 1990, and costs have risen since then. Development of asthma follows a bimodal distribution, with an early peak in the pediatric years (4 to 10 years of age) and a second peak after 40 years of age. A male predominance in childhood disappears by adolescence and reverses after age 40. A large percentage (80% to 85%) of early childhood wheezers (less than 2 years of age) will not progress to definitive asthma later in childhood. Many of these children with asthma may even “outgrow” their illness later in life, but a large percentage of children continue to experience asthma into adulthood. In adulthood, mean pulmonary function appears to decline at a greater than normal rate.

The incidence and severity of asthma have been increasing, but there is some evidence that we have reached a plateau in the past two to three years. The reasons for these increases in incidence and severity are not clear but likely include growing awareness of the disease, socioeconomic factors, and increases in indoor and outdoor air pollution. Outdoor air pollution (ozone, sulfur dioxide, particulates) does not appear to be causative but may exacerbate asthma and lead to increases in the subsequent reporting of it. African-American and Hispanic populations have higher incidence rates of asthma compared with other racial/ethnic groups, but perhaps more important, the African-American and Puerto Rican populations, specifically these populations in inner city areas, have considerably higher morbidity and mortality rates than other ethnic and socioeconomic groups. The factors that play a part in this higher incidence and severity are likely both environmental and genetic in nature.

The understanding of the genetics of asthma is at a very preliminary stage. Unlike such diseases as cystic fibrosis, which has been identified as the result of a single abnormal gene, the heterogeneity of asthma suggests that the genetic factors will prove to be multifactorial and strongly influenced by environment. Atopy appears to raise the risk of asthma. Since a majority of atopic/allergic individuals do not have asthma, however, other genetic and environmental factors likely play a part. Several chromosomes, including chromosomes 11 and 5, have been highlighted as containing potential genes (generally related to atopy) that could modify hereditary aspects of asthma. There is emerging information that certain genes may be more important in some racial/ethnic groups than in others.

ENVIRONMENTAL RISK FACTORS FOR THE DEVELOPMENT OF ASTHMA

In a child with atopic characteristics, exposure to indoor allergens, such as the house dust mite, cockroaches, and cats appears to increase the risk of asthma. In regions of lower humidity, cats and molds, such as *Alternaria*, may play a more important role. Outdoor allergens have not been linked to the development of chronic asthma. Removing susceptible individuals from their allergic environment may have a positive impact on the disease. Exposure to viruses, such as respiratory syncytial virus, during infancy/early childhood, also can influence the development of asthma in susceptible individuals. The most preventable risk factor is cigarette smoking by the mother, which likely poses the greatest risk prenatally through age 5 years. Occupational asthma can develop after exposure to either low- or high-molecular-weight compounds in the workplace. The disease is especially prevalent in the lumber, plastics, and paint industries and can develop de novo in patients with no history of it. Asthma has become more prevalent among hospital workers because of the prevalence of latex use and the attendant subsequent development of allergies and asthma. Although the disease usually improves after departure from the workplace, certain occupational stimuli (western red cedar) have been shown to induce a disease that does not fully resolve once the patient is separated from the initiating stimulus.

PHYSIOLOGY

Airflow limitation in asthma is based on a reduction in the ratio of forced expiratory volume in 1 second (FEV₁) to forced vital capacity (FVC). This ratio is normally over 75% in adults and 85% in children. Reversibility is defined as an improvement in FEV₁ of more than 12% to 15% after inhalation of a β₂-agonist, but this response may not always be seen. There may be naturally occurring changes in airflow throughout the day as well. Even though individuals with normal lungs will have some circadian variation in airflow, asthmatics often have exaggerated changes in peak flows over a 24-hour period (10% to 30%).

In addition to a decline in airflow, other physiologic changes include hyperinflation (increased thoracic gas volume, residual volume) and increased airway resistance. Routine measurement of these parameters is not indicated for most patients with asthma. Airway hyperresponsiveness is determined through methacholine, histamine, and/or exercise testing. A positive methacholine challenge demonstrates a fall in FEV₁ of 20% or more [provocation concentration (PC) 20] with 8 mg per milliliter or less of methacholine, but by itself this result is not adequate for diagnosis. Other diseases can cause increases in nonspecific airway responsiveness, including chronic obstructive pulmonary disease, congestive heart failure, bronchiectasis, and seasonal allergic rhinitis. Therefore, the methacholine test should be used as a confirmatory test in the appropriate clinical situation.

PATHOLOGY

It is now recognized that inflammation is a salient feature of asthma, present in mild and even newly diagnosed cases. Although many cell types may be involved in asthma, the predominant ones include lymphocytes, eosinophils, and mast cells. It is believed that for asthma to develop, a complex immunologic reaction must be initiated and maintained. Early on, naive T lymphocytes in the airways must be sensitized to specific allergens/antigens by antigen-presenting cells (perhaps monocytes, macrophages, or dendritic cells). The naive lymphocyte then alters its phenotype to that of a helper T cell type of lymphocyte (TH2), which produces cytokines (autocrine- and paracrine-acting proteins) that drive an IgE-associated, eosinophilic process. These cytokines include interleukin (IL)-4, IL-5, and IL-13. Functionally, these cytokines are involved in IgE production, mast cell and eosinophil migration, and survival and further generation of TH2 cells.

In contrast to TH2 cells, TH1 cells are active in other disease states (i.e., granulomatous diseases) and produce larger numbers of cytokines, such as IL-2 and interferon-γ. The IgE produced binds to mast cells (and perhaps other cells), which then can be activated by allergen cross-linking. Allergen exposure prompts mast cells to release preformed mediators, such as histamine, several proteases, and stored cytokines, and to generate lipid mediators, such as the cysteinyl leukotrienes (LTs) C₄, D₄, and E₄ and prostaglandin (PG) D₂. In addition to mast cell activation, asthmatic airways show broad up-regulation of activated lymphocytes and other cells, leading to increased amounts of tumor necrosis factor α, granulocyte-macrophage colony-stimulating factor (GM-CSF) and more typical TH2 cytokines, such as IL-4, IL-5, and IL-13. This up-regulation, which likely perpetuates the inflammatory process even after exposure to the allergen has ceased, increases the migration and the survival of eosinophils, neutrophils, and monocytes in the airways. This migration is thought to be under the control of chemotactic signals released by resident and nonresident airway cells and up-regulation of adhesion molecules on the surface of inflammatory cells and the endothelium/epithelium.

Potential chemotactic agents include the cytokines and chemokines (GM-CSF, RANTES, eotaxin, IL-5, and IL-8) and the LTs (both the cysteinyl LTs and LT B₄).

	Long-term Controller	Quick Relief	Education
Step 1: Mild, intermittent	None needed	Inhaled β_2 -agonist for symptom relief	Basic asthma facts How to recognize symptoms Proper use of medications Develop self-management plan Develop asthma action plan
Step 2: Mild, persistent	One daily inhaled anti-inflammatory (inhaled corticosteroid [low dose]) Alternative: Theophylline Cromolyn sodium Nedocromil	Inhaled β_2 -agonist for symptom relief	Develop self-management plan Step 1 asthma plan Basic self-monitoring Refer to general education Reassess goals with management plan
Step 3: Moderate, persistent	One daily inhaled anti-inflammatory (medium-dose inhaled corticosteroid) or Inhaled corticosteroid (low- to medium-dose) with long-acting β_2 -agonist (long-acting β_2 -agonist or theophylline) If needed: Add oral β_2 -agonist (high-dose inhaled corticosteroid and long-acting β_2 -agonist) or add oral β_2 -agonist	Inhaled β_2 -agonist for symptom relief	As for step 2
Step 4: Severe, persistent	One daily inhaled anti-inflammatory (high-dose inhaled corticosteroid and long-acting β_2 -agonist) or add oral β_2 -agonist	Inhaled β_2 -agonist for symptom relief	As for steps 1-3 Refer to individual education planning

TABLE 363.2. STEPWISE APPROACH FOR MANAGING ASTHAMA IN ADULTS AND CHILDREN >5 YEARS OLD

Long-term Controllers	Quick-relief Medications
Inhaled corticosteroids Beclomethasone Triamcinolone Fluticasone Fluticasone Budesonide Theophylline Cromones (cromolyn, nedocromil) Long-acting β_2 -agonists (salmeterol, formoterol) Leukotriene-modulating drugs Zafirlukast Montelukast Zileuton	β_2 -agonists Anticholinergics (atropine, ipratropium) Systemic corticosteroids (oral, intravenous, intramuscular)

TABLE 363.3. ASTHAMA MEDICATIONS

LONG-TERM CONTROL MEDICATIONS

Inhaled Corticosteroids

This class of drugs forms the cornerstone of the management of all but the most mild asthma. Inhaled corticosteroids (ICs) are effective and, in general, safe treatments for asthma. They are potent anti-inflammatory agents, decreasing both eosinophil and lymphocyte numbers in the airways after treatment. Corticosteroids also can affect the production of such cytokines as IL-4 and 5 and the up-regulation of adhesion molecules. ICs directly improve FEV₁ and airway hyperreactivity at doses ranging from about 200 μ g per day to 2,000 μ g per day. Higher doses (more than 1,000 μ g per day) have been studied only rarely, but systemic side effects begin to increase at about that dose. Although ICs improve airway obstruction, reactivity, and inflammation, discontinuation of therapy often leads to relapse; complete cures do not occur. Nonetheless, ICs remain the most clinically useful and cost-effective anti-inflammatory treatment available for asthma.

Although they are highly effective in children, inhaled corticosteroids remain a controversial treatment owing to issues of bone growth and the unknown potential for long-term residual effects. In adults, low to moderate doses of ICs have proved safe in clinical practice. The 5% incidence of oral thrush can be minimized by use of a spacer device, which diminishes oral deposition, as well as by rinsing the mouth after use. IC-induced dysphonia affects a small portion of the treated population. It is a trivial problem to most patients, but it can be a considerable annoyance to patients whose voice is an important aspect of their careers. Only about 10% of the inhaled dose of IC actually reaches the lung, but systemic effects can result from this inhaled portion or through absorption of the 90% that enters the gastrointestinal tract. The effect of ICs on the adrenal axis is related to dose and potency, as is the effect on osteoporosis. Older women treated with ICs are at greater risk of increased skin thinning and bruisability. Cataract formation and glaucoma have been associated with IC use in retrospective studies. The biggest limiting factor to ICs remains compliance with therapy on the part of patients.

It is likely that differences in potency (with subsequent differences in both efficacy and safety) exist among the five available corticosteroids. Although few direct comparisons exist, fluticasone, budesonide, and beclomethasone are likely more potent than fluticasone or triamcinolone. It is recommended that the patient start at a higher dose (more than 1,000 μ g per day) to relieve symptoms and then taper the dose as symptoms resolve (step-up/step-down therapy). The evidence to support this approach is minimal, however.

Cromones (Nedocromil Sodium, Cromolyn Sodium)

Despite the use of these compounds for more than 20 years, little is known regarding their mechanism of action. Although they are potent mast cell stabilizers in vitro, the clinical importance of this effect is less clear. Cromones are moderately efficacious drugs for controlling asthma symptoms. They protect against physiologic bronchoconstriction after challenges with allergens, ozone, sulfur dioxide, and exercise. Comparative studies have shown ICs to be more efficacious, but this class of drugs has proved remarkably safe. For this reason, cromolyn sodium has been the first-line controller for asthmatic children with mild to moderate disease, while it is second-line therapy for adults. There likely is very little difference between cromolyn and nedocromil. There may be a mild steroid-sparing effect with nedocromil. The anti-inflammatory or disease-modifying effects of this class of drugs remain doubtful.

Theophyllines

Theophyllines are nonspecific phosphodiesterase inhibitors with weak bronchodilating effects and some anti-inflammatory properties. They are effective for the treatment of asthma and are classified as second-line controller drugs for mild and moderate, persistent asthma. Inhaled corticosteroids, however, are more effective anti-inflammatory drugs. Seizures and arrhythmias can develop when recommended therapeutic concentrations are exceeded. Theophylline dosage is based on body weight and serum concentrations. Since many drugs interfere with the metabolism of theophylline by the P-450 enzyme system (erythromycin, cimetidine, zileuton, etc.), appropriate dosage adjustments should be made and drug levels monitored with any changes.

Long-acting Inhaled β_2 -agonists (Salmeterol, Formoterol)

These compounds are classified as controllers on the basis of their long duration of action, but there is minimal evidence to suggest that they have anti-inflammatory properties. Salmeterol is an effective bronchodilator for up to 12 hours (and beyond in some asthmatics). It has shown efficacy in preventing nocturnal symptoms and diurnal peak flow changes. Although these drugs were once recommended for long-term protection against exercise-induced bronchospasm, recent studies suggest that protection against bronchospasm associated with exercise that occurs several hours after dosing decreases within 1 to 2 weeks of initiating therapy. Long-acting β_2 -agonists should always be prescribed with a short-acting β_2 -agonist and with an anti-inflammatory agent (ICs). In several studies, the addition of a long-acting β_2 -agonist to ICs was more effective therapy than increasing the dose of ICs. For these reasons, long-acting β_2 -agonists are recommended for use primarily with ICs in moderate, persistent asthma.

Leukotriene Modulators (Zafirlukast, Montelukast, Zileuton)

LT modulators fall into two categories: LT D₄ receptor antagonists (zafirlukast, montelukast) and a 5-lipoxygenase (5-LO) inhibitor (zileuton). The LT D₄ receptor antagonists antagonize the cysteinyl LTs (LT C₄, D₄, and E₄), while the 5-LO inhibitors block production of both cysteinyl leukotrienes and LT B₄, giving them a potentially broader spectrum of activity. LT modulators have shown efficacy in allergen-, exercise-, and aspirin-induced asthma. There may be some anti-inflammatory effect, with reduction in inflammatory cells in lung fluids and tissue. There is a small (10% to 15%), immediate effect on FEV₁. Long-term improvement in FEV₁

continues for the first 1 to 3 weeks and then plateaus. Studies comparing LT drugs, such as montelukast and zafirlukast, to low-dose ICs show a greater effect on FEV₁ with ICs, but the improvement in symptom scores, β -agonist use, and exacerbations are more comparable. They may be particularly helpful for patients with aspirin-sensitive asthma—long-term studies have shown additional improvement in both upper and lower airway disease when these drugs are added to inhaled and even oral corticosteroids.

Few side effects have been reported with the receptor antagonists. However, Churg-Strauss syndrome, a type of eosinophilic vasculitis that presents with eosinophilia, pulmonary infiltrates, and/or cardiac, neurologic, and dermatologic changes, has been reported in patients treated with the receptor antagonists. Cause and effect is unclear, but practitioners should be aware of the association. The 5-LO inhibitor zileuton may cause abnormal liver function elevations in 3% of patients, and monitoring (at least in the first year) is suggested. The most recent National Institutes of Health guidelines suggest that these drugs be used in patients with mild, persistent asthma as alternatives to ICs, theophylline, and cromones. Recent studies in more severely affected patients suggest that these drugs may have a wider applicability as “add-on” therapy than was described originally.

QUICK-RELIEF MEDICATIONS

Short-acting β -agonists

Short-acting β_2 -agonists increase levels of intracellular cyclic AMP, causing smooth-muscle relaxation and bronchodilation. They also may stabilize mast cells but do not reduce airway inflammation. Short-acting β -agonists remain the acute bronchodilator of choice and the most effective pretreatment for exercise-induced asthma. There does not appear to be any added benefit to regular dosing, and there are some data to suggest that regular dosing may be detrimental.

Anticholinergics (Ipratropium, Atropine)

Anticholinergic agents inhibit increased vagal tone in the airways of patients with asthma through antagonism of muscarinic receptors (specifically the M3 receptor). About 50% of asthmatics experience bronchodilation with the use of anticholinergic agents, but, in general, the bronchodilating response is weaker than that seen with β -agonists. Anticholinergics have shown small additive effects to β -agonists in the treatment of status asthmaticus and are effective for therapy of β -blocker-induced bronchospasm.

Systemic Corticosteroids

Systemic corticosteroids are the most effective anti-inflammatory treatment for asthma. The onset of action is within 4 to 6 hours, and there does not appear to be a difference between intravenous and oral therapy. Although systemic corticosteroids are the most effective treatment for asthma, they are also probably the most toxic; every effort should be made to limit their long-term use.

SPECIAL SITUATIONS

Pregnancy

Symptoms improve in approximately one-third of asthmatic patients during pregnancy, worsen in one-third, and do not change at all in one-third. Treatment of pregnant women requires good medical control of asthma. It is likely that poor asthma control during pregnancy is more detrimental to the fetus than treatment with available drugs. Most drugs are poorly classified regarding risk in pregnancy, since very little reliable data exist in humans. The β -agonists have strong tocolytic effects, which may result in delayed or prolonged labor.

Status Asthmaticus

Asthma exacerbations can be initiated by a variety of factors, including noncompliance with medication; exposure to allergens, aspirin, and β -blockers; sinus and viral infections; and stress. Viral infections may account for up to 40% to 50% of exacerbations; rhinovirus is likely the most common factor. Although the best management of asthma exacerbations is prevention, the acute situation demands objective diagnosis and rapid treatment. All patients seen regularly by a physician for their asthma should have an action plan to begin treatment at home, including increased use of β -agonists and oral corticosteroid therapy if there is no initial response to β -agonists. Objective measures of lung function should always be obtained before treatment. Patients should continue to receive inhaled or nebulized β -agonist therapy at home and/or in the emergency room until they experience a favorable response.

The usefulness of other bronchodilating medications for the treatment of status asthmaticus in the emergency room is the subject of controversy. Anticholinergic (ipratropium bromide) solution has shown varying effects in improving FEV₁ beyond that of β -agonists alone, but an effect on hospitalization has not been established. Unless a patient is already on theophylline (in which case it should be continued), there is no indication for theophylline in the emergency management of asthma. Systemic corticosteroids have become a mainstay of therapy for those patients who fail initial treatment with β -agonists. The effects will not be seen until 6 to 8 hours after dosing, however. Dosing should be started at 60 to 120 mg of prednisone or the equivalent. A distinct dose response does not exist for steroid use in the emergency room, and there is no difference in oral or intravenous delivery. Patients who receive steroids in the emergency department should be given corticosteroids (likely both oral and inhaled) on discharge to limit a second exacerbation. These patients also need good long-term follow-up, since they are likely to be at higher risk for exacerbations in the future.

Exercise-induced Asthma

The mechanisms of exercise-induced asthma (EIA) remain incompletely defined, but they likely involve bronchoconstrictive effects stemming from abnormal heat and water fluxes in the bronchial tree. EIA normally develops 10 to 20 minutes after discontinuation of exercise. It is usually self-limited, resolving within 1 hour. It is exacerbated by exercise in cold, dry air. An initial warm-up period can induce a state of refractoriness, which limits bronchospasm during the planned exercise. In mild or intermittent cases, EIA is best treated with an inhaled β -agonist 15 to 30 minutes before exercise. Refractory or chronic cases require long-term therapy with ICs. Cromolyn and LT modulator drugs also are efficacious in this syndrome.

CHAPTER 364: CHRONIC OBSTRUCTIVE PULMONARY DISEASE

ANDREW L. RIES

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Chronic obstructive pulmonary disease (COPD) refers to a group of disorders that have in common the presence of persistent airflow obstruction. Specific conditions may be defined on the basis of clinical, anatomic, or physiologic criteria—such as chronic bronchitis, emphysema, and asthma—that may or may not be associated with chronic airflow obstruction. Chronic bronchitis typically is defined clinically by chronic cough and sputum production for at least 3 months for 2 successive years without other known causes. Emphysema is an anatomic, pathologic condition with abnormal permanent enlargement of airspaces distal to the terminal bronchioles, accompanied by destruction of walls but without fibrosis. Asthma is characterized by reversible airway narrowing and increased responsiveness to various stimuli. The overlapping diagnostic categories are illustrated in [Fig. 364.1](#).

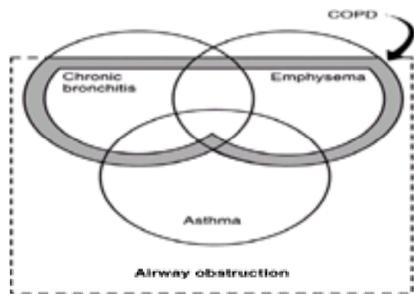

FIGURE 364.1. Nonproportional Venn diagram of the spectrum of overlapping conditions that make up chronic obstructive pulmonary disease (COPD). COPD includes airway obstruction and chronic bronchitis, emphysema, or irreversible asthma. Some persons with clinical or radiographic features of chronic bronchitis or emphysema may not have evidence of airway obstruction. (From Snider GL, Faling LJ, Rennard SI. Chronic bronchitis and emphysema. In: Murray JR, Nadel JA, eds. *Textbook of respiratory medicine*, second ed. Philadelphia: WB Saunders, 1994:1331–1397, with permission.)

From a clinical perspective, the term *COPD* has gained widespread use for several reasons. Many patients exhibit features of more than one disease (e.g., emphysema and chronic bronchitis or asthmatic bronchitis); it is often difficult to establish clearly one predominant source. Precise diagnosis is difficult, particularly in early-stage disease. Moreover, the clinical approaches to management are similar. Other terms may be encountered, such as chronic obstructive airways disease, chronic obstructive lung disease, chronic airflow obstruction or chronic airways obstruction, and chronic airflow limitation, but in this discussion they are considered identical to COPD. Specifically excluded are localized airways diseases, cystic fibrosis, bronchiectasis, and asthma without chronic airway obstruction.

INCIDENCE AND EPIDEMIOLOGY

COPD is a major cause of death and disability. Because COPD is insidious, with a long latency period before clinical recognition, official statistics underestimate morbidity and mortality rates. As of 1990, COPD had become the fourth leading cause of death in the United States. COPD was listed as the underlying cause of more than 106,000 deaths in 1996, accounting for about 4% of all deaths and contributing to an additional 5%. This represents an age-adjusted death rate of 21 per 100,000 in the population. In persons age 55 to 74, COPD as cause of death ranks third among men and fourth among women. More than 95% of deaths from COPD occur after the age of 55 years. In contrast to other major diseases, death rates from COPD have increased considerably in recent years—the rate was 47% between 1979 and 1993.

In the United States, the overall disease prevalence is about 4% to 6% in men and 1% to 3% in women; in adults older than 55, COPD is recognized in about 10% to 15%. The 1994 National Health Interview Survey estimated that 14 million adults had chronic bronchitis and two million had emphysema. In that year, the prevalence rates for COPD in older adults (65 years or older) were 119 per 1,000 men and 97 per 1,000 women. Recent trends indicate that prevalence rates are stable or declining among men but increasing among women. The impact of COPD on morbidity is even greater than on mortality. In the National Health Interview Survey in 1985, COPD accounted for 5% of doctors' office visits and more than 13% of all hospitalizations. COPD is an enormous cause of disability and reduced function among affected persons.

Epidemiologic studies have identified two main syndromes, with different risk factors and natural histories. The “usual” emphysematous form is associated closely with cigarette smoking. Airflow obstruction develops insidiously over many years with minimal symptoms, followed by clinical disease in later years with progressive symptoms and high morbidity and mortality rates. The second form of COPD, chronic asthmatic bronchitis, is associated with risk factors of atopy, high serum IgE levels, and bronchial hyperreactivity. Patients experience chronic airflow obstruction independent of smoking, though smoking may add to the risk. Asthmatic bronchitis is more amenable to medical therapy and has a better prognosis and survival rate than the emphysematous type.

Morbidity and mortality rates from COPD continue to rise despite declining smoking rates; this discrepancy is due to the long latency period between smoking exposure and clinical disease. Lower smoking rates ultimately will reduce the burden of COPD, but not for many years. With higher overall life expectancy and lower death rates from other major diseases, the impact of COPD will be magnified in our aging population.

ETIOLOGY

Cigarette smoking is the major risk factor and accounts for nearly 90% of COPD cases. Compared with nonsmokers, current smokers have about ten times the relative risk of COPD. The risk is equal for men and women. Previously, COPD was more common in men owing to their higher smoking rates, but in recent years the disease has manifested more gender equality, reflecting similar smoking rates for men and women. There is marked individual variation in susceptibility, and host factors play an important role. Only about 10% to 15% of smokers experience significant obstructive lung disease. In susceptible persons, smoking is associated with an accelerated decline in lung function over many years that is related to the amount of smoking ([Fig. 364.2](#)). Because of the large reserve in healthy lungs, disease typically is not recognized until later in life. From then on, progressive symptoms, disability, and death predominate. [Figure 364.2](#) also indicates the benefit of smoking cessation. Although lung function does not improve, the subsequent rate of decline slows to that in nonsmokers, which can significantly delay the onset of death and disability and justifies the emphasis on smoking cessation, even in persons with recognized disease.

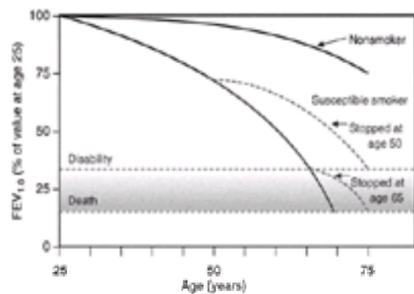

FIGURE 364.2. Age-related rate of decline in lung function ($FEV_{1.0}$) in a nonsmoker (*top*) and susceptible smoker (*bottom*). The dashed lines indicate the beneficial effects of smoking cessation with moderate and severe disease. The accelerated decline in lung function approaches the normal rate, significantly delaying the onset of disability and death. $FEV_{1.0}$, forced expiratory volume in 1 second. (From Fletcher CM, Peto R. The natural history of chronic airflow obstruction. *Br Med J* 1977;1:1645, with permission.)

Exposure of nonsmokers to the smoke of others in an indoor environment (second-hand smoke) is associated with an increase in respiratory infections and lung disease in children and with modest changes in lung function in adults. It has not been established clearly, however, that passive smoke exposure leads to clinically significant obstructive lung disease. There is some evidence that environmental exposures, such as air pollution and occupational dusts and fumes, are harmful for persons with underlying lung disease and may increase the risk of COPD, but it is unclear whether the effects are independent of smoking. There is also growing evidence that a history of childhood respiratory infections amplifies the risk of COPD in later life.

PATHOGENESIS

It is well established that cigarette smoking is the major risk factor for COPD, but the manner in which smoke produces airway disease is not entirely understood. In susceptible persons, smoking is associated with pathologic evidence of emphysema as well as inflammatory changes in the large and small airways. There is wide variability between persons, and there are poor correlations between the amount of cigarette smoking and the degree of emphysema, bronchiolar inflammation, and airway obstruction.

One credible theory about the pathogenesis of emphysema is that disease results from an imbalance between lung proteases and antiproteases, enzymes that promote injury and protect the lung against injury, respectively. An inherited deficiency of a α_1 -protease inhibitor (Pi) is associated with premature emphysema. α_1 -Pi is found in serum and alveolar fluid and is an acute-phase reactant in inflammatory states. Diagnosis of a α_1 -Pi deficiency can be made by measuring the serum level and by phenotyping. The gene is inherited in an autosomal recessive pattern—Pi MM is the normal phenotype and Pi ZZ the most common phenotype of homozygous deficiency. Although heterozygous persons have reduced levels of a α_1 -Pi, they do not have a clearly increased risk of disease. In congenital emphysema, anatomic changes predominate at the lung bases rather than in the upper lung fields. Additional evidence about the role of proteolytic enzymes in emphysema comes from animal studies in which human neutrophil elastase instilled into the lungs caused emphysema. The exact role of cigarette smoke in promoting enzymatic proteases or inhibiting the action of antiproteases is unknown.

In chronic bronchitis, pathologic changes in the airways include an inflammatory cell response, squamous metaplasia of ciliated epithelial cells, goblet cell proliferation, enlargement in submucosal glands with dilatation of ducts, and an increase in smooth muscle. These processes result in clinical symptoms of cough and sputum and sometimes airflow obstruction. There is controversy about whether asthma itself is part of the spectrum of COPD. Nonspecific airway hyperresponsiveness has been proposed as a risk factor that predisposes smokers to developing COPD (the “Dutch hypothesis”). Asthmatic bronchitis is one of the recognized epidemiologic patterns of COPD. Asthma can result in chronic airflow obstruction and should probably be included within the clinical spectrum of COPD ([Fig. 364.1](#)).

CLINICAL FINDINGS

COPD typically develops later in life. Dyspnea is the hallmark symptom that brings the patient to medical attention and leads to diagnosis. A careful history of the insidious onset of breathlessness on exertion, with or without a history of cough, sputum, or frequent lung infections, often provides the clue to diagnosis. Because of the slowly progressive course of disease and the large reserve in lung function, there is a long preclinical period in which the person who has smoked for years “without a problem” begins to note breathlessness with physical activities previously accomplished without difficulty. This breathlessness may be attributed to getting older or being out of shape. Reduced expiratory flow rates may be detected at this stage. Later, the patient often comes to medical attention after a critical event, such as a winter cold from which he or she never quite recovers. The person attributes the onset of illness to this time, but in truth this event simply pushed the already diseased lungs over the clinical edge, so to speak, much like a rope weakened by progressive fraying breaks when only a small weight is attached.

Cough (often called *smoker’s cough*) is a common symptom early in the course of disease. It is usually productive; sputum is described as mucoid. There may be a history of frequent respiratory infections associated with increased cough, purulent sputum, and breathlessness. The patient may note that it takes longer than usual to recover. Some patients with COPD experience abnormal gas exchange with hypoxemia or hypercapnia. Hypoxemia may be associated with cognitive or personality changes, polycythemia, and cyanosis. Chronic hypercapnia may cause headache, particularly on arising, and increased somnolence. During exercise, the PaO_2 may change significantly and unpredictably from the resting level. In many patients, the PaO_2 declines with physical activity; in others, it does not change or actually may increase.

On physical examination, it is important to assess maximum expiratory flow in high-risk persons (i.e., smokers). In early-stage disease, the examination may show normal results, but prolonged expiration or wheezing can be detected on forced exhalation at later stages. This symptom can be assessed easily with the forced expiratory time, a useful screening test for expiratory obstruction. In this maneuver, the patient exhales with maximal effort through an open mouth after a full inspiration. The examiner listens with the bell of the stethoscope over the trachea in the suprasternal notch and records the time in seconds until airflow ceases. Normal persons can exhale completely within 4 seconds. A forced expiratory time longer than 6 seconds signifies significant expiratory obstruction.

Other physical signs of COPD often are not present until the disease becomes moderate to severe. Overinflation of the lungs may result in an increased anteroposterior diameter of the thorax and a low, flat diaphragm with limited respiratory excursion. The flattened diaphragm contributes less to inspiration, placing more burden on the accessory breathing muscles (neck and intercostals) and producing greater respiratory movement in the upper chest. With severe hyperinflation, the diaphragm may even become inverted and move paradoxically—up on inspiration, down on expiration. This can be detected best with the patient supine, noting the inward movement of the lower rib cage and abdomen during inspiration. With advanced emphysema, the breath sounds are diminished owing to reduced flow and increased lung inflation. Signs of pulmonary hypertension and right-sided heart failure, such as peripheral edema and hepatic congestion, usually are not detected until an advanced stage of disease.

LABORATORY FINDINGS

The central diagnostic feature of COPD is reduced expiratory airflow resulting from increased airway resistance due to airway narrowing. Spirometry is the standard test for measuring maximal airflow and is relatively simple, reliable, and reproducible. It is useful for detecting airflow obstruction, staging severity, and following the disease course. A reduction in the forced expiratory volume in 1 second (FEV_1) in relation to the forced vital capacity (FVC)—the FEV_1/FVC ratio—is a standard bench mark of obstruction. The FEV_1 is the best measure of disease severity; it correlates with exercise tolerance and survival ([Fig. 364.3](#)). Other assessments of expiratory airflow also may be helpful (see [Chapter 387](#)). Peak expiratory flow can be calculated with relatively inexpensive peak flow meters that patients can be taught to use. It is most helpful for following changes over time, particularly in patients with reactive (i.e., asthmatic) disease.

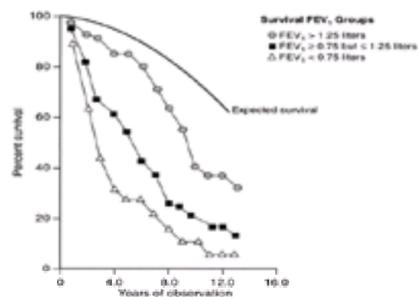

FIGURE 364.3. Long-term survival of 200 patients with chronic obstructive pulmonary disease grouped by initial FEV₁. (From Diener CF, Burrows B. Further observations on the course and prognosis of chronic obstructive lung disease. *Am Rev Respir Dis* 1975;111:719–724, with permission.)

Measures of lung volumes show an increase in residual volume, functional residual capacity, and, sometimes, total lung capacity in COPD. These tests can help confirm the diagnosis suspected on the basis of spirometry results. Emphysema produces a greater increase in total lung capacity than other obstructive diseases as well as a reduced carbon monoxide diffusing capacity of the lung (D LCO), primarily as the result of the loss of alveolar-capillary surface area. Nevertheless, D LCO is neither specific nor sensitive for emphysema.

Chest radiographs have limited usefulness in diagnosing or staging COPD. Early in the course of disease, they may show normal results. Their main use is in detecting other parenchymal lung or cardiovascular diseases that may have similar symptoms. In the context of advanced emphysema, the chest radiograph may evidence overinflation of the lungs, with a low, flat diaphragm and an increase in the retrosternal airspace (anterior to the heart) on the lateral film. The emphysematous lungs also can appear radiolucent, owing to bullous changes and a paucity of vascular shadows. High-resolution computed tomography may be useful in documenting pathologic evidence of emphysema, but the clinical usefulness of this test is unproved.

Arterial blood gas analysis may document hypoxemia and hypercapnia, particularly in advanced disease. The relationship between gas exchange abnormalities and other measures of lung function is poor. Hypoxemia can worsen with exercise, sleep, or changes in body position. Two characteristic clinical patterns of disease can be defined by blood gas findings. Patients with severe dyspnea, mild hypoxemia, and normal to low Pa CO₂ have been termed *pink puffers* (type A COPD), reflecting their color and increased breathing effort. Patients with severe hypoxemia, carbon dioxide retention, right-sided heart failure, and little dyspnea are called *blue bloaters* (type B COPD), indicating their bloated, cyanotic appearance and low ventilation. These differences may reflect variations in ventilation-perfusion (\dot{V}/\dot{Q}) mismatching and central respiratory drive. In clinical practice, most patients with COPD fall between these two extremes. The ECG usually shows normal results early in the course of disease; later, there may be signs of right-sided heart strain, including right axis shift, increased R waves over the right precordial leads (V₁ and V₂), and peaked P waves (so-called P pulmonale). These changes do not correlate well with the level of pulmonary hypertension.

OPTIMAL MANAGEMENT

COPD is by and large a chronic, progressive, and irreversible disease, so the primary goals of management should be directed toward preventive health strategies to slow progression and minimize complications. Secondary goals are to improve symptoms and function and treat reversible components of the disease. Optimal treatment depends on the stage of disease. For patients with mild to moderate disease, early detection and diagnosis and counseling regarding appropriate preventive health strategies are important. For patients with moderate to severe disease, symptomatic treatment also is indicated.

PREVENTION

There are several effective prevention strategies for patients with COPD throughout the natural history of disease ([Table 364.1](#)). Primary prevention strategies focus on suppressing the development of disease. Secondary prevention emphasizes early detection and halting of the course of clinical disease. Tertiary prevention methods involve minimizing complications for patients with symptomatic disease.

Primary: preventing development of disease
Prevent cigarette smoking—support public policy, encourage nonsmokers
Smoking cessation
Secondary: early detection and prevention of clinical disease
Smoking cessation
Expiratory flow rate measurement in high-risk persons (smokers)
α ₁ -protease inhibitor replacement for persons with proven genetic deficiency
Tertiary: minimizing complications in symptomatic disease
Smoking cessation
Influenza and pneumococcal vaccination
Pulmonary rehabilitation
Oxygen therapy for persons with hypoxemia

TABLE 364.1. PREVENTION STRATEGIES IN COPD

Cigarette Smoking

Controlling smoking behavior is the most important preventive strategy at all phases of disease. Physicians can play an important role by setting a smoke-free example in their personal lives, offices, and health care settings and by supporting social and political antismoking efforts (see [Chapter 33](#)). Public policies that encourage youths, who are the prime target of tobacco marketing, not to smoke can eliminate the epidemic of COPD, just as public health measures can control certain infectious diseases.

Smoking cessation should be a high priority for all patients with COPD. Although much of the disease is irreversible, there are clear, important benefits to quitting. Lung function may not improve after smoking cessation, but the accelerated loss of function due to smoking will slow and approach the normal, age-related rate of decline ([Fig. 364.2](#)). The Lung Health Study, a multicenter randomized clinical trial of 5,887 middle-aged smokers with spirometric evidence of early COPD, established that an aggressive smoking intervention program significantly lessened the age-related decline in FEV₁ over 5 years of follow-up.

The advice of physicians is important and effective in inducing smokers to quit. Several studies have found that only a few minutes of a physician's time inquiring about smoking status and providing advice to quit can achieve abstinence rates of up to 10% to 20% at 1 year. Physician counseling for high-risk smokers is even more effective. Even in patients with symptomatic and advanced disease, smoking cessation is important in delaying progression and limiting the consequences of the disease.

Preventing Influenza and Pneumonia

Patients with COPD are particularly vulnerable to lung infections. Influenza can be prevented or minimized in severity by immunization or chemoprophylaxis. Moreover, some bacterial pneumonias caused by pneumococci can be prevented by immunization. An annual influenza vaccine is produced from the strains of influenza A and B viruses expected to be most prevalent during the next flu season. Made from inactivated virus, it cannot cause infection. Persons at high risk should

be vaccinated annually because of changes in the viral strains each year.

Amantadine is an antiviral that is effective for prophylaxis of influenza A infection. It can be used during epidemics or with exposure, but it is effective only for the duration of administration. The usual dose is 100 mg taken orally twice daily for persons older than 10 years. It is particularly useful when vaccination is contraindicated and can be used with the vaccine during epidemics in the several weeks necessary to mount an antibody response. Side effects develop in about 10% of patients, including insomnia, nervousness, or difficulty concentrating. Rimantadine, a newer derivative, may have fewer side effects. Amantadine also may shorten the duration of influenza A infection, if started within 48 hours of symptom onset.

Pneumococcal vaccine should be given once to the same high-risk groups as for the influenza vaccine. In addition, patients over age 2 years with sickle cell disease or other causes of splenic dysfunction should be vaccinated. The current vaccine contains capsular polysaccharide antigens of the 23 serotypes of pneumococci responsible for more than 80% of serious, bacteremic pneumococcal infections. Although antibody levels decline over time, routine revaccination is not recommended because of the risk of allergic reactions.

Pulmonary Rehabilitation

Pulmonary rehabilitation is an established preventive health strategy that enhances standard therapy for persons with chronic lung disease to control and alleviate symptoms, optimize function, and limit the medical and economic burdens of disease. Multidisciplinary programs include education, respiratory and chest physiotherapy instruction, psychosocial support, and exercise training. As with other rehabilitation programs, the primary goal is to restore the patient to the highest possible level of independent function. This can be accomplished by helping patients become more knowledgeable about their disease, more actively involved in their own health care, more independent in daily care activities, and less dependent on family, friends, and health professionals and other expensive medical resources.

Benefits of pulmonary rehabilitation include improved exercise tolerance and symptoms and reduced hospitalizations and use of expensive medical resources. Patients report improved quality of life with a decline in respiratory symptoms, an increase in exercise tolerance and ability to perform physical activities of daily living, and improved psychological functioning, with less anxiety and depression and elevated feelings of hope, control, and self-esteem.

OXYGEN THERAPY

Long-term, continuous oxygen therapy has been shown to improve survival and lower morbidity in hypoxemic patients with COPD; in fact, this is the only treatment proven to prolong survival. Possible benefits of supplemental oxygen for nonhypoxemic patients or for patients who experience hypoxemia only under certain conditions (e.g., exercise, sleep) are less clearly defined. The results of two multicenter randomized clinical trials (one in Great Britain and the other in the United States) justify long-term oxygen therapy for patients with significant resting hypoxemia (PaO_2 55 of mm Hg or less or oxygen saturation of 88% or less). For patients with a PaO_2 between 56 and 59 mm Hg, oxygen is indicated if there is erythrocytosis (hematocrit of 55 or more) or cor pulmonale. The decision for long-term therapy should be made only in stable patients on optimal treatment for at least 30 days. Patients recovering from an acute illness should be reevaluated after a period of stability before committing to this expensive treatment. There are several options for long-term oxygen therapy. Home-care providers, respiratory therapy personnel, and pulmonary rehabilitation professionals are excellent sources of information about available options, including gas sources (liquid, compressed gas, concentrators) and delivery devices (nasal, transtracheal, or conserving catheters and inspiratory demand regulators).

α_1 -PROTEASE INHIBITOR REPLACEMENT

For patients with verified deficiency of α_1 -Pi, replacement therapy with the purified human protein is available. This treatment has presumed but not proven efficacy in slowing the progression of emphysematous lung destruction. The current treatment regimen is expensive: the drug alone can cost more than \$25,000 per year. According to American Thoracic Society guidelines, treatment should be reserved for patients with proven α_1 -Pi deficiency and abnormal lung function.

SYMPTOMATIC TREATMENT

Bronchodilators

For patients with recognized COPD, medical treatment is directed toward the reversible component of airway obstruction and control of secretions. Bronchodilators used to improve symptoms and increase airway caliber include sympathomimetic β -agonists, anticholinergics, and methylxanthines (theophylline). The decision to treat a patient with a bronchodilator should not depend on evidence of an acute response, because many patients respond later to regular therapy. Furthermore, these medications may have effects beyond just bronchodilation.

Sympathomimetic bronchodilators are used routinely. Newer β_2 agents are more selective and longer acting and have fewer side effects than older, nonselective drugs. The preferred method of administration is by inhalation with a metered-dose inhaler (MDI). This produces more bronchodilation with fewer side effects than administration via oral or other systemic routes. Used properly, an MDI is just as effective as and less expensive than a liquid nebulizer and can be used in acute-care and emergency department settings. Extensions or spacers can help persons who have difficulty coordinating the MDI, particularly children and older adults. The key to MDI use is proper technique (Table 364.2). In addition to bronchodilation, β -agonists also can minimize airway hyperresponsiveness and enhance mucociliary clearance. The most common side effects are tachycardia and skeletal muscle tremor.

Shake inhaler, remove cap, and hold upright.
Place inhaler 2–4 cm in front of open mouth.
Exhale to functional residual capacity or below.
Activate inhaler once just after the start of a slow, deep inhalation.
Hold breath for 5–10 seconds.
Exhale slowly.
Wait at least 1 minute before next puff.

TABLE 364.2. PROPER USE OF A METERED-DOSE INHALER

Anticholinergics have gained prominence in the treatment of COPD. Although their bronchodilating effects have been known for many years, the selectivity and few side effects of newer agents, such as ipratropium bromide, have enhanced their usefulness. Bronchodilation is thought to be due to inhibition of cholinergic-mediated bronchomotor tone. The drugs are reported to be more effective in larger airways, making them particularly useful for patients with COPD.

Theophylline preparations have been used in treating patients with COPD for many years, but their usage has declined because of frequent problems with toxicity, the need for regular monitoring of blood levels, and the advent of newer, more selective bronchodilating agents. The mechanism of bronchodilation from theophylline is not clearly defined. Theophylline has other potentially beneficial effects, such as improved diaphragmatic function, decreased dyspnea, increased mucociliary clearance, and stimulation of respiratory drive. Because of individual variability in metabolism and the many factors that can alter metabolism, monitoring blood levels is necessary with long-term therapy. The target therapeutic level is typically 10 to 20 μg per milliliter. Minor side effects, such as tremor, insomnia, irritability, and gastrointestinal upset, can develop with levels well below 20 μg per milliliter. More serious side effects, including vomiting, dysrhythmias, hypotension, and seizures, generally develop at higher blood levels. Older patients are particularly susceptible to toxicity.

Corticosteroids

Corticosteroids can be beneficial for some patients with COPD. A meta-analysis of 16 clinical trials of oral steroid therapy for stable patients found that a 20% improvement in FEV₁ occurred in about 10% more patients on steroids than on placebo. Many patients on corticosteroids report subjective symptom improvement, but long-term steroid use is associated with numerous serious adverse effects. A limited trial of corticosteroids probably is justified for patients who cannot be treated with standard bronchodilators alone. A single morning dose of 20 to 40 mg of prednisone for 5 to 7 days is a typical starting point. Treatment beyond a few weeks should be continued only if there is significant improvement in pulmonary function and symptoms. For long-term therapy, the dose should be kept as low as possible, to minimize side effects. Inhaled steroids, best taken in through a spacer device to minimize oral deposition, are safer, but their effectiveness in COPD has not been established.

Control of Secretions

For patients with chronic cough and sputum, techniques to control secretions are important. Patients should be encouraged to drink several glasses of fluid per day, but excessive hydration is not warranted. They also should be taught the technique of controlled coughing, which involves a deep inspiration, breath-holding for a few seconds, and then coughing two or three times. Postural drainage is effective in patients with heavy sputum production. The use of mucolytic agents to thin secretions and promote clearance is the subject of controversy. Theoretically, therapy with such drugs as oral iodinated glycerol, nebulized acetylcysteine, or, more recently, recombinant human DNase, works best in thinning secretions that are thick, mucoid, and heavy. Whether this produces physiologic or symptomatic improvement is unclear. Cough-suppressant therapy is generally not recommended, since cough is an essential protective mechanism.

Because of impaired mucociliary clearance and less effective cough, secretions may pool in dependent portions of the lung and be difficult to clear. For acute exacerbations, when sputum changes color and increases in volume, treatment with antibiotics is indicated. In many cases, a specific bacterial pathogen cannot be identified from purulent sputum. For such episodes of acute bronchitis, it is appropriate to institute a 7- to 10-day course of antibiotics empirically, without a sputum culture. Oral antibiotics, such as trimethoprim-sulfamethoxazole, ampicillin, amoxicillin-clavulanate, tetracycline, or erythromycin, often are chosen to cover pathogens colonizing the respiratory tract, including *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*.

CHAPTER 365: BRONCHIECTASIS

JOHN M. LUCE AND ROBERT M. JASMER

[Classification](#)
[Epidemiology](#)
[Pulmonary Function Abnormalities](#)
[Symptoms](#)
[Physical Findings](#)
[Diagnosis and Patient Evaluation](#)
[Principles of Management](#)
[Associated Conditions](#)

The term *bronchiectasis* derives from the Greek words *bronkos*, meaning windpipe, and *ektasis*, signifying stretching or extension. It refers to an abnormal dilatation of the proximal medium-size bronchi greater than 2 mm in diameter due to destruction of the muscular and elastic components of their walls. This dilatation typically is associated with chronic bacterial infection and the production of large quantities of foul-smelling sputum. Bronchiectasis need not always be associated with purulent expectoration, especially when it involves areas of the lung with dependent drainage, such as the upper lobes, which frequently are involved in patients with pulmonary tuberculosis. In this circumstance, the bronchiectasis is called “dry” to distinguish it from the more common “wet,” or productive, variety.

CLASSIFICATION

Several systems have been used to classify bronchiectasis, most of them based on anatomic abnormalities of the bronchi seen on bronchography or at autopsy. One common classification system developed by Reid consists of cylindrical bronchiectasis, in which sections of the bronchi are consistently widened; varicose bronchiectasis, in which local constrictions in cylindrical bronchiectatic sections cause an irregularity resembling that of varicose veins; and saccular or cystic bronchiectasis, in which dilatation increases toward the lung periphery so that the bronchi terminate in balloon-like structures. Note that few clinical, epidemiologic, or pathophysiologic differences have been found between cylindrical, varicose, and saccular bronchiectasis.

EPIDEMIOLOGY

Infectious bronchiectasis once was a common disease in the United States. However, it has become rare since the introduction of antibiotics and now is seen in very few Americans. Most affected persons have bronchiectasis in association with systemic disorders. Despite its decline in the United States and in other developed nations, infectious bronchiectasis persists in less developed parts of the world.

PULMONARY FUNCTION ABNORMALITIES

The pulmonary function abnormalities attributable to bronchiectasis are difficult to differentiate from those caused by the diseases that underlie or exist in concert with this condition. Most patients with bronchiectasis show some degree of airflow obstruction. Mild restriction also may be present, especially if the bronchiectasis is associated with a disease that reduces lung volumes. The diffusing capacity for carbon monoxide also may be diminished. Most patients have mild hypoxemia owing to ventilation–perfusion mismatching and intrapulmonary shunt. Normocapnia or hypocapnia is observed in all but the most advanced cases. Cor pulmonale occurs in only a minority of patients with bronchiectasis, because their hypoxemia is often not severe.

SYMPTOMS

Patients with bronchiectasis may have symptoms referable to the bronchiectatic process alone or to underlying disorders. Symptoms caused by bronchiectasis itself include chronic cough, purulent expectoration, fever, weakness, and weight loss. Sputum production often increases during acute respiratory infections. Dyspnea is reported by some patients with bronchiectasis but is not a universal finding. As might be expected, breathlessness is especially common among patients with extensive bronchiectasis seen on chest radiographs. Hemoptysis is also a typical finding among patients with bronchiectasis. It is generally mild, most often consisting of the expectoration of purulent sputum flecked with blood. Because the bleeding usually originates from bronchial arteries or bronchial-pulmonary anastomoses under systemic pressures, however, it may become massive, that is, in excess of 250 mL per day.

PHYSICAL FINDINGS

The physical signs of patients with bronchiectasis are neither sensitive nor specific for that process. The breath is fetid in some but not all patients. Digital clubbing also is an inconsistent finding, as are cyanosis and plethora reflective of polycythemia. Nasal polyps and signs of chronic sinusitis may be present. Rales are often found at the lung bases; rhonchi may be encountered, especially if active infection is present; and scattered wheezes may be heard.

DIAGNOSIS AND PATIENT EVALUATION

Bronchiectasis may be suspected on the basis of clinical signs and symptoms, especially if the process involves purulent expectoration and if such disorders as pneumonia, emphysema, and lung abscess have been ruled out. The onset of bronchiectasis may be traced to a clear-cut aspiration or febrile illness, especially in patients with postobstructive or infectious bronchiectasis. Sputum analysis should reinforce the clinical impression of bronchiectasis. Such analysis often includes visual inspection of expectorated sputum that has been allowed to settle into the characteristic three layers: an upper frothy and watery layer, a middle layer that is turbid and mucopurulent, and a bottom layer that is purulent and opaque. Bacteriologic studies of bronchiectatic sputum may confirm the presence of such microorganisms as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*, but these pathogens also can be present in the sputum of patients with chronic bronchitis. The finding of *Aspergillus* species is suggestive, but not diagnostic, of allergic bronchopulmonary aspergillosis.

Radiographic studies have long been the means by which the diagnosis of bronchiectasis is firmly established. Results of plain chest radiography may be normal in some patients with bronchiectasis, but most often radiography shows characteristic patterns. When cylindrical bronchiectasis is present, these patterns involve linear radiolucencies and thin parallel markings that radiate from the hili and are called tram tracks or tram lines ([Fig. 365.1](#)). The dilated bronchi may appear as thick parallel markings or so-called toothpaste lines.

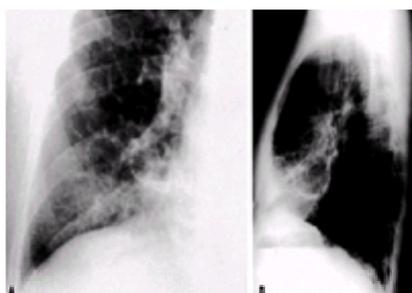

FIGURE 365.1. Tram tracks or tram lines. When cylindrical bronchiectasis is present, radiography shows patterns involving linear radiolucencies and thin parallel markings radiating from the hili.

Computed tomography (CT) of the chest, which involves little discomfort and few adverse complications, has virtually replaced bronchography in diagnosing bronchiectasis, especially among patients with generalized disease ([Fig. 365.2](#)). Thin-section high-resolution chest CT (HRCT) has a sensitivity and a specificity each in excess of 90% in detecting bronchiectasis at a segmental level. Bronchiectasis results in six characteristic HRCT findings, as originally described by Naidich et al.: bronchial dilatation, bronchial wall thickening, lack of normal bronchial tapering, gross irregularities in airway contact, and air-fluid levels in distended bronchi.

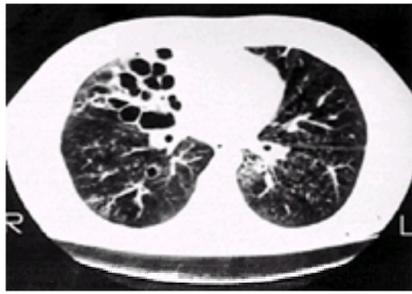

FIGURE 365.2. Computed tomography (CT) of the chest showing extensive cystic bronchiectasis of the right middle lobe and mucoid impaction of the left lower lobe.

Bronchoscopy is less helpful than bronchography or HRCT in making visible entire bronchiectatic segments. Bronchoscopy may, however, be useful in detecting aspirated foreign bodies and other obstructing lesions and is indicated when such lesions are suspected. Bronchoscopy also may be indicated for patients with hemoptysis, to localize the bleeding site or to determine from which lung blood is coming. In the United States and other developed countries, however, the detection of de novo bronchiectasis should prompt a search for its underlying cause. Depending on the type of patient, this search might include some or all of the following possibilities: serum protein electrophoresis for α_1 -antitrypsin deficiency; immunoglobulin levels, including IgG subclasses, for hypogammaglobulinemia; pilocarpine iontophoresis (sweat test) for cystic fibrosis; determination of immunoglobulins and *Aspergillus* precipitins for allergic bronchopulmonary aspergillosis; and electron microscopic examination of sperm or respiratory epithelium for primary ciliary dyskinesia.

PRINCIPLES OF MANAGEMENT

Antimicrobials have been the mainstay of treatment of bronchiectasis since their introduction more than 40 years ago. The choice of specific agents should be dictated by sputum or bronchoalveolar lavage fluid culture for aerobes, anaerobes, and mycobacteria whenever possible. If mixed flora are present, as is often the case, treatment consists of a broad-spectrum antibiotic such as amoxicillin, tetracycline, or trimethoprim-sulfamethoxazole. Most clinicians prefer to give antimicrobial agents during acute exacerbations of bronchiectasis, but some physicians prescribe them on a regular basis or during a given number of weeks each month, as is done for chronic bronchitis. Chest physical therapy with postural drainage, chest clapping, humidification, the use of mucolytics, and other measures to promote clearance of secretions also has been recommended.

In addition to these general measures, specific therapies may be appropriate when the underlying cause of bronchiectasis has been identified. For example, the regular administration of immunoglobulin in patients with immunodeficiency may lessen the incidence of sinopulmonary infection. The medical management of bronchiectasis should prove effective in the majority of patients. Nevertheless, consideration should be given to surgical resection in certain instances. Surgery is rarely indicated for bronchiectasis and should be limited to patients with massive hemoptysis who do not respond to bronchial artery embolization or patients with local disease unresponsive to antibiotics.

ASSOCIATED CONDITIONS

In countries such as the United States, the pathologic process called bronchiectasis usually develops in patients with underlying systemic disorders upon which airway infection is superimposed. Bronchiectasis often occurs in association with systemic diseases and other conditions ([Table 365.1](#)). Several of these conditions are reviewed in the following section in alphabetical order. For further information on cystic fibrosis, see [Chapter 370](#); for a review of allergic bronchopulmonary aspergillosis, see [Chapter 369](#).

Allergic bronchopulmonary aspergillosis
α_1 -antitrypsin deficiency
Bronchial obstruction (including middle lobe syndrome)
Bronchopulmonary sequestration
Congenital cartilage deficiency (Williams-Campbell syndrome)
Cystic fibrosis
Human immunodeficiency virus infection
Immunodeficiency
Infection
Inflammation
Primary ciliary dyskinesia
Rheumatoid arthritis
Tracheobronchomegaly (Mounier-Kuhn syndrome)
Unilateral hyperlucent lung (Swyer-James-MacLeod syndrome)
Yellow nail syndrome

TABLE 365.1. CONDITIONS ASSOCIATED WITH BRONCHIECTASIS

BRONCHIAL OBSTRUCTION

Investigators once assumed that a common pathogenetic factor was proximal airway obstruction with distal infection of the bronchial walls and, in many cases, the surrounding lung parenchyma. Although this assumption has proved to be incorrect, focal postobstructive bronchiectasis may indeed occur in patients with endobronchial tumors, broncholithiasis, bronchial stenosis from inflammatory disorders such as tuberculosis, and aspirated foreign bodies such as coins, nuts, and timothy grass heads. It also may develop as part of the middle lobe syndrome. This syndrome presumably results from the angulation of the lobar bronchus at its origin, impingement on the right middle lobe bronchus by enlarged lymph nodes, and a lack of collateral ventilation to that lobe. Although some patients with the middle lobe syndrome are symptomatic, the condition is frequently detected on a plain chest roentgenogram taken for other purposes.

IMMUNODEFICIENCY

Bronchiectasis and other chronic or recurrent sinopulmonary infections are common among patients with congenital or acquired immunodeficiency. Abnormalities of B-lymphocyte function most frequently are associated with bronchiectasis. Congenital or acquired hypogammaglobulinemia characterized by a decline or absence of circulating IgG has been described in several patients with bronchiectasis. Immunodeficiency states involving one or more of the four IgG subclasses in the context of normal total IgG levels are associated perhaps even more often with bronchiectasis. IgG subclass deficiencies are a typical cause of bronchiectasis, and serum subclass levels should be obtained whenever other causes of bronchiectasis have been ruled out.

INFECTION

In third world countries (and historically in developed countries), bronchiectasis typically results from necrotizing pulmonary infections that are poorly treated, if at all.

Rosenzweig and Stead first drew attention to bronchiectasis following bronchopulmonary necrosis due to *Klebsiella*, *Staphylococcus aureus*, other aerobic bacteria, and *Mycobacterium tuberculosis*. Since that time, bronchiectasis has been reported in patients with pulmonary disease caused by nontuberculous mycobacteria and aerobic bacteria, such as *Mycoplasma pneumoniae*.

TRACHEOBRONCHOMEGALY

Tracheobronchomegaly, also known as Mounier-Kuhn syndrome, is characterized by a striking dilatation of the intrathoracic trachea and major bronchi. Enlargement of the airways and the deep corrugations produced by redundant musculomembranous tissues between the cartilaginous rings gives a roentgenographic appearance of multiple diverticulae. The diagnosis is often made on CT scan. The cause of tracheobronchomegaly is unknown; although it has been attributed to severe, chronic bronchopulmonary suppuration, the latter condition may be a result of tracheobronchomegaly rather than its cause. Enlargement of the cartilaginous tracheal rings as well as the membranous trachea supports a congenital origin.

UNILATERAL HYPERLUCENT LUNG

Swyer and James originally described "unilateral lung transradiancy" on the chest roentgenograms of ten patients in the 1950s. These patients were initially thought to have emphysema stemming from bronchial obstruction, but such obstruction was not confirmed by bronchoscopy or bronchography. Nonetheless, cystic abnormalities were noted in the proximal bronchi. These abnormalities were presumably related to antecedent bronchopulmonary infections during infancy. Today, such infections are thought to cause hypoplasia of lung parenchyma and the pulmonary artery on the involved side.

YELLOW NAIL SYNDROME

The term *yellow nail syndrome* was coined in 1964 to describe the association of yellow discoloration of the fingernails and lymphedema. Since then, some, but not all, patients with these findings have been reported to have pleural effusions and bronchiectasis as well. In these cases, bronchiectasis has been attributed either to hypoplasia of the lymphatic system with altered lung drainage or to immunologic deficiencies that have been found in certain patients.

CHAPTER 366: DISEASES OF THE UPPER AIRWAY

MICHAEL G. GLENN AND ERNEST A. WEYMULLER, JR.

[Ear](#)
[Sinuses and the Face](#)
[Salivary Glands and Oral Cavity](#)
[Nose](#)
[Throat](#)
[Neck](#)

EAR

EXTERNAL OTITIS

Infection of the external auditory canal is characterized by progressive pain, itching, and discharge. There is often an antecedent history of local trauma or water in the ear canal. Characteristically, pressure on the tragus or auricular cartilage produces exquisite pain. The ear canal is erythematous and swollen, often to the point of obscuring the eardrum. In severe infections, periauricular cellulitis and even regional lymphadenopathy develop. Conductive hearing loss may result from severe edema of the external ear canal.

Pseudomonas aeruginosa and *Staphylococcus aureus* are most frequently responsible for the infection. Culture of the discharge is not necessary for routine cases. The key to successful treatment is removal of wax and desquamated debris from the ear canal by suction or irrigation. Any foreign body should be removed as well. If the ear canal is not occluded by edema, treatment with antibiotic eardrops for 7 to 10 days should resolve the infection. If the ear canal is narrowed, a wick can be inserted to ensure adequate distribution of antibiotic drops to the medial portion of the ear canal. Systemic antibiotics are not recommended unless the patient has periauricular cellulitis or regional lymphadenopathy. Patients should be cautioned to refrain from instrumentation of the external ear canal and to protect the ear canal during showering or hair washing by means of a cotton ball saturated with petrolatum ointment.

External otitis may be a much more severe problem in elderly diabetic patients, in whom the infection may extend into the surrounding soft tissues and bone. If standard therapy fails to control external ear canal drainage and pain after 1 or 2 weeks, so-called malignant external otitis should be considered. Careful examination shows granulation tissue at the junction of the bony and cartilaginous portions of the external ear canal. In addition, patients may evidence progressive cranial nerve deficits. Besides aggressive local care of the ear canal, treatment with intravenous antipseudomonal antibiotics is indicated. Several weeks of antibiotic therapy is necessary, and occasionally surgical debridement is required to remove sequestered bone.

OTITIS MEDIA

Although it is most prevalent in children, otitis media can occur at any age. It usually follows an upper respiratory tract infection. It is characterized by pain and conductive hearing loss. On physical examination, the landmarks of the eardrum are distorted by erythema, thickening, and bulging of the tympanic membrane. In advanced cases, a perforation of the eardrum with purulent discharge may be noted. Blockage or dysfunction of the eustachian tube is believed to be the pathophysiologic basis for otitis media. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the bacteria most frequently isolated from middle ear effusions in acute otitis media. Gram-negative enteric bacilli often are isolated from the effusions in neonates and infants up to 6 weeks of age; they are rarely present in the effusions of older children. Myringocentesis with aspiration of middle ear effusion is useful when treating infection in severely immunocompromised patients or nonresolving infections; otherwise empiric treatment with oral antibiotics effective against *H. influenzae* is appropriate for children and adolescents. The duration of treatment should be between 10 and 14 days.

Serous Otitis Media

Failure of fluid to clear from the middle ear cleft after acute otitis media may result in serous otitis media. In serous otitis media, the eardrum may vary in color from gray to blue to yellow. It may be retracted, and air bubbles may be visible behind it. A mild to moderate conductive hearing loss (10 to 30 dB) is also noted. Most serous effusions clear spontaneously or with the use of nonoperative therapy, including antihistamines and decongestants, antibiotics, or autoinflation (modified Valsalva maneuver). Pressure equalization tubes may be inserted in patients with effusions that persist more than 12 weeks or that fail to respond to medical therapy. These tubes are also useful in preventing recurrent infections in young children. Adults with persistent unilateral serous otitis media should be referred to a head and neck surgeon to exclude the possibility that nasopharyngeal carcinoma is the cause of eustachian tube blockage.

Chronic Otitis Media

Persistent eustachian tube dysfunction and recurrent acute infection may result in chronic perforation of the tympanic membrane with a recurring foul-smelling discharge. Occasionally, the eardrum is intact between periods of drainage, and the only evidence of disease is squamous debris or cholesteatoma in the pars flaccida of the eardrum. Patients should be referred for possible surgical management. Many small tympanic perforations and watery otorrhea should raise the suspicion of tuberculous otitis media.

Complications of Acute and Chronic Otitis Media

Acute mastoiditis classically occurs 1 to 2 weeks after an episode of acute otitis media. In a patient with chronic perforation, chronic drainage, or cholesteatoma, mastoiditis can develop at any time. The most common symptom is persistent discharge from the affected ear. Ordinarily, pain is not significant; when there is pain, abscess formation should be suspected. The patient may have a slight fever but frequently does not seem extremely ill. Severe pain and tenderness or systemic toxemia suggests a complication of mastoiditis. These complications result from extension of infection to involve structures adjacent to the temporal bone. Subperiosteal abscess, an extension of infection within the mastoid bone to the mastoid tip (Bezold's abscess) or to the root of the zygomatic bone, produces localized pain and swelling. Surgical drainage is typically required. Extension of infection through dehiscent bone or by destruction of bone overlying the facial nerve can result in facial nerve paralysis. Labyrinthitis and even fistulization of the semicircular canals can evolve through a similar process. Petrositis or Gradenigo syndrome is a result of an abscess or osteomyelitis at the apex of the petrous portion of the temporal bone and consists of a persistently draining ear with ipsilateral sixth cranial nerve palsy and pain behind the ipsilateral orbit.

Intracranial complications of otitis media include extradural abscess, subdural abscess, brain abscess, lateral sinus thrombophlebitis, and meningitis. In meningitis after acute otitis media, the usual infecting organism is either a gram-positive coccus or *H. influenzae*. Meningitis is a rare complication of chronic otitis media; the agent is usually a gram-negative organism. Initial management should be directed at identifying the organism and treating the meningitis. Once meningitis is under control, the otologic disease can be addressed. An extradural abscess in either the middle or the posterior cranial fossa produces symptoms of localized headache, fever, and meningismus. Signs of increased intracranial pressure also may be noted. Surgical intervention usually is required. Lateral sinus thrombophlebitis arises as a consequence of erosion by chronic infection through the lateral venous sinus plate, causing a focus of phlebitis. Usual organisms are group A streptococci and *S. pneumoniae*. The primary symptom is a persistent spiking fever. Between bouts of fever the patient is often well.

HEARING LOSS

Hearing loss is typically divided into two categories: sensorineural and conductive. Abnormalities of the cochlea, eighth cranial nerve, or central nervous system are responsible for sensorineural hearing loss. Processes affecting the external ear canal, tympanic membrane, and middle ear are responsible for conductive hearing loss.

Conductive Hearing Loss

The most common cause of conductive hearing loss is obstruction of the ear canal by cerumen or foreign body, typically associated with external otitis. Removal of the

obstruction and treatment of external otitis readily reverse the hearing loss. Middle ear effusion associated with acute or serous otitis media results in a mild to moderate conductive hearing loss. Chronic otitis media leads to hearing loss either by destruction of the tympanic membrane or by erosion of the ossicular chain.

Otosclerosis is a bony disorder of the otic capsule that causes conductive hearing loss owing to fixation of the stapes within the oval window. It is similar in histopathologic features to Paget's disease, except that involvement is limited to the temporal bone and involves all three layers of the otic capsule (endosteum, endochondral bone, and periosteum). Stapes fixation is also noted in patients with osteogenesis imperfecta tarda. Van der Hoeve syndrome is the constellation of conductive hearing loss, blue sclerae, and history of multiple fractures. Surgical replacement of the stapes can be successful in restoring normal hearing, though a hearing aid is also effective.

Sensorineural Hearing Loss

Sudden sensorineural hearing loss is a well-recognized entity. It is most commonly idiopathic, but patients must be evaluated thoroughly to exclude such conditions as Ménière's disease, perilymphatic fistula, or acoustic neuroma. As a general rule, about one-third of patients recover completely, one-third improve somewhat, and the remaining one-third fail to recover any hearing in the affected ear. High doses of glucocorticoids are frequently prescribed, but there are no conclusive studies that establish their benefit (except in patients with certain audiometric patterns).

Association of acute hearing loss with sudden exertion or head trauma should raise the suspicion of a rupture of the oval or round window membrane. In addition to hearing loss, these patients experience disequilibrium and occasionally nystagmus. When this condition is suspected, patients should immediately be referred for consideration of middle ear exploration.

Presbycusis is hearing loss resulting from degenerative changes associated with aging, which can be due to atrophy of the organ of Corti, loss of neural elements of the eighth cranial nerve, degeneration of the stria vascularis, or defects in the basilar membrane. Characteristically, higher frequencies are lost first. Patients typically complain of difficulty in understanding speech, especially in noisy situations, but the speech may seem loud enough. Any elderly patient complaining of hearing difficulties should be referred for audiometric examination. Sensorineural losses are not reversible, but hearing aid amplification provides invaluable benefit.

Noise-related hearing loss may stem from immediate or long-term effects. The first effect of exposure to excessive noise is a temporary loss of hearing accompanied by tinnitus. This is known as a temporary threshold shift and is maximal at about 4 kHz. If the exposure to a noise is repeated and prolonged, permanent hearing loss may result. Permanent loss is caused by damage of the hair cells in the organ of Corti and is not reversible.

Hearing loss due to syphilis is more likely to be a complication of congenital syphilis than of late-acquired syphilis. The deafness is bilateral, progressive, and usually associated with vestibular dysfunction. Diagnosis is important, because treatment with corticosteroids and antibiotics may be effective in controlling disequilibrium and in preserving or even improving hearing. Serologic tests for syphilis should be performed on all patients who have fluctuating or progressive hearing loss.

Ménière's disease is a syndrome characterized by fluctuating sensorineural hearing loss, intermittent tinnitus, and an episodic sensation of fullness in the affected ear. As these symptoms intensify, they may be followed by an attack of severe vertigo that lasts for several hours. The disease has a varying course and may remit spontaneously or progress to recurrent disabling vertigo and profound hearing loss. Bilateral involvement occurs 17% of the time. The hearing loss is typically most pronounced in the low frequencies. The characteristic histopathologic finding is hydrops (edema) of the endolymphatic space. Medical therapy involves diuretics and dietary salt restriction as well as the use of vestibular suppressants, such as antihistamines, benzodiazepine, or scopolamine. Surgical therapy is reserved for cases in which vertigo is unresponsive to aggressive medical management.

Tumors of the cerebellopontine angle can cause sensory hearing loss through direct pressure on the eighth cranial nerve. A diagnostic imaging scan of the temporal bone and brain stem is usually indicated in patients who show signs of asymmetric sensorineural hearing loss. The most common toxins associated with a hearing loss are aminoglycoside antibiotics and diuretics. Aspirin and other salicylates, quinine, nitrogen mustards, and cisplatin are also well-described ototoxic agents. Timely withdrawal of the offending agent can result in reversal of the hearing loss.

SINUSES AND THE FACE

Sinusitis is one of the most common causes of facial pain. Dental problems are another typical source. Acute unilateral facial pain in the absence of either of these disorders suggests a pathologic process of the fifth cranial nerve. Neurologic diseases, such as trigeminal neuralgia (tic douloureux) or herpes zoster, must be considered. If anesthesia is present in the area of pain, a comprehensive evaluation is indicated, to exclude an occult neoplasm of the affected branch of the trigeminal nerve.

SINUSITIS

Sinusitis is most often a complication of acute upper respiratory tract infection or allergic rhinitis. Pain is frequently described as a steady pressure and may be severe. It may be experienced in the anterior portion of the face or behind the eye; typically, the pain is exacerbated by hanging the head down. Fever is not a consistent finding. Intranasal examination may show purulent mucus draining from the sinus ostia, but the absence of discharge does not exclude sinusitis. The examiner should search for nasal polyps, foreign body, or tumor as possible causes of sinusitis, particularly in cases of disease limited to one side. Because infection in the upper teeth can produce symptoms similar to those of maxillary sinusitis, the mouth should be examined carefully. Transillumination of the sinuses may find a unilateral opacification, further aiding diagnosis. Sinus radiographs are not indicated for uncomplicated cases.

S. pneumoniae and *H. influenzae* are the usual infecting organisms. Antibiotics should be prescribed for a minimum of 14 days. Phenylephrine or oxymetazoline nasal spray administered for 3 to 5 days is also useful in minimizing edema of the nasal mucosa, allowing drainage and aeration of the involved sinuses. For severely immunocompromised patients or for patients in whom infection fails to respond to empiric antibiotic therapy, puncture of the anterior wall of the maxillary sinus is helpful in obtaining material for culture to identify the infecting organism and to wash out residual purulent debris.

Periorbital cellulitis or orbital abscess may result from extension of infection from the ethmoid sinuses, particularly in young children. The diagnosis is suggested by worsening pain in and behind the eye, erythema and swelling of the upper and lower eyelids, proptosis, chemosis, and diminishing ocular motility. Aggressive intravenous antibiotic treatment and appropriate surgical intervention aided by localization by computed tomography scanning is required. Osteomyelitis of the skull base, meningitis, epidural abscess, brain abscess, and cavernous sinus thrombosis can develop as well.

Aspergillus infection can develop in the maxillary sinus, particularly in diabetic patients with chronic sinusitis. The fungus is rarely invasive and usually responds well to local surgical debridement and drainage. In contrast, rhinocerebral mucormycosis is a severe acute fungal infection of the paranasal sinuses occurring in debilitated immunocompromised patients. It spreads rapidly to involve the eye and central nervous system. Therapy includes aggressive surgical debridement and amphotericin B. Even with optimal therapy there is a high mortality rate.

FACIAL PARALYSIS

Any lesion of the facial nerve from its nucleus in the brain stem to the motor end plate is considered peripheral. A peripheral lesion usually causes total unilateral facial paralysis, except when the lesion is distal to the branching of the nerve within the parotid gland. A lesion proximal to the facial nerve nucleus in the brain stem is considered central and provokes ipsilateral weakness in the lower two-thirds of the face. The forehead typically is unaffected because of its bilateral crossed motor innervation.

Bell's palsy is a diagnosis of exclusion, which can be made only after other treatable causes of facial weakness have been excluded. The origin is believed to be viral. Typically, the unilateral facial weakness progresses over 1 to 3 days and occasionally is associated with facial numbness or pain at the mastoid tip. Varying degrees of facial paralysis ensue, ranging from partial to complete. When the patient is asked to close the eye on the affected side, it closes incompletely, and the globe rotates upward (Bell's phenomenon). Further evaluation should include stapedius reflex testing, a Schirmer test, testing for taste sensation, and, for cases of complete paralysis, transcutaneous electrical stimulation of the main trunk of the facial nerve to determine stimulation threshold, which may help indicate the prognosis.

A short course of oral corticosteroids is believed to be helpful, but their use is the subject of controversy. A key aspect of management is protection of the affected eye

from the drying effects of constant corneal exposure. Methylcellulose drops in the eye every 2 to 4 hours during the day and taping the eyelid shut during sleep should prevent corneal ulceration. In Bell's palsy, the facial paralysis invariably improves to a greater or lesser degree over the ensuing 3 months. Patients who fail to improve by 3 months or patients with recurrent episodes of facial paralysis should be evaluated further, to exclude the possibility of intracranial or temporal bone tumors or even multiple sclerosis.

Patients with a variant of Bell's palsy, herpes zoster oticus (Ramsay Hunt syndrome), have painful herpetic eruptions of the ear canal and pinna associated with facial paralysis. Occasionally, there is sensorineural hearing loss. The cause is herpetic involvement of the ganglia of the seventh and eighth cranial nerves. There is no specific therapy for this problem, though acyclovir may help. Ramsay Hunt syndrome generally is considered to have a poor prognosis for eventual complete recovery of facial nerve function.

Partial or complete facial paralysis may develop during the course of acute otitis media. A patient with this complication should undergo myringotomy to decompress the middle ear space. Facial paralysis should lessen as the ear infection resolves with antibiotic therapy. Facial paralysis in a patient with chronic otitis media and cholesteatoma usually progresses slowly over several days. The patient should be evaluated for surgical decompression of the involved portion of the facial nerve.

Malignant parotid tumors may cause gradual paralysis of any of several peripheral branches of the facial nerve. The tumor frequently can be palpated on physical examination. Gradual paralysis of the nerve over several weeks suggests the possibility of a facial nerve neuroma. Acoustic neuroma, a benign tumor of the vestibular nerve, also can take the initial form of facial paralysis, but the patient's primary complaints are usually vertigo and hearing loss. Glomus jugulare tumor may be suspected in patients with facial paralysis associated with pulsatile tinnitus and conductive hearing loss. On examination, a pulsatile reddish mass may be evident behind the eardrum, and the ninth, tenth, or twelfth cranial nerve may be involved. Other rare tumors of the temporal bone causing facial paralysis include eosinophilic granuloma and metastatic tumors (most commonly from the breast, kidney, or lung). In these instances, lytic or blastic lesions of the temporal bone may be identified on computed tomography. Disorders of the central nervous system, such as multiple sclerosis, stroke, or arachnoiditis, can manifest as facial paralysis, though other signs and symptoms usually make these diagnoses apparent.

SALIVARY GLANDS AND ORAL CAVITY

Sialolithiasis with local ductal obstruction can lead to recurrent sialadenitis, the most common cause of sudden salivary gland swelling. Conversely, recurrent inflammation may lead to stone formation. Stones composed of inorganic calcium and sodium phosphate salts are believed to develop around the nidus of a small mucus plug. Salivary stones prompt recurrent episodes of acute pain with associated swelling of the involved gland.

Acute suppurative sialadenitis is uncommon. It can involve either the parotid or the submaxillary gland and typically develops in patients with general debility because of uncontrolled diabetes, dehydration, or cardiovascular disease. Progressive pain and swelling of the affected gland occurs over 1 to 3 days. There is often associated fever and leukocytosis. The salivary gland is firm, indurated, and tender; palpation may express pus from the ductal orifice. Any available discharge from the duct should be evaluated by Gram stain and culture. The most common causative organism is coagulase-positive *Staphylococcus*. Treatment involves vigorous rehydration and control of any systemic conditions, such as diabetes. An appropriate cephalosporin or antistaphylococcal penicillin antibiotic should be prescribed. Local application of warm, moist heat; massage of the affected gland, and sialagogues (such as lemon drops) are useful adjunctive measures. Open surgical drainage should be considered if response is not rapid.

Both benign and malignant tumors of the salivary gland can manifest as gland swelling. A discrete mass is usually palpable. Facial paralysis in association with a parotid neoplasm suggests a malignant process. Salivary gland swelling also is seen in the context of tuberculosis, sarcoidosis, and Sjögren's syndrome. Other causative factors include toxic inflammation from ingestion of heavy metals, such as lead, copper, or mercury, or halogens, such as bromide or iodide, in which case the glandular swelling is frequently diffuse and bilateral.

Ludwig angina is a painful swelling in the anterior floor of the mouth that causes dysphagia and eventually respiratory obstruction. It often follows a dental infection or dental extraction. Lymphadenopathy typically is minimal, but the patient may show signs of sepsis. The airway obstruction that can result from edema and displacement of the tongue caused by progression of the infection makes Ludwig angina a life-threatening disease. A mixture of mouth organisms often is responsible for the infection. Treatment is high-dose corticosteroids and broad-spectrum intravenous antibiotics with careful monitoring of the airway. Intervention with intubation or tracheotomy may be needed for airway control. Incision and drainage are indicated if antibiotic treatment fails to bring about rapid resolution. Fluctuance is rarely evident, but surgical exploration and drainage of the sublingual space may effect control of the progressive soft-tissue infection.

The most common malignancy of the upper digestive tract is squamous cell carcinoma. Minor salivary gland tumors, melanomas, and sarcomas are found from time to time. Squamous cell carcinoma of the oral cavity is related to excessive use of alcohol and tobacco, particularly chewing tobacco. It also is associated with the use of betel nut. The outcome of treatment of oral cavity carcinomas is related directly to the size and extent of the lesion, highlighting the need for careful evaluation of any suspicious lesions and early referral for treatment. Leukoplakia (white patch) or erythroplasia (red patch) on the oral mucosa may indicate a malignant lesion. Full-thickness biopsy is necessary to determine whether dysplasia, carcinoma in situ, or invasive carcinoma is present; it is best done by the specialist who is treating the cancer. Therapeutic options range from local excision to irradiation or a combination of surgery and irradiation for advanced lesions.

NOSE

EPISTAXIS

Local irritation and excessive dryness of the blood vessels of the anterior portion of the nasal septum is the most common cause for epistaxis. Other important sources to consider include hypertension, coagulopathy, foreign body, and acute upper respiratory tract infection or exacerbation of allergic rhinitis. Benign nasal tumors infrequently bleed, but malignant tumors may cause unilateral bleeding. Nasopharyngeal angiofibroma, a tumor most often found in adolescent males, may manifest in the form of epistaxis and nasal obstruction. It should be considered in the differential diagnosis of epistaxis in these patients. Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome) is an autosomal dominant trait causing dilated thin-walled capillaries and veins throughout the body. The syndrome is characterized by recurrent nasal bleeding and telangiectasia of the lip and oral mucosa.

Localization of the specific bleeding point is of utmost importance in the management of epistaxis. If the identified bleeding point is anterior, it can be cauterized with silver nitrate or electrocautery. Posterior bleeding is typically more severe and more difficult to control. Before placing a nasal pack, the examiner should attempt to determine whether bleeding is from the upper or lower half of the nose, because specific arterial ligation may be necessary later if packing fails to control the bleeding. In patients with coagulopathy or immunosuppression, all attempts short of placing a pack should be made to control the bleeding.

Nasal packing is usually left in place for 3 to 5 days. If bleeding is severe enough to require placement of a pack in the posterior nasopharynx, the patient should be hospitalized and undergo monitoring of oxygenation status. Placement of a posterior pack is known to cause hypoventilation and hypoxia. Prophylactic antibiotics should be administered while the nasal packing is in place, with the specific aim of preventing the possibility of sinusitis and toxic shock syndrome. Should these conservative attempts at hemostasis be unsuccessful, direct ligation of branches of the internal maxillary artery can be carried out. The anterior ethmoid artery may be ligated through an external approach for superior bleeding sites. An alternative in patients with coagulopathy or severe anesthetic risk is selective embolization of the bleeding vessel.

NASAL OBSTRUCTION

The most common cause of acute nasal obstruction is the common cold. A patient in the first stages of a cold usually has nasal discharge and possibly a low-grade fever with minimal clinical findings. As viral infection spreads from the portal of entry to adjacent mucous membranes, the nose becomes progressively more obstructed with associated sneezing and watery rhinorrhea. A sore throat may develop, which typically persists for 3 to 5 days. A mild infection begins to resolve at this time, but with bacterial superinfection, increased mucopurulent nasal discharge and signs of systemic illness may progress. Bacterial superinfection causes a rise in temperature, sinus tenderness, mucopurulent nasal discharge, erythema of the throat, and possibly regional adenopathy. The symptoms of allergic rhinitis, vasomotor rhinitis, and rhinitis medicamentosa may all be confused with those of the initial stages of a cold.

There is no specific therapy for a cold; symptomatic treatment should be adjusted to the age and general medical condition of the patient. Antihistamines, decongestants, and topical vasoconstrictive agents aid in the relief of symptoms and may prevent the complication of sinusitis and otitis media. Nasal drops containing phenylephrine or oxymetazoline may be administered, but the patient should be warned not to use them for more than 1 week. Antibiotics should not be

prescribed in the initial stages of a cold.

Allergic rhinitis (hay fever) classically manifests as nasal irritation, itching, nasal obstruction with frequent sneezing, and copious clear rhinorrhea (see also [Chapter 174](#)). The patient also may have a history of other allergic traits, such as asthma or eczema. Episodes are usually seasonal, and there may be a strong family history of allergic disease. On examination, the patient has a watery nasal discharge and pale, swollen nasal mucosa. The turbinates may have a bluish appearance because of venous engorgement. Often the conjunctivae are red, which is associated with increased lacrimation. Similar, usually milder symptoms may be caused by perennial allergens, typically foods in children and inhalants, such as dust and molds, in adults. Drugs that may produce allergic reactions include salicylates, iodides, quinidine, sulfa compounds, and penicillins. A test to identify the specific allergens, followed by desensitization, is the most specific form of therapy. For most patients whose symptoms are not severe enough to warrant this evaluation, symptomatic treatment with oral antihistamines, corticosteroid nasal sprays, or nasal inhalation of cromolyn is usually sufficient.

At times, it may be difficult to differentiate allergic rhinitis and vasomotor rhinitis. A patient with vasomotor rhinitis lacks a history of other allergic tendencies, and there is no family history of allergic rhinitis. Typically, the patient complains of exacerbation of nasal obstruction and discharge on exposure to heat, cold, or nonspecific irritants, such as smoke or dust. A nasal smear for eosinophils may help distinguish allergic from vasomotor rhinitis. Oral decongestants may be helpful in providing relief, as are corticosteroid nasal sprays or aerosolized atropine.

Use of decongestant nasal sprays, such as oxymetazoline or phenylephrine, for an extended period can result in a condition known as rhinitis medicamentosa. With repeated use, tachyphylaxis (decreased sensitivity to the medication) develops, as does a rebound phenomenon in which the nasal obstruction and discharge become progressively more severe on loss of the vasoconstrictor effect. On examination, severe congestion of the nasal mucosa, with a profuse watery discharge, is evident. Treatment centers on gradual withdrawal of the offending agent, often aided by interim use of a corticosteroid nasal spray. Occasionally, a short course of oral corticosteroids may be helpful in providing relief during the period of withdrawal from topical decongestant sprays.

Persistent unilateral nasal obstruction is most often due to an anatomic abnormality of the nasal septum. This can be readily documented by examination after application of a topical vasoconstrictor. In small children with unilateral obstruction and nasal discharge, a foreign body in the nose should be suspected. If the object is not visible and cannot be removed in the outpatient clinic, examination under anesthesia may be required. Similarly, in adults with persistent unilateral symptoms, a careful examination must be carried out, to rule out the possibility of a tumor of the nose or paranasal sinuses.

ANOSMIA

The most common sources of absent or diminished sensation of smell are nasal obstruction by polyps, damage to the sensory epithelium after an upper respiratory tract infection, and damage from blunt head trauma to first cranial nerve fibers at the point where they pass through the cribriform plate. A less typical cause is a tumor of the frontal lobe or optic chiasm. Shrinkage of nasal polyps with topical or systemic corticosteroids or treatment by surgical removal often restores the sensation of smell. Oral corticosteroids may be useful for patients with anosmia after an upper respiratory tract infection.

THROAT

ACUTE UPPER AIRWAY OBSTRUCTION

In most cases of acute upper airway obstruction, there is a clear-cut history suggesting foreign body, infection, or trauma. It is important to determine whether the patient has experienced stridor or hoarseness for an extended time, because this symptom implies a chronic infection, tumor, or other long-standing laryngeal problem that tends to be less rapidly progressive in terms of acute airway obstruction. In general, a patient with upper airway obstruction has stridor on inspiration. As obstruction progresses, suprasternal retraction, tachycardia, and biphasic (inspiratory and expiratory) stridor develop. Particularly in patients with previously compromised cardiopulmonary function, complete airway obstruction may evolve rapidly as respiratory muscle fatigue and airway edema progress.

In treating a patient with acute upper airway obstruction, every effort short of tracheotomy should be made to secure an airway. A true emergency tracheotomy or cricothyrotomy is a difficult and dangerous procedure; endotracheal intubation is preferred if at all feasible. A fiberoptic endoscope specifically designed for use with intubation may be helpful for transoral or transnasal intubation of patients with an abnormal upper airway. Like any technical procedure, however, intubation requires practice to be effective in the emergency situation. If it is recognized that a tracheotomy will be required for long-term airway management, it is still preferable to undertake the procedure after endotracheal intubation rather than on a patient with an uncontrolled airway. Tracheotomy under local anesthesia is an acceptable alternative in the hands of an experienced surgeon.

In the event that endotracheal intubation is not possible, the most expeditious way to secure an airway is by emergency cricothyrotomy. Common indications for this procedure are foreign-body obstruction, facial or laryngotracheal trauma, inhalation thermal injury or caustic injury of the upper airway, angioneurotic edema, upper airway hemorrhage, epiglottitis, or croup. The patient is placed in a supine position with support under the shoulders and hyperextension of the neck. The spaces between the thyroid and cricoid cartilages are identified by palpation. A skin incision is made over the cricothyroid membrane, and the subcutaneous tissues are bluntly dissected. A 1-cm horizontal incision is made between the cricoid and thyroid cartilages. Any flat instrument, such as a scalpel handle, is inserted in the incision and rotated 90° to hold the incision open. The incision can be kept open by introduction of a small endotracheal tube.

As soon as the patient's condition permits, this temporary airway should be replaced by a standard tracheotomy placed between the second and third tracheal rings. Although cricothyrotomy is an excellent method for securing an airway rapidly with minimal blood loss, it risks significant damage to the cricoid cartilage, the thyroid cartilage, and the vocal cords. This damage can result in chronic laryngeal stenosis with airway obstruction and hoarseness. Standard tracheotomy involves dissection through considerably more subcutaneous tissue as well as the need to divide and ligate the isthmus of the thyroid gland. It is advisable to take a postoperative chest radiograph, because pneumothorax can complicate an emergency cricothyrotomy or tracheotomy, especially in children, in whom the apical pleura lies close to the trachea proximal to the clavicle.

A poorly secured tracheotomy tube may become dislodged. If this happens in the first 48 to 72 hours, urgent re-intubation or a second tracheotomy may be required. After 3 or 4 days, the tracheotomy track is established, and the tube can be reinserted easily. The tube can become occluded. To prevent accumulation of a dry mucous crust, the inner cannula is removed and cleaned every 6 to 8 hours. Inspired air should be well humidified, because this also minimizes obstruction of the tube.

HOARSENESS

Acute inflammation of the larynx from bacterial or viral infection may develop in isolation or in conjunction with other signs of upper respiratory tract infection. It also can result from inhaled irritants. It may even be due to simple overuse of the voice, especially in singers, other performers, and children. Treatment consists of voice rest and avoidance of irritants, such as tobacco smoke. Cough suppressants are useful in preventing recurrent irritation of the vocal cords with harsh coughing. Hoarseness persisting for more than 2 weeks should be evaluated by indirect or fiberoptic laryngoscopy.

The differential diagnosis of chronic hoarseness is extensive. Long-term vocal abuse with formation of nodules on the vocal cords, prolonged inhalation of irritants (including smoking), chronic sinus and throat infection with postnasal discharge, recurrent acute laryngitis, laryngeal papillomas, chronic reflux of gastric acid into the posterior pharynx, tuberculosis, syphilis, and laryngeal cancer all can manifest with the chief complaint of hoarseness. The most common tumor of the larynx is squamous cell carcinoma. Lesions on the vocal cords first appear in the form of hoarseness and are thus more likely to be diagnosed at an early stage. Tumors in the region of the tongue base, epiglottis, and supraglottic larynx may become symptomatic only when they are large, owing to their lack of effect on the voice or airway at earlier stages. These tumors are more likely to be associated with pain (including referred otalgia), dysphagia, or odynophagia early in the course of disease. Pharyngeal carcinomas also are more likely to show signs of regional lymphatic metastases at the time of diagnosis.

NECK

DEEP INFECTIONS

A deep neck infection usually stems from infection of one of three areas: a tooth, the pharynx, or the parotid gland. Often the patient has been taking antibiotics for

tonsillitis or an infected dental extraction site. Signs of progression include fever, swelling and tenderness of the neck or submaxillary area, trismus, pain on motion of the neck or tongue, and stridor. The physician should search for an obvious primary site of infection, such as tonsillitis, peritonsillar abscess, infected tooth, dental extraction site, or parotitis. Antibiotics can mask obvious signs of sepsis. Infection of the pharyngomaxillary space as an extension of tonsillitis or mastoid infection is common in children. Signs include trismus and swelling of the parotid region, the lateral pharyngeal wall, or both. The anterior part of the neck usually is infected after esophageal or hypopharyngeal trauma. Symptoms include tenderness along the sulcus between the sternocleidomastoid muscle and larynx, hoarseness, stridor, and dysphagia. Anteroposterior and lateral radiographs of the neck may aid in evaluation of the airway. Fluid replacement and broad-spectrum antibiotics should be given, and the patient should be hospitalized for intensive therapy and possible operative drainage. Early surgical consultation should be obtained. If airway compromise is present, intubation may be required.

Retropharyngeal abscess is a deep space infection that develops most often in infants. Infection occurs in the fascial space between the posterior pharyngeal wall and the prevertebral fascia, usually after an upper respiratory tract or tonsil infection. Airway management and supportive care, along with possible surgical drainage, are appropriate.

Peritonsillar abscess is a complication of acute tonsillitis resulting from spread of infection into the peritonsillar space (between the tonsil capsule and the pharyngeal constrictor muscle). Dysphagia, trismus, and severe pain are present. The swelling may extend to the soft palate and displace the uvula to the contralateral side. Needle aspiration can determine if an abscess is indeed present and provide material for culture and sensitivity testing. Repeated aspirations and intravenous antibiotics may be adequate therapy. Alternatively, drainage through a small incision in the soft palate just above the tonsil or even a tonsillectomy may be required to drain the abscess adequately. Hospitalization is indicated for administration of intravenous antibiotics as well as monitoring of the status of the airway. Intravenous antibiotics are given until there is significant reduction in trismus.

NECK MASS

Any patient with a new neck mass of more than 2 weeks' duration needs evaluation, depending on the size and location of the mass as well as the relative risk factors for cancer in the patient's history. The physician must be more vigilant in the case of older patients with a history of tobacco and alcohol abuse than for young, otherwise healthy persons. Masses that have progressed in size, masses larger than 2 cm, hard or fixed lesions, and lesions in the anteroinferior triangle of the neck deserve more aggressive evaluation. The most common midline lesion is a thyroglossal duct cyst; another possibility is a dermoid cyst. In the anterosuperior triangle of the neck, the most common cause is inflammation of lymph nodes from tuberculosis or atypical microbacterial infection. Metastatic carcinoma from the upper aerodigestive tract as well as a primary tumor of the parotid or submaxillary gland are also possibilities.

Rarer lesions include Zenker's diverticulum, laryngocele, chemodectoma, and carotid artery aneurysm. Adenopathy due to lymphoma can be found in any part of the neck. The primary considerations for posterior triangle neck masses include nasopharyngeal tumor metastases, lymphoma, local skin infections, metastatic thyroid disease, and neurofibroma. Lesions in the supraclavicular or anteroinferior triangle suggest metastatic carcinoma from the lung, breast, or gastrointestinal tract. Thyroid tumors and aneurysm of the great vessels may take the form of a mass in this region. Branchial cleft cysts characteristically are located along the anterior border of the sternocleidomastoid muscle.

In the patient with a neck mass, careful measurement and documentation of the precise size and location of the lesion is important. Particular attention should be paid to whether the lesion is fixed to the deep tissues and whether it is tender or mobile or fluctuant. A complete examination of the upper aerodigestive tract, including the nasopharynx, hypopharynx, and larynx, is mandatory. Inspection of the gingiva after removal of any dentures or partial plates as well as close scrutiny of the ventral surface of the tongue are important in identifying early-stage oral cavity lesions. Even small oropharyngeal carcinomas may have extensive neck metastases. Needle aspiration should be undertaken in the case of any nonpulsatile lesion that enlarges or fails to resolve or is suggestive of malignancy. If fluid is aspirated, it should be sent not only for cytologic study but also for culture and sensitivity testing. Skin tests for tuberculosis should also be done. Incisional or excisional biopsy of neck masses should be carried out only by a surgeon familiar with treating head and neck cancer.

CHAPTER 367: LUNG ABSCESS

HUGH A. CASSIERE AND MICHAEL S. NIEDERMAN

[Pathogenesis](#)
[Microbiology and Classification](#)
[Clinical Features](#)
[Treatment](#)

A lung abscess is a localized (usually more than 2 cm in diameter), suppurative necrotizing process within the pulmonary parenchyma. Several processes, either respiratory or systemic, can lead to abscess formation. Most abscesses are primary and result from necrosis in an existing parenchymal process (usually an infectious pneumonia). Among the causes of necrotizing pneumonitis, infections and neoplasms are the most commonly identified. When an abscess complicates septic vascular emboli (e.g., right-sided endocarditis), bronchial emboli (e.g., aspirated foreign bodies), or rupture of an extrapulmonary abscess into the lung (e.g., empyema), it is termed secondary.

Numerous infectious agents can be responsible for abscess formation, but classically anaerobes are the most common, although aerobic bacilli, fungi, parasites, and mycobacteria may also be responsible. Primary squamous carcinoma of the lung is the most common malignancy associated with abscess formation. Between 8% and 18% of lung abscesses are associated with neoplasms in all age groups, but as many as 30% of patients over age 45 have an associated cancer.

In the postantibiotic era, the incidence of lung abscess has declined, presumably as a result of improved treatment regimens for pneumonia. In fact, over the past 40 years, the incidence has declined tenfold, while the mortality rate has fallen to 5% to 10%. Diagnosis and treatment have changed little over the years and are largely dictated by past clinical practices, as lung abscesses are uncommon and it is difficult to obtain enough patients to perform controlled clinical trials. Nonetheless, the mainstay of therapy is antibiotics, and surgery is rarely needed. The role of newer antimicrobials is still controversial, but they may represent an advance over traditional therapeutic agents (penicillin), especially as drug-resistant bacteria become more prevalent.

PATHOGENESIS
