Detection of a heart murmur requires confirmation and assessment of severity. Table 68.4 outlines an approach to dealing with presumed organic heart murmurs. Follow-up employs the history, periodic physical examinations, and serial Doppler echocardiography. The health implications of subacute bacterial endocarditis prophylaxis, pregnancy, and athletic and job participation are generally related to the functional impact of the lesion in question, although endocarditis prevention strategies are relevant for even mild or trivial structural abnormalities.

Significant Murmurs
 Identify common variety of murmur heard in practice
 Identify associated or associated murmurs
 Consider degree of associated cardiovascular abnormalities and possible non-cardiac causes
 Identify common organic structures to consider
 Aortic sclerosis of the aorta
 Aortic stenosis
 Aortic regurgitation
 Mitral valve prolapse
 Mitral regurgitation
Diastolic Murmurs
 Aortic regurgitation
 Mitral regurgitation
 Mitral stenosis
Flow Murmurs
 Flow murmurs in atrioventricular valve regurgitation
 Pulmonary regurgitation
 Tricuspid regurgitation
Other
 Echo-Doppler study mandatory if a definite organic murmur is diagnosed or suspected
 Establish severity of lesion
 Careful assessment of ventricular size and function
 History taking to consider
 Rheumatic fever, syphilis, drug use, or other causes
 Exercise test for cardiovascular and general function
 Cardiac catheterization
Special Situations
 Subacute bacterial endocarditis prophylaxis
 Consideration of functional limitation, exercise or job restrictions, pregnancy issues

TABLE 68.4. APPROACH TO THE PATIENT WITH A MURMUR

For moderate to severe hemodynamic abnormalities, cardiac catheterization or radionuclide angiography may be required in addition to conventional Doppler echocardiography (see Chapter 77).

DEFINITION

The term *syncope* derives from the Greek, *sunkopé*, “to cut short.” Syncope is defined clinically as a transient loss of consciousness due to an acute and critical decrease in cerebral blood flow. It is thus distinguished from faintness or dizziness, neither of which is accompanied by true loss of consciousness. Its differential diagnosis is broad, with several benign and a few life-threatening causes. The challenge for the clinician is first to distinguish among the various causes of syncope on the basis of the history, examination, and directed laboratory studies and then to design an effective strategy of treatment and prevention.

EPIDEMIOLOGY

Syncope is a common symptom, accounting for as many as 3% to 5% of all emergency room visits and up to 6% of hospital admissions. By conservative estimates, more than 1 million people in the United States seek evaluation and treatment for syncope each year, at a cost in excess of \$1 billion. The prevalence of syncope increases with age; elderly (age greater than 65 years) patients are more likely to have a serious cardiac or neurologic cause. As many as 40% to 50% of patients will have only a single isolated episode and will not require detailed evaluation or complicated treatment. As recently as the 1980s, a cause of syncope was not ascertained in up to 40% of patients. In a tertiary cardiology referral center with emphasis on tilt-table and electrophysiologic testing, the proportion of undiagnosed cases was more recently estimated at only 25%. Diagnosis and treatment remain, in several instances, expensive and not particularly cost-effective, largely because of an overreliance on cardiac and neurovascular testing when the clinical presentation points elsewhere. For the evaluation and management of patients with suspected neurocardiogenic syncope, for example, cost may exceed \$16,000 per patient. Attention to the details surrounding the presentation, past medication/drug use, examination (general, cardiac, neurologic), and routine laboratory studies should allow a focused and more cost-effective approach.

PATHOPHYSIOLOGY

The loss of consciousness that defines syncope derives from a critical decrease in cerebral perfusion pressure, leading specifically to a fall in blood flow to the reticular activating system of the brainstem. A fall in mean arterial pressure to 50 mm Hg or below will usually suffice, but preexistent cerebrovascular disease or a rapid fall in mean pressure to a higher minimum level in a patient with chronic hypertension might also precipitate a syncopal event. In most instances, the patient is upright (standing, sitting) and several seconds of premonitory symptoms (light-headedness, visual disturbance, yawning, diaphoresis, nausea) precedes the loss of consciousness, often allowing time for self-protection. A cardiac cause, such as high-grade atrioventricular (AV) block, termed Stokes–Adams–Morgagni attack, may not be accompanied by such a prodrome. Unconsciousness generally persists for a variable but short period of time (second to minutes), during which the skeletal musculature may relax completely and a few myoclonic jerks or even brief tonic–clonic movements can be seen. The patient will usually regain consciousness without persistent neurologic sequelae. Headache and/or prolonged confusion may point to an alternative diagnosis (e.g., seizure). Alteration in the essential nutrients of the blood necessary for cerebral metabolism, such as with hypoglycemia, hypoxia, or hypercarbia, can cause transient loss of consciousness. However, these disorders are more often associated with somnolence, coma, or another prolonged alteration of mental status.

ETIOLOGIC FACTORS

The major causes of syncope are listed in [Table 69.1](#). The principal cardiovascular causes can be grouped into four general categories that comprise disorders of vasomotor control, cardiopulmonary mechanical lesions, arrhythmias, and cerebrovascular disease. [Table 69.2](#) provides a summary estimate of the relative incidence of the various causes of syncope from among several large and unselected patient populations.

(Table content is illegible due to low resolution)

TABLE 69.1. CAUSES OF LOSS OF CONSCIOUSNESS

Cause	Incidence (%)
Reflex-mediated	
Neurocardiogenic	18
Situational	5
Orthostatic hypotension	8
Cardiac	
Arrhythmias (tachyarrhythmia and bradyarrhythmia)	14
Organic heart disease	4
Neurologic seizures, transient ischemic attacks, migraines	10
Medications	3
Psychiatric	2
Unknown	34

TABLE 69.2. RELATIVE INCIDENCE OF THE VARIOUS CAUSES OF SYNCOPE

ABNORMALITIES OF VASOMOTOR CONTROL

At least half of all syncopal episodes are related to abnormalities of the autonomic control of the heart and circulation. This category includes postural syncope, neurocardiogenic (vasovagal) syncope, glossopharyngeal syncope, carotid sinus syndrome, and situational syncope (post tussive, micturition, deglutition, defecation, and after other strenuous activities). Receptors in various locations (carotid body, aortic arch, myocardium) are activated by a variety of painful or mechanical stimuli. Afferent nerve impulses then travel to the nucleus tractus solitarius and/or medullary vasodepressor region, stimulating either a release of parasympathetic influences or a withdrawal/inhibition of sympathetic output, resulting in peripheral vasodilatation (vasodepressor component), a fall in blood pressure, and in many instances a concomitant slowing of the heart rate (cardioinhibitory component).

ORTHOSTATIC HYPOTENSION

Orthostatic hypotension (also called postural syncope) is often observed in the elderly and may result in substantial morbidity and mortality from associated falls. It is commonly defined as a decrease of 20 mm Hg or more in systolic blood pressure or 10 mm Hg in diastolic blood pressure upon assumption of the upright posture. Such changes can be detected in as many as 20% of medical outpatients older than 65 years of age. Standing results in the pooling of approximately 500 to 700 mL of blood in the lower extremities, splanchnic beds, and pulmonary circulations. The decreased venous return results in a fall in cardiac output and stimulation of cardiopulmonary, aortic, and carotid baroreceptors, which reflexively increase sympathetic, and decrease parasympathetic, tone to maintain the systemic blood pressure. Several conditions, including hypovolemia (hemorrhage, vomiting, diarrhea) and certain drugs (diuretics, nitrates, α -adrenoreceptor blockers, calcium channel) and other agents used in the treatment of hypertension or ischemic heart disease, may contribute to this syndrome.

Patients with autonomic dysfunction not unexpectedly have an increased susceptibility to postural syncope. Autonomic dysfunction may be secondary to systemic disease, such as diabetes mellitus, syphilis, alcoholism, amyloidosis, or adrenal insufficiency. A variety of central and peripheral nervous system disorders, such as Shy-Drager syndrome, Parkinson's disease, Wernicke's encephalopathy, syringomyelia, and inflammatory myelopathies, may also manifest as syncope. These patients often have disturbances of bowel and bladder function and impairment of sweating. They also have chronotropic incompetence, which compounds the hypotension initiated by the inability to increase systemic vascular resistance.

NEUROCARDIOGENIC OR VASOVAGAL SYNCOPE

Neurocardiogenic syncope, also known as neurally mediated, vasovagal, or vasodepressor syncope, is a common disorder of autonomic cardiovascular regulation. Although neurocardiogenic syncope is not life threatening, it can result in significant injury, and failure to recognize this common cause of syncope may result in an unnecessarily costly evaluation. Episodes are often preceded by a prodromal period lasting for a few seconds to a few minutes. Triggers associated with the development of neurocardiogenic syncope are those that either reduce ventricular filling or increase catecholamine synthesis and release. These include the sight of blood, pain, prolonged standing, a warm environment, hot shower, exercise, or stressful emotional encounters. The individual might be sitting or standing and experiences weakness, nausea, diaphoresis, light-headedness, and, often, a sense of impending darkness. The decreased venous return and fall in cardiac output trigger a paradoxical reflex. The arterial baroreceptors are activated with resultant catecholamine release. When combined with reduced ventricular filling, the sympathetic stimulation leads to vigorous contraction of a volume-depleted ventricle. There is initially tachycardia, decreased blood pressure, and pallor. In susceptible individuals, the mechanoreceptors and vagal afferents (C fibers) in the heart (particularly in the inferior posterior portion of the left ventricular myocardium) are activated. These C fibers project centrally to the dorsal vagal nucleus of the medulla, with the resultant withdrawal of sympathetic influences and increased vagal (parasympathetic) output. This produces cardiac slowing, diaphoresis, pupillary constriction, and, eventually, syncope. The duration of unconsciousness is rarely longer than a few minutes if the conditions that provoke the event can be reversed. Assumption of the supine position or other maneuvers to increase venous return, such as placing the head between the knees when sitting, also help to ameliorate the situation.

Patients with transplanted (denervated) hearts have also experienced cardiovascular responses identical to those observed during neurally mediated syncope. This should not be possible if the response depends solely on the reflex mechanisms described previously. Neurocardiogenic syncope likely results from a variety of mechanisms with various degrees of increased efferent vagal activation and sympathoinhibition. Several neurotransmitters are believed to facilitate neurocardiogenic syncope by inhibiting the release of central sympathetic neurotransmitters. In addition to catecholamines, opioid peptides, arginine vasopressin, nitric oxide, and serotonin are likely to be involved in the modulation of the central nervous system blood pressure and heart rate regulation.

The head-upright tilt-table test is a provocative test for neurocardiogenic syncope. It is generally performed for 30 to 45 minutes at an angle of 60 to 80 degrees. This posture induces the venous pooling that initiates the reflex ([Fig. 69.1](#)). Some patients manifest a prominent vasodepressor response, whereas others have a more pronounced cardioinhibitory response. This latter aspect is of importance as only those patients with a significant cardioinhibitory component usually benefit from pacing therapy.

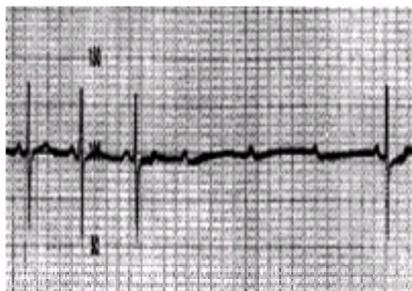

FIGURE 69.1. Surface electrocardiographic lead in a patient who experienced syncope during upright tilt-table testing. Note heart rate slowing followed by high grade atrioventricular block. Loss of consciousness with myoclonic jerks occurred shortly thereafter.

CAROTID SINUS HYPERSENSITIVITY

Carotid sinus hypersensitivity is an uncommon but potentially treatable cause of syncope. Diagnosis is made by performing carotid sinus massage, which should be carried out in the supine position under continuous electrocardiographic monitoring, after listening for bruits. Light massage on alternate sides is then performed for 5 seconds. An abnormal response is defined by asystole for 3 or more seconds and/or a decrease in systolic blood pressure of 50 mm Hg. A tight collar, shaving, and turning of the head to one side may increase pressure on the carotid sinus. Carotid hypersensitivity occurs predominantly in men, 70% of whom are 50 years of age or older. Activation of carotid sinus baroreceptors, which are located just cephalad to the bifurcation of the common carotid artery, results in inhibition of efferent sympathetic nerve fibers to the heart and blood vessels, activation of cardiac vagal efferent nerve fibers, or both. In susceptible individuals, these responses may result in sinus arrest or AV block (cardioinhibitory response, 34% to 78% of cases), vasodilatation (vasodepressor response, 5% to 10% of cases), or both (mixed response). Certain drugs can cause an abnormal carotid sinus response (digoxin, alpha methyl dopa) and should be discontinued if possible. Avoidance of triggers constitutes the primary treatment. Only in severe cases with a clear cardioinhibitory component should a pacemaker be considered.

GLOSSOPHARYNGEAL NEURALGIA

Syncopal episodes due to glossopharyngeal neuralgia are preceded by pain in the oropharynx, tonsillar fossa, or tongue, frequently induced by space occupying oropharyngeal tumors. Loss of consciousness is usually associated with asystole rather than with vasodilatation. Afferent impulses in the glossopharyngeal nerve activate efferent cardiac vagal motor neurons in the nucleus ambiguus and the dorsal motor nucleus of the vagus. This results in efferent vagal activation and bradycardia.

SITUATIONAL SYNDROMES

Other less common syndromes that may be caused at least in part by abnormal autonomic cardiovascular control include micturition syncope, defecation syncope, deglutition syncope, and cough syncope. Micturition syncope occurs predominantly in older men, frequently those with prostatic hypertrophy and bladder neck obstruction. Straining (Valsalva) against an obstructed bladder neck and/or activation of bladder mechanoreceptors may contribute to this syndrome. Syncope usually occurs at night during or immediately after voiding. Defecation syncope occurs in both men and women.

Cough syncope typically occurs in men with chronic obstructive lung disease during or immediately after prolonged coughing fits.

Deglutition syncope is rare but may be associated with diseases of the esophagus, particularly esophageal spasm. Activation of esophageal sensory receptors may result in reflex sinus bradycardia or AV block and is triggered by certain foods and liquids.

CARDIOPULMONARY MECHANICAL DISORDERS

Syncope related to cardiopulmonary mechanical disorders often occurs because of an inability to increase cardiac output in the setting of peripheral vasodilatation. The inadequate increase in cardiac output is usually caused by obstruction to ventricular outflow, but it may also result from severe myocardial disease, external cardiac compression, or even severe inflow obstruction. Peripheral vasodilatation may be appropriate (after exercise) or may be caused by activation of mechanoreceptors in the left ventricle, as described previously. In patients with aortic stenosis, syncope is thought to result from mechanical obstruction to LV outflow as well as from the activation of myocardial mechanoreceptors, which impairs the normal vasoconstrictor response in nonexercising vascular beds. Patients with hypertrophic obstructive cardiomyopathy (HOCM) also fail to increase cardiac output normally with exercise and are susceptible to both exertional and postexertional syncope, independent of any rhythm disturbance (such as ventricular tachycardia, or VT), for similar reasons.

Atrial myxoma, a ball-valve thrombus complicating a mechanical prosthesis, and, rarely, severe mitral stenosis may impair left ventricular filling to such an extent that cardiac output becomes significantly reduced and incapable of further augmentation with stress. Underfilling of the left ventricle may result in mechanoreceptor stimulation as described above.

Syncope occurs in as many as 10% of patients with massive (more than 50% obstruction of the pulmonary vascular bed) pulmonary embolism. It may also occur in patients with severe pulmonary hypertension. In these patients, syncope is usually accompanied by other symptoms (e.g., chest pain, dyspnea). In both cases, syncope results from an inability of the right ventricle to maintain or augment cardiac output in the face of pulmonary vascular obstruction. Right ventricular outflow may also be severely restricted in patients with tetralogy of Fallot and infundibular (dynamic) pulmonic stenosis.

Syncope rarely occurs in patients with pericardial tamponade or severe pericardial constriction as a result of decreased ventricular filling and hypotension. Syncope in the setting of acute type A aortic dissection is more commonly due to pericardial tamponade than to stroke.

CARDIAC ARRHYTHMIAS

Common arrhythmic causes of syncope include bradyarrhythmias due to sinus node dysfunction or AV block, and tachyarrhythmias. Ventricular tachycardia as well as supraventricular tachycardia can result in syncope especially when accompanied by underlying structural heart disease. In normal individuals, cardiac output and systemic arterial pressure usually remain at levels that maintain consciousness at heart rates between 30 and 180 beats per minute. As heart rate decreases, ventricular filling time and stroke volume increase to maintain cardiac output at normal levels. Below 30 beats per minute, stroke volume can no longer increase to compensate for the decrease in heart rate, and syncope may occur. At rates exceeding 180 beats per minute, diastolic filling time is too limited to maintain adequate stroke volume.

Tolerance to an altered heart rate is decreased in association with other comorbidities and selected circumstances such as anemia, cerebrovascular disease, upright posture, cardiopulmonary mechanical disorders, myocardial ischemia, and abnormalities of cardiovascular control. Certain cardiac structural abnormalities are associated with tachyarrhythmias or bradyarrhythmias. For example, hypertrophic cardiomyopathy is associated with VT and sudden death. Patients with cardiac sarcoid are at increased risk for ventricular tachyarrhythmias, cardiac conduction abnormalities, and advanced heart block. Of patients with Ebstein's anomaly of the tricuspid valve, 10% to 25% have AV bypass tracts.

Syncope associated with bradyarrhythmias often occurs with little or no warning. Patients usually regain consciousness and an awareness of their surroundings promptly. Bradyarrhythmias may result from disorders of impulse generation (e.g., sinoatrial arrest) or impulse conduction (e.g., AV block). Bradyarrhythmias are more likely to cause syncope in the elderly or in patients with structural heart disease. Patients with the sick sinus syndrome may have frequent sinus pauses or sinus arrest (more than 3 seconds). Recent pacemaker trials have reported that atrial fibrillation occurs frequently and without symptoms or awareness in this patient population. The need for rate control of rapid atrial fibrillation may exacerbate a tendency to bradycardia among such patients and mandate pacemaker therapy. Atrial fibrillation can be induced by vagal stimulation in some patients. Patients with syncope associated with paroxysmal atrial fibrillation are predisposed to an abnormal (vagal mediated) neural response such that blood pressure falls at the onset of atrial fibrillation because of the vasodepressor reflex previously described. Although often associated with evidence of cardiac conduction system disease (e.g., prolonged PR interval, bundle-branch block), high-degree AV block may occur episodically in patients with otherwise normal AV conduction. In patients with sinus node dysfunction or AV conduction system abnormalities, attempts should always be made to demonstrate an association between the patient's symptoms and the bradyarrhythmia, so as to target pacemaker therapy.

Syncope due to tachycardia is frequently preceded by rapid palpitations but may occur without warning. In the absence of structural heart disease, supraventricular tachycardia rarely causes syncope in adults. However, in patients with the Wolff-Parkinson-White syndrome and atrial fibrillation, conduction across the accessory AV connection may result in particularly rapid ventricular rates and syncope. Atrial fibrillation may also cause syncope in patients with structural heart disease (e.g., HOCM).

Ventricular tachycardia is a common cause of syncope in patients with structural heart disease. Patients with an acute MI may present with syncope due to ventricular arrhythmias (ventricular tachycardia/ventricular fibrillation; VT/VF). A history of prior MI identifies the substrate for reentrant VT. Certain types of VT may cause syncope in younger individuals without apparent structural heart disease. These include the idiopathic focal VTs, the most common locations of which are the right ventricular outflow tract and the left anterior fascicle. These latter two types of VT are not life threatening but can result in syncope. Patients with abnormalities of ventricular repolarization with long QT syndrome are at risk for polymorphic VT (torsade de pointes). QT prolongation may be congenital and related to the genes encoding for sodium or potassium channels. Many patients with the syndrome have a family history of syncope or early sudden death. In other patients, the disorder is acquired as a result of drug therapy, such as quinidine, procainamide, disopyramide, sotalol, phenothiazines, or electrolyte abnormalities (hypokalemia, hypomagnesemia) that prolong ventricular repolarization. Certain antihistamines (e.g., terfenadine) in combination with drugs (e.g., erythromycin, ketoconazole) or conditions that inhibit hepatic cytochrome P450 metabolism may prolong the QT interval and cause torsade de pointes ([Fig. 69.2](#)).

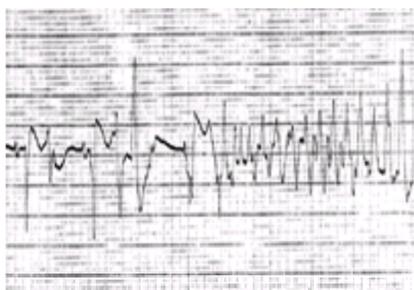

FIGURE 69.2. Acquired long QT syndrome from quinidine therapy with associated bradycardia results in polymorphic ventricular tachycardia (torsade de pointes)

CEREBROVASCULAR DISEASE

It is very unusual for cerebrovascular disease to be the lone cause of syncope. More commonly, cerebrovascular disease lowers the threshold for syncope in patients with other disorders. Syncope as a manifestation of carotid artery disease may occur if the ischemia involves both hemispheres but rarely occurs in the absence of coexistent vertebrobasilar disease. Subclavian steal syndrome can usually be diagnosed on the basis of the history and physical examination. When transient ischemic attacks cause syncope, they are almost always vertebrobasilar in location. Cortical strokes may cause loss of consciousness because of an associated seizure disorder.

Fainting is reported by 12% to 18% of patients with migraine. An uncommon form of migraine may affect the basilar artery in adolescents and cause syncope.

DIFFERENTIAL DIAGNOSIS

SEIZURES

Seizures can mimic syncope and account for loss of consciousness in up to 5% to 10% of patients in reported series. Although profound hypotension associated with bradyarrhythmias or ventricular tachyarrhythmias may result in syncope in supine individuals, loss of consciousness in this position is more often caused by a seizure. Syncope due to cardiac arrhythmia is of rapid onset and brief duration, without preceding aura, and is not followed by a postictal confusional state. Seizure activity is uncommon, as is tongue biting or incontinence, but tonic-clonic movements can occur if the arrhythmia resulting in syncope is prolonged. Epileptic movements within seconds of the onset of syncope are more likely to be indicative of a central nervous system disorder than a cardiac rhythm disturbance. Temporal lobe seizures can be confused with syncope. These seizures may last for several minutes and are characterized by changes in consciousness, confusion, and a variety of autonomic signs, such as flushing and olfactory hallucinations. The clinical picture may be confounded by a syncopal episode that resulted in head trauma and confusion.

Seizure-like activity may occur as a result of syncope when the episode of cerebral anoxia is prolonged. As noted, it is not uncommon for a patient with prolonged episodes of vasovagal syncope to develop myoclonic jerks, particularly if the individual is unable to achieve the supine position. Conspicuous motor activity accompanies syncope due to ventricular arrhythmias in as many as 30% to 40% of cases.

PSYCHIATRIC ILLNESSES

Hysterical fainting is a syncopal disorder felt secondary to a psychiatric condition. It can mimic syncope and be difficult to differentiate from a neurocardiogenic etiology. These episodes usually occur or recur in the presence of observers or in emotionally charged situations, and rarely result in physical injury.

Hyperventilation may cause transient loss of consciousness due to the resultant respiratory alkalosis and cerebral vasoconstriction that may be sufficient to induce cerebral ischemia. Patients usually experience light-headedness, facial pallor, and digital and circumoral numbness and tingling that are not relieved by recumbency.

METABOLIC AND DRUG-RELATED CAUSES

Loss of consciousness associated with drugs or metabolic abnormalities (e.g., hypoglycemia, hypoxia, hypercarbia) is more often prolonged than transient. The onset (and offset) of symptoms associated with these factors is also more gradual than for those associated with true syncope. Common drugs causing syncope are listed in [Table 69.3](#).

Vasodilators
Nitrates
Calcium channel blockers
Angiotensin-converting enzyme inhibitors
Propranolol (especially first dose)
Hydralazine
Psychotropic drugs
Phenothiazines
Antidepressants (e.g., tricyclic agents, monoamine oxidase inhibitors)
CNS depressants (e.g., barbiturates)
Drugs associated with torsades de pointes
Quinidine
Procainamide
Disopyramide
Flecainide
Sotalol
Terfenadine
Cisapride
Mebutal
Sedatives
Eucalyptus
Other mechanisms
Vincristine and other neurotoxic drugs
Digitalis
Insulin
Morphine
Alcohol
Cocaine

TABLE 69.3. DRUGS CAUSING SYNCOPE

TRAUMA

Differentiation of syncope from primary head trauma is important and may be difficult in patients who fall. Younger patients with head trauma may experience retrograde amnesia, complicating the diagnosis of the episode.

HISTORY AND PHYSICAL EXAMINATION

A detailed history of the event from the patient and witnesses is the critical first step in the evaluation of syncope. A diagnosis may be possible on the basis of the history and examination alone in approximately 30% to 50% of cases. Every effort should be made to obtain information from a witness, when available, who may provide observations of the patient's behavior before, during, and after the event. Such information helps to differentiate syncope from other states of altered consciousness such as dizziness, vertigo, coma, and seizure. Critical issues that should be addressed in the history and physical examination are summarized in [Table 69.4](#).

History
Prior history of syncope; frequency, severity of episodes
Posture before and during the event
Exertional symptoms
Positive family history long QT, syncope, or sudden death
Palpitations, organic heart disease
Premonitory symptoms or sensations
Postictal symptoms, confusion, incontinence, tongue biting
Situational symptoms, coughing, urinating, swallowing, defecating, sensation of pain
Head and neck position before and during event
Time course of onset and recovery from event
Other underlying diseases
Alcohol or drug ingestion
Medications
Physical Examination
Orthostatic blood pressure
Blood pressure in both arms
Skin color and turgor; nail beds
Evidence of trauma or tongue biting
Presence of heart murmurs, rubs, gallops, or bruits
Carotid sinus massage if no bruits
Neurologic examination

TABLE 69.4. HISTORY AND PHYSICAL EXAMINATION

LABORATORY STUDIES AND DIAGNOSTIC TESTS

After a complete history and examination further information can be derived from the results of carefully selected tests. The relative frequency with which selected test lead to specific diagnosis is listed in [Table 69.5](#).

Test	Percentage
History and physical exam	32
Electrocardiogram	7
Prolonged ECG monitoring	12
Electrophysiologic study	2
Exercise tolerance test	<1

TABLE 69.5. RELATIVE FREQUENCY OF DIAGNOSIS PROVIDED BY DIAGNOSTIC TESTS

BLOOD TESTS

Routine blood work to help establish the cause of syncope should include serum electrolytes, glucose, and complete blood count. Cardiac arrhythmia may result from hypokalemia. Cardiac enzymes should be evaluated in patients with a history consistent with MI. Blood and urine toxicology screens may reveal the presence of alcohol or other drugs.

ELECTROCARDIOGRAM

The electrocardiogram (ECG) can serve as a useful test and helps to provide a diagnosis in 7% of cases. The ECG may document bradyarrhythmias or tachyarrhythmias. It more commonly provides clues and directs further evaluation. For example, AV block is suggested when bundle-branch block or PR prolongation is present. A prolonged QT interval raises the possibility of polymorphic VT (torsade de pointes) especially in the setting of bradycardia. Q waves consistent with prior MI provide the substrate for reentrant scar-related ventricular arrhythmias as the cause of syncope. Patients hospitalized for syncope should undergo continuous ECG monitoring.

Holter monitoring is appropriate for certain patients evaluated in the ambulatory setting. Prolonged ECG monitoring may establish or confirm the cause of syncope in as many as 12% to 15% of patients. Beyond 24 to 48 hours of ECG monitoring, the diagnostic yield diminishes considerably. Correlation between patients' symptoms and ECG observations is imprecise and occurs in only 25% to 50% of patients. Due to the expense associated with prolonged hospital stays and the imperfect correlation between ECG monitoring and symptoms cited above, there is an increasing reliance on the use of trans-telephonic ECG monitors or event recorders. These monitors are small, portable recorders that are patient-activated to record two ECG channels for up to 30 to 40 seconds. The heart rhythm can be transmitted live or stored for transmission at a later time. The trans-telephonic monitor is particularly useful for patients with palpitations or light-headedness who are at low risk for serious arrhythmia (no structural heart disease) and who have adequate time to activate the recorder during symptoms. For patients with short-lived episodes, continuous recorders with 30 to 45 seconds of activated memory or loop recorders can be provided. These recorders must be worn continuously in order to document events and are typically provided for 2 to 3 weeks. Signal-averaged electrocardiography (SAE) has not been adopted widely in routine practice.

EXERCISE ELECTROCARDIOGRAPHY

Exercise testing is important in those patients with documented or suspected coronary artery disease whose syncope may be due to an arrhythmia triggered by ischemia. Automatic VT and supraventricular tachycardia can also be catecholamine-triggered and exercise-induced. Pharmacologic stress with intravenous dobutamine or adenosine may be useful in patients who cannot exercise. Nuclear or echocardiographic imaging may increase the sensitivity for the detection of myocardial ischemia and is required when pharmacologic stress is necessary. Patients in whom aortic stenosis (AS) or HOCM is the suspected cause of syncope should not undergo exercise testing.

ECHOCARDIOGRAPHY

Echocardiography is indicated in any patient with a suspected cardiac cause (mechanical, arrhythmic) of syncope. In patients in whom adequate acoustic windows can be obtained, transthoracic echocardiography with Doppler interrogation is a highly sensitive and accurate tool for the detection and characterization of valvular (AS), myocardial (HOCM, MI, dilated cardiomyopathy), pericardial (tamponade), and right-sided (pulmonary hypertension) abnormalities associated with syncope. Transesophageal imaging is infrequently required but may be useful when the transthoracic echocardiographic images are technically suboptimal or when a left atrial (myxoma, thrombus) or an aortic (dissection) pathologic process is suspected.

CARDIAC ELECTROPHYSIOLOGIC STUDY

The indications for formal electrophysiologic study in patients with syncope have not been systematically defined. An abnormal study is more likely to be found in patients with underlying heart disease such as those with prior MI, cardiomyopathy (dilated, hypertrophic, or ischemic) bundle-branch block, preexcitation (Wolff-Parkinson-White syndrome), or for whom documentation of an arrhythmia on ECG or ambulatory monitoring has been obtained. The frequency of diagnoses that result from invasive electrophysiologic testing is shown in [Table 69.6](#). Diagnostic and prognostic information regarding sinus node function, AV nodal and His-Purkinje system conduction, and supraventricular and ventricular arrhythmias can be obtained. Abnormal findings include the induction of sustained monomorphic VT ([Fig. 69.3](#)) induction of a supraventricular tachycardia associated with hypotension, prolongation of the HV interval, and prolongation of the sinus node recovery time. Programmed stimulation for induction of ventricular arrhythmias is most sensitive and specific in patients with coronary artery disease. The sensitivity and specificity of the technique are considerably diminished in patients with normal hearts or with structural heart disease due to nonischemic causes.

Diagnosis	Percentage
Sustained ventricular tachycardia	12
Nonsustained ventricular tachycardia	19
Abnormal sinus node function	7
Prolonged HV interval	3
Abnormal AV node function	2
Supraventricular tachycardia	5
No diagnosis	52

TABLE 69.6. FREQUENCY OF DIAGNOSES RESULTING FROM ELECTROPHYSIOLOGIC STUDY FOR UNKNOWN SYNCOPE

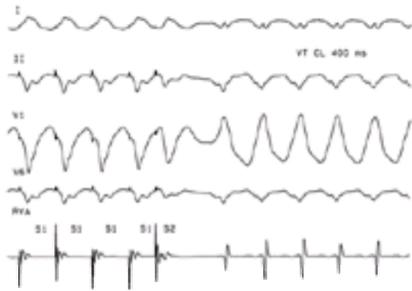

FIGURE 69.3. Surface electrocardiogram leads I, II, V₁, and V₆ and intracardiac electrograms from the right ventricular apex. The figure shows programmed ventricular simulation with administration of a single premature ventricular extra stimulus and the induction of monomorphic ventricular tachycardia with a cycle length of 400 milliseconds. RVA, right ventricular apex; VT, ventricular tachycardia.

Prolongation of the HV interval and infrahisian block may indicate that His-Purkinje disease could have been responsible for the syncope. An HV interval longer than 90 milliseconds is abnormal and an indication for pacing in patients with syncope. Some patients with shorter (normal) intervals may still be at risk for AV block.

Prolongation of the sinus node recovery time (more than 1,500 milliseconds) is a specific finding (88% to 100%) but has a low sensitivity for the diagnosis of sinus node dysfunction sensitivity. Continuous ECG monitoring is usually more effective for diagnosis of this abnormality.

Depending on the patient subgroup studied, electrophysiologic testing can establish a cause for syncope in 12% to 70% of subjects. Twenty percent of patients with negative or nondiagnostic study have recurrent syncope; however, the mortality rate is as low as 2%. In contrast, in patients with a possible cardiac cause of syncope, the recurrence rate is approximately 15%, with an associated mortality rate of 7%.

Cardiac catheterization and coronary angiography are necessary in some patients to determine the presence and severity of coronary artery disease or the possible anatomical and physiologic basis for an abnormality detected but incompletely characterized by noninvasive means (e.g., tamponade, AS with low cardiac output).

UPRIGHT TILT-TABLE TEST

Upright tilt-table testing at 80° for 60 minutes rarely induces syncope in healthy individuals. However, in patients with neurocardiogenic syncope, this test often induces an event ([Fig. 69.1](#)). Upright tilt-table testing for 60 minutes has a sensitivity of 75% and a specificity of 93% for the detection of neurocardiogenic syncope. Addition of intravenous isoproterenol to the tilt protocol increases the sensitivity but decreases the specificity of the test. In severe cases, repeat testing may be considered to evaluate the efficacy of therapeutic intervention.

CAROTID ULTRASONOGRAPHY

Carotid ultrasonography is indicated to define the extent and severity of suspected carotid artery disease, particularly among older patients with audible bruits. Controversy exists as to whether non-invasive carotid testing should be obtained in all patients with syncope at risk for atherosclerotic vascular disease (smoking, hyperlipidemia, audible bruit, claudication, angina). On occasion, magnetic resonance angiography is required for anatomic delineation.

ELECTROENCEPHALOGRAPHY

The diagnostic yield of electroencephalography is very low when seizures are considered unlikely. This test should be reserved for patients in whom the history suggests seizure or in whom comprehensive evaluation has not revealed a cause for loss of consciousness and there remains a suspicion of a neurologic etiology.

CRANIAL COMPUTED TOMOGRAPHY OR MAGNETIC RESONANCE IMAGING

The yield of computed tomography or magnetic resonance imaging, when performed for transient loss of consciousness, is also very low. These studies should be used when the history and physical examination suggest an intracranial process or when head injury is suspected.

STRATEGIES FOR OPTIMAL MANAGEMENT

The treatment of syncope depends on the diagnosis. Syncope that is felt to be secondary to a correctable cause should be addressed first. Examples are correction of electrolyte and metabolic abnormalities, removal of offending drugs, and revascularization.

Primary therapy for neurocardiogenic syncope of mild severity includes reassurance and salt loading, when necessary. β -adrenoreceptor antagonists are the next line of treatment and act by decreasing myocardial contractility.

Other pharmacologic agents that have been used to treat this disorder include theophylline, disopyramide, scopolamine, serotonin reuptake inhibitors, and ephedrine. Mineralocorticoids and support stockings may provide additional benefit in patients in whom hypovolemia or venous pooling initiates syncope. Cardiac pacing alone rarely prevents syncope but may be necessary in patients in whom asystole or severe bradycardia is the predominant mechanism. The natural history of neurocardiogenic syncope is variable. Many patients have single or very infrequent episodes, and such patients might not benefit from therapy. There are no known markers that differentiate patients who benefit from therapy from those who do not.

Cardiac arrest survivors, with VT/VF not precipitated by MI, have improved survival with implantable cardiac defibrillators. Anti-arrhythmic therapy may be required for treatment of supraventricular tachycardia. However, for serious episodes or patients who are intolerant of drug therapy, consideration of electrophysiologic study with possible radiofrequency ablation is indicated. Pacemaker therapy is indicated in patients with syncope and conduction system disease not secondary to drug therapy or ischemia.

Hospital admission is required for all patients suspected of cardiac syncope. Patients with cardiac syncope face the highest risk of death in the first 1 to 6 months after presentation. The results of large studies suggest that hospitalization is necessary for patients with evidence of underlying heart disease, a history of chest pain, prior history of arrhythmia, or for those who use medications with proarrhythmic potential. Elderly patients are often hospitalized due to the serious consequences of falling. Motor vehicle driving is regulated by state laws but should be considered on an individual basis. Until it is clear that the syncope has been effectively treated, patients should be instructed to avoid situations such as driving a motor vehicle or operating heavy mechanical equipment.

The cost of an evaluation for syncope will vary depending on the tests ordered and the need for hospitalization. An algorithm for evaluation is outlined in [Fig. 69.4](#). A detailed history, physical examination, and 12-lead ECG is recommended for all patients. A careful drug/medication history is also warranted, especially for the elderly. Specific cardiac testing with echocardiography should be obtained in patients with suspected cardiac syncope. Exercise testing should be performed for patients with exertional symptoms who do not have AS or HOCM.

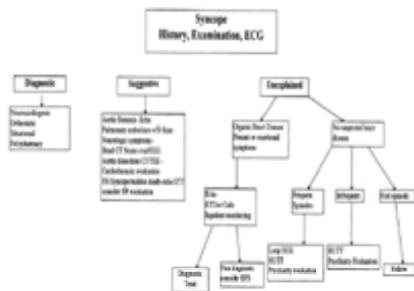

FIGURE 69.4. Flow diagram for the evaluation of syncope. CT, computed tomography; ECG, electrocardiography; EEG, electroencephalogram; EPS, electrophysiology study; ETT, exercise tolerance test; FH, family history; HUTT, head-up tilt test; v/Q, ventilation perfusion. (Modified from Linzer M, Yang EH, Estes NA III, et al. *Ann Intern Med* 1997;127:76–86.)

Electrophysiologic studies are most useful in patients with structural (particularly ischemic) heart disease and unexplained syncope (or VT). Patients with structurally normal hearts may benefit from tilt-table testing if the history suggest a neurocardiogenic cause. Neurologic evaluation (electroencephalography, computed tomography, carotid and transcranial Doppler) should be limited to those patients with focal neurologic signs, seizure activity, or carotid bruits.

A complete history and physical examination with directed tests should be initiated by the emergency room physician. Those patients with ECG abnormalities, history of prior MI, family history of sudden death, or structural heart disease should be referred to a cardiologist/electrophysiologist. Patients with clear seizure activity or focal neurologic deficits warrant cranial computed tomography and additional evaluation. This neurologic workup does not preclude simultaneous cardiac evaluation as 40% of patients with VF will manifest tonic–clonic movements.

PROGNOSIS

Patients with a defined cardiac cause of syncope are at increased risk for sudden and total cardiac death, compared to those with a non-cardiac or unknown cause. Indicators of high risk include significant left ventricular dysfunction, valvular heart disease (AS), hypertrophic cardiomyopathy (with or without obstruction), pulmonary hypertension, known coronary artery disease, long QT syndrome, and preexcitation of the Wolff–Parkinson–White type. Younger patients (under 60 years) without identifiable cardiovascular disease have an excellent prognosis with a low risk of sudden death. However, such patients do experience more frequent recurrences of syncope, though usually without bodily trauma. A normal physical examination and ECG, coupled with the absence of a specific personal or familial cardiac history, usually identifies a low-risk subset.

CHAPTER 70: APPROACH TO THE PREGNANT PATIENT WITH HEART DISEASE

G. MICHAEL FELKER AND KENNETH L. BAUGHMAN

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

A greater number of women with known or potential cardiovascular disease are considering or attempting pregnancy, and internists and cardiologists are often consulted to manage cardiovascular complications related to pregnancy. As women become pregnant at older ages, it seems likely that the number of patients with either preexisting or new-onset cardiovascular disease during pregnancy will continue to expand. In this chapter we briefly define the normal physiologic changes that occur during pregnancy, as well as discuss changes in the physical examination and use of noninvasive tests that can complicate the evaluation of these patients. The differential diagnosis of cardiac symptoms appearing during pregnancy is discussed. The diagnosis and treatment of cardiac disorders specific to pregnancy as well as those disorders exacerbated by the physiologic stresses of pregnancy are addressed. Special attention is given to the risks of both diagnostic tests and therapeutic interventions to fetal development and maternal health.

PRESENTATION

The initial signs and symptoms of cardiovascular disease in the context of pregnancy are not significantly different from those in the nonpregnant patient. Evaluation of these signs and symptoms in the pregnant patient, however, is made more difficult by the fact that many symptoms, such as dyspnea on exertion, palpitations, and fatigue, are common during normal pregnancy in women without cardiovascular disease. The unique changes in cardiovascular physiology that occur during pregnancy can mimic other cardiac disorders and are discussed in detail herein.

PATHOPHYSIOLOGY

An appreciation of the normal adaptations of the cardiovascular system to pregnancy is required to understand and treat potential cardiovascular complications associated with pregnancy. Echocardiography has provided substantial insight into the cardiovascular changes that take place during normal pregnancy. The primary changes in cardiovascular physiology are related to increases in cardiac output and circulating blood volume. The time course of changes in cardiac output associated with normal pregnancy is shown in [Fig. 70.1](#). Cardiac output in pregnancy begins to increase as early as 5 weeks after the last menstrual period and peaks at 45% over baseline at 24 weeks of gestation. Amplified cardiac output is achieved through rises in both stroke volume and heart rate. During labor, cardiac output increases further, in response to higher demand, primarily accomplished by a rise in stroke volume. Stroke volume is persistently higher in the time period immediately after delivery, possibly owing to relief of venocaval obstruction and a subsequent increase in venous return. These changes in cardiac output may persist into the postpartum period, usually returning to normal within 10 days to 2 weeks after delivery.

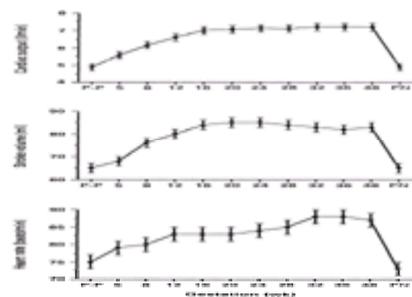

FIGURE 70.1. Changes in cardiac output, stroke volume, and heart rate during pregnancy. P-P, pre-pregnancy; PN, postnatal. (From Hunter S, Robson SC. Adaptation of the maternal heart in pregnancy. *Br Heart J* 1992;68:540–543, with permission.)

In addition to cardiac output, intravascular volume is substantially increased during pregnancy. Plasma volume rises approximately 40% and red cell volume 30% over baseline levels, resulting in mild relative anemia. Multiple changes in neurohumoral activation contribute to this increase in blood volume. Stimulation of the renin–angiotensin axis in response to higher levels of estrogen amplifies circulating aldosterone levels, resulting in enhanced renal tubular absorption of sodium and a subsequent marked increase in total body water, by as much as 8 L by the time of delivery. Mobilization of extracellular fluid and brisk diuresis occur shortly after delivery, resulting in a return to baseline circulating blood volume by 2 weeks postpartum. Systolic blood pressure is relatively unchanged in pregnancy, but diastolic blood pressures are typically 15% lower than in the nonpregnant state, with a concomitant widening of the pulse pressure. These changes are due to a decrease in systemic vascular resistance caused by arteriovenous shunting in the uterus and changes in aortic compliance.

HISTORY AND PHYSICAL EXAMINATION

Cardiac evaluation of the pregnant patient is complicated by the difficulty of differentiating between physiologic and pathologic processes. Many pregnant women have symptoms of palpitations, swelling, dyspnea on exertion, or fatigue despite having no evidence of heart disease. Such symptoms as exertional chest pain or frank syncope are relatively uncommon in pregnancy, however, and require cardiovascular evaluation. Additionally, the significant changes in cardiac physiology that develop during pregnancy can alter substantially the physical examination findings of the pregnant patient. It is crucial for the consulting cardiologist or internist to understand the expected changes in physical findings, to be able to distinguish physiologic from pathologic changes.

Increased total plasma volume results in elevation of jugular venous pressure and lower-extremity edema in more than 80% of normal pregnant women. Growth in uterine size as pregnancy progresses leads to upward movement of the diaphragm and a decrease in lung volumes. Diaphragmatic elevation and higher blood volume may also result in lateral displacement of the left ventricular point of maximal impulse during inspection and palpation of the precordium. Increased stroke volume may produce a rise in the sounds of aortic and pulmonic valve closure as well as a “functional” early systolic murmur over the pulmonic area. In general, diastolic murmurs and gallop rhythms are not normal findings of pregnancy and should suggest underlying structural or functional cardiac abnormalities. In as many as 15% of women, however, a physiologic diastolic murmur is audible at the left sternal border. This murmur is generated by increased blood flow through the internal mammary artery, which stems from enhanced blood flow to the breasts during pregnancy. This mammary soufflé may persist in lactating mothers even after delivery. The higher pulse pressure normally seen in pregnancy may also cause Quinke’s sign in the peripheral nail beds, leading to confusion between benign mammary soufflé and aortic regurgitation. Echocardiography may be required to distinguish between a physiologic process and underlying valvular heart disease.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Cardiovascular diagnostic testing in the pregnant patient is complicated by the need to avoid potentially harmful radiation exposure to the developing fetus. Additionally, the interpretation of some diagnostic studies may be made more difficult by the physiologic changes of pregnancy. Diagnostic studies should be selected to minimize risk to the fetus while providing the maximum possible diagnostic information. The potential hazards and benefits of various diagnostic methods are discussed in detail in later sections. Surface electrocardiography and transthoracic echocardiography remain the mainstays of noninvasive cardiac testing in the pregnant patient, providing detailed information on cardiac structure and function without risk to fetal development.

Owing to the elevation of the diaphragm, standard surface electrocardiography may show a leftward shift of the axis of ventricular activation or increased ventricular voltage. These changes are typically within the normal limits of variability, and marked changes from the baseline electrocardiogram should prompt further evaluation for possible cardiac disease. In addition to the changes in stroke volume discussed earlier, echocardiographic studies have shown a mild to moderate increase in left ventricular mass and wall thickness during normal pregnancy. Otherwise, the findings on echocardiography are not substantially different from those of the nonpregnant patient. Visibility of cardiac structures is not impeded by pregnancy, and an adequate echocardiographic window usually can be obtained. The consideration of additional cardiac testing, particularly tests involving radiation exposure—such as with radionuclide studies or coronary angiography—must include careful assessment of the risk to the fetus as well as potential diagnostic or therapeutic benefit to the mother.

RADIATION EXPOSURE AND PREGNANCY

The possibility that radiation exposure will injure the developing fetus is a major concern in evaluating the appropriateness of cardiovascular diagnostic testing in pregnancy. Radiation exposure damages cells both directly and through the generation of ionized water and free radicals. Radiation exposure's potential harmful effects to the developing fetus include growth impairment, structural deformity, gonadal damage, and neoplasia. An increased risk of childhood malignancy associated with in utero radiation exposure has been well documented, as has a dose response with increasing levels of radiation exposure. Exposure during the first trimester is considered more hazardous than later exposure, though there is increased risk associated with exposure during any trimester of pregnancy. There is virtually no data establishing significant fetal damage below 1 rad, though no level of radiation exposure can be considered to carry no risk. The amount of fetal radiation exposure from a given radiologic procedure varies based on a multitude of factors, including the type of radiation source, size of the patient, distance from the area of investigation, and use of uterine shielding. Consideration of diagnostic testing that uses radiation must include assessment of the dose of radiation to the fetus, fetal age and development, and potential harm to the mother by delaying testing or using alternative means of cardiovascular assessment.

CARDIAC CATHETERIZATION

Standard cardiac catheterization results in an exposure of approximately 500 Gray to a shielded uterus compared with 50 Gray for a standard radiograph. The actual degree of radiation exposure varies, depending on the length and complexity of the procedure. If catheterization is deemed necessary, brachial as opposed to femoral access should be used. Noninvasive studies, such as echocardiography, can generally provide sufficient data regarding left and right ventricular performance to obviate the need for ventriculography during cardiac catheterization. If pulmonary artery catheterization is required for monitoring of hemodynamics in pregnant patients with severe or unstable cardiac disease, it almost always can be performed via an internal jugular approach without the need for fluoroscopically guided catheter placement.

RADIONUCLIDE IMAGING

Radionuclide imaging is frequently used in the nonpregnant patient for noninvasive evaluation of coronary blood flow or ventricular function. Although the degree of fetal radiation exposure is less with these agents than with standard radiologic studies, there is still an increased risk of childhood malignancy associated with the use of these agents in the pregnant patient. In particular, radionuclides eliminated by the kidney may collect in the maternal bladder, resulting in exposure at close proximity to the fetus. In general, these agents should be avoided if possible, especially during the first trimester. If cardiac stress testing is required, stress or dobutamine echocardiography may be used to provide similar information without the potential risks of radiation exposure.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is a relatively new technique in the evaluation of cardiovascular disease and holds the promise of a greater degree of noninvasive structural and functional cardiac evaluation than is available with current techniques. There are no data that suggest any untoward effects of this imaging method on either the fetus or the mother, though little long-term data are available. Given this lack of long-term safety data, MRI should be used with caution in the pregnant patient, especially during the first trimester. If this technique proves to be safe, it is hoped that it will allow detailed cardiac evaluation without the fetal radiation exposure inherent in other diagnostic tests.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cardiovascular symptoms in the pregnant patient is broad and complicated by the difficulties of distinguishing between physiologic and pathologic processes. Some cardiovascular disorders are specific to the pregnant patient, while others are common in the nonpregnant population but require special consideration during pregnancy. In pregnant patients with complaints of dyspnea, palpitations, or fatigue, interpretation of the history and physical examination may be difficult. In addition to a careful history and physical examination, echocardiography is often a critical aid to establishing a diagnosis in women with undiagnosed cardiovascular disease initially seen in the context of pregnancy. As in the assessment of the nonpregnant patient with heart disease, maintaining a wide differential diagnosis is critical to arriving at appropriate diagnostic conclusions.

In women with known preexisting cardiac disorders, such as valvular or congenital heart disease, the diagnosis is usually straightforward, since an exacerbation of a preexisting condition is more likely than the appearance of a new disorder. In women without known preexisting cardiac disorders, rare but potentially life-threatening cardiovascular disorders, such as peripartum cardiomyopathy or coronary artery dissection, must be prominent among the potential diagnoses if they are not to be overlooked. Hypertensive disorders of pregnancy, including chronic hypertension, gestational hypertension, and preeclampsia, are the most common cardiovascular disorders during pregnancy and are usually apparent on careful evaluation. Optimal management of specific conditions likely to be encountered in the pregnant patient is discussed in detail in the next section.

STRATEGIES FOR OPTIMAL CARE

Optimal treatment of the pregnant woman with cardiac disease must address and balance the well-being of both mother and fetus, requiring an understanding of both maternal pathophysiology and the potential fetal effects of contemplated therapies. Optimal care of the patient with complex cardiac disease in the context of pregnancy often requires close cooperation among members of a multidisciplinary team, including specialists in cardiology, obstetrics, neonatology, and anesthesia. Issues related to the diagnosis and management of specific important cardiovascular disorders in the pregnant patient are discussed herein.

HYPERTENSION IN PREGNANCY

Elevated blood pressure may occur in as many as 10% of pregnancies, and this complication remains a major cause of maternal and fetal morbidity and mortality. Hypertension during pregnancy is associated with higher rates of preterm deliveries, perinatal mortality, and fetal neurologic impairment. Three categories of hypertension in pregnancy are generally recognized: chronic hypertension, gestational hypertension, and preeclampsia. Chronic hypertension is defined as hypertension existing before pregnancy or blood pressure of at least 140/90 mm Hg before 20 weeks' gestation. Owing to the normal physiologic changes of pregnancy, many women with chronic hypertension before pregnancy will be normotensive before 20 weeks' gestation.

Women with severe chronic hypertension (diastolic blood pressure greater than 110 mm Hg) are at higher risk of complications, such as preeclampsia and placental abruption, and pharmacologic treatment in these patients clearly lowers the risk of fetal and maternal morbidity and mortality. In general, fetal and maternal outcomes in patients with mild chronic hypertension (diastolic blood pressure less than 110 mm Hg) are good, and the value of treatment for this degree of hypertension during pregnancy is less clear. Gestational hypertension is defined as asymptomatic elevation of blood pressure after 20 weeks of gestation in a woman with normal blood pressure before pregnancy. Although care must be taken to ensure that gestational hypertension is not an early manifestation of preeclampsia, fetal and maternal outcomes appear to be good with or without treatment in women with simple gestational hypertension. Women with mild, uncomplicated chronic hypertension or gestational hypertension can generally be treated as part of routine obstetrical care. Severe hypertension, especially with evidence of end-organ damage, should prompt inpatient admission and referral to a cardiologist or an obstetrical specialist experienced in dealing with hypertensive disorders of pregnancy.

Pharmacologic treatment of hypertension in pregnancy must be guided by an understanding of both the mechanisms of hypertension and the potential effect of therapy on fetal development. The safety of various antihypertensive medications in pregnancy is outlined in [Table 70.1](#). Methyldopa is a safe and cost-effective antihypertensive agent and traditionally has been the antihypertensive drug of choice in pregnancy. It has an established long-term safety record and substantial evidence of improved fetal outcomes with its use. Despite early concerns about the possibility of fetal growth retardation, b-blockers have now been shown to be

relatively safe in pregnancy for the treatment of hypertension. Selective b-blocking agents are preferred over nonselective agents.

TABLE 70.1. MATERNAL AND FETAL CONSIDERATIONS IN THE USE OF CARDIOVASCULAR DRUGS

Diuretics generally should not be used to treat hypertension in pregnant women, though women with chronic hypertension whose blood pressure has been controlled well by diuretic therapy before pregnancy may continue diuretics during pregnancy. Diuretic therapy should be discontinued if signs of preeclampsia develop. Dihydropyridine calcium-channel blocking agents, such as nifedipine or amlodipine, have not been well studied in pregnancy but have been used safely to treat hypertension in this context. Angiotensin-converting enzyme (ACE) inhibitors have been shown to be teratogenic in both animal and human studies and should be strictly avoided by women who are pregnant or who are contemplating pregnancy.

Preeclampsia is the most severe hypertensive disorder of pregnancy and may progress to eclampsia, a life-threatening seizure disorder. Preeclampsia is defined as the presence of hypertension, edema, and proteinuria after 20 weeks' gestation in a previously normotensive woman. This diagnosis may be difficult to establish in women with preexisting chronic hypertension. The development of proteinuria in a woman with chronic hypertension should strongly suggest the possibility of superimposed preeclampsia. Preeclampsia appears to result from the failure of the normal cardiovascular adaptations of pregnancy, with decreased cardiac output and blood volume and increased systemic vascular resistance. This failure of cardiac adaptation to pregnancy may be the result of failure of the uterine spiral arteries to develop, prohibiting arteriovenous shunting in the uterus and thereby increasing systemic vascular resistance. The precise cause of preeclampsia remains unclear, and many potential etiologic factors, including immunologic phenomena, prostaglandin deficiency, and endothelial dysfunction, have been proposed.

Treatment of preeclampsia depends on the severity of hypertension and proteinuria. Patients with mild preeclampsia may be monitored as outpatients, and the wisdom of aggressive management of hypertension in these patients is unclear. Women with severe preeclampsia or those with progressive symptoms should be treated as inpatients by physicians with experience in the management of this disorder. In women with severe manifestations of preeclampsia or women at term, delivery is the ultimate therapy. Pharmacologic therapy with hydralazine, labetalol, or nifedipine should be used to lower diastolic blood pressure to below 105 mm Hg in women with severe hypertension. Diuretic therapy should be avoided, since volume depletion is common in women with preeclampsia. Women with severe hypertension despite aggressive pharmacologic therapy should undergo delivery regardless of fetal viability. Intravenous magnesium therapy should be given at about the time of delivery to lower the risk of seizure.

VALVULAR HEART DISEASE

Despite a decline in the incidence of rheumatic heart disease, valvular heart disease remains a relatively common concern in both pregnant patients and women contemplating pregnancy. The changes in cardiovascular physiology that accompany pregnancy can unmask previously asymptomatic valvular heart disease or exacerbate a known preexisting condition. Cardiologists and internists can be consulted to assist in the treatment of pregnant patients with native valvular heart disease or prosthetic heart valves or to recommend an appropriate choice of artificial valve for women contemplating future pregnancy.

For patients with disease of native valves, the location and nature of the valvular lesion dictate management. Despite the declining incidence of rheumatic heart disease, the majority of acquired valvular heart disease encountered during pregnancy is rheumatic in origin. Twenty-five percent of women with chronic rheumatic heart disease show initial manifestations during pregnancy, and acute rheumatic fever may recur during pregnancy. Mitral stenosis is by far the most common rheumatic valvular lesion seen in pregnancy and is poorly tolerated, owing to the hemodynamic changes of the pregnant state. The increases in heart rate and blood volume that accompany normal pregnancy may lessen the time for diastolic ventricular filling and greatly amplify the pressure gradient across the stenotic mitral valve. These changes can result in increases in left atrial pressure and a higher incidence of atrial fibrillation, further impairing ventricular filling.

The incidence of symptoms in pregnant women with mitral stenosis increases up to 20 weeks' gestation, by which time the hemodynamic changes of pregnancy are usually maximal. Management of pregnant women with mitral stenosis should include attempts to decrease circulating blood volume and prevent tachycardia. Diuretic therapy may be indicated in women with pulmonary congestion, but care must be taken to avoid hypovolemia and uterine hypoperfusion. Restriction of physical activity lowers the heart rate and limits cardiac work, and b-blocking agents may be required to further decrease heart rate. Digoxin may be added in patients at high risk of atrial fibrillation, such as those with significant left atrial enlargement.

Vaginal delivery can be accomplished in most women with mitral stenosis, though hemodynamic monitoring may be required during and immediately after delivery. Mitral valvuloplasty or replacement can usually be deferred with careful medical management, but some patients with severe symptomatic mitral stenosis may require correction before delivery. The risks to the mother of open commissurotomy, closed commissurotomy, or valve replacement are similar to those in nonpregnant patients. The risk of fetal loss, however, is higher for both open commissurotomy and valve replacement. Closed commissurotomy is therefore recommended as providing the best chance for satisfactory fetal outcome in centers with experience in this technique. Balloon valvuloplasty has been performed with a low incidence of maternal and fetal complications, but experience with this technique is limited.

Mitral regurgitation and aortic regurgitation are relatively well tolerated in pregnancy, owing to unloading of the left ventricle caused by the decreased systemic vascular resistance accompanying pregnancy. Diuretic therapy and hydralazine for afterload reduction may be safely used in pregnancy for symptomatic patients. Mitral valve prolapse is relatively common in women of childbearing age. Outcomes of pregnancy in the context of this disorder are generally good, even if prolapse is associated with valvular thickening or mitral regurgitation. Isolated rheumatic aortic stenosis rarely occurs, and most patients with aortic valve obstruction have a congenitally bicuspid aortic valve. Moderate aortic stenosis is usually well tolerated, but severe aortic stenosis (aortic valve area less than 1 cm²) may require termination of pregnancy or surgical intervention.

Evaluation of the safety of pregnancy in women with preexisting prosthetic heart valves must take into account the type of valve, the valve position, and the symptomatic state of the patient. Women with prosthetic heart valves and significant symptoms of heart failure have a substantial risk of both maternal and fetal morbidity and should be strongly discouraged from attempting pregnancy. Even in women without symptoms of heart failure, both bioprostheses and mechanical heart valves present significant difficulties in management. Although bioprosthetic heart valves avoid the necessity for systemic anticoagulation, there is substantial evidence that pregnancy and delivery accelerate the deterioration of such valves. This increased incidence of valve failure appears to be related to the amplified hemodynamic stresses and higher calcium turnover associated with pregnancy.

Alternatively, pregnant patients with mechanical heart valves are at substantially increased risk of thromboembolic complications, and no satisfactory anticoagulation regimen exists for these patients. Mechanical valves in the mitral position are more prone to thromboembolic complications than aortic valves. The optimal regimen for anticoagulation in pregnant patients with mechanical heart valves is not well established. Warfarin must be avoided in the first trimester of pregnancy, owing to its harmful effects on embryonic development; it also may increase the risk of spontaneous abortion or premature delivery. Unfortunately, the use of alternative regimens, such as dose-adjusted subcutaneous heparin, is associated with an increased incidence of potentially severe thromboembolic complications, even when there is an appropriate increase in the activated partial thromboplastin time. Subcutaneous heparin, therefore, does not appear to be sufficient as a sole anticoagulation agent during pregnancy, especially in patients with mechanical mitral valves. Additionally, long-term heparin use is associated with an enhanced risk of severe osteoporosis. Low-molecular-weight forms of heparin may offer an effective and safe alternative to unfractionated heparin or warfarin, but little data are available on their use in pregnancy to date. Most authorities recommend systemic heparin therapy during the first trimester of pregnancy, followed by warfarin therapy from 12 weeks of

gestation until 2 to 3 weeks before delivery. Heparin can then be restarted until delivery. Warfarin may be given safely in the postpartum period, even to mothers who are breast-feeding.

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy is defined as cardiomyopathy developing during the last month of pregnancy or the first 5 months postpartum, in the absence of preexisting heart disease or other causes of left ventricular dysfunction. Peripartum cardiomyopathy is a rare disorder—it is seen in 1 in 1,300 to 1 in 4,000 deliveries in the United States. Traditional risk factors for this condition include older maternal age, toxemia, twin pregnancies, and multiparity, though new studies have suggested that women without these risk factors may be equally at risk. The source of this condition is unknown. Multiple autoimmune, infectious, toxic, and metabolic factors have been proposed, but none have been verified. Many investigators have found a high incidence of histologic myocarditis in patients with this disorder, but other studies have not reproduced this finding. We have reported the presence of histologic myocarditis in 78% of women with peripartum cardiomyopathy who underwent endomyocardial biopsy early after the diagnosis was clinically established. Most authorities favor an immunologic origin of this disorder, but definitive triggers for autoimmunity have not been identified.

Eighty percent of women with peripartum cardiomyopathy experience symptoms in the first 4 months postpartum, usually symptoms of congestive heart failure, hemoptysis, or embolic phenomena. These symptoms can be confused with those of other disorders, such as toxemia or pulmonary embolism, and some published series on this disorder have created confusion by including patients who did not fit the strict diagnostic criteria outlined here. The diagnosis can be difficult to establish in patients showing initial signs before or immediately after delivery, when symptoms of dyspnea on exertion or orthopnea may be thought to be related to normal pregnancy. In our experience, patients who experience symptoms soon after delivery tend to have a more severe case than patients whose symptoms develop later. The physical examination of patients with peripartum cardiomyopathy shows standard findings of congestive heart failure, including a third heart sound, pulmonary rales, jugular venous distension, and peripheral edema.

Electrocardiography usually shows non-specific ST- and T-wave changes, and echocardiography typically shows severely depressed left ventricular function, with or without left ventricular dilatation. Pulmonary artery catheterization often indicates increased filling pressures and decreased cardiac output, suggesting a diagnosis of cardiomyopathy. Although endomyocardial biopsy can identify patients with histologic myocarditis, the therapeutic benefit of this finding is uncertain, since immunosuppressive therapy is of unclear benefit in these patients. Our practice is to defer endomyocardial biopsy and pulmonary artery catheterization in patients with peripartum cardiomyopathy, except those patients who fail to improve after 2 weeks of standard heart failure therapy. Standard heart failure therapy in patients who experience peripartum cardiomyopathy after delivery is similar to that in nonpregnant patients and should include ACE inhibitors, diuretics, and digoxin. In patients who show signs of peripartum cardiomyopathy during the last month of pregnancy, ACE inhibitor therapy must be avoided, owing to its potential impact on the fetus. Hydralazine may be safely administered as an alternative afterload reduction agent until after delivery in these patients. Thromboembolic complications are common in this disorder, and anticoagulation is recommended after delivery, especially for those patients with persistent left ventricular dysfunction.

The prognosis for patients with peripartum cardiomyopathy varies. Some patients have spontaneous recovery of left ventricular function, and others progress to end-stage dilated cardiomyopathy. The prognosis of patients who recover left ventricular function is excellent, while the prognosis for patients with persistent left ventricular compromise is similar to that for patients with other forms of dilated cardiomyopathy. No features have been identified that predict which patients are likely to make a spontaneous recovery of left ventricular function. Those who recover ventricular function almost always do so within 6 months of their initial symptoms. In patients who progress to dilated cardiomyopathy, cardiac transplantation has been performed, with long-term outcomes similar to those for age-matched controls.

The safety of subsequent pregnancy in women with a history of peripartum cardiomyopathy is the subject of controversy. Women with persistent left ventricular dysfunction are at extremely high risk with subsequent pregnancies and should be advised against conception. In women who have normalized ventricular function, the risk of recurrence with subsequent pregnancy is unknown. Some authors have reported a substantial incidence of recurrence of cardiomyopathy, while other series have indicated no increased risk with subsequent pregnancy and delivery. Stress or dobutamine echocardiography may identify those patients with apparently normal ventricular function at rest who may lack contractile reserve and therefore be at higher risk of recurrence of heart failure under the physiologic stress of pregnancy.

OTHER CARDIOMYOPATHIES AND CARDIAC TRANSPLANTATION

Patients with preexisting left ventricular dysfunction due to dilated cardiomyopathy are at high risk of both maternal and fetal complications during pregnancy. The hemodynamic stresses of pregnancy increase the likelihood of cardiac decompensation in these patients, and ACE inhibitor therapy must be discontinued owing to its teratogenic effects. The hypercoagulable state of pregnancy also raises the risk of thromboembolic complications in this predisposed population. Dilated cardiomyopathy is therefore considered a contraindication to pregnancy.

Hypertrophic cardiomyopathy is usually tolerated well in pregnancy. The changes in hemodynamics that occur with normal pregnancy may serve to diminish obstruction of left ventricular outflow, making severe symptoms during pregnancy less likely. Outflow obstruction can be exacerbated by the acute increases in cardiac contractility and blood loss that occur during delivery, however, and care must be taken to ensure adequate preload and to avoid excessive diuresis. The presence of arrhythmia in women with hypertrophic cardiomyopathy necessitates a thorough evaluation, since sudden death is the most common mode of death in these patients. The β -adrenergic blocking agents are the drugs of choice if pharmacotherapy is required for treatment of arrhythmia. Digoxin should be avoided, because it may enhance the obstruction to ventricular outflow. Patients with hypertrophic cardiomyopathy should be considered for prophylaxis against bacterial endocarditis during delivery.

Pregnancy in women who have undergone cardiac transplantation frequently is complicated by hypertension and hypercholesterolemia and the necessity of immunosuppressive therapy. Women who become pregnant after cardiac transplantation have a higher risk of rejection as well as preterm delivery and other neonatal complications. Routine surveillance for graft rejection via endomyocardial biopsy must be interrupted in light of concerns regarding fetal radiation exposure, leading to potential delays in the recognition of graft rejection until hemodynamic compromise has occurred. Although successful pregnancy and delivery have been reported after cardiac transplantation, pregnancy in this group is generally considered high risk and is discouraged.

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension (PPH) is a rare disorder of unknown cause, resulting in fixed elevation of pulmonary pressures without evidence of left-sided heart disease, congenital heart disease, or chronic pulmonary emboli. Since this disease disproportionately affects young women, it may be encountered in women who are pregnant or who are considering pregnancy. The prognosis for nonpregnant patients with PPH is grim, and the hemodynamic stresses of pregnancy further exacerbate this condition. Pregnancy in PPH is associated with a maternal mortality rate as high as 50% in the peripartum period; for this reason, pregnancy is contraindicated in the context of PPH. Termination of pregnancy should be recommended to women with this disorder who become pregnant. If delivery is attempted, it should be performed in an intensive care unit with the use of invasive hemodynamic monitoring and subspecialty care in cardiology, maternal–fetal medicine, and anesthesia.

CONGENITAL HEART DISEASE

With improvements in the recognition and treatment of congenital heart disease, more women with these disorders are reaching childbearing age and attempting pregnancy. Although a full discussion of the risks of pregnancy in the various forms of congenital heart disease is beyond the scope of this chapter, several general points can be made. A woman with congenital heart disease who is considering pregnancy should undergo genetic counseling regarding the potential for transmission of congenital heart disease to her children as well as counseling regarding the risks to maternal and fetal health. Children of women with congenital heart disease are at two to tenfold increased risk of having congenital heart disease, depending on the genetics of the specific condition. Treatment of these patients requires a multidisciplinary team approach, including specialists in cardiology, obstetrics, pediatrics, genetics, and anesthesia.

In general, any disorder associated with fixed increases in pulmonary vascular resistance dramatically raises the risk of pregnancy. Eisenmenger syndrome—pulmonary hypertension, right-to-left shunting, and cyanosis—is associated with maternal mortality rates of 40% or more and should be considered an absolute contraindication to pregnancy. As outlined earlier for women with primary pulmonary hypertension, women with pulmonary hypertension stemming from congenital heart disease who attempt delivery should be cared for in an intensive care unit with invasive hemodynamic monitoring. Other forms of uncorrected or partially corrected cyanotic congenital heart disease, such as tetralogy of Fallot, are also associated with poor maternal and fetal outcomes. In general, however, both

maternal and fetal outcomes in noncyanotic forms of congenital heart disease are good.

Women with Marfan's syndrome are at risk of aortic dissection during pregnancy, particularly patients with aortic root dilatation, aortic regurgitation, or left ventricular dysfunction. Women with normal aortic root diameters and ventricular function may undertake pregnancy, although cases of aortic dissection in women without aortic root dilatation have been reported. Other forms of inherited connective tissue disease also may predispose to aortic dissection under the increased hemodynamic stresses of pregnancy and delivery. Women with congenital heart disease who wish to become pregnant should undergo careful cardiac evaluation, including echocardiography and stress testing, to evaluate their cardiac reserve and ability to handle the hemodynamic stresses of pregnancy.

PROPHYLAXIS FOR BACTERIAL ENDOCARDITIS

Indications for bacterial endocarditis are generally similar to those in nonpregnant patients. The American Heart Association guidelines do not recommend antibiotic prophylaxis for women with structural heart disease undergoing uncomplicated vaginal delivery, although other authorities do recommend standard antibiotic prophylaxis before delivery for patients with forms of heart disease for which prophylaxis is indicated. Antibiotic prophylaxis is not required for delivery via caesarean section. The standard regimen is 2 g ampicillin administered intravenously or intramuscularly plus gentamicin, 1.5 mg per kilogram, within 30 minutes of delivery, followed by 1 g amoxicillin taken orally or 1 g intravenous or intramuscular ampicillin 6 hours following delivery. Vancomycin may be used in patients with allergy to amoxicillin or ampicillin.

ARRHYTHMIA MANAGEMENT DURING PREGNANCY

The hemodynamic stresses of pregnancy can exacerbate arrhythmia in women with underlying structural heart disease, such as atrial fibrillation in mitral stenosis, or increase the risk of new arrhythmias in women without known cardiac disease. In women with new, unexplained arrhythmias occurring during the final month of pregnancy or in the first 5 months after delivery, the possibility of peripartum cardiomyopathy must be considered. Pharmacologic management of cardiac arrhythmias during pregnancy is complicated by variations in drug absorption and metabolism, resulting in uncertain therapeutic drug levels and necessitating frequent monitoring to avoid toxicity. Moreover, some commonly used antiarrhythmic medications may have adverse effects on fetal development, especially in the first trimester of pregnancy. The safety of many antiarrhythmic medications commonly used during pregnancy is outlined in [Table 70.1](#) and is discussed herein.

In general, pharmacologic antiarrhythmic therapy should be avoided in pregnancy if at all possible. Some of the class I agents, such as procainamide, quinidine, and lidocaine, are considered safe for use during pregnancy, though their efficacy in the long-term management of malignant ventricular arrhythmias is questionable in nonpregnant patients. Phenytoin is contraindicated in pregnancy owing to a strong potential for teratogenicity with long-term use. It may be given in acute cases for digoxin toxicity. Although there is some concern about the potential for β -blocking agents to cause growth retardation or fetal bradycardia, these agents are considered to be relatively safe for use during pregnancy. Class III agents, such as sotalol and amiodarone, should be avoided in pregnancy, except in the case of life-threatening ventricular arrhythmias. Calcium channel blocking agents are considered relatively safe in pregnancy, but experience is limited, and they should be used with caution. Digoxin is deemed safe for the treatment of supraventricular arrhythmias, though careful monitoring of drug levels is required to avoid the potential for digoxin toxicity. If possible, nonpharmacologic methods should be used to manage arrhythmias during pregnancy. Electrical cardioversion and cardiac pacing can be performed without untoward effects on the fetus. Electrophysiologic studies or catheter ablation procedures should be deferred until after delivery if possible, to avoid the risk of fetal radiation exposure.

MYOCARDIAL ISCHEMIA AND INFARCTION

Myocardial infarction is a rare complication of pregnancy, but it may become more common with the increasing numbers of older women attempting pregnancy. The mortality rate of myocardial infarction in the context of pregnancy is reported to be as high as 50%. Myocardial ischemia during pregnancy may stem from coronary artery disease, coronary vasospasm, a hypercoagulable state such as the antiphospholipid antibody syndrome, or coronary dissection. Coronary dissection is a rare cause of myocardial ischemia, but it is more common in pregnancy, especially in the immediate postpartum period. Significant fixed coronary artery disease is rare in women of childbearing age, but it could become more common as more women defer childbearing until later in life. In general, women with known coronary artery disease before pregnancy should be discouraged from becoming pregnant, given the increased metabolic demands of the normal changes in cardiovascular physiology, which may worsen symptoms of angina and myocardial ischemia.

Women with coronary artery disease who do become pregnant usually can be treated successfully with medical therapy. If diagnostic testing or risk stratification is required, stress or dobutamine echocardiography should be used, instead of radionuclide techniques. Management of acute coronary syndromes in pregnant patients is complicated by the difficulty in applying the standard therapies used for nonpregnant patients. Thrombolytic therapy should be considered high risk, though little data exist on its use in pregnancy. Heparin may be administered as an antithrombotic agent. Low-dose aspirin, β -blocking agents, and nitrates can be used with caution to treat myocardial ischemia. Calcium channel blocking agents, such as nifedipine, can be administered if coronary vasospasm is suspected.

Coronary angioplasty has been performed during pregnancy, but it should not be done unless absolutely necessary, to avoid fetal radiation exposure. No data exist on the use of primary angioplasty for acute myocardial infarction in pregnant patients. Cardiopulmonary bypass surgery may be attempted during pregnancy if it is required, but it is associated with substantial risk to the fetus from hypothermia and decreased perfusion of the uteroplacental unit. If cardiopulmonary bypass is required, normothermic bypass at high flow volumes is recommended. Patients at more than 20 weeks' gestation should be placed in the left lateral decubitus position to prevent uterine obstruction of venous return. Preparation must be made for emergency caesarean section, in case of severe fetal distress during surgery.

and orthostatic hypotension may respond to nonselective β -blockade. Such β -blockers as propranolol, which block both the β_1 - and β_2 -adrenoreceptors, can assist in the treatment of orthostatic hypotension by preventing the vasodilatory effect of beta stimulation.

SHOCK

The first known references to the clinical entity of shock came from the eighteenth century in descriptions of dying, war-wounded French soldiers, who were seen to *secousse* (jar) and *ébranlement* (shake). This term was later translated by the English to the expression currently in use (shock). The condition of circulatory shock is a syndrome that occurs when the blood perfusion of the body's organs and tissue is inadequate to meet the ongoing metabolic needs of the cells. If the condition persists, it results in multisystemic derangement of function, organ damage, cell injury, and death.

The initial physiologic response to shock is compensation to the reduction in cardiac output or hypotension. The body responds to the ineffective circulating volume or pressure by recruiting a series of mechanisms of action directed at maintaining adequate perfusion pressure and flow, particularly to vital organs (brain, heart, lungs). Vascular and cardiac baroreceptor reflexes are activated by hypotension, diminished flow, and reduced wall tension (and chemoreceptors by hypoxia) to heighten sympathetic nervous system tone and enhance norepinephrine release at the nerve ending, with eventual spillover into the systemic circulation. The adrenomedullary production and release of epinephrine is enhanced. The renin-angiotensin-aldosterone axis is activated by the heightened sympathetic tone and by a drop in renal blood flow. The elevated angiotensin II levels, along with the augmented sympathetic activity, constrict systemic arterioles to increase systemic blood pressure. The increase in aldosterone and the drop in renal blood flow and glomerular filtration rate lead to salt and water retention by the kidneys. Antidiuretic hormone is released in shock states by a number of nonosmotic stimuli, including angiotensin II, heightened sympathetic tone, and reflex release through volume receptors (e.g., atrial volume-stretch receptors), resulting in water retention.

The retention of salt and water, combined with the constriction of venous capacitance beds by enhanced sympathetic tone, increases central venous and cardiac blood volume, thus augmenting stroke volume and cardiac output. Cardiac output also is increased by baroreceptor reflex-induced tachycardia. The shock syndrome can be arrested at this point if the underlying cause abates or if the condition is recognized early and is effectively treated. If the condition remains untreated or progresses despite the maximal recruitment of compensatory mechanisms, the patient enters the stage of organ and tissue hypoperfusion and dysfunction, which eventually advances into the final stage of cell injury and death.

CLINICAL MANIFESTATIONS OF SHOCK

Appreciating the spectrum of the clinical manifestations of shock is crucial to making the distinction between hypotension and shock and to monitoring the course and treatment of shock. The initial symptoms and signs of circulatory shock represent the clinical and laboratory test indications of multisystemic hypoperfusion and dysfunction, multiple organ dysfunction and failure, widespread cell injury and death, and the body's responses to this threatening situation. The diagnosis of the shock syndrome is made on the basis of the resulting symptoms and clinical signs ([Fig. 71.1](#)).

FIGURE 71.1. Major steps in the management of circulatory shock. The evaluation and treatment of the shock patient must occur simultaneously and in a proficient manner.

BLOOD PRESSURE AND PULSE

Although blood pressure and pulse are not the *sine qua non* of shock, they remain central factors and should be checked at frequent intervals. The pulse of a patient in shock may be found to be rapid and faint, or “thready.” Reduction of stroke volume in patients in advanced stages of shock may result in blood pressure so low that the usual Korotkoff sounds are not heard with a stethoscope. In this case, a portable Doppler apparatus may aid in the definition of lower systolic pressures. An intra-arterial catheter can be helpful in providing a measurement of the arterial pressure on a continuous basis.

SKIN

Intense vasoconstriction of dermal and subcutaneous arterioles occurs during states of systemic hypoperfusion. The skin, lips, and nail beds appear pale to light blue. The skin becomes cool to the touch, and the palms are frequently moist. In prolonged shock, skin necrosis and ulcers may develop on the digits, particularly when the cutaneous vasoconstriction is complicated by prolonged administration of vasopressor drugs (norepinephrine, dopamine) or the presence of occlusive peripheral vascular disease or coagulopathy. Skin temperature and color may be normal or even warm and pink during the early stages of the venovasodilatory forms of shock (septic shock); the term *warm shock* has been used in this context.

CARDIOVASCULAR SYSTEM

The cardiovascular manifestations of shock generally are a result of inadequate perfusion of organs and tissue. In the hypovolemic and cardiogenic forms of shock, systemic hypoperfusion is related to depressed cardiac output; in the vasodepressor (venovasodilatory) shock states, an abnormality in blood distribution and delivery causes hypoperfusion, despite normal or high cardiac output. A reduction in diastolic arterial pressure to 60 mm Hg or less results in a substantial drop in myocardial perfusion. Myocardial ischemia, particularly of the subendocardial region, is likely to occur in patients with severe untreated shock. During the advanced and terminal stages of shock, certain metabolic factors (e.g., acidosis) also may contribute to myocardial depression.

PULMONARY SYSTEM

Ventilatory defects or ventilation—perfusion mismatch is common in all stages of shock and can account for a significant reduction in the oxygen content of blood. These abnormalities can arise in the context of clear lung fields, as evidenced on physical examination, but often are accompanied by radiographic evidence of atelectasis and diffuse alveolar and interstitial infiltrates. Arterial hypoxemia is markedly exacerbated if adult respiratory distress syndrome (ARDS) develops. The formation of ARDS lung edema is enhanced by an elevation of pulmonary capillary wedge pressure or a drop in plasma oncotic pressure, but neither is a requirement. Cardiogenic forms of shock can result in pulmonary edema on the basis of high left ventricular filling pressure, which is transmitted to the pulmonary vasculature as high pulmonary venous and pulmonary capillary pressures. ARDS and cardiogenic pulmonary edema may exist together in the same patient (see [Chapter 357](#)). The clinical manifestations of bronchoconstriction (wheezing, hypoxemia) may be noted in patients with anaphylactic shock, massive pulmonary embolization, or cardiogenic shock accompanied by high left ventricular filling pressures.

KIDNEYS

Shock with renal hypoperfusion often impairs sodium and water excretion. At this stage, urine output is reduced but generally remains at a level more than 20 mL per hour. The urine sodium concentration drops below 15 mEq per liter, and urine osmolality increases and remains above 400 mOsm. The plasma blood urea nitrogen

(BUN)/creatinine ratio increases to more than 10:1; the urine/plasma ratio of BUN remains above 5 and that of creatinine above 30.

Acute renal failure may develop in severe or advanced shock; this threatening condition is often accelerated by underlying renal disease or various drugs (certain antibiotics, nonsteroidal antiinflammatory drugs). In contrast to hypoperfused (but functioning) kidneys, kidneys in failure show signs of dysfunction and anatomic disruption of tubules. Urine sodium concentration usually exceeds 40 mEq per liter, urine osmolality approaches that of plasma (less than 350 mEq per liter), and urine output usually drops to less than 20 mL per hour. Plasma BUN and creatinine values rise, but the plasma BUN/creatinine ratio usually remains at 10:1 or less; the urine/plasma ratio of BUN drops to less than 3 and that of creatinine to less than 20. Coarse granular, renal tubular, or pigmented casts may appear in the urinary sediment. A form of renal failure with high urine output (more than 40 mL per hour) occurs in isolated instances and can occasionally follow a period of oliguric renal failure.

GASTROINTESTINAL SYSTEM

Varying degrees of gastrointestinal hemorrhage that result from gastritis, stress ulcers, and scattered mucosal erosions are common in all stages of shock. Adynamic ileus is not uncommon. Severe shock can cause bowel infarction on the basis of hypoperfusion and intense vasoconstriction, particularly in patients with concomitant mesenteric atherosclerosis. Hepatic hypoperfusion can lead to an elevation of the plasma levels of enzymes, indicating liver cell injury, which may evolve into hepatic necrosis in severe shock. Icterus, a common sign in shock, stems from the liver's inability to conjugate and excrete bilirubin and occasionally to an increased bilirubin load (hemolysis). Hypoglycemia, hypoalbuminemia, depressed clotting factors, and elevated blood lactic acid and ammonia levels may be caused or exacerbated by hepatic hypoperfusion and dysfunction. Plasma amylase may increase as the result of the release of amylase from the pancreas.

NERVOUS SYSTEM

The patient's mental status may range from anxiety in mild shock to confusion, combativeness, lethargy, disorientation, and somnolence in moderate levels of shock and on to obtundation and coma in prolonged or severe stages of shock. Although hypoperfusion is the predominant underlying cause of these symptoms and signs, metabolic factors (hypoglycemia, uremia, hyperammonemia) may contribute to them. Marked cerebral hypoperfusion, ischemia, and edema may elicit decorticate or decerebrate posturing. Advanced stages of shock often are accompanied by dysfunction of vital control centers of the central nervous system, such that abnormal cardiac, vascular, and ventilatory control may ensue. The resulting manifestations include inappropriate heart rate responses, refractory vasodilatation, pooling of intravascular volume in capacitance vascular beds, abnormal ventilatory patterns, inadequate or inappropriate ventilatory responses to acid–base shifts, and profound depression of ventilatory drive.

HEMATOLOGIC SYSTEM

The hematocrit varies widely among patients in shock, depending on the status of extracellular fluid shifts, blood loss, and volume replacement. Varying degrees of coagulopathy stemming from endothelial injury, platelet activation, and hepatic dysfunction are seen in many patients in shock. Disseminated intravascular coagulation (DIC) with diffuse uncontrollable hemorrhage often accompanies terminal stages.

IMMUNE SYSTEM

Although they are not yet well delineated in the context of circulatory shock, immunologic derangements (dysfunction of the reticuloendothelial system, leukocyte dysfunction) may well contribute to the predisposition to infectious complications in the patient with shock. Immune mechanisms play a role in the local release of histamine, cytokines, and other substances in various shock conditions and occupy center stage in the pathophysiologic picture of anaphylactic shock.

MUSCULOSKELETAL SYSTEM

Hypoperfusion of skeletal and muscle structures, in part related to vasoconstriction, can evoke complaints of myalgia, arthralgia, and bone pain. Elevated plasma levels of lactate, creatine phosphokinase (MM type), and other muscle enzymes and myoglobin are manifestations of hypoperfusion of muscle. The release of lactate (lactic acid) from the body's largest organ, skeletal muscle, contributes greatly to the metabolic acidosis present in many shock patients, and the release of myoglobin may contribute to the development of renal failure.

CAUSATIVE CLASSIFICATION OF CIRCULATORY SHOCK

A classification of shock according to causative factors is presented in [Table 71.2](#). In the care of critically ill patients, it is crucial to understand the causative classification of shock because the most important step in the management of this condition is to recognize and treat the underlying cause.

The diagram is a flowchart titled 'GENERAL ETIOLOGIC CLASSIFICATION OF CIRCULATORY SHOCK'. It branches into three main categories: Hypovolemic Shock, Cardiogenic Shock, and Distributive Shock. Hypovolemic Shock is further divided into Hemorrhagic and Non-hemorrhagic. Cardiogenic Shock is divided into Left-sided and Right-sided. Distributive Shock is divided into Anaphylactic, Septic, and Neurogenic. Each category lists specific etiologies and clinical features.

TABLE 71.2. GENERAL ETIOLOGIC CLASSIFICATION OF CIRCULATORY SHOCK

HYPOVOLEMIC SHOCK

Shock caused by a severe reduction in intravascular volume generally is referred to as hypovolemic shock. This type of shock also has been termed *cold shock* because peripheral hypoperfusion and vasoconstriction result in cold distal extremities. The severity of hypovolemic shock typically is related to the amount and rate of loss of intravascular volume and the responsiveness of the compensatory mechanisms (vasoconstriction, salt and water retention by the kidneys) to the sudden or excessive loss of volume. An acute loss of intravascular volume of 25% or more is required to place a normal person in circulatory shock. Losses in excess of this amount usually overwhelm the compensatory mechanisms and result in severe hypotension and inadequate tissue perfusion. Loss of the same volume over a number of days may not elicit the shock syndrome because, with adequate time, the compensatory responses can reestablish and maintain sufficient intravascular volume and tissue perfusion. Aging and various disease states can reduce the volume loss required to produce circulatory shock and diminish the proficiency of the compensatory responses to avert the development of shock during volume loss.

The most common form of hypovolemic shock is that caused by blood loss, usually through injury. Patients may lose large volumes of blood externally through open lacerations or gastrointestinal lesions or by severe hemoptysis. A source of bleeding may be more difficult to define when the hemorrhage is located in internal body cavities or tissues. For example, each side of the chest cavity can hold 2 to 3 L of blood. Other sites of internal bleeding leading to shock may include the peritoneal space, retroperitoneum, pelvis, and tissues surrounding large bone fractures.

Hypovolemic shock also may occur when plasma volume or extracellular fluid is lost. The patient with major burns can lose large amounts of extracellular fluid into the burn wound, owing to edema and loss of the skin barrier. Similarly, patients with desquamating or exudative skin lesions also may experience hypovolemic shock. A less common source of hypovolemic shock is severe gastrointestinal dumping syndromes due to interference with the normal pyloric mechanism. Contraction of the intravascular space results from hyperosmolar solution in the small intestine. This combines with the release of vasoactive hormones (serotonin, bradykinin, and

vasoactive intestinal peptide) to lead to what can be a severe hypotensive condition.

Dehydration can result from a variety of conditions ([Table 71.2](#)), which can produce hypovolemic shock. Gastrointestinal losses from vomiting and/or diarrhea are common in infants and in others infected with viruses, bacteria, or parasites. High urine output states, such as diabetic ketoacidosis, diabetes insipidus, renal tubular injury, and overaggressive diuresis, are common sources of hypotension and hypovolemic shock. Lack of fluid intake, inadequate fluid replacement, or excess sweating can also lead to dehydration and hypovolemic shock.

INCREASED VASCULAR CAPACITANCE

Shock precipitated by marked venous dilatation is often referred to as distributive shock, because the central blood volume is redistributed to the peripheral vasculature, particularly to venous capacitance beds. In a broad sense, venodilatory shock could be considered a type of hypovolemic shock, since the increased vascular capacitance of these patients causes a reduction of central venous pressure, leading to inadequate diastolic filling of the ventricles. In many cases, venodilatory shock can be appropriately termed *warm shock*. In contrast to the vasoconstriction of hypovolemic shock, venodilatory shock commonly is associated with hyperthermic or normothermic hands and feet, at least until intense cutaneous vasoconstriction develops during the later stages. Although venodilatory shock can be caused by a number of factors ([Table 71.2](#)), sepsis and drugs are the most common sources.

Severe sepsis is the most common form of increased vascular capacitance, or venodilatory, shock. The study of the sepsis syndrome has elucidated several factors that may contribute to the deterioration to shock. Endotoxin produced by gram-negative bacteria is one of the major factors leading to the fever, systemic hypotension, and tachycardia that characterizes septic shock. Nonetheless, septic shock unrelated to endotoxin may result from infections caused by gram-positive organisms, viruses, *Rickettsiae*, and fungi. Infections also lead to host responses that feed into the syndrome of septic shock. One key element of this response is cytokines. The toxic stimulus (endotoxin) triggers the production of the proinflammatory cytokines tumor necrosis factor and interleukin-1. These compounds promote adhesion of polymorphonuclear cells to the site of the infection, which then produce numerous secondary inflammatory mediators, such as prostaglandins, leukotrienes, bradykinin, and proteases. The hypotensive state created by sepsis mediators may lead to cardiac end-organ damage. Myocardial contractility may also be reduced, owing to circulating myocardial depressant factors and/or DIC.

Anaphylactic shock usually manifests precipitously in response to exposure to an antigen, either in the natural environment or as a result of drug administration. In sensitized persons, the antigen interacts with the IgE-specific antibody on mast cells and other cell surfaces. Mediators liberated from the stimulated cells include histamine, serotonin, kinins, cytokines, and others. Life-threatening anaphylaxis may occur within minutes after exposure to the antigen and is characterized by a varying combination of venodilatation, respiratory distress from laryngospasm or bronchospasm, reduction of plasma volume with hemoconcentration, abdominal discomfort, and diarrhea, pruritus, and urticaria.

Shock may also arise from loss of hypotension induced by exogenous vasodilatory agents, such as anesthetics and antihypertensive agents. Patients taking an overdose of prescription or illicit barbiturates, benzodiazepines, or narcotics may experience increased vascular capacitance shock. Hypovolemia, if present, can greatly enhance the tendency to shock in patients taking these medications.

Injury to the spinal cord can produce systemic vasomotor paralysis in the areas caudal to the injury. The loss of peripheral vascular resistance in the involved area can precipitate a drop in central venous pressure, leading to low cardiac output and subsequent organ failure. There is a similar scenario in some patients with cerebral injury and in patients with severe dysautonomia. The drop in systemic blood pressure will usually respond to administration of intravenous fluids or vasoconstrictive medications.

Heat stroke, caused by the inability of the body to dissipate heat fast enough to regulate body temperature, can lead to a form of venodilatory shock. In these patients, the body temperature rises to 40°C or higher, with ensuing cutaneous vasodilatation and low peripheral resistance. In this sense, heat stroke is a form of stroke caused by increased vascular capacitance, but it may also be complicated by dehydration, myocardial depression, and DIC.

CARDIOGENIC SHOCK

Shock states associated with cardiac pump failure, generally referred to as cardiogenic shock, are those caused by impaired ventricular systolic performance, inadequate ventricular diastolic filling, cardiac valvular dysfunction, or a combination of these. In cardiogenic shock the impairment of cardiac function leads to compromised oxygen delivery and resultant organ dysfunction and ischemia. Renal responses to depressed cardiac output and systemic pressure (reduced glomerular filtration, increased renin secretion) are often the most sensitive indicator of severe myocardial dysfunction, thus leading to progressive vasoconstriction and salt and water retention. Ventricular filling pressures rise in response to renal factors, leading to a tendency for pulmonary edema and hypoxia and progressive cardiac dysfunction.

Acute myocardial infarction is the most common cause of cardiogenic shock (see [Chapter 73](#)). Shock occurs in 5% to 10% of patients hospitalized for acute myocardial infarction and implicates a 40% or higher loss of functioning ventricular myocardium. The Multicenter Investigation of the Limitation of Infarct Size trial determined that older age (more than 65 years), reduced ejection fraction (less than 0.35), infarct size (MB-CPK more than 160 IU per liter), diabetes mellitus, or previous myocardial infarction magnified the probability of cardiogenic shock developing after acute myocardial infarction. Rupture of the ventricular free wall or septum happens in 1% to 2% of patients with acute myocardial infarction and is often heralded by hypotension and shock.

Despite advances in hemodynamic monitoring, pharmacologic intervention, and intra-aortic balloon counterpulsation, the in-hospital mortality rate for postinfarction cardiogenic shock remains higher than 75%. Several studies (uncontrolled) have shown, however, that early reperfusion (within the first 6 to 12 hours) by coronary angioplasty or bypass surgery can reduce in-hospital mortality rates to less than 60%, with probable improvement in long-term survival as well. In-hospital deaths appear to be related directly to age, infarct size, extent of hemodynamic decompensation, and lack of early reperfusion.

Factors other than ischemia can contribute to the development of cardiogenic shock in patients with myocardial infarction. For example, with infarction of the inferior wall, bradycardia and hypotension may be induced by myocardial vagotonic reflexes (Bezold-Jarish reflex); parasympatholytic (atropine) therapy improves this transient, but potentially lethal event in most patients.

Cardiogenic shock may develop in patients with acute myocardial injury from the myocarditides or in patients with severe progressive systolic dysfunction from chronic cardiomyopathy or chronic valvular dysfunction. In these patients, shock is characterized by systemic hypotension (systolic blood pressure less than 90 mm Hg) and depressed cardiac index (less than 2.0 L per minute per square meter) despite an elevated pulmonary capillary wedge pressure (more than 15 mm Hg). Many patients with chronic myocardial weakness may be able to compensate to this level of hemodynamic derangement and remain ambulatory until more critical thresholds are reached.

Acute mitral valvular insufficiency, such as that caused by rupture of the chordae tendineae or papillary muscle, can lead to shock on the basis of inadequate ejection of blood into the aorta. Sudden activation of atrial stretch receptors and reflexes can contribute to hypotension and the hypoperfusion state of massive acute mitral regurgitation. Certain cardiac dysrhythmias, such as ventricular tachycardia or rapid supraventricular tachycardia, often lead to inadequate filling or emptying of the ventricles. The ventricle in fibrillation or asystole does not eject any blood; if this condition is not corrected, shock and death are imminent.

Acidosis can produce myocardial depression in patients who have a pH of less than 7.10 to 7.15. In this context, impaired myocardial function may be associated with the generation of the free radicals O_2^- and OH^- . Severe acidosis also tends to cause arterial vasodilatation, venous vasoconstriction, and a tendency to capillary stasis. Myocardial function may also be depressed in the context of acidosis, owing to the development of DIC and/or pulmonary vasoconstriction. When acidosis alone is the cause of cardiac dysfunction, correction of acidosis by treating the source of the problem (ketoacidosis, uremia, severe diarrhea) will usually result in improved myocardial function.

OBSTRUCTION TO FLOW

Failure of the heart's pumping mechanism also may result from inadequate filling of the ventricles. The prototype for inadequate ventricular filling is pericardial tamponade, in which the pericardial space is filled with fluid or blood under high pressure, preventing adequate filling of the ventricular and atrial chambers. The resultant stroke volume is small, and the heart rate increases in response to the progressive reduction in stroke output. If cardiac output cannot be adequately

maintained, blood pressure falls, and shock ensues.

A massive pulmonary embolus may lead to circulatory shock by preventing the emptying of the right ventricle and the filling of the left ventricle. Other causes of shock from obstruction to flow include tension pneumothorax, dissecting aortic aneurysm, and occlusive intracardiac tumors or thrombi. Patients with low central venous pressures may have hypotension and low cardiac output in response to positive pressure ventilation, a form of shock caused by obstruction to flow.

CLINICAL APPROACH AND MANAGEMENT OF SHOCK

Although it is more convenient to discuss the evaluation and treatment of shock separately, the optimal management of shock conditions never allows the separation of these activities. When a patient first shows physiologic signs of shock, a source is not always apparent. The severe hemodynamic derangement and impending organ damage and/or death compel the physician to initiate empirical treatments in an attempt to resuscitate the patient and prevent or minimize long-term consequences. The goal is to stabilize the patient so that definitive diagnosis and treatment are possible.

INITIAL EVALUATION AND TREATMENT

The first step is the recognition of shock, with all subsequent activity directed at stabilizing and treating the shock condition while aggressively and systematically determining the cause. The patient in shock often enters the emergency department with historical evidence (chest pain, recent penicillin injection) or physical signs (trauma, hematemesis) of the cause of shock. In these situations, diagnostic and therapeutic activity is directed toward the suspected problem. Many patients in shock, however, do not have any initially obvious historical or physical clues regarding cause. If the patient is intact mentally, the physician must systematically direct a series of questions to the patient. Many patients in shock enter the emergency department in a lethargic or obtunded state. In this case, the emergency medical technicians, police, family members, or friends accompanying the patient must be questioned. In such cases, an examination of the patient's purse, wallet, and pocket contents for information on medical history, medications, the patient's primary physician, and a friend or relative is usually necessary.

As the patient's clothes are being removed, the physician usually performs a general inspection and palpatory examination, looking for signs of infection, blood loss, trauma, needle marks, and systemic illness. The physical evaluation then must incorporate an examination of the head and neck and major organ systems and regions, including a rectal examination with stool guaiac testing. The physical examination, in concert with the historical information, should at this point provide important clues to the cause and severity of shock and suggest a direction for further diagnostic studies and treatment. Decisions on therapy must parallel all of this activity. With respect to cardiopulmonary resuscitation and life-support measures, the need to initiate these interventions may precede the history, the physical examination, and any laboratory testing. The physician also must be alert to the fact that these life-support measures may have to be instituted, based on established criteria, anywhere along the clinical course.

If the patient appears to ventilate adequately throughout this early course and the initial set of arterial blood gases shows sufficient oxygenation without hypercapnia, a mask oxygen-delivery system would suffice. An arterial blood sample, however, should be drawn, and the blood should be monitored regularly for gases (partial pressures of oxygen [PO_2] and carbon dioxide [PCO_2]), pH, and lactic acid concentration. If ventilation appears to be inadequate or the arterial blood gas studies indicate hypoxemia or hypercapnia, the patient should be intubated and given assisted ventilation. A catheter should be introduced into an artery, to provide continuous direct recordings of systemic blood pressure and to serve as a convenient conduit for obtaining arterial blood samples. Blood pressure readings using a cuff sphygmomanometer during shock are usually inaccurate or not obtainable, particularly when marked reflex vasoconstriction is present. Conversely, it is imperative not to delay therapy for shock for the sake of placing an arterial catheter.

Twelve-lead electrocardiography is performed early in shock management, particularly for rhythm disturbances or if it is reasonable to suspect that myocardial ischemia–infarction will lead to the patient's demise (because of a history of coronary disease or risk factors). If ischemia or an infarction pattern is present on the electrocardiogram, the physician should consider administering thrombolytic therapy or should call the cardiologist to perform emergency cardiac catheterization/coronary angiography in the patient entering cardiogenic shock, with the intent of achieving early reperfusion via angioplasty or coronary bypass surgery.

The insertion of an intravenous catheter of sufficient size (16 gauge or larger) soon after the patient arrives in the emergency department is important from both a diagnostic and a therapeutic standpoint. As the catheter is inserted, blood samples can be drawn for appropriate laboratory studies (hematocrit, hemoglobin, total white blood cell count with differential cell count, serum electrolytes, glucose, BUN, creatinine, and calcium). About 30 mL of the blood should be refrigerated in the event that a certain analysis is needed on baseline or untreated blood at a later point. In patients with depressed mental status or a history of diabetes mellitus, 50 mL of 50% dextrose solution should be injected into an intravenous line immediately after the withdrawal of blood, to treat the possibility of insulin-induced hypoglycemic shock or shock-induced hypoglycemia. Unless signs of hypervolemia are present, fluid (0.9 N sodium chloride) should be infused as rapidly as possible. Precise recording of fluid input and output and all medications administered begins at this time. Serum electrolytes must be tested on a regular basis throughout the clinical course.

If marked hypotension (systolic pressure less than 70 mm Hg) persists after the rapid infusion of more than 2,000 mL of fluid and in the absence of evidence of hypervolemia, the patient is treated by additional volume administration and low infusion rates of a pressor, such as dopamine (starting at 4 to 5 μ g per kilogram per minute). Packed red blood cells should be administered if blood loss was the cause or a major contributor to the shock syndrome. In general, systolic and mean arterial pressures should be brought up to at least 80 mm Hg and at least 65 to 70 mm Hg, respectively, to perfuse the brain and kidneys, and the diastolic pressure should be brought up to at least 60 mm Hg, to perfuse the heart.

The placement of a balloon-tipped, flow-directed pulmonary artery (Swan-Ganz) catheter in the pulmonary artery is one of the early steps in the management of cardiogenic shock. Determination of the left ventricular filling pressure (usually approximated closely by the pulmonary capillary wedge pressure) is crucial in the appropriate and proficient treatment of cardiogenic shock. As many as 20% of patients with acute myocardial infarction and hypotension or shock have inadequate left ventricular filling pressures, some cases caused by volume depletion and others by infarction predominantly involving the right ventricle. Left ventricular filling pressure is poorly estimated by clinical examination, even when it is accompanied by a chest film and central venous pressure recordings.

The Swan-Ganz catheter can greatly assist the physician in the treatment of the shock patient. Placement of this catheter must be considered at this point, particularly if the patient has not yet responded to the previously mentioned therapeutic measures or if a cardiogenic basis for the shock condition is suspected. The pulmonary artery catheter, when interfaced with a pressure-recording system and a thermodilution cardiac output computer, gives an assessment of right and left ventricular filling pressures, cardiac output, stroke volume, and pulmonary arterial pressures. When combined with the data derived from the indwelling systemic arterial catheter, several other hemodynamic parameters can be derived (vascular resistances, stroke work index).

From the directly measured and derived parameters, the physician can rationally direct fluid volume administration and pharmacologic support. For example, a condition of low right and left ventricular filling pressures, low cardiac output and systemic blood pressure, and peripheral hypoperfusion is managed by the additional administration of fluid volume. The same recordings in the context of high cardiac output and low pulmonary and systemic vascular resistances, particularly if marked hypotension or shock persists after more than 3,000 mL of volume administration, suggest a state of profound arteriovenous vasodilatation (sepsis); additional volume administration and vasopressor therapy (dopamine) serve as the primary circulatory support measures in this situation.

The measures used to improve and stabilize cardiovascular status are monitored by the combination of left and right ventricular filling pressures, systemic blood pressure, cardiac output, and clinical status (tissue and organ perfusion, urine output, symptoms). If a patient with infarction-induced cardiogenic shock is found to have a low (less than 12 mm Hg) left ventricular filling pressure, intravenous fluid administration (0.9 N sodium chloride) is begun immediately and continued to bring the left ventricular filling pressure to 15 to 18 mm Hg. If systemic blood pressure, peripheral perfusion, and clinical status improve to a relatively normal level, fluid administration is continued and monitored to keep left ventricular filling pressures at 12 to 18 mm Hg. If the same patient's systemic blood pressure returns to normal (more than 100 mm Hg systolic) but tissue and organ perfusion remains compromised (particularly if cardiac output is less than 2.20 L per minute per square meter), the judicious infusion of a vasodilator is warranted. Nitroglycerin is usually the initial intravenous vasodilator selected. Nitroprusside is a more powerful vasodilator and is chosen when a higher level of afterload reduction is required.

A nasogastric tube should be inserted and the gastric contents visually examined for blood and tested for a guaiac reaction. If the cause of shock is unknown, the gastric specimen should be sent to the special laboratories of the hospital for toxicologic analysis. The nasogastric tube is placed on continuous suction, and the volume withdrawn is recorded. Of course, if gastrointestinal bleeding is suggested earlier as a cause of shock, the nasogastric tube is put in place earlier in the course

of treatment.

DIRECTED EVALUATION AND TREATMENT

The management of shock at this point is based on the identification of the type of shock.

Hypovolemic Shock

When hypovolemic shock is recognized, initial management includes elevation of the legs and rapid volume replacement. As the solution is being infused at wide-open rates, a central pressure–monitoring catheter (a flow-directed, balloon-tipped pulmonary artery catheter or, if no cardiopulmonary disease is apparent or suspected, a central venous pressure line) is inserted. Using arterial pressure and systemic perfusion as major end points, the intravascular volume is expanded to raise the central venous pressure to 8 to 12 mm Hg or the pulmonary artery occlusive (pulmonary capillary wedge) pressure to 15 to 18 mm Hg. If the patient remains hypotensive or in shock at these levels, a cardiogenic component must be considered. If the ventricular filling pressures remain low after the infusion of a substantial volume (at least 4 L) and shock persists, continued volume loss or an arteriovenous vasodilatory component must be considered as contributory factors.

There is no single optimal ventricular filling pressure for all patients in shock. A pulmonary capillary wedge pressure of 18 mm Hg may be required to bring cardiac output into an acceptable range in a patient with acute myocardial infarction, whereas a wedge pressure above 15 mm Hg may evoke pulmonary edema in a septic patient with low plasma oncotic pressure. If the plasma oncotic pressure minus the pulmonary capillary wedge pressure exceeds 8 to 10 mm Hg, the risk of pulmonary edema is small. If, however, the wedge pressure approaches or exceeds the plasma oncotic pressure, or if capillary endothelial cell injury has occurred, pulmonary edema is likely to develop. As shock enters a protracted phase and is complicated by pulmonary edema or arterial hypoxemia, the determination of plasma oncotic pressure occasionally may be useful in guiding volume replacement.

Packed red blood cells are given to patients with a depressed hematocrit (30% or less) to expand intravascular volume with little pulmonary extravascular leakage. Local or surgical control of bleeding is obviously important and is initiated early to prevent additional blood loss. Although they are the subject of controversy, large-molecular-weight colloids can be used in an attempt to restrict the administered fluid volume to the intravascular space. The colloids include human serum albumin, plasma substitutes, and glucose polymers (dextrans, hydroxyethyl starch). Human serum albumin, 5 g per deciliter, is an effective but expensive volume expander, particularly in patients whose clinical courses may be adversely affected by low serum albumin and low plasma oncotic pressure. Plasma itself carries the risk of transmitting hepatitis (as does whole blood), and although purified plasma protein derivatives do not transmit hepatitis, they do contain vasoactive contaminants that can cause hypotensive reactions.

The regular use of dextrans (glucose polymers produced by streptococci) has been tempered by their serious side effects, which include anaphylactic reactions, bleeding through interference with platelet function and coagulation, and renal dysfunction. Hydroxyethyl starch (hetastarch), another polysaccharide colloid volume expander, is generally nonallergenic, causes fewer bleeding complications (in doses less than 1,500 mL), and does not lead to renal failure. In contrast to packed red blood cells, a major limitation of the crystalloid and colloid volume expanders is their eventual escape into and equilibration with extravascular spaces, particularly in patients with loss of capillary integrity (ARDS, septic shock).

Increased Vascular Capacitance Shock

A characteristic feature of venovasodilatory shock is its refractoriness to volume-replacement therapy. The acute administration of 4 L or more may have little effect on central filling or systemic pressures or on the clinical manifestations of the shock state. Although intravascular capacity is greatly increased in most of these patients, much of the fluid administered enters extravascular spaces by a drop in the ratio of precapillary to postcapillary sphincter tone and, occasionally, through enhanced capillary permeability. Some patients respond to volume administration alone, but most also require a therapeutic intervention directed at reducing intravascular capacity or effecting a more normal distribution of intravascular volume by augmenting vascular tone.

The patient with marked hypotension (systolic pressures less than 70 to 75 mm Hg) due to venovasodilatory shock is treated initially with vasopressor therapy, such as phenylephrine. Phenylephrine is initiated as a 1 µg per kilogram intravenous loading dose, followed by a drip at 0.5 µg per kilogram per minute; dosing is advanced as needed up to a maximal dose of 5 µg per kilogram per minute (until the mean arterial blood pressure exceeds 65 to 70 mm Hg). Dopamine, given at a starting dose of 5 µg per kilogram per minute and gradually advancing the infusion rate to 10 to 15 µg per kilogram per minute, as needed, may be helpful in patients with severe hypotension and poor renal perfusion. Norepinephrine bitartrate, 0.05 to 0.20 µg per kilogram per minute, may be used in patients who appear to be unresponsive to phenylephrine or dopamine.

As in all forms of shock, the crucial factor for improvement and survival is the prompt recognition and treatment of the underlying cause. It is usually not that difficult to recognize the neurogenic causes of venovasodilatory shock (cerebral or spinal cord injury); diagnosis is based primarily on a good clinical examination. The pharmacologic causes of shock that occur in the hospital or clinic (anesthesia, drug therapy) are readily identifiable and treatable with fluid volume and vasopressors. A similar therapeutic approach can be implemented for unknown drug overdose, with consideration given to the administration of naloxone in certain instances (narcotic overdose). The therapy of anaphylaxis should be initiated immediately on making the diagnosis and includes removing the antigen source or load, if feasible, and administering epinephrine, 0.1 mg intravenously and 0.4 mg subcutaneously. Other support drugs might include bronchodilators, antihistamines, and glucocorticoids.

One of the most difficult forms of venovasodilatory shock to diagnose early is septic or endotoxic shock. The initial manifestation may be only one of the following: hyperventilation, tachycardia, hypotension, reduced tissue perfusion, diminished urine output, altered sensorium (confusion, lethargy), chills, fever, hypothermia, or a change in the white blood cell count. Suspicion should be aroused if one or more of these symptoms is found in a patient who is hospitalized, institutionalized, elderly, subjected to instrumentation (diagnostic tests, indwelling catheters), immunosuppressed, injured (trauma, burns), or chronically ill (chronic renal failure, cirrhosis, diabetes mellitus) or who has undergone recent surgery. Early recognition, complete acquisition of cultures, a rational selection and prompt parenteral administration of antibiotics, and circulatory support (volume and vasopressor therapy) are key to survival. The routine use of high-dose parenteral corticosteroids in septic shock is not supported by good clinical trials. A more specific and detailed presentation of the management (e.g., antibiotic selection) of septic shock is presented in [Chapter 268](#).

Cardiogenic Shock

Acute myocardial infarction is the most common cause of cardiogenic shock (see [Chapter 73](#)). The continued high mortality rate of this condition has set the stage for a more aggressive diagnostic and therapeutic approach (thrombolytic therapy, catheterization, coronary angioplasty, bypass surgery) in patients with occlusive coronary artery disease.

Unless a patient enters the hospital with symptoms of a myocardial infarction of more than 12 hours' duration, immediate intravenous thrombolytic therapy should be considered. If the patient appears to be advancing to or already shows signs of cardiogenic shock despite early supportive measures (administration of fluid volume or cardiovascular drugs), he or she should undergo urgent cardiac catheterization/coronary angiography in a setting where a catheterization laboratory and cardiologist are readily available and capable of proficiently introducing intra-aortic balloon counterpulsation, performing coronary angioplasty, or directing the patient to emergency coronary bypass surgery. When quickly initiated, this protocol is performed in lieu of thrombolytic therapy in patients who are likely to require invasive studies, considerable instrumentation, or emergency bypass surgery. The overall objective of thrombolytic therapy or catheterization is to pursue the measures necessary to reduce infarct size and minimize the amount of threatened myocardium, thus lessening the patient's chances of progressing to cardiac failure and cardiogenic shock.

After initial hemodynamic stabilization, most patients who have recently experienced myocardial infarction and continued or recurrent circulatory impairment should undergo emergency cardiac catheterization and coronary angiography. The objective is to diagnose and treat definitively a remedial, but otherwise catastrophic lesion (high-grade left main coronary artery obstruction, high-grade proximal obstruction of two or more coronary arteries, ruptured ventricular septum or wall, massive mitral regurgitation) while the patient is relatively stable. Once the patient has entered a state of clinical shock, the morbidity and mortality rates of cardiac catheterization, coronary angiography, and cardiac surgery rise dramatically. The same general principles apply to the management of noninfarction catastrophic cardiac events (acute severe aortic valvular insufficiency, chordal rupture with severe mitral regurgitation).

Most patients with infarction-induced cardiogenic shock have left ventricular filling pressures higher than 15 mm Hg. Intravenous infusion of nitroglycerin or

nitroprusside can be effective in improving cardiac output in patients with preserved arterial pressure, reducing elevated left ventricular filling pressures, and minimizing the degree of mitral regurgitation. The patient with marked hypotension (systolic pressures less than 70 to 75 mm Hg), cardiogenic shock, and left ventricular filling pressure of 18 mm Hg or higher is treated initially with vasopressor therapy, such as phenylephrine. Phenylephrine is initiated as a 1 µg per kilogram intravenous loading dose, followed by a drip at 0.5 µg per kilogram per minute; dosing is advanced as needed up to a maximal dose of 5 µg per kilogram per minute until the mean arterial blood pressure exceeds 65 to 70 mm Hg. The main objective of vasopressor therapy in this context is to elevate systemic blood pressure to achieve and maintain adequate coronary blood flow and perfusion of noninfarcted myocardium. Alternatively, patients with impaired renal blood flow may benefit from intravenous dopamine infusion at a drip rate of 5 to 15 µg per kilogram per minute. Once the mean arterial pressure has increased to more than 70 to 75 mm Hg, dobutamine may be added to augment myocardial contractility if needed.

If peripheral perfusion and systemic blood pressure do not improve to adequate levels with pharmacologic therapies in a patient who otherwise is a reasonable candidate for a major definitive intervention (coronary bypass surgery, heart transplant), mechanical support should be considered (intra-aortic balloon counterpulsation, ventricular assist device). The primary objective of the aforementioned pharmacologic interventions and mechanical support is to stabilize the patient hemodynamically for definitive diagnostic studies (cardiac catheterization and angiography) and a potentially life-saving reparative procedure (coronary angioplasty, bypass surgery, valve replacement). Intra-aortic balloon counterpulsation augments cardiac output by reducing afterload, increases coronary blood flow by enhancing diastolic perfusion pressure and perfusion time, and may decrease myocardial oxygen consumption (Fig. 71.2). Diastolic inflation (30 to 40 mL) and systolic deflation are regulated by electrocardiographic synchronization. Contraindications to balloon counterpulsation include aortic regurgitation and aortic aneurysm.

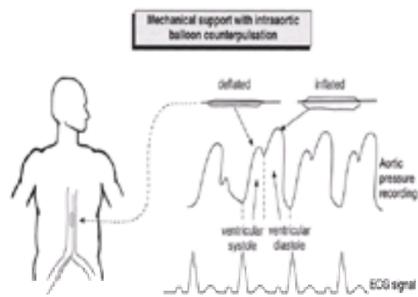

FIGURE 71.2. Intra-aortic balloon counterpulsation augments central and systemic hemodynamics by balloon inflation within the blood-filled aorta during diastole, thereby increasing coronary myocardial, organ, and peripheral tissue perfusion; diminishing ventricular afterload (resultant increase in stroke volume and cardiac output); and decreasing myocardial oxygen consumption. Balloon inflation and deflation are positioned (“gated”) via a continuous electrocardiographic signal.

Obstruction to Flow

Systolic function of the ventricle is directly linked to its state of diastolic filling (preload), as described by the Frank-Starling relation. Diastolic filling of the ventricles can be drastically reduced by several disorders. Pulmonary embolization and cardiac tumors (myxoma) are examples of intracardiac or intravascular obstructions to flow and ventricular filling. Extracardiac or extravascular obstruction of flow by compression occurs during cardiac tamponade, tension pneumothorax, and high positive end-expiratory pressure (PEEP) ventilation. Inadequate ventricular diastolic filling, with resultant reduced stroke volume and cardiac output, is the major mechanism of hypotension and shock in each case.

In the management of cardiogenic shock caused by inadequate filling, it is important to remember that most of the causes are detectable by careful clinical examination and laboratory testing (echocardiography), and most are completely reversible (pericardiocentesis or pericardiectomy for tamponade, chest tube for pneumothorax, resection for myxoma). This group of disorders is among the readily and definitively treatable causes of shock; when any of these conditions is suspected as a cause of hypotension or shock, select diagnostic studies and interventions are initiated as early as possible in the clinical course (e.g., echocardiography and pericardiocentesis for pericardial tamponade).

Complications

The most effective treatment of the complications of shock is prevention. Complications accrue as the severity and duration of shock intensify, and a favorable outcome of shock is lessened greatly as the severity and number of complications increase. Clinically significant ventilatory defects or ventilation–perfusion abnormalities are best detected by the regular analysis of systemic arterial blood gases and should be suspected when the arterial P_{O_2} falls below 85 mm Hg while the patient is breathing room air. The development of ARDS, the most common cause of death in noncardiogenic shock, should be suspected with a falling arterial PO_2 (particularly as the fraction of inspired oxygen [F_{O_2}] increases), an arterial PO_2 less than 60 mm Hg, or the finding of diffuse pulmonary infiltrates on the chest film (in the presence of pulmonary capillary wedge pressures less than 15 mm Hg). A systemic arterial P_{O_2} greater than 60 mm Hg while breathing room air generally can be managed by external oxygen delivery systems (e.g., a mask). A PO_2 less than 60 mm Hg often requires ventilator therapy, occasionally with PEEP, to bring the arterial PO_2 to 60 mm Hg or higher. Ventilator therapy plus PEEP with an FO_2 of 50% or less is generally preferable to non-PEEP high- F_{O_2} delivery (100% oxygen by mask), since a high FO_2 may lead to toxic changes in the lung within a few hours.

Aspiration pneumonia is not an uncommon complication of shock and can be prevented in most patients by optimal nursing support, proper endotracheal care, and appropriate nasogastric suctioning. Once aspiration pneumonia is suspected and diagnosed, tracheal suction specimens should be submitted for culture. Shortly thereafter, antibiotic therapy is begun.

Renal function is always a major concern in shock states. Once intravascular volume seems adequate or high but urine output remains low (less than 20 mL per hour), a diuretic drug (e.g., intravenous furosemide, starting at 40 to 80 mg) might be administered (see [Chapter 140](#)). Failure to respond to incremental doses of the diuretic often heralds the onset of acute renal failure. Select patients with renal dysfunction stemming from renal hypoperfusion may respond favorably to low-dose (1 to 4 µg per kilogram per minute) infusions of dopamine. Drugs with nephrotoxic potential should be avoided or used with caution in shock states because of the marked increase in the susceptibility of the kidneys to injury in this condition. The dosing schedule of drugs cleared by the kidney must be modified once renal dysfunction has developed. Hyperkalemia is a common problem in renal failure of any cause, including shock. Peritoneal or bedside renal dialysis may be required to manage shock-induced renal failure.

Gastrointestinal bleeding is a common complication of shock and is always a threatening event, particularly when coagulation abnormalities develop. Visual inspection and guaiac testing of gastric contents, regular guaiac testing for fecal blood, and monitoring of hematocrit usually allow detection of gastrointestinal bleeding at relatively early stages (before major hemorrhage and the superimposition of hypovolemic shock). Superficial gastric ulceration is the most common source of gastrointestinal bleeding in shock. Gastrointestinal lesions can serve as entry points for infecting organisms and harmful components of luminal contents. Antacids or sucralfate is administered via nasogastric tube and a histamine receptor antagonist (cimetidine, ranitidine) is given intravenously, in an effort to retard and reverse the development of gastrointestinal ulceration. On rare occasions during the clinical course of shock, surgery may have to be performed to stop major uncontrollable gastrointestinal hemorrhaging (e.g., from an eroded artery) or to remove a segment of infarcted bowel.

The consumption of clotting factors commonly accompanies shock and may evolve into the serious condition DIC. Regular clotting studies (prothrombin time, partial thromboplastin time, platelet count) usually uncover the evolution of coagulopathy; these studies, in conjunction with fibrinogen levels, levels of fibrin split products, and thrombin time, serve to establish the diagnosis of DIC. Often a catastrophic event signaling the terminal stages of shock, DIC can cause generalized microthrombi and hemorrhage, damage to more than one organ, renal cortical necrosis, and local (from endotracheal, nasogastric tube, and catheter sites) and diffuse hemorrhage. Fresh-frozen plasma or platelets (if the platelet count is depressed) may be required to stop hemorrhage caused or exacerbated by the consumptive coagulopathy. When more than 2 L of blood is infused in hemorrhagic shock, a unit of fresh-frozen plasma should be administered to avert thrombocytopenia and the dilution of

blood clotting factors.

The shock syndrome and its management constitute the ideal situation for iatrogenic complications. Often, diagnostic and monitoring procedures must be performed and major therapies instituted on an emergency basis in settings that are not ideal. Few physicians are optimally trained and experienced in each of the procedures and therapies ultimately required to treat all shock patients. Organizing the management of shock in diagnostic and therapeutic stages, with recruitment of specialists at appropriate times along the clinical course, is an important and effective means of minimizing the complications of shock treatment. A keen awareness of the complications of the diagnostic and therapeutic maneuvers used and vigilance for their occurrence are crucial in the overall treatment of shock. For more information, refer to [Chapter 268](#), [Chapter 355](#), [Chapter 357](#), and [Chapter 388](#).

CHAPTER 72: CORONARY ARTERY DISEASE

MIHAI GHEORGHIADU AND ROBERT O. BONOW

Chronic Coronary Artery Disease
 Silent Ischemia
 Acute Coronary Syndrome
 Variant Angina Pectoris

In the United States, atherosclerotic coronary heart disease (CAD) is the leading cause of death in both men and women and is a clinically significant disease process in about 11 million persons. The economic toll of CAD is in excess of \$60 billion per year. CAD may be asymptomatic; may take the form of stable angina; or, when atherosclerotic plaques rupture and stimulate platelet aggregation and thrombosis, may result in unstable angina, non-Q-wave or Q-wave myocardial infarction (MI), or sudden death. CAD is also the leading cause of left ventricular dysfunction and heart failure in the industrialized world. During the past two decades, the age-adjusted mortality rate from CAD has declined by 50% as a direct result of improved prevention methods and treatment of patients. Despite this progress, cardiovascular disease still accounts for more than 50% of all deaths. The lifetime risk of a CAD-related event (MI or death) at age 40 is 1 in 2 for men and 1 in 3 for women. In less than 1% of patients, CAD is caused by conditions other than atherosclerosis ([Table 72.1](#)).

TABLE 72.1. CAUSES FOR CORONARY ARTERY DISEASE OTHER THAN ATHEROSCLEROTIC HEART DISEASE

Several factors predispose the coronary arteries to the development and progression of the atherosclerotic process ([Table 72.2](#)). Cigarette smoking, hypercholesterolemia, and hypertension can induce changes in endothelial structure and function and promote smooth-muscle-cell proliferation. Diabetes mellitus, genetic factors (family history of premature CAD, ethnic characteristics), male gender, advancing age, and menopause are other strong risk factors that contribute to the progression of coronary atherosclerosis. Additional factors implicated in an increased risk of CAD are physical inactivity, obesity, and psychological factors. Studies indicate that elevated plasma homocysteine levels may also predispose to atherosclerosis, because homocysteine impairs nitric oxide production, stimulates smooth-muscle proliferation, and increases thrombogenicity. Elevated levels of serum lipoprotein(a) appear to correlate with rapid angiographic progression of CAD. Focal inflammation in the coronary arteries in response to reactivation of dormant cytomegalovirus or chlamydia pneumoniae and helicobacter pylori infections may be involved in the pathogenesis of unstable coronary syndromes and could be a risk factor for CAD. Estrogen deficiency, plasma fibrinogen, factor VII, endogenous tissue plasminogen activator, plasminogen activator inhibitor type 1, D-dimer, and C-reactive protein are also emerging cardiovascular risk factors. The importance of genetic factors is underscored by the marked racial differences in the prevalence of coronary risk factors. In the future, genomic analysis will make it possible not only to predict early in life a genetic predisposition for CAD but also to identify the type of pathophysiologic disruption and to develop a rational preventive strategy specific to each person. For example, the Arg3500Gin mutation in the apolipoprotein B gene, which is responsible for familial defective apolipoprotein B-100, causes severe hypercholesterolemia and an increase in the risk of ischemic heart disease.

TABLE 72.2. CARDIOVASCULAR RISK FACTORS: THE EVIDENCE SUPPORTING THEIR ASSOCIATION WITH DISEASE, THE USEFULNESS OF MEASURING THEM, AND THEIR RESPONSIVENESS TO INTERVENTION

CHRONIC CORONARY ARTERY DISEASE

Several million persons in the United States suffer from chronic stable angina. Stable angina is characterized by poorly localized chest or left arm discomfort associated with physical exertion or emotional stress and relieved promptly by rest or sublingual nitroglycerin. The discomfort is related to myocardial ischemia that is transient and does not cause myocardial necrosis. It is considered stable if the pattern does not change over a 2-month period.

PATHOPHYSIOLOGY

The most common cause for stable angina pectoris is stenosis of the proximal segments of the left anterior descending, right, or circumflex coronary artery by an atherosclerotic plaque. During an angina attack, myocardial ischemia develops from an imbalance between oxygen demand and oxygen supply, resulting in anaerobic metabolism with formation of lactic acid from glycogen. Causes and effects of myocardial ischemia are illustrated in [Fig. 72.1](#).

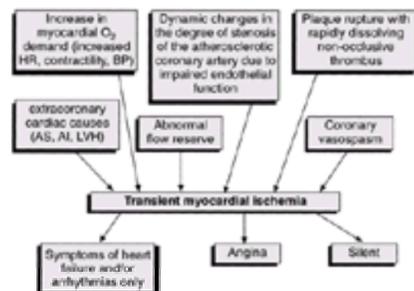

FIGURE 72.1. Causes and effects of transient ischemia. AI, aortic insufficiency; AS, aortic stenosis; BP, systemic blood pressure; HR, heart rate; LVH, left ventricular hypertrophy. (From Maseri A. Role of coronary artery spasm in symptomatic and silent myocardial ischemia. *J Am Coll Cardio.* 1987;9:249–262, with permission.)

Myocardial Oxygen Demand

Most episodes of angina arise from increases in oxygen demand during physical or emotional stress. Myocardial oxygen demand is determined by heart rate, myocardial contractility, and myocardial wall tension. Wall tension, in turn, is related to chamber pressure and volume. An increase in any or all of these variables may develop during exercise or emotional stress and may precipitate myocardial ischemia in patients with compromised oxygen supply.

Myocardial Oxygen Supply

Myocardial oxygen supply is determined by coronary blood flow and the arteriovenous oxygen difference across the coronary bed. Because the arteriovenous oxygen difference is near maximal at rest in most patients, changes in oxygen supply are almost entirely mediated by alterations in blood flow.

Diminished Coronary Vasodilator Reserve

Autoregulation of blood flow occurs primarily at the level of the small coronary arterioles (diameter roughly 200 μm). Coronary vasodilator reserve in the normal coronary circulation allows for a four- to fivefold increase in blood flow to the myocardium in response to physiologic stimuli that promote arteriolar vasodilatation. In contrast, vasodilator reserve is limited or absent in patients with critical atherosclerotic stenoses in the large epicardial arteries. Normal resting flow can be maintained in this context only through compensatory arteriolar dilatation. Thus, coronary vasodilator reserve, which is normally used only during stress, is expended under resting conditions in the patient with CAD to defend resting flow, resulting in diminished reserve during stress. In coronary arteries with severe stenoses that decrease the luminal diameter by 90% to 95%, vasodilator reserve may be completely exhausted under resting conditions.

Thus, the classic understanding of angina pectoris is that myocardial ischemia comes about during stress, when progressive increases in myocardial oxygen demand exceed the ability of the coronary circulation to amplify myocardial blood flow. Although this pathophysiologic mechanism of action does occur and is operative in many patients with CAD, this factor alone is insufficient to explain the full clinical spectrum of chronic stable angina, since it implies that each patient has a stable ischemic threshold—that is, that there is a stable threshold of oxygen demand, determined by heart rate, blood pressure, and contractility, below which ischemia is not present and above which ischemia develops. If this were the case, each patient would have a fixed angina threshold and would experience angina at identical workloads on many different occasions. In clinical practice, this is usually not the case; patients often experience varying thresholds of intensity of exercise at which angina develops.

Endothelial Dysfunction

It is now apparent that patients with coronary atherosclerosis have dynamic fluctuations in the severity of stenosis that may lead to varying angina thresholds. A major component of the pathophysiologic picture of angina is endothelial dysfunction of atherosclerotic arteries, including arteries with plaques that are not themselves flow limiting. Normal arterial endothelial cells produce several vasodilating substances; the most notable of them is endothelial-derived relaxing factor (EDRF), which has been identified as nitric oxide. Nitric oxide is the most potent endogenous vasodilator that is responsible for maintaining normal vascular tone and for inhibiting smooth-muscle growth and proliferation, leukocyte adhesion to the endothelial surface, and platelet aggregation. The release of EDRF by healthy endothelium is continuous and is augmented in response to increases in blood flow. In addition, under normal conditions, both endogenous (acetylcholine, serotonin, thrombin) and exogenous (exercise, mental stress, cold) stimuli promote EDRF production and release, resulting in coronary vasodilatation. In contrast, atherosclerotic coronary artery segments with disrupted endothelium lose the normal ability to dilate in response to these stimuli and manifest a paradoxical vasoconstrictor response that may precipitate an angina attack. Independent of the atherosclerotic process, hypertension, diabetes mellitus, estrogen deficiency, hypercholesterolemia, and cigarette smoking are also associated with abnormal endothelial function.

Circadian Variation

The dynamic alterations in coronary blood flow may follow a circadian pattern. Ischemic episodes become more frequent and occur at lower levels of demand in the early morning hours. This is related to increases in plasma catecholamines and cortisol concentrations that often result in a decrease in coronary blood supply stemming from heightened coronary vascular resistance. In addition, the aggregability of platelets peaks, and fibrinolytic activity declines in the early morning hours.

Pathophysiologic Effects of Myocardial Ischemia

Myocardial ischemia initially causes left ventricular diastolic dysfunction (relaxation failure), since early-stage ischemia impairs the intracellular sequestration of calcium ion in the sarcoplasmic reticulum of the myocyte, allowing persistent tension development during diastole and thus higher left ventricular diastolic pressures. This is followed by regional systolic dysfunction (contraction failure), manifested by diminished systolic thickening and inward systolic wall motion of the ischemic myocardium. These effects of ischemia on left ventricular function usually precede the development of electrocardiographic changes or chest discomfort.

CLINICAL MANIFESTATIONS

Symptoms

Angina pectoris is usually experienced as substernal pressure, heaviness, tightness, burning, or numbness that develops during exercise or emotional stress and is relieved within minutes by resting. The patient often cannot pinpoint the exact location of discomfort. The symptoms often radiate to the left shoulder and the inner surface of the left arm. They may also affect the neck, jaw, and teeth and, less frequently, the left ear, wrist, hand, and the fourth and fifth fingers. Many times, the discomfort is felt only in the neck, shoulder, or arm, without any chest discomfort. In many patients, chest discomfort is associated with dyspnea, and at times it may be perceived only as dyspnea. Patients also may experience diaphoresis, nausea, weakness, or dizziness. The severity is often defined by the grading system developed by the Canadian Cardiovascular Society ([Table 72.3](#)).

indicative of previous infarction may be unaware of having had an MI, because up to 25% of MIs are unrecognized. Although left or right bundle-branch block, left anterior hemiblock, and atrial or ventricular premature beats may be present, these findings are not specific to CAD.

NONINVASIVE DIAGNOSTIC TESTS

The usefulness of any test in the diagnosis of CAD is its ability to establish the likelihood that atherosclerotic CAD is or is not present. This likelihood, termed the predictive accuracy, is determined by two factors: sensitivity and specificity. Sensitivity measures the percentage of patients with CAD who have a positive test response, and specificity represents the percentage of patients without CAD who have a negative test response. The sensitivity and specificity of common diagnostic tests are noted in [Table 72.5](#).

Test	Sensitivity (%)	Specificity (%)	Criteria for Positive Response	Markers of High Risk	Limitations	Relative Cost
Exercise ECG	85	85	ST depression of 1 mm	ST depression of 1 mm or more of any lead with ST-T wave changes in 2 or more leads	Non-specific; insensitive for detection of early CAD	Low
Myocardial perfusion imaging	85	85	Nonviable regional perfusion	Normal ST-T wave; ST depression of 1 mm or more in 2 or more leads; ST-T wave changes in 2 or more leads	Minimization artifact; Stress; Radiation	High
Radionuclide angiography	85	85	Nonviable regional perfusion	Normal ST-T wave; ST depression of 1 mm or more in 2 or more leads; ST-T wave changes in 2 or more leads	Four monitor to chest; Radiation; Limited resolution	High
Stress echocardiography	85	85	Nonviable regional perfusion	Normal ST-T wave; ST depression of 1 mm or more in 2 or more leads; ST-T wave changes in 2 or more leads	ST depression of 1 mm or more in 2 or more leads; ST-T wave changes in 2 or more leads	High
Exercise ECG	75	75	ST depression of 1 mm	ST depression of 1 mm or more of any lead with ST-T wave changes in 2 or more leads	Non-specific; insensitive for detection of early CAD	Low

TABLE 72.5. NONINVASIVE DIAGNOSTIC TESTS FOR DETECTION OF CORONARY ARTERY DISEASE

Another factor that strongly influences the predictive accuracy of any diagnostic test is the prevalence of CAD in the population under study (Bayes theorem), which indicates the likelihood of CAD before testing is performed. The influence of pretest likelihood on the predictive accuracy of a test with high sensitivity and specificity is shown in [Fig. 72.2](#). In patients with a low disease prevalence, such as a general population undergoing routine cardiovascular screening, a test with excellent sensitivity and specificity yields more than three times the number of false-positive as true-positive results. Thus, diagnostic testing is usually reserved for patients with a more moderate pretest likelihood, such as patients with symptoms or several coronary risk factors. In patients with a high probability of disease, such as middle-aged men with typical angina and hypercholesterolemia, the diagnosis is usually well established without further testing. Because women have a lower prevalence of CAD than men, the predictive accuracy of any diagnostic test is usually lower in women.

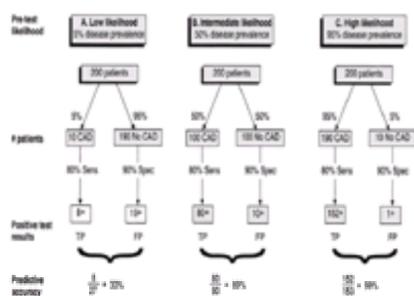

FIGURE 72.2. Effect of disease prevalence, or pretest likelihood, on predictive accuracy of a diagnostic test (Bayes theorem). Three populations of 200 patients undergo a diagnostic test with high sensitivity (Sens) and specificity (Spec), such as tomographic thallium perfusion imaging or stress echocardiography. The sensitivity and specificity determine the number of expected true-positive (TP) and false-positive (FP) responses, from which the predictive accuracy is determined. When applied to patients with low disease prevalence, such as a general population of asymptomatic middle-aged men undergoing routine cardiovascular screening, the test with excellent sensitivity and specificity yields poor predictive accuracy, with over three times the number of false-positive as true-positive test results. The same test achieves higher predictive accuracies in populations with intermediate and high levels of disease prevalence.

Exercise Electrocardiography

Exercise electrocardiographic testing is usually performed on a motor-driven treadmill that increases in speed and inclination every few minutes according to a preset exercise protocol. Occasionally, exercise electrocardiographic testing is done on a stationary bicycle. Exercise is continued until the patient manifests a cardiac symptom or fatigue or reaches at least 85% of the maximal heart rate predicted for his or her age. The heart rate, blood pressure, and product of heart rate and systolic blood pressure (the rate-pressure product) achieved during exercise are indirect measures of myocardial oxygen demand. The exercise ECG is considered to be indicative of ischemia if at least 1 mm of flat or downsloping ST-segment depression develops during exercise or during the 3- to 5-minute recovery period. ST-segment changes cannot be interpreted in the context of left bundle-branch block, Wolfe-Parkinson-White syndrome, or artificial pacemakers; in these instances, stress testing should be performed with one of the imaging methods discussed later herein. Moreover, exercise-induced ST-segment depression has a lower specificity for CAD in women and in the context of left ventricular hypertrophy, digoxin therapy, mitral valve prolapse, aortic stenosis, supraventricular tachycardia, and anemia.

In addition to ST-segment changes, other variables from the exercise test provide important information regarding the severity of CAD. They include exercise tolerance, exercise-induced symptoms, maximum heart rate and blood pressure, and the heart rate and workload at the onset of ischemia. Exercise-induced hypotension, ST-segment depression of 2 mm or more, ST-segment depression persisting more than 6 minutes during the recovery phase, ischemia at low exercise workloads, and exercise-induced ventricular tachycardia associated with ischemic changes have been linked to extensive CAD.

Myocardial Perfusion Imaging

Thallium 201 (²⁰¹Tl)

After intravenous administration, thallium is extracted by myocardial cells in proportion to regional myocardial blood flow. Images of the heart soon after thallium administration reflect regional myocardial perfusion. When thallium is administered at peak exercise, regions with exercise-induced ischemia show perfusion defects. Although thallium washes out of the myocardium in proportion to blood flow, it also accumulates in viable myocardium in a manner analogous to potassium ion. Hence, over 2 to 4 hours, thallium defects in previously ischemic myocardium improve or normalize, a phenomenon termed thallium redistribution. Defects related to an infarct do not redistribute and remain irreversible over time. Thallium imaging has a higher sensitivity, specificity, and predictive accuracy than exercise electrocardiographic testing.

In addition to detecting CAD, thallium imaging indicates the functional severity of CAD. The number, size, and location of stress-induced myocardial perfusion defects reflect the location, extent, and severity of coronary artery stenoses. Lung uptake of ²⁰¹Tl occurs when left ventricular filling pressures are elevated and is a marker of stress-induced left ventricular dysfunction, usually associated with multivessel CAD. Transient dilatation of the left ventricle after stress is also a marker of severe ischemia and generally indicates multivessel disease. Normal exercise thallium perfusion images are highly predictive of an excellent prognosis, even in patients with known CAD, with a risk of death or MI below 1% per year.

Technetium Tc 99m (^{99m}Tc) Perfusion Agents

Technetium Tc 99m—based agents have a shorter half-life than thallium (6 versus 73 hours), which allows for administration of a higher dose. The higher dose and the higher energy of technetium yield a better image quality and better delineation of perfusion defects than thallium. Sestamibi is the most widely used technetium perfusion agent. Because sestamibi undergoes only a small amount of washout after initial myocardial uptake, the distinction between transient stress-induced perfusion defects and fixed perfusion defects requires two separate injections, one during stress and one at rest. Newer techniques using these agents permit determination of left ventricular function in addition to myocardial perfusion.

Pharmacologic Stress Imaging

In patients who cannot exercise at all or who cannot exercise maximally, perfusion imaging can be done with dipyridamole, adenosine, or dobutamine during pharmacologic stress. This group includes patients with peripheral vascular disease, chronic arthritis, pulmonary disease, and neurologic disorders. In addition, patients receiving β -blockers or rate-lowering calcium channel blockers may not achieve adequate heart rates during exercise and may be candidates for pharmacologic stress imaging.

Radionuclide Angiography

First-pass or gated radionuclide angiography using technetium Tc 99m is useful for the accurate determination of left and right ventricular ejection fractions at rest and during exercise. Although changes in left ventricular function during exercise are sensitive indicators of CAD, the diagnostic accuracy of this test is limited by lack of specificity, since several factors affect the ejection fraction response to exercise. These factors include age, gender, hypertension, left ventricular hypertrophy, and concomitant valvular or myocardial disease. Hence, this test is usually reserved for patients with known CAD, to evaluate left ventricular function as an index of prognosis.

Stress Echocardiography

Stress echocardiography, with imaging either after exercise or during pharmacologic stress, has become another important noninvasive test for CAD. Even though echocardiography cannot quantify the left ventricular ejection fraction as accurately as radionuclide angiography, its ability to assess regional ventricular function is far superior. Diminished regional systolic wall motion and systolic wall thickening are sensitive markers of regional myocardial ischemia, and the diagnostic accuracy of stress echocardiography is similar to that of myocardial perfusion imaging. The overall sensitivity for detecting the presence and extent of ischemic myocardium, however, appears to be higher with myocardial perfusion imaging.

Cardiac Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) makes visible the heart in any tomographic plane with excellent spatial resolution and precise identification of endocardial and epicardial borders. MRI has a high level of accuracy in determining ventricular volume, ejection fraction, and left ventricular mass, and cine MRI provides accurate assessment of regional wall motion and wall thickening during cardiac cycle. Dobutamine stress testing with cine MRI has been used for CAD detection.

Electron Beam Computed Tomography

Electron beam computed tomography (EBCT) is a widely promoted technique for the detection of calcification within atherosclerotic coronary lesions. Calcification of coronary arteries is a clear indicator that atherosclerosis is present. Nevertheless, calcium detected in coronary arteries by EBCT is a sensitive but perhaps not a specific indicator of angiographically obstructive atherosclerotic lesions. The role of EBCT is primarily to identify patients with early CAD, to establish preventive strategies rather than to identify patients with advanced CAD with coronary artery obstructions. Preliminary evidence has linked calcification to risk of ischemic events, but it is uncertain whether this risk prediction enhances that achieved by assessing more traditional risk factors. The current role of EBCT in clinical practice remains to be determined.

Ambulatory Electrocardiography

Ambulatory electrocardiographic monitoring provides an estimate of the frequency and duration of ischemic episodes that occur during routine daily activities. By quantifying the total duration of ischemia during a 24-hour period, this form of testing has potential value in patients with known CAD, but its sensitivity for detecting CAD is less than that of exercise electrocardiographic testing. Hence, it rarely enters into the diagnostic strategy for CAD diagnosis.

CORONARY ANGIOGRAPHY

In patients with known or suspected CAD, coronary angiography is performed for diagnosis, for risk stratification, and for assessment of the appropriateness and feasibility of myocardial revascularization with coronary artery bypass graft surgery (CABG) or percutaneous coronary revascularization (PCR). Coronary angiography is relatively safe, with a risk of death of less than 0.2% and of a major nonfatal event of less than 0.5%. The most serious nonfatal complications are stroke, MI, and severe bleeding. Coronary angiography is indicated in patients with known or suspected atherosclerotic heart disease, particularly when they are classified by noninvasive testing as being at high risk of experiencing ischemic events. It is also indicated in patients with stable angina who continue to be symptomatic or have signs of ischemia during noninvasive testing, despite adequate medical therapy. Patients who have survived sudden death or who have sustained ventricular tachycardia should also undergo coronary angiography.

At the time of angiography, coronary atherosclerotic lesions are classified as concentric with smooth borders; type 1 eccentric, with smooth borders; type 2 eccentric, with irregularly scalloped borders; or having multiple irregularities. In stable angina, the lesions are usually concentric and smooth. Less frequently, the lesions are eccentric and scalloped, with irregular borders, and may have a hazy appearance. Such complex lesions are thought to represent a ruptured plaque or a partially occlusive thrombus and are more common in unstable angina than in chronic stable angina.

PROGNOSIS AND RISK STRATIFICATION

The prognosis in patients with CAD is related to the extent, severity, and morphologic features of coronary atherosclerotic lesions; left ventricular systolic function; and the severity of myocardial ischemia. Numerous studies indicate that patients with left main coronary artery stenosis or left main equivalent (proximal high-grade stenosis of both the left anterior descending and left circumflex arteries) have the worst prognosis during medical therapy. Coronary anatomy also influences survival in patients without left main disease. In the Coronary Artery Surgery Study registry, in which more than 23,000 patients with suspected or established CAD were evaluated, the 12-year survival was 74% for patients with one-vessel disease, 59% for two-vessel disease, and 40% for three-vessel disease. In patients with preserved systolic function and at least one-vessel disease, 12-year survival was 73%. For moderate left ventricular dysfunction the respective rate was 54%, and for severe left ventricular dysfunction it was 21% (Fig. 72.3). These factors are additive, such that patients with left main disease or three-vessel disease who have left ventricular dysfunction or inducible myocardial ischemia are at greatest risk during medical therapy.

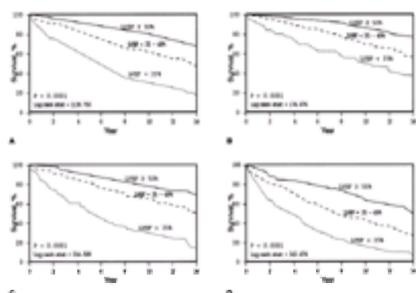

FIGURE 72.3. Graphs showing survival rates for medically treated Coronary Artery Surgery Study (CASS) patients (n = 12,387). **A:** Patients with one-, two-, or three-vessel disease by left ventricular ejection fraction (LVEF). **B:** Patients with one-vessel disease by ejection fraction. **C:** Patients with two-vessel disease by ejection fraction. **D:** Patients with three-vessel disease by ejection fraction. (From Emond M, Mock MB, Davis KB, et al. Long-term survival of medically treated patients in Coronary Artery Surgery Study (CASS). *Circulation*. 1994;90:2645, with permission.)

Medically treated women with one- and two-vessel disease and no left main CAD have a survival advantage over men with the same number of diseased vessels. No advantage for women has been observed in the subgroups with three-vessel or left main CAD. In addition to the number of coronary vessels involved, ischemia, and left ventricular function, other factors, such as age, smoking, diabetes, and previous MI, are associated with a poorer prognosis. The smoking history ranks among the most important predictors of survival. Patients on dialysis with a history of MI have a high cardiac mortality (60% at 1 year).

MANAGEMENT

Acute cardiac events, including unstable angina, MI, and sudden cardiac death, are known to result from a disrupted atherosclerotic plaque that leads to occlusive or nonocclusive thrombosis. The atherosclerotic plaque does not need to be stenotic to rupture and cause occlusive thrombosis. Disruption of a nonstenotic plaque may also lead to a mural thrombus, causing growth of the plaque but no acute symptoms. The severity of the stenosis serves as a marker of the extent of the number of nonstenotic plaques in the coronary artery. The likelihood of rupture is related to plaque composition, hemodynamic stress, endothelial factors, and inflammatory causes. Therapy should be aimed at the prevention of plaque disruption and growth, which can lead to both progression and an acute cardiac event. An important decision is whether to treat the patient with medical therapy or to proceed with myocardial revascularization. In either case, risk factors should be addressed and modified appropriately, and general measures should be followed.

Risk Factor Modification

Since modification of risk factors can significantly improve prognosis by slowing plaque progression and disruption, every effort should be made to achieve these goals. [Table 72.6](#) depicts the consensus panel recommendations of the American Heart Association. The major modifiable risk factors are hypertension, hypercholesterolemia, smoking, sedentary lifestyle, obesity, and, possibly, the loss of estrogen effects in postmenopausal women.

TABLE 72.6. GUIDE TO COMPREHENSIVE RISK REDUCTION FOR PATIENTS WITH CORONARY AND OTHER VASCULAR DISEASES

Hypertension should be treated aggressively with medications that are likely to lessen left ventricular mass and improve the balance between oxygen supply and oxygen demand, such as b-blockers and angiotensin-converting enzyme (ACE) inhibitors. The use of nisoldipine, a long-acting dihydropyridine calcium channel blocker has been associated with an increased risk of MI in hypertensive patients who have diabetes.

Lowering levels of total cholesterol and LDL cholesterol by diet and drug therapy improves endothelium-dependent coronary vasomotion, thereby contributing to improved myocardial perfusion. In addition, a significant decrease in the serum cholesterol level can prevent atherosclerotic plaque rupture and halt progression (and possibly promote regression) of coronary atherosclerosis. Aggressive management of hypercholesterolemia with diet and a lipid-lowering agent (especially 3-hydroxy-3-methylglutaryl reductase coenzyme A inhibitors or statin) lowers the risk of death and MI and the need for CABG ([Table 72.7](#)). Gemfibrozol also reduces cardiovascular events in patients with low HDL. In patients with CAD, total cholesterol should be lowered to below 200 mg per deciliter and LDL cholesterol to below 100 mg per deciliter (2.6 mmol per liter), and HDL cholesterol should be increased to above 35 mg per deciliter (0.9 mmol per liter). Aggressive lipid lowering therapy with statins may be as effective as PCR in stable angina.

TABLE 72.7. EFFECT OF STATINS ON CARDIOVASCULAR (CV) EVENT REDUCTION AND LDL-CHOLESTEROL LEVELS

Exposure to carbon monoxide and nicotine from tobacco smoke causes immediate constriction of the epicardial coronary arteries and can impair endothelial-mediated endothelial vasodilatation. Cigarette smoking significantly lessens the anti-ischemic effects of nitrates, b-blockers, and calcium channel blockers. Patients who continue to smoke after successful myocardial revascularization procedures are at greater risk of MI and death than nonsmokers. Smoking cessation lessens the risk of MI, which may return to a level similar to that of a person who never smoked. Passive cigarette smoking can also increase the risk of a cardiac event in patients with stable angina.

Weight reduction to an ideal body weight should be achieved. Physical activity is beneficial and may help control hypertension, hypercholesterolemia, and diabetes. A low cholesterol diet lowers serum cholesterol significantly only when combined with high levels of aerobic exercise. Heavy physical exertion, however, can trigger the onset of an acute MI, particularly in sedentary patients.

Hormone replacement therapy in postmenopausal women may be beneficial in limiting cardiovascular events. The use of estrogen combined with a progestational agent is associated with a better lipid profile than the use of estrogen alone, but it is uncertain whether this effect translates into better outcomes. One study has shown that therapy with estrogen and progesterone did not lessen the number of CAD events in postmenopausal women with established CAD. There was a higher rate of thromboembolic events and gallbladder disease early in the course of therapy, which may have offset any long-term beneficial effects from hormone replacement. Given the favorable effects of hormone replacement after several years of therapy, it is appropriate for women already taking these medications to

continue.

There is an association between elevated homocysteine and atherosclerosis. Although homocysteine levels can be lowered with folic acid, pyridoxine hydrochloride, and cyanocobalamin, an association between a decrease in homocysteine and improved clinical outcome has not yet been verified. Conditions that lower the threshold for angina, such as anemia, thyrotoxicosis, fever, and hypoxemia, should be corrected. Decongestants (α -antagonists) may aggravate angina and should be avoided if possible. Patients with postprandial symptoms should abstain from large meals. Anxiety should be controlled with medications. Exposure to very low temperatures should be discouraged; however, if they cannot be avoided, the patient should cover the mouth and nose and avoid strenuous exercise. Because sexual intercourse can precipitate angina, nitrates, β -blockers, and calcium channel blockers may be used prophylactically. The use of sildenafil (Viagra) is contraindicated in patients taking nitrates or in patients with severe angina.

Drug regimens, dietary restriction, and the importance of not smoking should be discussed. Patients and family members should be instructed to recognize a change in symptoms that might signal unstable angina or acute MI and to seek medical attention. This is particularly important, because about 50% of patients who have an acute MI experience an increase in the frequency or intensity of angina 1 or 2 weeks before the event. The prognosis of a patient who has an acute MI is related to the time delay in arriving at an emergency department. Although it is important to discuss the prognosis, reassuring the patient and family is also important, since there is an association between anxiety and fatal coronary events, in particular, sudden death.

Medical Therapy

Aspirin permanently inhibits platelet cyclooxygenase, resulting in suppression of the biosynthesis of platelet thromboxane A_2 , which induces platelet aggregation. Aspirin may also have a beneficial anti-inflammatory effect that results in plaque stabilization. Aspirin, particularly at high doses, may limit the salutary effects of ACE inhibitors in patients with CAD and heart failure. In stable angina, aspirin lowers the risk of MI and sudden death and should be used in all patients at a daily dose of 81 to 324 mg, unless contraindicated.

Clopidogrel, a new thienopyridine, and ticlopidine also block the adenosine diphosphate (ADP) activation of platelets by selectively and irreversibly inhibiting the binding of ADP to its platelet receptor. Both agents can be used instead of aspirin. Clopidogrel may be superior to aspirin in decreasing the combined risk of ischemic stroke, MI, and vascular death. The dose of clopidogrel is 75 mg once a day, and that of ticlopidine is 250 mg twice a day. There are no known interactions between these two agents and ACE inhibitors.

Nitrate preparations are potent systemic venous and coronary arterial vasodilators. The paradoxical constriction of atherosclerotic coronary arteries in response to exercise or mental stress, related to endothelial dysfunction and decreased levels of EDRF, can be abolished by nitroglycerin. Nitrates also lower systemic blood pressure and myocardial oxygen demand and inhibit platelet aggregation.

To abort an angina attack, sublingual nitroglycerin or nitroglycerin spray (average dose, 0.4 mg) is the most effective preparation. Nitroglycerin may also be taken prophylactically before activities that typically produce angina. Several long-acting nitrate preparations are available in the form of tablets, topical ointments, and transdermal patches, but these preparations are ineffective in treating an acute angina attack. Tolerance develops rapidly to long-acting nitrate preparations, manifested by the diminished effectiveness of a particular dose and the need for higher doses to maintain efficacy. Intermittent nitroglycerin therapy, consisting of 8- to 12-hour nitrate-free intervals, can be effective in preventing tolerance. Hydralazine, ACE inhibitors, vitamin E, and carvedilol may lessen tolerance to nitrate therapy. Long-acting nitrates may improve exercise tolerance and curb the frequency and severity of angina. There is no evidence, however, that nitrate preparations prevent MI or improve survival.

Nitrate administration is associated with increased production of superoxide anion and the vasopressor hormone endothelin. Intermittent therapy with nitroglycerin may be associated with rebound myocardial ischemia or infarction and heightened sensitivity to endothelin during nitrate-free periods. The most common side effects of nitroglycerin preparations are headaches and dizziness. Dizziness is usually caused by hypotension and can be corrected by assuming a supine position. Patients with critical aortic stenosis or obstructive hypertrophic cardiomyopathy should avoid nitrate preparations. Administration of sildenafil (Viagra) is contraindicated in patients taking nitrates, since the vasodilatory actions are profoundly amplified, resulting in severe hypotension and a potentially fatal event.

The dose of nitrates that prevents angina varies from patient to patient. In general, one should start with a relatively low dose and increase the dose until ischemia is prevented or side effects develop. One of the most common long-acting preparations is isosorbide dinitrate, but 70% to 80% of the oral dose is degraded by its first pass through the liver. In contrast, isosorbide 5-mononitrate, an active metabolite of dinitrate with similar antianginal properties when given orally, is 95% bioavailable because it has a negligible first-pass extraction. Nitroglycerin patches vary in effectiveness among patients, with unpredictable absorption into the systemic circulation.

The β -adrenergic blocking agents are among the most important therapies for CAD. These drugs diminish the frequency of angina attacks and improve exercise tolerance. Although they are well tolerated, such side effects as fatigue and weakness, nightmares, depression, bronchoconstriction, sexual dysfunction, and memory loss can occur. The β -blocking agents differ in their β -receptor selectivity, intrinsic sympathomimetic activity, lipid solubility, and associated β -adrenoreceptor blocking activity. Nonselective β -blockers include propranolol and timolol. Cardioselective β_1 -receptor blocking agents (metoprolol) cause less bronchoconstriction and vasoconstriction, but this selectivity is lost when therapeutic doses are used. Some β -blockers (pindolol) have intrinsic sympathomimetic activity, producing low-grade β -stimulation at rest and a β -adrenergic blocking effect during exercise. Lipid-insoluble β -blockers (atenolol) are less likely to cross the blood-brain barrier, causing fewer central nervous system side effects. Other β -blockers (labetalol, carvedilol) have vasodilatory properties through a β_2 -agonist effect, an α -adrenergic blocking effect, and a direct vasodilatory effect. They are useful in patients with stable angina who have hypertension or are in heart failure.

Although therapy with β -blockers may increase triglyceride and decrease HDL levels, there is no evidence that they cause progression of atherosclerosis; on the contrary, they substantially limit the rate of reinfarction and mortality in patients recovering from acute MI. They are generally well tolerated but are contraindicated in patients with asthma, atrioventricular conduction defects, profound bradycardia, tachy-brady syndrome, severe hypotension, peripheral artery disease, Raynaud's phenomenon, and pheochromocytoma. They should not be used with monoamine oxidase inhibitors, as the unopposed β effect may result in severe hypertension. They should be administered with extreme caution to patients with severe heart failure. Nonetheless, patients with conditions that are often considered contraindications to β -blockade, such as heart failure or pulmonary disease, or older patients, appear to benefit significantly from β -blocker therapy. In particular, post-MI patients with a history of heart failure or left ventricular dysfunction appear to derive the major benefit from β -blockers. Although the potential exists for worsened heart failure in patients with systolic dysfunction, patients receiving ACE inhibitors, diuretics, and digoxin generally tolerate β -blockers well (in particular, extended-release metoprolol, carvedilol, and bisoprolol) when an initially low dose is used (e.g., 12.5 mg extended-release metoprolol once a day, 3.125 mg carvedilol twice a day, or 1 mg bisoprolol per day) followed by a careful, gradual increase in the dose. These agents appear to improve survival substantially in patients with systolic heart failure due to CAD who are already receiving ACE inhibitors.

Because there may be up-regulation of β -receptors during prolonged therapy with β -adrenergic blockers, they should not be discontinued abruptly in patients with ischemic heart disease; this may precipitate unstable angina or MI related to an increase in heart rate and blood pressure. These medications should be weaned gradually over several weeks, if possible. If withdrawal is necessary, strenuous exercise should be avoided, and, if possible, the β -blocker should be replaced with verapamil or diltiazem to decrease heart rate and blood pressure. The β -blockers should be used with caution in patients receiving verapamil and diltiazem, since the combined effect may result in hypotension, bradycardia, and decreased cardiac contractility. ACE inhibitors, in particular ramapril, reduce the rate of death, MI, and stroke in high risk patients for cardiovascular events. This therapy should be strongly considered in patients with stable angina.

Calcium channel blockers (or calcium antagonists) inhibit the entry of calcium ions into the cells via the voltage-dependent L-type calcium channel, which is present in myocytes and vascular smooth-muscle cells. All calcium antagonists cause relaxation of vascular smooth muscle in the arterial and coronary circulation. The net effect on cardiac contractility is a complex interaction between the direct depression of contractility noted with all calcium channel blockers and the reflex sympathetic activation caused by their effect on vascular resistance. Calcium antagonists may lessen the frequency of angina and enhance exercise tolerance. Calcium antagonists are generally well tolerated, but they should be used with extreme caution, if at all, in patients with systolic heart failure, because they may worsen heart failure and increase mortality rates. The use of short-acting calcium antagonists, particularly dihydropyridines, has been associated with a higher risk of MI.

Dihydropyridines (amlodipine, felodipine, isradipine, nifedipine, nocardipine, nimodipine, nitrendipine, nisoldipine) have a predominant effect on the vascular system. Owing to the powerful vasodilatory properties of therapeutic doses, these agents may amplify adrenergic nervous system activity, particularly the short-acting preparations. As a result, these agents usually produce no appreciable slowing of sinoatrial or atrioventricular conduction and may actually increase heart rate and cardiac output. The elevation in heart rate increases myocardial oxygen demand and may also diminish coronary blood flow by shortening the diastolic portion of the

cardiac cycle, during which coronary perfusion occurs. Dihydropyridines also may accentuate the circadian variation of adrenergic tone that predisposes to plaque rupture. Thus, short-acting dihydropyridines, alone or in combination with nitrates, may be associated with an increase in anginal attacks or even unstable angina or MI. The intensification of adrenergic nervous system activity may be prevented by a b-blocker; in this context, the negative inotropic effects of the calcium antagonist may predominate. Amlodipine is safe when used for angina, even in patients with systolic dysfunction when it is added to an ACE inhibitor. This may be related to the fact that amlodipine does not enhance neuroendocrine activity (serum norepinephrine concentrations).

Diltiazem and verapamil have balanced myocardial, electrophysiologic, and vascular effects, resulting in a decline in heart rate, atrioventricular conduction, blood pressure, and, particularly with verapamil, cardiac contractility. Bepridil has complex pharmacologic properties, and, in addition to a calcium channel blocking effect, it also inhibits the sodium channel. This may result in prolongation of the QT interval and, occasionally, induction of ventricular tachycardia (torsades de pointes). Bepridil, verapamil, and diltiazem should be avoided by patients with extensive first-degree atrioventricular block (more than 0.24 seconds), second- or third-degree atrioventricular block, tachy-brady syndrome, bradycardia, or atrial fibrillation with a slow ventricular response.

Other adverse effects of calcium antagonists include headache, dizziness, hypotension, ankle edema, and nausea. Some of these side effects are limited by the use of long-acting preparations. Constipation is a common complaint in patients receiving verapamil. Verapamil significantly increases the plasma levels of digoxin. Both verapamil and diltiazem raise the level of cyclosporine, and hence they should be used only with extreme caution in patients who have undergone organ transplant and are receiving immunosuppressive therapy. Therapy with b-blockers is preferred over calcium channel blockers in the treatment of stable angina. Patients with stable angina should consume a balanced diet with emphasis on antioxidant-rich fruits and vegetables and whole grains. The need for further supplementation with vitamins E, C, and beta-carotene remains to be determined by the ongoing studies. Medical therapy for stable angina pectoris in patients who have other common medical conditions is shown in [Table 72.8](#).

TABLE 72.8. MEDICAL THERAPY FOR STABLE ANGINA ASSOCIATED WITH OTHER MEDICAL CONDITIONS

Myocardial Revascularization

Percutaneous Coronary Revascularization

An estimated 482,000 percutaneous coronary revascularization (PCR) procedures were performed in 1996 in the United States. From 1987 to 1996, the number of procedures increased 211%. In 1996, 67% of PCR procedures were performed on men; 51% were performed on people under age 65. The average cost of PCR in 1995 was \$20,370. In many laboratories stents are now used in more than 50% of cases. PCR is the nonsurgical treatment of a stenotic artery that results in dilatation of the coronary lumen by a balloon catheter and/or by another intracoronary device. Balloon angioplasty increases the size of the arterial lumen by disrupting the atherosclerotic plaque and stretching and tearing the media and adventitia. With intracoronary ultrasonographic imaging, arterial dissection is detected in 50% to 80% of patients undergoing this procedure.

Several other devices have been introduced, such as atherectomy catheters, laser catheters, and ablation catheters. Only intracoronary stents with postdeployment inflation and adjunctive therapy with aspirin and ticlopidine or clopidogrel have been proved to decrease angiographic and clinical re-stenosis compared with conventional balloon dilatation. Stenting also can be used for treatment of prolonged total occlusion and coronary vein graft disease. PCR is successful in 90% of patients who undergo this procedure, with success defined as an increase in luminal diameter of at least 20% and a final stenosis severity of less than 50% of the luminal diameter.

Complications develop in less than 5% of patients; they include death (0% to 2%), MI (3% to 5%), and the need for emergency CABG (3% to 7%). Abrupt vessel closure occurs in 2% to 8% of procedures, with an attendant mortality rate of 4% to 10%. Aspirin lowers the rate of abrupt closure when used the day before and the day of angioplasty. Inhibition of the platelet glycoprotein IIb/IIIa receptor, together with low-dose, weight-adjusted heparin, lessens the risk of acute ischemic complications in patients undergoing PCR ([Table 72.9](#)). Women and patients with unstable angina have a higher risk of abrupt closure. Angiographic characteristics associated with a high risk of abrupt closure include coronary thrombus, eccentric stenoses, calcified stenoses, stenoses more than 10 mm long, and diffusely diseased arteries. Abrupt closure may require emergency coronary bypass surgery, but now it is successfully managed with percutaneous devices, most notably intracoronary stents.

Trial ^a	N	% All Events ^b		% Death + MI		% MI	
		Placebo	Drug	Placebo	Drug	Placebo	Drug
ERIC	2089	12.8	8.3	16.3	6.9	6.6	5.2
CAPURE	1305	15.9	11.3	9.8	4.8	8.2	4.1
IMPACT	2792	11.7	5.2	9.1	3.8	8.7	3.7
IMPACT II	4939	11.6	9.1	8.6	6.9	8.3	6.6
RESTORE	2141	18.5	8.0	6.4	5.0	5.7	4.2
Pooled	12307	12.1	8.1	8.7	5.7	8.0	5.0

^a Each trial is a 30-day study.
^b ERIC, CAPURE, and IMPACT data (as shown) reflect intention-to-treat analyses and represent the primary study end point (all events = death, MI, or urgent revascularization or coronary bypass surgery). Data from IMPACT II (epifluoride) and RESTORE (bifluoride) are derived data, calculated on a treatment-intent basis and adjusted to reflect the primary end point used for all other trials. Both IMPACT and IMPACT II evaluated two treatment strategies against placebo data for the last treatment comparison as shown. Pooled data are average results for each group weighted for number of patients in each trial.
 (From Mason DT, Benowitz SO, Thong HJ, Egeberg M, et al. Efficacy of IIb/IIIa receptor inhibitors. Circulation 1998;98:202-208, with permission.)

TABLE 72.9. CLINICAL TRIALS OF GLYCOPROTEIN IIb/IIIa ANTAGONISTS IN CORONARY INTERVENTION: 30-DAY OUTCOMES

PCR is indicated in any patient with significant stenosis in a major epicardial artery whose angina does not respond to medical therapy or who has evidence of myocardial ischemia in the territory of the artery to be dilated. This recommendation applies to patients with single or multivessel CAD. PCR should not be performed in arteries with a stenosis of less than 50% and is not indicated in the left main coronary artery.

The main limitation of balloon angioplasty is coronary re-stenosis, which occurs in 30% to 50% of patients within the first 6 months after the procedure. The rate of re-stenosis is much lower after intracoronary stents. Stenting also results in improved outcomes in patients who experience re-stenosis after conventional balloon dilatation. Several factors are associated with an increased risk of re-stenosis. Clinical factors include male sex, cigarette smoking, unstable angina, diabetes mellitus, hypertension, hypercholesterolemia, end-stage renal disease, and vasospastic angina. An elevated lipoprotein(a) concentration is also a marker for an increased risk for re-stenosis. Procedural characteristics that predispose to re-stenosis include dilatation of proximal stenoses, saphenous vein grafts, persistently occluded arteries, and stenoses more than 10 mm long. Residual stenosis of more than 30%, a small residual lumen, and the use of an undersized balloon also predispose to re-stenosis. Not all patients who experience re-stenosis after successful balloon angioplasty have recurrent angina. Since re-stenosis is a relatively slow process, it rarely results in MI. The antioxidant agent probucol appears to be effective in lowering the rate of re-stenosis after balloon angioplasty. Stents and platelet

glycoprotein IIb/IIIa receptor blocking agents lower the rate of re-stenosis.

Coronary Artery Bypass Graft Surgery

In the United States in 1996 an estimated 598,000 CABGs were performed on 367,000 patients. From 1979 to 1996 the number of procedures increased 424.6%, and the number of patients grew 227.7%. Segments of autologous saphenous vein have been used as conduits, but internal mammary artery grafts are being used more and more, since they have a higher long-term patency rate, particularly when used to bypass the left anterior descending artery. The 10-year patency rate of saphenous vein grafts is 50%; that of an internal mammary graft is about 90%. Endarterectomy is occasionally used in combination with CABG procedures. CABG has been shown to be highly effective in relieving angina and prolonging life. The perioperative mortality rate is usually less than 4%, and the perioperative MI rate has declined from 5% to 8% two decades ago to about 2.5% as methods of myocardial protection during surgery have improved. In patients with chronic CAD, factors associated with an increased risk of perioperative death are age, female sex, severe left ventricular dysfunction, diabetes, and emergency surgery after failed PCR.

MI is uncommon in the first few years after CABG. The return of angina soon after surgery is related to either incomplete revascularization or early graft closure. Angina occurring very late is related to closure or narrowing of the bypass grafts or progression of atherosclerotic disease in the native vessels. Early use of platelet inhibitor therapy clearly prolongs graft patency. Aspirin should be used in the perioperative period, preferably before but not later than 48 hours after surgery. Usually, 81 to 324 mg of aspirin is an effective dose. Continued cigarette smoking is the most significant risk factor for early graft closure.

The main indication for CABG is relief of symptoms that are not responsive to medical therapy or PCR. Relative contraindications are the complete absence of viable myocardium in the areas supplied by a stenotic artery and coexisting severe noncardiac conditions with a poor prognosis. CABG improves survival in patients with left main disease, three-vessel disease, or two-vessel disease when one of the two vessels involved is a large left anterior descending coronary artery with severe proximal stenosis (Fig. 72.4). This benefit is particularly evident in patients who have left ventricular systolic dysfunction. Some reports suggest that the benefits of CABG on the beating heart, whether through full or limited access (minimally invasive CABG), result in lower mortality and morbidity rates and an earlier return to normal activities.

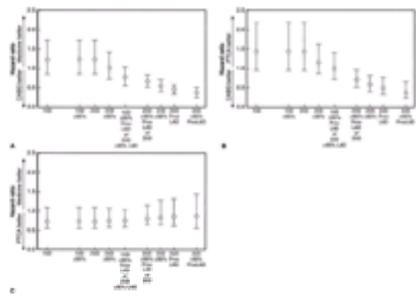

FIGURE 72.4. Hazard (mortality) ratios for coronary artery bypass surgery (CABG) versus medicine (A), for CABG versus percutaneous transluminal coronary angioplasty (PTCA) (B), and for PTCA versus medicine (C), calculated from the Cox regression model to evaluate relative survival differences. Points indicate hazard ratios for each level of the coronary artery disease index indicated on the horizontal axis. Bars indicate 99% confidence intervals. The horizontal line at a ratio of 1.0 indicates the point of prognostic equivalence between treatments. Hazard ratios above or below the line favor the treatment indicated. VD, vessel disease; Prox LAD, proximal left anterior descending coronary artery. (From Mark DB, Nelson CL, Califf RM, et al. Continuing evolution of therapy for coronary artery disease: initial results from the era of coronary angioplasty. *Circulation*. 1994;89:2015–2025, with permission.)

In selected patients with multivessel CAD, PCR and CABG show similar rates of death or MI and similar improvement in exercise capacity. Patients with diabetes who are on insulin or oral therapy have a significantly lower mortality rate with CABG than with PCR. Patients undergoing PCR are more likely to have persistent angina requiring antianginal medications and a greater need for additional revascularization procedures, including repeated PCR or CABG. For patients with disease of the left main coronary artery, multivessel disease affecting the proximal left anterior descending artery, or three-vessel disease and impaired left ventricular systolic function, CABG is preferred over PCR (see Fig. 72.4).

Angiogenesis

Angiogenesis is an investigational therapy for inducing the growth of new blood vessels. Angiogenic growth factors include vascular endothelial growth factor (VEGF) and fibroblast growth factor. VEGF is a naturally occurring angiogenic peptide that exists in four isoforms. This peptide may stimulate endothelial cell growth, proliferation, and migration. Both recombinant VEGF protein and VEGF gene therapy have produced angiogenesis in animal models. Encouraging results were obtained in patients who were not ideal candidates for coronary revascularization and who received escalating doses of intracoronary recombinant human VEGF. Similar results were obtained with intramuscular injection of the naked DNA coding for VEGF. Although the initial experience with angiogenic growth factors is promising, conclusions are limited by the preliminary nature of the clinical data, including the small number of patients, short follow-up times, and lack of controls.

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization may be used as adjunct therapy for patients with ischemic heart disease who are not suitable candidates for PCR or CABG. This technique uses a carbon dioxide laser to create transmyocardial channels for direct perfusion of the ischemic heart in patients with angina. There is a significant decline in the frequency of angina episodes and the number of hospital admissions for angina after this procedure. The reason for this symptomatic improvement is the subject of uncertainty and controversy, however, since data establishing an improvement after transmyocardial laser revascularization are quite limited.

SILENT ISCHEMIA

Silent ischemia is myocardial ischemia associated with electrocardiographic or hemodynamic abnormalities not accompanied by chest pain or chest discomfort or other anginal symptoms, such as dyspnea. The electrocardiographic and hemodynamic changes during painless episodes are identical to those associated with symptomatic attacks but are of lesser magnitude and duration. Silent ischemia may occur in patients who are completely asymptomatic, patients with stable or unstable angina, or patients recovering from acute MI. As noted previously, 60% to 70% of patients with chronic angina pectoris have episodes of silent ischemia. A circadian distribution, as is found for angina in patients with chronic CAD, has also been noted for silent ischemia, with episodes taking place mostly in the early morning. In patients with CAD, the prognosis is the same for silent or symptomatic ischemia found during ambulatory electrocardiographic monitoring or stress testing. Because ST-segment shifts on a Holter monitor or on a stress test may not always represent ischemia, medical treatment should be reserved for patients who have angiographically documented CAD, patients recovering from MI, and patients with objective evidence of ischemia, such as positive radionuclide or echocardiographic stress test results.

Medical therapy consists of the use of nitrates and β -blockers. If these agents do not suppress or significantly lessen the ischemic episodes, calcium channel blockers should be added. The β -blockers are superior to calcium channel blockers in abolishing silent ischemia, and among the calcium channel blockers, the nondihydropyridines, such as diltiazem, are more effective than the dihydropyridines, such as nifedipine. Revascularization should be considered in patients with silent ischemia who have severe CAD, especially those with left ventricular dysfunction or inducible ischemia on exercise testing.

ACUTE CORONARY SYNDROME

Acute coronary syndrome (ACS) is a clinical syndrome characterized by an increase in the intensity or frequency of angina episodes and is associated with an increased risk of MI and cardiac death. Several scenarios fulfill this broad definition of the syndrome, including a single episode of prolonged rest angina (at least 20 minutes), the new onset of angina (less than 2 months), and acceleration of angina (an angina pattern that becomes more frequent, longer in duration, or lower in threshold). Variant angina, non-Q-wave MI, and postinfarction angina (more than 24 hours) are considered part of the spectrum of ACS. The diagnosis of unstable

angina and non-Q-wave MI are usually considered together because they cannot be distinguished clinically or angiographically. In 1990, there were 850,000 new hospitalizations in the United States for this condition, the most common cardiovascular cause for hospital admission.

PATHOPHYSIOLOGY

ACS appearing in the form of prolonged chest pain at rest often results from fissuring or rupturing of the atherosclerotic plaque, leading to thrombus formation. Plaques that are prone to rupture are often insignificant in angiographic features and not flow limiting, and they contain large amounts of extracellular cholesterol covered by a thin cap of fibrotic tissue. The immediate site of plaque rupture is usually marked by an inflammatory process (macrophage-rich areas), suggesting that inflammation plays a role in destabilizing the fibrous cap tissue. Hyperlipidemia, high angiotensin levels, elevated acetoacetic acid levels (as in diabetes), nicotine, and circulating immune complexes may predispose to plaque rupture. Rupture of the fibrous cap most commonly occurs at the junction between the normal and atherosclerotic segments of an eccentric stenosis. Plaque disruption leads to brief periods of intraluminal and intramural platelet and fibrin-type thrombus formation. Both platelets and damaged endothelial cells release potent vasoconstrictive substances that may lead to coronary vasospasm. There are higher levels of endothelin-1, a potent vasoconstrictor peptide produced by endothelial cells and macrophages present in the atherosclerotic plaques, in patients with ACS, which may explain the increase in vasoreactivity associated with this condition.

CLINICAL MANIFESTATIONS

In patients with ACS, the chest discomfort is somewhat similar to that of stable angina, though in patients with rest angina or crescendo angina, it is usually more severe and lasts longer. The discomfort is often associated with diaphoresis, a fourth or third heart sound, a systolic murmur, and even a dyskinetic apical impulse. Electrocardiographic findings during an angina attack may show ST-segment depression or elevation or T-wave abnormalities; sometimes these electrocardiographic abnormalities persist after the discomfort disappears. If they persist for several hours, they are often associated with elevation of creatine kinase-MB. When there is a typical rise and fall of the creatine kinase-MB level without development of new Q waves, the diagnosis of a non-Q-wave MI is usually made. Troponin T and I may be released into the serum, providing useful prognostic information and permitting the early identification of patients with a higher risk of death. A normal ECG does not exclude the possibility of unstable angina, but it makes the diagnosis less likely.

Coronary arteriographic findings in patients with ACS are related to the population being studied. In the TIMI-IIIB (Thrombolysis in Myocardial Ischemia) study, about 5% of patients had left main disease, 15% had three-vessel disease, 30% had two-vessel disease, and 35% had one-vessel disease; 15% had no significant CAD. In contrast, in the Veterans Administration study of unstable angina, 47% had three-vessel, 35% had two-vessel, and 18% had one-vessel disease. Although the extent of coronary stenoses in unstable angina and stable angina appears to be similar, the morphologic features of plaque differ; there are more eccentric lesions with more irregular or hazy borders in patients with unstable angina, suggestive of disrupted atherosclerotic plaques with thrombus formation. Up to 40% of patients studied early after the onset of rest angina have angiographic evidence of coronary thrombi.

NATURAL HISTORY AND PROGNOSIS

Earlier studies reported an infarction rate of 20% to 40% within 3 months of the onset of ACS. In the Veterans Administration studies of unstable angina, the 10-year cumulative mortality was 38% for patients treated medically and 39% for those treated surgically. At present, since patients are initially treated aggressively with b-blockers, nitrates, aspirin, heparin, and glycoprotein IIb/IIIa receptor antagonists and high-risk patients are identified and undergo revascularization, the outcome has improved considerably.

EVALUATION AND MANAGEMENT

Patients with suspected ACS should be evaluated initially in a medical facility. The ECG should be obtained during the course of chest discomfort and after its relief. According to the US Agency for Health Care Policy Research, it is important in evaluating patients with chest pain to assess both the likelihood of CAD ([Table 72.10](#)) and the likelihood of adverse outcomes ([Table 72.11](#)). Elevated troponin I predicts a higher mortality in ACS patients. On the basis of this first evaluation, the patient should be assigned to one of four categories: non-CAD, stable angina, acute MI, or unstable angina. Patients who are judged in the initial evaluation and treatment phase to be at low risk of experiencing adverse outcomes can be evaluated further as outpatients. The follow-up evaluation of these patients should generally occur within 72 hours of their first evaluation. Therapy should consist of aspirin (81 to 324 mg per day), sublingual nitroglycerin as needed, oral b-blockers, and long-acting topical or oral nitrates ([Table 72.9](#)). Aspirin lowers the risk of MI by 71%. Ticlopidine and clopidogrel are also acceptable therapy for secondary prevention in patients who cannot tolerate aspirin.

High Likelihood	Intermediate Likelihood	Low Likelihood
Any of the following features: History of myocardial infarction or sudden death or other known history of coronary heart disease Definite angina: male <60 or female <70 years of age T-wave inversions or electrocardiographic changes during pain Variant angina pain with reversible ST segment elevation or depression >1 mm Marked symmetric T-wave inversion in multiple precordial leads	Absence of high-likelihood features and any of the following: Definite angina: male <60 or female <70 years of age Probable angina: male <60 or female <70 years of age Chest pain probably not angina in patients with diabetes Chest pain probably not angina and two or three risk factors other than diabetes Exercisable vascular disease ST depression 0.5-1 mm T-wave inversion >1 mm in leads with dominant R waves	Absence of high- or intermediate-likelihood features but any of the following: Chest pain classified as probably not angina One risk factor other than diabetes T-wave flattening or inversion <1 mm in leads with dominant R waves Normal electrocardiogram

*Coronary artery disease risk factors include diabetes, smoking, hypertension, and elevated cholesterol.
From Agency for Health Care Policy and Research Clinical Practice Guidelines: Unstable Angina, Myocardial Ischemia, and Management. U.S. Department of Health and Human Services Publication No. MA-92-1094, with permission.

TABLE 72.10. LIKELIHOOD OF SIGNIFICANT CORONARY ARTERY DISEASE IN PATIENTS WITH SYMPTOMS SUGGESTING UNSTABLE ANGINA

High Risk	Intermediate Risk	Low Risk
At least one of the following features: most to present Prolonged (lasting > 20 min) rest pain Pulmonary edema, most likely related to ischemia Angina at rest with dynamic ST changes >1 mm Angina with new or worsening MI Angina with ST or non-ST-segment elevation Angina with hypertension	No high-risk features but must have any of the following: Prolonged (> 20 min) rest angina, new, increased, with moderate or high likelihood of CAD Rest angina > 20 min or relieved with rest or sublingual nitroglycerin Normal angina Angina with dynamic T-wave changes Recurrent QECG, R or T waves in the past 2 weeks with moderate or high likelihood of CAD Pathologic Q waves or resting ST depression >1 mm in multiple lead groups (anterior, inferior, lateral) Age > 60 years	No high- or intermediate-risk features but any of the following: Increased angina frequency, severity, or duration Angina predicted at 1 hour threshold New-onset angina with onset 2 weeks to 2 months before presentation Normal or unchanged electrocardiogram

CAD, coronary heart disease; QECG, Canadian Cardiovascular Society classification.
*Calculation of the short-term risk of death and nonfatal MI in unstable angina is a complex and multifaceted problem that cannot be fully specified in a table such as this. Therefore, the table is meant to offer general guidance and direction rather than rigid algorithms.
From Agency for Health Care Policy and Research Clinical Practice Guidelines: Unstable Angina, Myocardial Ischemia, and Management. U.S. Department of Health and Human Services Publication No. MA-92-1094, with permission.

TABLE 72.11. SHORT-TERM RISK OF DEATH OR NONFATAL MYOCARDIAL INFARCTION IN PATIENTS WITH UNSTABLE ANGINA

Patients at high or intermediate risk of death or nonfatal MI should be admitted to an intensive or intermediate care unit and have serial cardiac enzyme measurements and ECGs to exclude the possibility of acute MI. These patients should be treated with aspirin, intravenous heparin or low-molecular-weight heparin, glycoprotein IIb/IIIa antagonists ([Table 72.12](#)), nitrates, and b-blockers (see [Table 72.13](#)). Calcium channel blockers should be reserved for patients with hypertension; those with refractory ischemia despite the use of aspirin, heparin, nitrates, and b-blockers; and those with variant angina. Dihydropyridines should not be used as monotherapy. Intravenous thrombolytic therapy is not indicated in patients with ACS unless they have symptoms of prolonged rest pain and elevation of the ST segments in two consecutive leads or a left bundle-branch block.

single-vessel disease and variant angina refractory to medical management can be successfully treated with PCR, but the re-stenosis rate is higher than in patients with stable angina. Patients should be continued on calcium channel blockers after PCR.

PATHOGENESIS

Several pivotal observations have significantly altered the diagnosis and treatment of patients with acute myocardial infarction (MI):

1. Acute MI is almost always associated with a thrombus superimposed on significant coronary atherosclerosis.
2. MI is a regional disease limited to the vascular territory of one of the three major vessels or their branches.
3. Q-wave and non-Q-wave infarctions have distinct natural histories. Patients recovering from a Q-wave infarction have a high-risk period of 6 to 12 weeks, followed by a low mortality rate in subsequent years. Patients with Q-wave infarction undergoing early reperfusion (thrombolysis or percutaneous transluminal coronary angioplasty, or PTCA) have the highest risk in the first 24 to 72 hours. In contrast, non-Q-wave infarction has an initially low mortality rate, followed by a prolonged high-risk period of 1 to 2 years; after this interval, the accumulated mortality rate is similar to that of Q-wave infarction.
4. More than half the patients with a first episode of MI (about one-third of the total population) have significant obstructive atherosclerosis in only one vessel, emphasizing the potential for a second ischemic event.
5. Based on direct experimental and indirect clinical evidence, irreversible injury requires at least 15 to 20 minutes of ischemia.
6. Myocardial necrosis stemming from ischemia begins in the subendocardium and spreads to the epicardium. If the coronary occlusion is complete and sustained, depending on the collateral blood supply, 50% to 90% of the involved myocardium distal to the lesion undergoes ischemia and, subsequently, necrosis, requiring 4 to 6 hours.
7. The evolution of myocardial necrosis is influenced by factors that alter myocardial oxygen supply and demand. Although decreasing demand may limit infarct size, it now appears that increasing supply via coronary perfusion is more effective.
8. Studies indicate that acute MI, at least Q-wave infarction, is more likely to be initiated in the morning (4 a.m. until noon), which corresponds to the time of diminished adrenergic activity, increased plasma fibrinogen levels, and enhanced platelet adhesiveness. The potential causative role of these factors remains to be elucidated.
9. Right ventricular infarction, once considered rare, is now known to occur in conjunction with left ventricular damage in most patients with inferior infarction.

CLASSIFICATION

Traditionally, patients who manifest a Q wave on the electrocardiogram (ECG) have been referred to as having transmural infarction, implying that the pathologic injury extends from the endocardium to the epicardial surface. Subendocardial or nontransmural infarction indicates that injury is restricted to the subendocardium and is associated with electrocardiographic changes limited to the ST-T segments. Because the correlation between electrocardiographic findings and postmortem morphologic findings is often poor, electrocardiographic classification into Q-wave (transmural) and non-Q-wave infarction (subendocardial) is recommended.

CLINICAL FEATURES

The predominant initial symptom is chest discomfort, frequently referred to as discomfort, tightness, or difficulty in breathing rather than pain. Cardiac pain typically radiates to the arm and neck and, less often, to the jaw. Occasionally, the pain starts in the wrist, elbow, or shoulder, or rarely as a toothache, and radiates to the chest. The most consistent feature of chest pain is the retrosternal component. Pain originating or radiating below the rib cage is rare, and pain restricted to the left inframammary region is seldom cardiac in nature. Chest pain associated with infarction is usually not relieved by nitroglycerin. Nausea and vomiting may accompany chest pain, particularly in association with inferior infarction. Esophageal pain is virtually identical to cardiac pain and may also be relieved by nitroglycerin, albeit not immediately, as is often the case with angina. The duration of the pain, its character, and its distribution are extremely unreliable characteristics in differentiating reversible and irreversible injury: fewer than one-third of patients admitted to the coronary care unit are subsequently found to have acute MI.

On physical examination ([Table 73.1](#)), one should pay careful attention to the physical appearance, the jugular venous pulses, palpation of the arterial pulses and precordium, and auscultation of the precordium. The patient should be examined in the supine and left lateral decubitus positions. The typical patient is usually anxious, with an ashen or pale face beaded with perspiration, and has the sensation of difficulty in breathing, so that he or she usually lies still with the head propped up on pillows. The patient with severe chest pain may clench the fist and motion toward the sternum, the so-called Levine sign. The patient's appearance, posture, and gestures are in large part dictated by the severity and duration of the chest pain.

TABLE 73.1. PHYSICAL FINDINGS OF ACUTE MYOCARDIAL INFARCTION

The peripheral arterial pulse is often normal, although the rate initially may be slower than normal (60% of patients with inferior infarction in the initial hours) and gradually increase over the next few hours, or it may be faster, as it often is with extensive anterior infarction. Persistent sinus tachycardia beyond the initial 24 hours carries a very high mortality rate. The blood pressure is usually normal, but it may be high as the result of anxiety or low from cardiac failure. Patients with inferior infarction may show signs of bradycardia and hypotension stemming from the so-called von Bejold–Jarish reflex. Most patients with inferior infarction have concomitant right and left ventricular injury, which can manifest as increased jugular venous pressure, an accentuated A wave, or lack of a decline in venous pressure on inspiration (Kussmaul's sign) owing to the diminished compliance of the right ventricle. The jugular venous pressure may be elevated owing to right ventricular or biventricular failure. About 60% to 70% of patients with inferior infarction in the initial hours show no decrease in jugular venous pulsation on normal inspiration as the result of concomitant right ventricular involvement, despite the absence of right-sided failure.

Depending on the severity, MI may have no discernible effect, may induce an area that is hypokinetic or akinetic, or may actually bulge in the opposite direction during systolic contraction. Within 24 hours of onset of infarction, one can usually palpate an abnormality of the precordial pulsations in patients in the left lateral decubitus position—either lack of a point of maximal impulse or the presence of diffuse contraction. In about 30% to 40% of the patients, atrial contraction is palpable.

The intensity of the first heart sound may be diminished because of decreased contractility. A fourth sound is heard in practically all patients (and, in fact, in many normal persons over age 45). A third heart sound (S_3) is heard in about 20% to 30% of patients, reflecting some degree of left ventricular dysfunction; this may be the only manifestation of cardiac decompensation. In cases of extensive damage, the second heart sound may be single; however, a paradoxical split is rare and reflects severe ventricular decompensation. The presence of a systolic murmur from papillary muscle dysfunction is found at least transiently in most patients in the first 24 hours of acute MI. The pericardial friction rub does not develop as a rule until about 48 to 72 hours. In patients with Q-wave infarction, it is said that if one listens frequently, a transient pericardial rub is heard in most patients; otherwise, it is heard in about 10%.

Patients who have experienced an infarction may show symptoms of worsening cardiac failure. The predominant clinical picture may be one of pulmonary edema, ventricular tachycardia, atrial fibrillation, shock, stroke, pulmonary embolus, heart block, fever, or syncope. Various conditions simulate acute MI, notably acute pulmonary embolus, acute pericarditis, dissecting aortic aneurysm, esophagitis, hiatal hernia, cholecystitis, pancreatitis, and spontaneous pneumothorax.

DIAGNOSIS

ELECTROCARDIOGRAPHIC DIAGNOSIS

The findings on the ECG of acute ischemia or infarction are discussed in [Chapter 84](#). In fewer than half of patients with MI, serial analysis by electrocardiography shows a characteristic profile of ST-segment elevation followed by the development of new Q waves. The rest of the patients may have only minor changes or marked changes consisting of ST-T-segment elevation or depression. When the changes are restricted to the ST-T segment, confirmation by enzymatic and radiographic assessment is essential, since these changes also are associated with ischemia without irreversible injury. In patients with previous MI and residual Q waves or left bundle-branch block, the development of new Q waves may be masked; thus, an electrocardiographic diagnosis becomes more difficult (see [Chapter 84](#)).

On the basis of the ECG, patients are divided into those with Q-wave and those with non-Q-wave infarction. In patients with posterior infarction, the more specific manifestation is that of a large R wave in V_1 that is equal to or exceeds that of the S wave, together with new ST changes. In the case of lateral infarction, often the only manifestation is ST-segment depression in the lateral leads; Q waves develop in less than 30% of patients. In patients with inferior infarction who have concomitant right ventricular involvement, one should perform right precordial leads; ST-segment elevation present in these leads is highly suggestive of right ventricular infarction, but otherwise it is difficult to diagnose right ventricular infarction from the ECG. Atrial infarction is suspected if there is an elevation or depression of the PQ segment; changes in the morphologic features of the P wave; or atrial dysrhythmias, such as frequent premature apical beats, atrial flutter, or fibrillation.

DIAGNOSTIC BIOCHEMICAL MARKERS FOR THE EARLY AND LATE DIAGNOSIS OF MYOCARDIAL INFARCTION

More than five million patients with chest pain are seen in emergency clinics throughout the United States annually, but only about 10% of these individuals have suffered acute MI, and about 20% have unstable angina. More than 30% of these individuals have pain of noncardiac origin, and the remainder have pain of cardiac origin with or without ischemia. A major difficulty lies in distinguishing cardiac ischemia from MI, since the history and physical examination are seldom helpful in this regard and the ECG provides a positive specific diagnosis in only about 5% of patients with chest pain (40% of patients with acute MI). This difficulty often results in a large number of patients being admitted unnecessarily to the hospital for exclusion of infarction, such that it is estimated that more than \$12 billion is spent in unnecessary admissions. This situation is reflected in the observation that more than 50% of patients admitted with the diagnosis of unstable angina are being discharged within 12 to 24 hours with a noncardiac diagnosis.

The importance of making a diagnosis within hours of arrival in the emergency room is also emphasized by the need for early thrombolytic therapy, which has a mortality of 1% when given immediately compared with 10% when given 6 hours from onset of symptoms. Furthermore, it was shown in the Thrombolysis in Myocardial Infarction (TIMI-III) trial that there was an increased incidence of MI and death among patients with unstable angina who received thrombolytic therapy, compared with the incidence with conventional therapy. The use of glycoprotein IIb/IIIa inhibitors in unstable angina, as opposed to thrombolytic therapy, also emphasizes the need for markers that can differentiate irreversible cardiac injury from the injury of ischemia. Thus, the necessity for early and more appropriate therapy coupled with cost-effective use of resources has underscored the importance of early diagnosis in the emergency room. For the past two decades the diagnostic biochemical marker relied on primarily has been plasma total creatine kinase-MB (CK-MB). While CK-MB has high sensitivity and specificity relative to other conventional markers (lactate dehydrogenase and aspartate aminotransferase), it is not an early marker, since exclusion of infarction may require up to 12 hours from onset of symptoms.

It must be emphasized that in the emergency room a test specific for infarction will be negative 90% of the time, since 90% of patients have not had MIs. The only markers that offer the potential sensitivity and specificity for early diagnosis within the first 6 hours from onset of symptoms are myoglobin and CK-MB subforms. The newly introduced biochemical markers troponin T and troponin I are highly sensitive and specific for MI, but similarly to total CK-MB, they do not increase above normal levels to exclude MI reliably with 90% confidence until about 14 to 16 hours from the onset of symptoms. This delay stems from the fact that only a small amount is released in the early hours. In contrast, myoglobin with a molecular weight of only 17,000 is released rapidly and reaches significant levels above the normal range within 2 to 3 hours. Upon release into the circulation, the tissue isoenzyme CK-MB is acted on by the enzyme carboxypeptidase B, which cleaves the terminal lysine from the MM subunit, resulting in a more negatively charged molecule. This generates two plasma subforms of CK-MB, one referred to as MB-2 (the unmodified tissue form newly released from the tissue) and the other as MB-1 (the modified form being more negative owing to loss of the positively charged terminal lysine), which are normally present in equilibrium in amounts of only one to two units of each subform per liter.

In the initial hours, only minute amounts of CK-MB (MB-2) are released into the circulation of patients with MI, such that exceeding the normal upper limit for total CK-MB in many patients may require 10 to 12 hours. Even the release of one to two units of MB-2, however, will drastically change the ratio from 1:1 to 2:1. Taking advantage of this early change in the ratio provides for a highly specific and early diagnosis of infarction. A prospective, multicenter, double-blind trial was performed in patients with initial symptoms of chest pain. Patients were enrolled consecutively, comparing the sensitivity and specificity of all of the markers for early (less than 6 hours from onset of symptoms) and late diagnosis (more than 6–8 hours) of infarction. The results are summarized in [Table 73.2](#). The CK-MB subforms accurately detected 92% of the patients with infarction within 6 hours of onset and myoglobin detected 79%, with specificity for both markers of 90%. In contrast, total CK-MB and the cardiac troponins had sensitivities of only 75% and 60%, respectively.

Marker	Early Diagnosis			Late Diagnosis			
	2	6	6	10	16	18	22
CK-MB subforms							
Sensitivity (%)	91.1	94.4	91.5	92.2	92.8	92.9	93.1

TABLE 73.2. DIAGNOSTIC SENSITIVITY AND SPECIFICITY OF MARKERS FOR MYOCARDIAL INFARCTION BASED ON A PROSPECTIVE, DOUBLE-BLIND, MULTICENTER TRIAL

Furthermore, it was shown that two samples, one taken on arrival at the emergency room and another 1 hour later, accurately diagnosed 91% of patients with infarction using CK-MB subforms; 78% of patients were diagnosed using myoglobin. Both assays are automated and require about 20 minutes to perform. It is recommended that a sample be obtained on admission and again at 1 hour and every 2 hours thereafter, if necessary, until 6 hours from onset of symptoms. If the plasma ratio of the CK-MB subform remains normal at 6 hours from onset of symptoms, MI can be excluded with a negative predictive value of 99%. Myoglobin analyzed and found to be normal at 6 hours from onset of symptoms has a reliability of 80%. It is also recommended that patients admitted to the hospital with the

diagnosis of infarction should be tested every 6 to 8 hours for 24 hours to determine peak activity, to obtain baseline values for patients undergoing such procedures as cardiac catheterization or PTCA, and to detect early reinfarction. The MB-2 subform returns to normal within about 24 hours and is the most sensitive marker for detection of early reinfarction. The total CK-MB level remains elevated for 72 to 96 hours, and troponin I and T levels remain high, on average, for about 10 days.

The conventional markers, namely, total CK-MB, troponin T, and troponin I, are reliable markers for diagnosis after 12 to 16 hours from onset of symptoms. If CK-MB subforms are used to make an early diagnosis, then the same assay can be used for late diagnosis, since total CK-MB activity can be derived from the subforms. If one chooses to use troponin I or troponin T for late diagnosis, it can be combined with the CK-MB subforms or myoglobin for early diagnosis. There is no advantage to assaying both troponin T and I, since they have a similar plasma temporal profile; troponin I is slightly more specific than troponin T.

The plasma total level of the CK-MB isoenzyme of CK, as assessed by quantitative techniques, is elevated within 6 to 10 hours of onset of infarction and peaks between 12 and 28 hours, with return to normal levels after 72 to 96 hours ([Fig. 73.1](#)). Troponin T and troponin I are contractile proteins with a molecular weight of 37,000 and 23,000, respectively. The troponins are released within 6 to 10 hours of onset of infarction, similarly to total CK-MB, and peak at 24 to 36 hours, returning to normal levels within 10 to 12 days. CK has been shown in the conscious canine model to be released only if myocardial necrosis occurs. CK-MB and CK-MB subforms have been shown not to be released in patients with known coronary artery disease (documented on coronary angiograms) during exercise-induced ischemia (documented on thallium scans). It remains to be determined whether troponin T or troponin I is released in the context of myocardial ischemia without necrosis; it is highly unlikely, since these are structural proteins of the sarcomere.

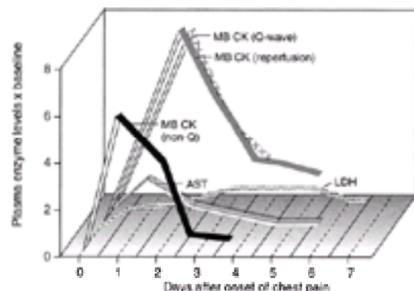

FIGURE 73.1. Typical plasma profiles for the MB isoenzyme of creatine kinase (MB CK), aspartate amino transferase (AST), and lactate dehydrogenase (LDH) activities after onset of acute myocardial infarction.

In patients with unstable angina, manifesting as clinical symptoms of pain at rest or increased frequency or severity of angina, total CK-MB activity was elevated in 7%, troponin T in 13%, myoglobin in 18%, troponin I in 20%, and CK-MB subforms in 27% (Zimmerman et al., 1999). The upper limit of normal for total CK-MB is 7 ng per milliliter, for troponin I is 1.5 ng per milliliter, for troponin T is 0.1 ng per milliliter, and for myoglobin is 85 ng per milliliter. The diagnosis based on CK-MB subforms consists of MB-2 \geq 2.6 IU per liter, with a ratio of MB-2 to MB-1 of \geq 1.7 IU per liter. CK-MB and cardiac troponin T levels may be elevated owing to release from skeletal muscle and as the result of musculoskeletal disorders, while cardiac troponin I appears to be highly specific for cardiac injury. False elevations of CK-MB and cardiac troponin T may be observed in patients with renal failure, but these markers will not increase and then decrease, as observed with myocardial injury. Cardiac troponin I is not elevated in patients with renal failure.

MI after noncardiac surgery is also determined reliably from serial analysis of plasma CK-MB, cardiac troponin T, and cardiac troponin I levels every 4 to 6 hours. Levels of other enzymes are markedly elevated as a result of tissue trauma, but these markers are quite specific to myocardial damage. In the context of cardiac surgery, the level of CK-MB, like those of other cardiac enzymes (lactate dehydrogenase, troponin T and I), is almost always elevated, owing to manipulation and involvement of the myocardium; thus, it is not a reliable diagnostic test for infarction.

OTHER LABORATORY FEATURES

The blood glucose may become elevated in the latent diabetic and the electrolytes may be abnormal. Within 24 hours, significant leukocytosis develops, which persists for 7 to 10 days and often reaches levels of 10,000 to 15,000 per milliliter. The sedimentation rate characteristically increases after the first 48 hours.

TREATMENT

In the United States in 1997, about 1.5 million persons experienced MI; one-third died, 350,000 of them outside the hospital within 1 to 2 hours of onset of symptoms. Hospitalization of patients in the cardiac care unit has now become routine. Under constant electrocardiographic monitoring and with highly trained medical and nursing personnel, the treatment of dysrhythmias in the cardiac care unit has lowered the mortality rate from MI to 10% to 15%. Most deaths are due to pump failure from destruction of myocardium; thus, the next phase in the approach to therapy was limitation of infarct size, which has been initiated with early reperfusion induced by thrombolytic therapy and, more recently, by primary PTCA. The application of thrombolytic therapy has lowered the in-hospital mortality rate to 6%. The highly vulnerable period for ventricular fibrillation and ventricular tachycardia associated with MI is over after about 36 to 48 hours, so patients are often moved from the cardiac care unit after 2 or 3 days. Patients without complications are generally discharged after about 5 to 8 days.

INITIAL ASSESSMENT

In the initial assessment, the vital signs are checked, and an intravenous infusion is begun. Lidocaine is administered if ventricular dysrhythmias are present, oxygen is given, and pain is relieved with morphine. An ECG is obtained, and the patient usually is connected to some form of continuous electrocardiographic monitoring ([Table 73.3](#)). Aspirin should be given immediately, and the patient should be assessed for thrombolysis and a thrombolytic agent administered within 30 minutes, if there are no contraindications.

- Vital signs
- Electrocardiograms
- Establish I.V. access
- Determine if candidate for thrombolytic therapy

TABLE 73.3. INITIAL ASSESSMENT OF ACUTE MYOCARDIAL INFARCTION

ASSURANCE AND PAIN RELIEF

Morphine remains the drug of choice and is extremely effective. It should be given intravenously in small doses (2 to 4 mg), which can be repeated every 5 minutes until relief is obtained. Other analgesics, such as meperidine, may be substituted for morphine, but they tend to be less effective and are just as likely to produce side

effects. Intravenous b-blockers are also safe and effective in the relief of pain with acute MI. If the patient is particularly emotionally disturbed, a mild tranquilizer should be given in addition to morphine to allay anxiety.

OXYGEN THERAPY

Hypoxemia often occurs in patients with acute MI, generally as the result of pulmonary edema. Traditionally, oxygen is given routinely via nasal prongs (2 to 4 L). In patients with severe pulmonary edema, it may be necessary to intubate and give oxygen under positive pressure. If the partial pressure of oxygen is normal, oxygen therapy should be discontinued. In patients with uncomplicated infarction, oxygen by nasal prongs is uncomfortable, expensive, and unnecessary.

THROMBOLYTIC THERAPY

Thrombolytic therapy with recombinant tissue-type plasminogen activator (rtPA), streptokinase, acylated plasminogen streptokinase activated complex (APSAC), or recombinant plasminogen activator (rPA) improves ventricular function and diminishes infarct size and mortality rates when administered within the initial 4 to 6 hours. The importance of early administration is shown in [Table 73.4](#): the mortality rate is lessened by almost 50% in patients treated within the first hour, with no significant difference after 6 hours. Studies show some benefit even in patients treated up to 12 hours, but maximal benefit is derived from treatment within the initial 1 to 2 hours. In 60% to 70% of patients, the vessel will recanalize spontaneously after 5 to 10 days. Streptokinase restores coronary patency in about 50% to 60% of patients with acute MI; rtPA or rPA restores patency in about 70% to 80%. Patients undergoing thrombolytic therapy should receive heparin and aspirin. Aspirin lowers mortality and reinfarction rates and is associated with minimal side effects. Heparin, in conjunction with rtPA, has a patency of 80%; with aspirin alone, it is only 52%.

Time from Onset (hr)	Reduction in Mortality (%)	p Value
<1	47	0.0001
<3	23	0.0005
3-6	17	0.03
6-9	11	NS

NS, not significant.

TABLE 73.4. EFFECT OF STREPTOKINASE ON ACUTE MORTALITY

In view of a reocclusion rate of 15% to 20% and a reinfarction rate of 5% to 10% after thrombolysis, there is concern as to whether cardiac catheterization should be performed immediately, followed by angioplasty in patients with appropriate anatomy. The role of conservative versus invasive strategies and immediate versus delayed angioplasty was assessed in several large trials. The TIMI-IIA trial showed that angioplasty performed within 2 hours of receiving rtPA was deleterious compared with angioplasty performed at 18 to 48 hours; similar results were observed in the Thrombolysis in Acute Myocardial Infarction trial and in the European trial. In the second part of the TIMI-II trial, patients were given rtPA within the initial 4 hours of onset of infarction, and half of them underwent cardiac catheterization at 18 to 48 hours, followed by angioplasty if the anatomy was appropriate; the other half were treated conservatively.

The mortality rate at 6 weeks was 4.7% in the conservatively treated group and 5% in the invasively treated group, and at 3 years the mortality rate was 11% in the conservatively treated group and 12% in the invasively treated group. In the conservative group, patients underwent cardiac catheterization for angioplasty or surgery only if there were recurrent ischemic events or if the patient exhibited ischemia on exercise. A similar trial Should We Intervene Following Thrombolysis? (SWIFT) in England showed virtually identical results. A newer trial referred to as Partial Angioplasty Combined with Thrombolysis (PACT), however, showed that thrombolysis induced by rtPA followed by angioplasty was associated with minimal bleeding and lower mortality rates than rtPA alone. Further studies are required to confirm these results before PTCA is adopted as routine treatment following thrombolysis.

The role of primary angioplasty has now been assessed in several trials and shown to be associated with a patency of more than 90%, which is consistently better than that of thrombolysis. If primary angioplasty can be performed within 45 minutes of the time the patient arrives at the hospital and if there are skilled surgeons experienced in angioplasty available, PTCA is an acceptable alternative to thrombolysis. In patients with contraindications, such as bleeding disorders, stroke, or hypertension, primary angioplasty is recommended over primary thrombolysis. For patients who have relative contraindications, such as elderly patients who have had a stroke but have no residual dysfunction, primary angioplasty is recommended. Angioplasty with or without thrombolytic therapy also is used often in patients in cardiogenic shock, but the benefit of this strategy remains to be determined. The long-term effect of angioplasty versus thrombolytic therapy on relief of symptoms and morbidity and mortality rates remains to be determined, particularly since about 30% to 50% of patients experience restenosis within 6 to 8 months after angioplasty. In patients receiving thrombolytic therapy in addition to aspirin and heparin in the TIMI-II trial, a b-blocker (metoprolol) was well tolerated when given on an emergency basis. In patients receiving it within 2 hours of thrombolytic therapy, as opposed to 7 days, there was no difference in ventricular function or mortality rates, but there was a lower incidence of reinfarction and ischemia. These results suggest that b-blockers should be used for immediate rather than delayed treatment.

Patients with chest pain who have ST-T-segment elevation or bundle-branch block and no contraindications are candidates for thrombolytic therapy, but patients with ST-T-segment depression or T-wave inversion are not ([Table 73.5](#)). Patients with a bleeding tendency, a previous stroke, hypertension, or peptic ulcer are excluded, as are patients who have undergone surgery in the past 6 weeks ([Table 73.6](#)). Age is not a contraindication. Should patients with non-Q-wave infarction receive thrombolytic therapy, considering that early reperfusion probably occurs spontaneously? In the International Study of Infarct Survival (ISIS)-II trial, a subset of patients with ST-segment depression who received streptokinase showed no benefit compared with placebo. The large prospective TIMI-IIIB trial indicated that patients with unstable angina with ST- or T-wave changes who received rtPA had higher mortality and infarction rates than those who underwent conventional therapy (aspirin and heparin). In patients with non-Q-wave infarction, there was no difference in the incidence of infarction or death compared with placebo.

Chest pain
 Electrocardiogram ST ↑ or bundle-branch block
 ≤12 hr from onset
 No contraindications

TABLE 73.5. INDICATIONS FOR THROMBOLYTIC THERAPY

Absolute contraindications
 Active internal bleeding
 Suspected aortic dissection
 Recent head trauma or known intracranial neoplasm
 Recorded blood pressure >200/120 mm Hg
 Previous allergy to thrombolytic therapy (streptokinase or APSAC only)
 Pregnancy
 Hemorrhagic cerebrovascular accident within 3 mo
 Trauma or surgery within 2 wk
Relative contraindications
 Hemorrhagic retinopathy
 Trauma or surgery >2 wk
 Active peptic ulcer disease
 History of cerebrovascular accident
 Known bleeding diathesis
 Previous treatment with streptokinase/APSAC
 Menstruation
 Prolonged or traumatic CPR

APSAC, acylated plasminogen streptokinase activated complex;
 CPR, cardiopulmonary resuscitation.

TABLE 73.6. CONTRAINDICATIONS TO THROMBOLYTIC THERAPY

In this study, thrombolytic therapy was initiated, on average, 9 hours from onset of symptoms. The lack of benefit of thrombolytic therapy in unstable angina is in keeping with the results of several other small trials. It indicates that a nonoccluding thrombus requires an antithrombin to prevent occlusion, whereas a thrombolytic agent increases the levels of plasma thrombin (released from the clot) and has other pro-coagulative effects that induce complete occlusion in some patients. The lack of effect of thrombolysis in patients with non-Q-wave infarction most likely is due to early spontaneous lysis; this precluded any benefit in the TIMI-IIIB trial, since therapy was initiated late (average of 9 hours from onset). Early thrombolytic therapy, such as therapy instituted before hospitalization, may be beneficial, but until such data are available, thrombolytic therapy is contraindicated in patients with chest pain who also have electrocardiographic changes other than ST-segment elevation or bundle-branch block ([Fig. 73.2](#)).

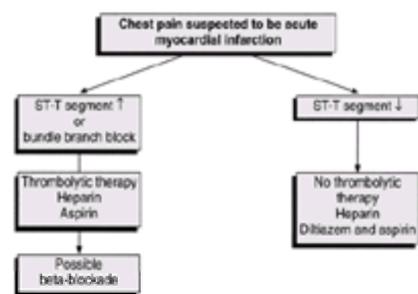

FIGURE 73.2. Algorithm for treatment of chest pain suspected to be acute myocardial infarction.

Thrombolytic therapy shows maximal benefit when administered in the first 2 to 3 hours after onset of symptoms, but significant benefit occurs when it is given up to 6 hours after onset. Some benefit is documented, particularly for rtPA, up to 12 hours, but there is no benefit after 12 hours. An accelerated dosing regimen of 100 mg rtPA over 90 minutes is recommended. A bolus of 15 mg is followed by an infusion of 50 mg in the next 30 minutes and 35 mg in the remaining 60 minutes. More accelerated dosing regimens are now being evaluated. Streptokinase should be administered as an intravenous infusion of 1.5 million units over 30 to 60 minutes. APSAC is given as a bolus of 30 units over 5 minutes; rPA is given as an initial bolus of 15 microunits followed by a second bolus of 15 microunits in 30 minutes. This is followed by full heparinization to maintain the partial thromboplastin time at 1.5 to two times normal for 1 to 3 days. Aspirin also is given throughout this time, at 90 mg per day, followed by 90 to 325 mg per day indefinitely after discontinuation of heparin. Patients with recurrent ischemia or those who exhibit ischemia on stress testing before discharge should undergo cardiac catheterization for possible angioplasty or surgery.

CALCIUM CHANNEL BLOCKERS

Nifedipine and verapamil have been assessed in more than 10,000 patients, and results in unstable angina or acute infarction have shown that these agents are not effective in limiting infarct size or lowering the incidence of reinfarction or death. Diltiazem was shown to limit infarct size in only one study with a small sample size. Thus, the routine use of calcium channel blockers is not indicated for the limitation of infarct size. Nifedipine was shown to be ineffective in preventing reinfarction. Diltiazem was found to be efficacious in preventing reinfarction and death in patients recovering from non-Q-wave infarction and is recommended as a routine prophylactic agent in patients with non-Q-wave infarction (see the section on prophylaxis). Verapamil was shown to be capable of lessening reinfarction and death rates in patients after infarction. In unstable angina, nifedipine should be used only in combination with b-blockers.

NITROGLYCERIN

Studies assessing the effect of intravenous nitroglycerin on the limitation of infarct size are inadequate to derive any definitive conclusions, but all the studies to date have suggested a beneficial effect on infarct size. Two large randomized studies have been performed using nitroprusside: one showed a significant limitation of infarct size, but the other showed opposing results. Nitroprusside is contraindicated in the first 12 hours of acute MI. Neither nitroglycerin nor nitroprusside is recommended for limitation of infarct size; however, in patients with MI and cardiac failure who require a vasodilator, nitroglycerin is recommended over nitroprusside. Three large trials administering nitroglycerin after infarction found no survival benefit.

OTHER ADJUNCTIVE THERAPY

Two large trials recently completed indicate that magnesium was without benefit in the treatment of patients with acute MI. Magnesium was also assessed and found to have no effect on survival. Angiotensin-converting enzyme (ACE) inhibitors have been shown to prolong life in patients with left ventricular dysfunction or cardiac failure. Patients with an ejection fraction of 0.45 or less or those in clinical cardiac failure should routinely receive ACE inhibitors (see [Chapter 90](#)).

PHYSICAL ACTIVITY

Patients with uncomplicated infarction should be confined to bed for the first 24 hours, but during this time the patient may use a bedside commode. On the second day, the patient may be permitted out of bed for a total of 1 hour and on the third day for up to 2 hours. It is common practice to transfer the patient out of the cardiac care unit after about 3 days, providing he or she can be moved to a step-down unit or a regular cardiac ward where telemetry or some form of continuous dysrhythmia monitoring is available. By the fifth or sixth day, patients are permitted to ambulate in the room, and by the eighth or ninth day they are usually using the shower by themselves. Early use of a bedside commode often avoids the difficulty of constipation, which may cause straining and precipitate dysrhythmias. Patients are generally discharged at 8 to 10 days and are encouraged to walk daily at home for the next 3 to 6 weeks. They should be followed carefully and frequently by their physicians and typically can return to work in 6 weeks. Many patients engage in submaximal exercise before discharge, which restores confidence and provides information for further stratification. For further discussion of cardiac rehabilitation after MI, see [Chapter 89](#).

DIET

A soft diet is recommended for the first 2 days. The customary suggestion of a diet low in cholesterol, saturated fat, and caffeine during the first 2 to 3 days is probably without scientific basis and should not be routinely applied. Patients are usually given a stool softener to prevent constipation and straining.

TREATMENT OF DYSRHYTHMIAS

For specific examples of the dysrhythmias discussed in this section and discussion of the drugs used, see [Chapter 76](#) and [Chapter 90](#).

Ventricular Dysrhythmias

Although the incidence of ventricular tachycardia or fibrillation has been minimized both during transport of the patient and within the hospital, more than 300,000 patients die before reaching the hospital, presumably as the result of dysrhythmias; this is largely because they cannot be reached in time for treatment.

The most effective first-line therapy for the treatment of premature ventricular contractions and prevention of ventricular tachycardia and fibrillation is intravenous lidocaine. In smaller hospitals, where the nursing personnel may be less experienced with MI or where there is no 24-hour coverage by house staff, prophylactic lidocaine may be appropriate. In patients receiving thrombolytic therapy, lidocaine is given consistently as prophylaxis before thrombolytic therapy. In hospitals with a well-trained and experienced cardiac care unit staff, lidocaine should be administered when any of the following types of dysrhythmia appear: five or more isolated ectopic ventricular beats per minute, multifocal ventricular extrasystoles, ventricular beats superimposed on the T wave, or runs of three or more ectopic ventricular beats. Intravenous lidocaine should be given in a bolus of 1 mg per kilogram, followed by an infusion of 2 to 4 mg per minute. Ventricular dysrhythmias, whether they are isolated premature ventricular contractions or runs of ventricular tachycardia, usually subside by 36 to 48 hours. If ventricular ectopy increases with the infusion, an additional bolus of lidocaine can be given.

Patients who experience sustained ventricular tachycardia unresponsive to lidocaine should undergo prompt electrical defibrillation. Patients who have ventricular fibrillation should undergo immediate electroconversion, as should patients with ventricular tachycardia and hemodynamic deterioration. If ventricular fibrillation cannot be immediately cardioverted, it may be necessary to initiate cardiac resuscitation for improved oxygenation before attempting further electroconversion. If ventricular tachycardia or fibrillation persists or recurs despite the use of lidocaine and electrocardioversion, a second antiarrhythmic agent must be added. An effective agent is procainamide, given intravenously in a bolus of 1 to 2 mg per kilogram over 5 to 10 minutes, followed by an intravenous infusion of 20 to 80 mg per kilogram per minute. If this treatment is ineffective, lidocaine is continued, and other agents may be substituted for procainamide (see also [Chapter 90](#)). In the case of premature ventricular beats associated with hemodynamic compromise that persists despite lidocaine, procainamide or β -blockade should be considered. In treating dysrhythmias, the physician must also remain cognizant of possible associated hypoxemia, electrolyte imbalance, acidosis, or hypokalemia and hypomagnesemia.

For ventricular fibrillation resistant to repeated electroshock, lidocaine, or other dysrhythmics, bretylium tosylate, 5 mg per kilogram, can be administered intravenously and repeated every 10 to 20 minutes if necessary. If this treatment is effective, an intravenous infusion can be initiated at a rate of 2 mg per minute. If the dysrhythmia continues to recur, electroshock is often more effective after a bretylium bolus. Resistant ventricular fibrillation sometimes can be rendered more susceptible to cardioversion by administering epinephrine, which often converts the fine ventricular fibrillation to a more coarse pattern, which is then more responsive to drugs and electroshock.

Supraventricular Dysrhythmias

The common supraventricular dysrhythmias—sinus tachycardia or bradycardia, atrial ectopic beats, flutter, or fibrillation—seldom require treatment in and of themselves in the acute phase of MI. If sinus tachycardia, which occurs in 20% to 30% of patients, is due to ventricular failure, treatment of the underlying failure is indicated. In patients with persistent sinus tachycardia with minimal myocardial damage and normal hemodynamics, intravenous β -blockade should be initiated. If the tachycardia persists, it may precipitate cardiac failure or more severe dysrhythmias or ischemia. Sinus bradycardia, if it is not associated with hypotension or other symptoms, should not be treated.

Conduction Disturbances

Ischemic injury during MI can induce disturbances in the conduction system at three different levels: the atrioventricular node, the bundle of His, or the right or left bundle branches. The mechanisms of action and treatment are discussed in [Chapter 76](#). First-degree heart block occurs in 5% to 10% of patients with MI and is generally due to disturbances in the conduction system above the bundle of His. It should be watched carefully but in itself does not require treatment. Second-degree heart block is divided into two types, Mobitz type I (Wenckebach) and Mobitz type II. Of patients with acute MI who show signs of second-degree heart block, 90% have Mobitz type I block. The conduction disturbance is due to ischemia of the atrioventricular node. It is associated with a narrow QRS complex and commonly occurs in patients with inferior MI. It is usually transient and does not persist beyond about 96 hours. It may be intermittent and only rarely progresses to complete atrioventricular block.

Because the conduction disturbance is in the atrioventricular node, there is often a functional escape rhythm with a ventricular response of 60 to 80 beats per minute. If the rate is less than 60 beats per minute or there are symptoms, a transvenous pacemaker is indicated, with the rate set to maintain adequate cardiac output. If complete atrioventricular block develops in this context, it usually progresses from first-degree to Mobitz type I and then to complete heart block in that sequence; it is usually transient and regresses within 5 to 7 days, in a reverse manner to the progression. A pacemaker is indicated in these patients with complete heart block. The mortality rate of complete heart block with inferior infarction is about 25% to 30%, and it remains doubtful whether mortality rates are lowered by a pacemaker. Nonetheless, a pacemaker may relieve the symptoms of cardiac failure. Complete heart block with inferior MI is seldom permanent.

Mobitz type II second-degree heart block is rare, occurring in less than 1% of patients with MI. It is due to a defect below the bundle of His in the fascicles and is almost always associated with anterior infarction and a wide QRS complex. It often progresses to complete atrioventricular block. The mortality rate is 80% to 90% with or without a pacemaker, though a pacemaker is always indicated in the case of Mobitz type II and with complete heart block.

Intraventricular conduction disturbances occur in the right bundle or the anterior or posterior divisions of the left bundle in up to 5% of patients with acute MI. There is no evidence that a pacemaker is helpful for intraventricular conduction defects, but it is generally agreed that patients with existing right bundle-branch block in whom either anterior or posterior fascicular block develops or bilateral bundle-branch block occurs anew (i.e., right bundle-branch block with left anterior or posterior divisional block or alternating right and left bundle-branch block) should have a temporary transvenous pacemaker put in place (see also [Chapter 76](#)). The development of concomitant first-degree atrioventricular block adds further risk to these conduction disturbances and should also be considered as an indication for a transvenous pacemaker. It has been suggested that patients surviving acute MI who had bundle-branch block and experienced transient second- or third-degree heart block during infarction should have permanent pacemakers. In one study of such patients, a pacemaker was associated with a decline in the rate of sudden death.

INDICATIONS FOR HEMODYNAMIC MONITORING

Swan-Ganz catheters are probably indicated in less than 10% of patients with MI and remain a somewhat arbitrary choice. Nevertheless, when there is doubt about the fluid status or if a patient is not responding as expected, one should consider Swan-Ganz catheterization. The following indications serve only as guidelines: cardiogenic shock, hypotension, acute MI during or subsequent to surgery, cardiac failure unresponsive to therapy, persistent sinus tachycardia, vasodilator therapy in patients with systolic blood pressure of less than 120 mm Hg, severe lung disease and suspected left ventricular failure, right ventricular failure from suspected or proven right ventricular infarction, development of mitral regurgitation or ventricular septal defect, or cardiac failure but with unexplained coma, restlessness, hypoxia, acidosis, or oliguria. An intra-arterial catheter for continuous measurement of systemic arterial pressure seldom is used today. The automatic sphygmomanometer devices that periodically estimate blood pressure and transmit the results to a central station often are adequate. In cases of severe hypotension and vasoconstriction, the cuff pressure may be 5% to 10% lower than that of an arterial catheter, but one is primarily interested in the change in pressure, which is correctly reflected by the cuff or automatic devices.

COMPLICATIONS

POSTINFARCTION ANGINA

The complications of acute MI are common and varied ([Table 73.7](#)). Chest pain associated with acute MI usually subsides within 12 to 24 hours. Persistent or recurrent pain beyond 24 to 48 hours of onset is an important prognostic symptom reflecting the presence of viable myocardium that is undergoing ischemia, and it indicates that the patient is at increased risk of recurring pain, reinfarction, and death, both immediately and in the long term. Chest pain is much more common after non-Q-wave infarction. In a prospective study of 576 patients with non-Q-wave infarction, the incidence was 43% in the initial 2 weeks, and in two large retrospective studies it was 46% and 50%, respectively. Thus, the incidence of angina after non-Q-wave infarction is 40% to 50% during the 2-week hospital stay, compared with only about 10% to 15% after Q-wave infarction. The incidence of early reinfarction and death in patients with postinfarction angina is three- to fourfold greater than in

patients without angina.

Arrhythmias

TABLE 73.7. COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

Many studies have shown that more than 90% of patients with postinfarction angina and electrocardiographic changes exhibit multivessel disease on coronary angiography. About 10% have left main disease. Patients should be stabilized with nitrates and diltiazem, after which they may undergo coronary angiography (see the section on postinfarction stratification and investigation). Patients whose condition is refractory to oral nitrates and diltiazem should receive a continuous infusion of nitroglycerin and, if necessary, b-blockers. If their condition remains refractory to medical therapy, coronary angiography should be performed in consideration of surgery or angioplasty. Patients admitted with non-Q-wave infarction without cardiac failure should be treated with diltiazem, 240 to 360 mg per day, in addition to nitrates. Results of a prospective double-blind trial in patients with non-Q-wave infarction showed that diltiazem lowered the incidence of reinfarction and refractory angina by 50%. This salutary effect of diltiazem was in addition to any benefit from nitrates or b-blockers.

EARLY REINFARCTION

The overall incidence of early reinfarction, confirmed by a secondary elevation in plasma CK-MB activity, is 10% to 15% in non-Q-wave infarction. The incidence of reinfarction after thrombolytic therapy is about 5% to 10%. The incidence after Q-wave infarction without thrombolytic therapy is estimated to be less than 5%. Recurrent postinfarction angina, particularly if it is associated with electrocardiographic changes, is highly predictive of reinfarction (see the preceding section on postinfarction angina). Patients recovering from non-Q-wave infarction should undergo routine plasma CK-MB analysis every 12 hours throughout their hospital stay. Patients recovering from Q-wave or non-Q-wave infarction who show signs of postinfarction angina should undergo CK-MB analysis serially every 12 hours for the remainder of the hospital stay. Early reinfarction is an indication for coronary angiography, preferably performed after the patient is stabilized.

An estimated 75% of patients who experience early reinfarction are recovering from non-Q-wave infarction, so early preventive therapy is recommended. In a prospective, double-blind study of 576 patients with non-Q-wave infarction, patients receiving diltiazem (360 mg per day) in combination with conventional therapy exhibited a 50% reduction in early reinfarction and severe angina compared with patients receiving only conventional therapy (80% received nitrates, and 60% were given b-blockers). A new long-term study shows that diltiazem is effective over a 4- to 5-year period in lowering mortality and reinfarction rates in patients with non-Q-wave infarction.

CARDIAC FAILURE

Cardiac failure associated with acute MI develops when 20% or more of the left ventricle is affected. It occurs transiently in 20% to 30% of patients. The decrease in ventricular function is in part reversible: most patients experiencing cardiac failure for the first time recover in 24 to 48 hours. The diminished contractility results in an increase in end-diastolic volume, which, together with decreased compliance from changes in the myocardium or the pericardium, contributes to increased diastolic pressure and pulmonary congestion. In most cases, adrenergic stimulation compensates for the failure; this stimulation increases the heart rate and the force of contraction of the remaining nonischemic myocardium. Heart size remains normal, as does cardiac output (usually).

Because patients are usually normovolemic before the onset of infarction, the sudden development of cardiac failure and loss of fluid into the lungs are associated with decreased vascular volume and relative hypovolemia, which is partly compensated for by increased vascular resistance. Patients in the initial days of cardiac failure associated with acute MI do not retain significant salt and water. Thus, the loss of fluid into the lungs at the expense of vascular volume may precipitate hypotension, which could jeopardize coronary perfusion. Patients with acute MI, due to decreased compliance, are usually operating on the ascending limb of the Starling curve and thus require higher filling pressures to maintain adequate cardiac output. In patients with inferior infarction, particularly with significant right ventricular involvement, the administration of a diuretic may be catastrophic and may produce a condition that simulates cardiogenic shock.

In patients with inferior infarction and pulmonary edema, diuretics should be withheld until the fluid status is assessed. Placement of a Swan-Ganz catheter is indicated, to assess right ventricular function, particularly end-diastolic pressure. If there is hypovolemia, fluids should be administered; if the cardiac output does not rise, dobutamine is indicated. If the jugular venous pressure is elevated, indicating normal fluid states, diuretics and vasodilators should be avoided. If the patient is hypotensive, an intravenous inotropic agent, such as dobutamine (2 to 5 µg per kilogram per minute), should be given, using as an end point the heart rate, which should not be permitted to increase by more than 10%. Patients with mild failure, indicated by a third heart sound with or without basal rales without symptoms of dyspnea, need morphine for pain together with oxygen and the usual supportive measures. In patients with more significant rales who are experiencing hypoxemia or dyspnea, a vasodilator would be appropriate and would achieve the same result as a diuretic without the loss of vascular volume. The preferred vasodilator is intravenous nitroglycerin, initiated at 5 to 10 mg per minute and increased so that there is no more than a 10% decline in blood pressure or heart rate.

In patients whose blood pressure is borderline low and who are in moderate to severe failure, an inotropic agent should be initiated immediately without a vasodilator. Dobutamine is preferred, since it decreases the ventricular filling pressure and induces mild peripheral vasodilatation, which increases coronary flow. In contrast, dopamine does not lower the ventricular filling pressure and, in moderate to high doses, causes vasoconstriction and increased ventricular filling pressure. Dopamine may be combined with a vasodilator or with dobutamine. In patients who are in failure with hypotension or cardiogenic shock, therapy should be initiated with a vasoconstricting agent such as dopamine. If a diuretic is used in the treatment of cardiac failure, a low dose is recommended (e.g., 20 mg furosemide); if this dose is inadequate, a vasodilator or inotropic agent should be added (see [Chapter 71](#)).

Digitalis has minimal inotropic effects compared with catecholamines and a long half-life, and it achieves maximal effect after only a loading dose, preferably given over 24 hours. Because most episodes of failure are transient, the initial use of an agent that acts rapidly and has a short half-life is preferred; if failure persists, patients may be started on oral digoxin. Amrinone, another inotropic agent, is given intravenously as a loading dose of 1.5 mg per kilogram, followed by an infusion at 10 to 20 µg per kilogram per minute. Its onset of action is rapid, and its half-life is 1 to 2 hours in patients with cardiac failure. Amrinone, like dobutamine, increases contractility (although less so), lowers left ventricular filling pressure and systemic vascular resistance, and has minimal effect on systemic arterial pressure and heart rate.

CARDIOGENIC SHOCK

Cardiogenic shock occurs in 5% to 10% of inpatients with acute MI and is the most common cause of death. The mortality rate associated with cardiogenic shock is 80% to 100%; the only effective treatment is prevention. Postmortem studies show myocardial necrosis involving 40% or more of the ventricular mass, with areas of old and new infarction indicating previous episodes of infarction. Occasionally, patients with an initial MI may experience shock after an early extension of the infarct. It is rare for patients without histories of ischemic heart disease to experience cardiogenic shock within hours of their first admission. Despite this gloomy prognosis, some patients have reversible injury, and with support they may recover. Every step must be taken to attempt to maintain the systemic circulation until a definitive diagnosis is made and all treatable lesions are excluded.

Cardiogenic shock is a severe form of cardiac failure with manifestations of impaired perfusion of several organs ([Table 73.8](#)). Several clinical criteria have been proposed for the diagnosis. These factors are primary cardiac abnormality, a sustained drop in systolic blood pressure to less than 85 mm Hg, a ventricular filling

pressure of 16 mm Hg or more, and peripheral organ involvement evidenced by two or more of the following manifestations: oliguria less than 20 mL per hour, impaired mentation or cold and clammy skin, or a cardiac index less than 1.5 L per minute per square meter. The patient is usually drowsy and restless and, in addition to the obvious findings of cardiac failure, has signs of tachycardia, tachypnea, and peripheral vasoconstriction. Hypovolemia, such as may occur with the use of diuretics or vasodilators, dehydration, or sustained ventricular or supraventricular dysrhythmias, must be excluded. Other causes of shock to be excluded are right ventricular infarction, pulmonary embolus, and tamponade. Now and then, a patient may have hypotension and severe cardiac failure owing to the use of intravenous antiarrhythmic agents, such as procainamide or quinidine, in the context of moderate to severe left ventricular dysfunction.

Primary cardiac abnormality

BP \leq 85 mm Hg

Ventricular filling pressure \geq 16 mm Hg

Systemic involvement: oliguria, cold skin, cardiac index \leq 1.5 L/min/m²

BP, blood pressure.

TABLE 73.8. CRITERIA FOR CARDIOGENIC SHOCK

If adequate oxygen cannot be given by nasal prongs, the patient must be intubated. Every effort must be made to restore the blood pressure. Vasodilators and drugs with a negative inotropic effect are discontinued, pain is relieved, and hemodynamics are monitored. Dopamine should be initiated as an intravenous infusion at a rate of 2 to 5 μ g per kilogram per minute and increased as needed by increments of 2 μ g per kilogram per minute up to 60 μ g per kilogram per minute, if necessary. In monitoring the hemodynamic response, one must assess cardiac output, blood pressure, and overall organ perfusion, as reflected, for example, by urine output. An attempt should be made to improve perfusion with the least possible increase in heart rate. If blood pressure can be maintained at about 90 mm Hg, the use of dobutamine is preferred, since it tends to produce better myocardial perfusion with less of an increase in systemic vascular resistance. Moreover, by lowering pulmonary wedge pressure, it relieves the symptoms of pulmonary congestion. Dobutamine should be initiated as an intravenous infusion of 5 μ g per kilogram per minute and increased by 1 to 5 μ g per kilogram per minute up to 40 μ g per kilogram per minute.

Because the basic defect in cardiogenic shock is impaired contractility, mechanical assist devices should be considered, such as the percutaneous aortic balloon. This device does not improve survival, but in the case of correctable lesions, it helps keep the patient alive until specific therapy for such lesions can be applied. It is particularly useful for patients with ventricular septal or papillary muscle rupture waiting to undergo surgery.

PAPILLARY MUSCLE RUPTURE

Rupture of the papillary muscle occurs now and then within 2 to 7 days after onset of infarction and is characterized by the sudden onset of pulmonary edema stemming from massive pulmonary hypertension and cardiogenic shock. An aggressive surgical approach is indicated, because if the effect of the rupture can be overcome, there is usually enough viable myocardium to allow the patient to survive.

The characteristic finding on auscultation is the new onset of a low-pitched holosystolic decrescendo murmur heard over the precordium with radiation to the axilla. There is often an S₃ as well as an S₄; if there is tachycardia, a summation gallop is present. The arterial pulse may show a brisk, rising upstroke, and, depending on the degree of left ventricular dysfunction, a hyperdynamic apical impulse may be present. Other features can include a giant a wave in the jugular venous pulse as a result of enhanced right atrial contraction from pulmonary hypertension together with a sustained right ventricular impulse along the left parasternal border. There may be wide splitting of S₂ from the shortening of the left ventricular ejection period, as most of the blood is ejected through the mitral valve. Simultaneous palpation with both hands detects the early systolic apical impulse and the late systolic parasternal impulse, which impart a rocking motion to the chest. Diffuse rales are usually evident on auscultation of the lungs.

Prompt recognition is important, and the diagnosis usually can be confirmed by the large v wave in the Swan-Ganz catheter tracing. If it is uncertain whether the patient has a ruptured papillary muscle or a ruptured ventricular septum, analysis of oxygen saturation can be performed with the Swan-Ganz catheter. If no step-up oxygenation from the pulmonary artery to the right atrium is found, this is evidence of a ruptured papillary muscle. In general, an attempt is made to stabilize and maintain the patient on aortic balloon and medical therapy as long as possible before surgery. The mortality rate without surgery is about 90%; early surgery has a mortality rate of about 50%.

VENTRICULAR SEPTAL RUPTURE

Rupture of the ventricular septum is rare after MI; it occurs in less than 1% of patients. It is more common after anterior infarction, and the defect is evident in the apical muscular portion of the septum. If it develops in the context of inferior infarction, the defect is in the basal portion. This complication is more common with the first Q-wave infarction, usually between the first and fifth days of recovery. Ventricular rupture initiates a left-to-right shunt that is always significant, resulting in biventricular failure, pulmonary edema, and cardiogenic shock with rapid deterioration. The predominant feature—over and above the sudden clinical deterioration—is the sudden appearance of a harsh holosystolic murmur that is associated with a thrill felt best at the parasternal area in more than 50% of cases. Rupture of a ventricular septum leads to a hyperdynamic precordium, unless there is severe hypotension; it is always associated with an S₃ and an S₄ and, if tachycardia is present, a summation gallop. Rupture of the ventricular septum is accompanied almost always by massive myocardial damage (in contrast to a ruptured papillary muscle, in which injury may be only moderate). Ventricular septal rupture is more likely to be associated with conduction defects, such as intraventricular or bundle-branch block, than is a ruptured papillary muscle. Right-sided heart failure and elevated jugular venous pressure are more common than with a ruptured mitral papillary muscle.

The diagnosis can be confirmed at the bedside using a Swan-Ganz catheter by finding an oxygen saturation step-up at the right ventricular level. The large v wave observed in the pulmonary occlusive wedge tracing with mitral valve rupture is rare with ventricular septal rupture; when the rupture is massive and associated with significant pulmonary hypertension, it may be present. Patients with this complication almost always require surgery.

CARDIAC RUPTURE

Cardiac rupture after MI is a catastrophe that occurs in less than 1% of patients and is said to be the third most common cause of death in acute MI. Typically, the patient has a Q-wave infarction, and the rupture involves the free wall of the left ventricle. It is more common in women over age 65 and is more likely to occur after the first attack; patients often have preexisting hypertension. Cardiac rupture usually takes place within the first 5 days of an uneventful recovery from acute MI. The event often is heralded by prolonged chest pain, dyspnea, hypotension, neck vein distention, tamponade, and electrocardiographic evidence of electrical mechanical dissociation. Death usually occurs within minutes.

In some cases, the course may be somewhat slowed, and sometimes it may indeed develop into a chronic situation in which the ventricle ruptures into the pericardial cavity. If the pericardium contains the blood, a so-called pseudoaneurysm is formed. The diagnosis of such a false aneurysm can be made by echocardiography or radionuclide ventriculography and confirmed by cardiac catheterization. Treatment of false aneurysm is surgery, which should be performed shortly after the diagnosis because of the danger of rupture of the pericardium. In the more typical urgent cardiac rupture, there is seldom time to initiate therapy. If cardiac rupture is suggested, however, the possibility of taking the patient to the operating room rapidly should be considered; occasionally a patient has been saved.

PERICARDITIS

Pericarditis usually does not develop until at least 48 hours after infarction. It occurs in 5% to 10% of patients with Q-wave infarction and is usually heralded by the

appearance of pleural, pericardial pain, as well as pericardial friction rub. The treatment is aspirin. Pericarditis may be the cause of recurring chest pain after the first 48 to 72 hours. It is important to search for pericarditis in patients who have recurrent pain, since it may be inappropriately treated with nitrates or b-blockers or even aggravated by the use of anticoagulants.

DRESSLER'S SYNDROME

Dressler's syndrome is characterized by fever and pleural or pericardial chest pain and usually occurs within 2 to 6 weeks after MI. It is often associated with pain and stiffness of the left shoulder and rarely with a pleural effusion. It is believed to be autoimmune in origin, and the incidence has declined markedly in the past 10 years. Initial treatment consists of salicylates; if the condition does not respond, corticosteroid therapy is instituted.

PROGNOSIS OF Q-WAVE AND NON-Q-WAVE INFARCTION

In patients with Q-wave infarction, most deaths occur early. Patients with non-Q-wave infarction do not exhibit the same profile (Fig. 73.3). In patients with non-Q-wave infarction, a highly vulnerable period of reinfarction and death continues throughout most of the first year. Because of this extended period, cumulative survival with non-Q-wave infarction becomes similar to that of Q-wave infarction after about 1 year. The prolonged propensity for reinfarction and ischemia in patients with non-Q-wave infarction is believed to be the major factor accounting for the disparity between the initial and long-term mortality rates (Table 73.9). The hospital mortality rate from non-Q-wave infarction is only 3% to 5%, but the incidence of early reinfarction or extension during the hospital recovery phase in patients with non-Q-wave infarction is about 15%, compared with only 3% to 5% in patients after Q-wave infarction.

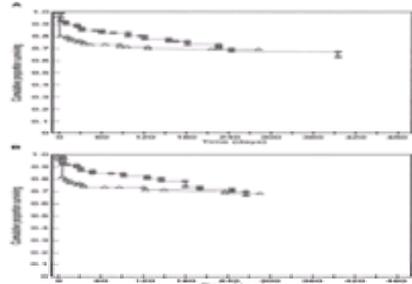

FIGURE 73.3. Survival of patients with Q-wave (*triangles*) and non-Q-wave (*circles*) infarction. **A:** Data from all patients. **B:** Patients without a previous infarction antedating the index infarction. Patients with previous infarction were excluded from the analysis. The cumulative mortality rate is similar in Q-wave and non-Q-wave infarction after about 1 year.

Characteristics	Q-Wave MI	Non-Q-Wave MI
Prevalence	47%	13%
Complete coronary obstruction	80-90%	15-25%
Elevated ST segment	80%	2%
Depressed ST segment	20%	75%
Postinfarction angina	15-25%	30-40%
Early reinfarction	5-8%	15-25%
1-yr mortality rate	10-15%	3-5%
2-yr mortality rate	30%	30%
Infarct size	Moderate to large	Usually small
Residual ischemia	15-20%	40-50%
Acute complication	Common	Uncommon
Thrombolysis	Indicated	Not indicated
β -Adrenergic blockers	Indicated	Not indicated
Calcium channel blockers		Not indicated
Nifedipine	Possibly detrimental	Not determined
Diltiazem	Not indicated	Recommended
Verapamil	Beneficial	Possibly beneficial but not established

MI, Myocardial infarction.

TABLE 73.9. COMPARISON OF Q-WAVE VERSUS NON-Q-WAVE MI

Several factors that significantly influence the prognosis of survivors of acute MI are applicable to Q-wave and non-Q-wave infarction. Predominant among these factors are age, infarct size, the number of vessels with obstructive disease, the site of infarction, residual left ventricular function, and complex dysrhythmias. The most important factors are probably left ventricular function and age. Residual left ventricular function is determined by infarct size, site of infarction, and, to a lesser extent, the number of diseased coronary vessels. The risk of dying with an ejection fraction of less than 0.40 is several times greater than that associated with normal ventricular function. Similarly, the risk of death increases significantly with age and is independent of the other factors. In one series, the 3-year mortality rate of patients under age 50 was 6%, compared with 44% in patients age 70 to 79. The prognosis for survival after infarction is also significantly worse for women than for men, but this may in part reflect the fact that infarction occurs much later in women. Survival for patients after inferior infarction, at least during the first 3 years, is substantially greater than after anterior infarction (Fig. 73.4). In a 15-year study, the proportion surviving after an infarction was 48%, 28%, 18%, and 9% for patients with one-, two-, and three-vessel disease and left main artery disease, respectively.

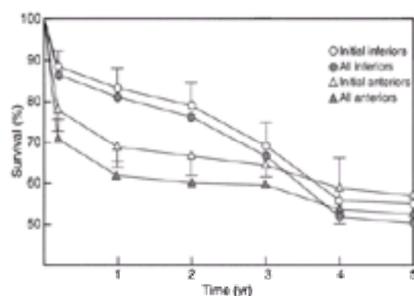

FIGURE 73.4. Survival curves for patients with inferior infarction compared with patients with anterior infarction. Separate curves identify patients with initial infarction as opposed to those who sustained previous infarction. The mortality rate of anterior infarction exceeded the mortality rate of inferior infarction ($p < 0.01$), regardless of initial or previous infarction.

POSTINFARCTION STRATIFICATION AND INVESTIGATION

Simple, noninvasive testing, together with cardiac catheterization in selected cases, allows for improved management (Fig. 73.5). The physician should consider which of the following treatment plans should be initiated and to what extent: modification of lifestyle; selective pharmacotherapy to relieve symptoms and prolong life; treatment of existing factors, such as smoking, hypertension, or hypercholesterolemia; and revascularization with angioplasty or surgery.

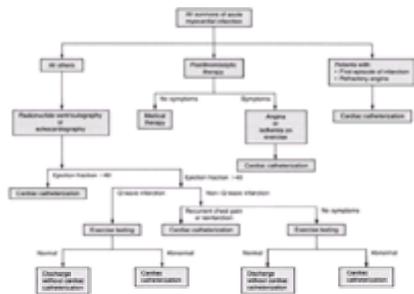

FIGURE 73.5. Protocol to be followed in determining whether patients should undergo noninvasive testing or cardiac catheterization. **EVIDENCE LEVEL: C. Expert Opinion.**

The need for stratification is emphasized by the estimate that only 25% of patients are at high risk after infarction, but they account for about 50% of the deaths. Their symptoms are characterized by an ejection fraction of less than 0.40, electrocardiographic evidence of ischemia on exercise testing, and frequent or complex ventricular dysrhythmias. In contrast, a low-risk group with a 2% mortality rate in the first year make up about 25% of the patients; they have no significant risk factors. This leaves 55% of patients at intermediate risk, with about a 10% chance of dying in the first year. The challenge to the physician is to select those patients in the intermediate group who are likely to have features that, if corrected, would lessen their chance of dying in subsequent years.

All patients surviving MI should undergo an assessment of left ventricular function by radionuclide ventriculography or echocardiography before discharge. Patients treated by thrombolysis probably should have cardiac catheterization only if there is evidence of spontaneous myocardial ischemia or if it is documented on exercise. Patients who have experienced their first episode of infarction should have coronary arteriography and a predischARGE stress test. Patients who exhibit an ejection fraction of less than 0.40 to 0.45 should undergo coronary arteriography. All patients who experience refractory pain or early reinfarction should undergo angiography. The remaining patients with normal left ventricular function should undergo exercise testing if one or more risk factors are present. In view of their propensity for recurrent chest pain (40% to 50%), reinfarction, and death both early and late, all patients with non-Q-wave infarction should be considered for some form of stress testing before discharge, preferably with thallium imaging; those who show significant ischemia should have coronary arteriography.

PROPHYLACTIC THERAPY AFTER INFARCTION

b-BLOCKERS AND CALCIUM CHANNEL BLOCKERS

Four different b-blockers assessed in trials involving more than 30,000 patients have been shown to prolong life in patients after infarction: timolol, propranolol, metoprolol, and atenolol. Who should receive b-blockers? About 10% of patients who are at high risk of sudden death or reinfarction and who are likely to benefit from b-blockers have contraindications, such as heart failure, asthma, conduction disturbances, or Prinzmetal's angina. Some patients who have a low annual mortality rate of about 2% also should not receive b-blockers prophylactically. The following are guidelines for the use of b-blockers ([Table 73.10](#)) in patients with Q-wave infarction who do not have contraindications to their use:

After myocardial infarction
 ≥60 yr old
 Q-wave infarction with ischemia
 Ejection <0.45
 Concomitant disease (e.g., hypertension)
 After cardiac arrest
 Ventricular dysrhythmias

TABLE 73.10. INDICATIONS FOR b-BLOCKADE FOR PATIENT

1. Patients over age 60
2. Patients with Q-wave infarction who exhibit ischemia on exercise
3. Patients with abnormal left ventricular function (ejection fraction less than 0.45)
4. Patients who require b-blockers for concomitant symptoms or disease, such as angina or hypertension
5. Patients who experience an episode of sustained ventricular tachycardia or ventricular fibrillation or have had cardiac arrest during the hospital stay

ANTIPLATELET THERAPY

Most of our therapeutic efforts to date have concentrated on decreasing myocardial demand or attempting to increase flow, but it is now well recognized that coronary thrombosis, partial or complete, has a major role in acute MI, and there is a growing body of evidence that thrombosis plays a part in rest angina. Several studies have shown that aspirin therapy after unstable angina is effective in lowering the incidence of MI and death. The trials assessing aspirin in patients after MI have shown no effect on mortality rates. When coronary events were combined (namely, nonfatal infarction and death), however, a significant beneficial effect was observed. The Food and Drug Administration has approved the use of aspirin once a day in patients after MI; however, there is still little evidence that this treatment is effective. Therefore, the use of aspirin is cautiously recommended in patients at high risk, such as those with a diminished ejection fraction, a previous episode of infarction, or recurring episodes of postinfarction chest pain and those who have been shown to have three-vessel disease or residual ischemia on exercise testing or cardiac catheterization. Patients who undergo angioplasty are routinely treated on a long-term basis with aspirin.

ANGIOPLASTY AND SURGERY

Patients with left main vessel disease or triple-vessel disease and an ejection fraction below 0.45 are clearly candidates for bypass surgery, using an internal mammary artery if possible. The role of angioplasty is less well defined. It is highly recommended after successful thrombolytic therapy as a means of maintaining patency, despite the fact that 30% of the arteries may re-stenose over the next 6 to 8 months. This therapy is new, and there are no clinical trials assessing medical therapy versus angioplasty. Several trials show comparable results on relief of symptoms with angioplasty or surgery in patients with one- and two-vessel disease. Patients with three-vessel disease in whom an operation would be difficult or in whom the risk of complications could exceed the possible benefit should be considered for angioplasty only in a center experienced with three-vessel angioplasty. Patients with 80% to 90% obstruction of the left anterior descending artery should be considered for angioplasty. About 4% to 5% of the patients who undergo angioplasty require emergency surgery. Only 60% to 70% of patients surviving MI who might otherwise be candidates for angioplasty have the appropriate anatomy for angioplasty. In addition, the high incidence of re-stenosis is a significant factor.

Myocardial disease may be defined in several ways. From a clinical standpoint, the term refers to a disorder of heart muscle that leads to demonstrable cardiac dysfunction. Myocardial diseases may be primary—originating in the heart muscle itself—or secondary—that is, resulting from a specific extramyocardial abnormality, such as coronary artery disease, valvular abnormalities, or a systemic process such as hypertension. Many of the primary types of myocardial disease, however, are similar in morphologic and pathophysiologic characteristics to certain secondary cardiomyopathies, and, in fact, they may have common pathogenetic features. The 1995 Task Force on the Definition and Classification of Cardiomyopathies of the WHO/ISFC defined the following types: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, arrhythmogenic right ventricular dysplasia, and unclassified forms. The heart muscle diseases associated with specific cardiac or systemic disorders, such as ischemic heart disease, are defined as specific cardiomyopathies. Therefore, the term *cardiomyopathy* denotes any pathologic process that leads to clinically significant myocardial dysfunction. This chapter presents a pathophysiologic, diagnostic, and therapeutic approach to myocardial disease and heart failure.

DILATED CARDIOMYOPATHY

The term *dilated cardiomyopathy* is applied primarily to a form of heart muscle disease characterized by systolic dysfunction and left ventricular dilatation. The most common means of detecting left ventricular dilatation is by echocardiography, in which a left ventricular end-diastolic diameter (LVEDD) of more than 2.7 cm per square meter, coupled with a reduced ejection fraction (less than 0.45), establishes the diagnosis of dilated cardiomyopathy. Although there is usually some degree of cellular hypertrophy in dilated cardiomyopathy on histologic examination, increased wall thickness is not a common feature. The contraction abnormality typically is global, but in diffuse types of heart muscle disease, such as idiopathic dilated cardiomyopathy, there are often areas where segmental contraction is selectively impaired. Similarly, left and right ventricular dysfunction may be disproportionate, with left ventricular dysfunction not uncommonly more prominent. These regional differences in dysfunction tend to disappear as heart failure progresses, such that generalized, globally severe, biventricular dysfunction is the rule at the end stage in most patients with dilated cardiomyopathy.

CAUSES OF DILATED CARDIOMYOPATHY

[Table 74.1](#) lists some of the causes of dilated cardiomyopathy. In the United States, the most common cause of dilated cardiomyopathy is coronary artery disease, listed in [Table 74.1](#) as “postinfarction cardiomyopathy.” Depending on the geographic area and other factors, the percentage of cases of heart failure that stem from postinfarction cardiomyopathy ranges from 50% to 90%. In an era in which the treatment of hypertension is aggressive and generally available, the second most common cause of heart failure in our experience is idiopathic dilated cardiomyopathy. A third typical cause is valvular heart disease, particularly after several cardiac surgeries for valve replacement. Hypertension remains a leading cause of heart failure in some regions, but it is decidedly unusual as an obvious cause of heart failure in many others. Alcohol cardiomyopathy is relatively common but depends on cultural patterns. These five types of heart muscle disease constitute more than 90% of the cases encountered in most regions of the United States.

TABLE 74.1. PARTIAL LIST OF INITIAL CAUSES OF DILATED CARDIOMYOPATHY

There are numerous other types of dilated cardiomyopathy ([Table 74.1](#)), and, depending on the region and referral pattern, some of them are relatively common. For example, cardiomyopathy related to chemotherapy with doxorubicin (Adriamycin) may be common in hospitals with large oncologic practices. Peripartum cardiomyopathy may be prevalent where the risk factors for this disorder prevail (e.g., in inner-city hospitals). Myocarditis may become relatively commonplace after epidemics of cardiotropic viruses. A practical approach to finding the source of dilated cardiomyopathy is to construct a differential diagnosis geared toward detecting the types of heart muscle disease that may be reversible ([Table 74.2](#)).

- Myocarditis (idiopathic, drug reactions, collagen vascular disease)
- Sarcoidosis
- Hemochromatosis
- Ischemia (“hibernating” myocardium)
- Valvular heart disease (aortic stenosis)
- Amyloidosis
- Infiltrative neoplastic process (lymphoma)

TABLE 74.2. POTENTIALLY REVERSIBLE CAUSES OF CARDIOMYOPATHY DETECTABLE BY CATHETERIZATION OR BIOPSY

Although the initial injury that produces cardiac damage in dilated cardiomyopathy may have several sources, the fact is that the end result is a dilated, poorly contractile ventricle producing a clinical picture that is quite similar across diverse origins. Although some dilated cardiomyopathies do have morphologically unique features, most are indistinguishable on histologic evaluation. Moreover, the clinical signs of biventricular failure are essentially the same regardless of cause.

There are at least two general reasons why diverse causes of dilated cardiomyopathy may have common features. The first is that different types of initial cardiac damage can produce a similar kind of cellular cardiac injury, involving a final common pathway that includes membrane damage, calcium overload, and energy exhaustion. The second reason is that the compensatory mechanisms called into play to cope with pump dysfunction exert powerful influences in their own right, some of which may be harmful. For example, activation of the adrenergic nervous system is an invariable response to pump failure. The physiologic consequences of this activation include peripheral vasoconstriction, which increases systolic wall stress; activation of cardiac adrenergic nerves, leading to amplified cardiac norepinephrine levels and initially to positive chronotropic and inotropic responses, which elevate myocardial oxygen requirements; a contribution to the development of hypertrophy, which increases wall tension and subsequently raises myocardial oxygen demand; and finally, receptor-mediated or non-receptor-mediated cardiotoxicity. Because the adrenergic nervous system invariably is activated after damage to the contractile apparatus, it is not surprising that this powerful compensatory mechanism would contribute to the development of morphologic and dysfunctional features common to diverse etiologic types. The same argument can be put forth for activation of the renin-angiotensin-aldosterone systems and enhanced vasopressin and endothelin secretion, which increase afterload and preload. These multiple harmful signaling pathways produce the aforementioned toxic effects, as well as activating gene programs that lead to progressive remodeling and myocardial dysfunction.

GENETIC BASIS OF CARDIOMYOPATHIES

New studies have confirmed that idiopathic dilated cardiomyopathy is frequently inherited. A defined genetic trait is found in 20% to 35% of cases, but it can be suspected in up to 50%: in these patients, the primary defect lies at the DNA level. At present, the molecular genetics of several systemic diseases that give rise to dilated cardiomyopathy have been defined. Duchenne's muscular dystrophy and myotonic muscular dystrophy result from mutations in the genes encoding dystrophin and MD kinase, respectively. Friedreich's ataxia, a rare cause of cardiomyopathy, has been mapped to chromosome 9 and found to be due to mutations in the frataxin gene. Mutations of the delta-sarco-glycan gene, encoding a cytoskeletal protein of the dystrophin complex, have been identified in the cardiomyopathic Syrian hamster and in human familial cardiomyopathy.

Concerning the adult form of dilated cardiomyopathy, nine different chromosomal loci have been linked to the disease. These map on chromosome 1, 2, 3, 9, 10, 15, X, and a familial dilated cardiomyopathy associated with limb-girdle muscle dystrophy has been mapped on chromosome 6. Two disease genes were identified: cardiac actin, which connects the sarcomere to the cytoskeleton (chromosome 15), and dystrophin (chromosome X), which causes X-linked dilated cardiomyopathy. In this form, with no male-to-male transmission, only the heart is affected in terms of clinical symptoms, and there is no muscle dystrophy. Very recently, the lamin A/C gene has been found to cause an autosomal dominant form of familial dilated cardiomyopathy with conduction defects and variable skeletal muscle involvement. This gene encodes another cytoskeletal protein, an intermediate filament that provides one of the layers of the nuclear envelope, the nuclear lamina. Infantile dilated cardiomyopathy, which can be associated with endocardial fibroelastosis, is caused by the G4.5 gene, which maps on chromosome X and also causes Barth syndrome. The gene function is still unknown.

STRUCTURAL ABNORMALITIES

MORPHOLOGIC CHANGES

With the exception of postinfarction cardiomyopathy, in which the left ventricle has been replaced by scar tissue, the morphologic findings in dilated cardiomyopathy are usually nonspecific. Increased cell volume and enlarged cardiac nuclear size (both manifestations of hypertrophy) as well as fibrosis are present to a varying degree. In idiopathic dilated cardiomyopathy, however, the amount of fibrosis and hypertrophy does not correlate well with hemodynamic function or with prognosis. Hypertrophy presumably is a response to the increased wall tension and wall stress in the dilated heart as well as to direct effects of hormones and neurotransmitters. The amount of fibrosis in dilated cardiomyopathy is inconsistent, increasing, on average, in control hearts from 4% to 15% to 20% of the total tissue volume on microscopic sections. Some hearts, however, show little or no fibrosis, whereas others have replacement of as much as one-fourth to one-third of the myocardial cell volume. In most cases, the degree of fibrosis does not appear to be extensive enough to cause changes in systolic and diastolic function.

It is relatively common to find a patient with severe heart failure stemming from idiopathic dilated cardiomyopathy with only mild cardiac hypertrophy and little or no fibrosis. The hypertrophy is less advanced than that seen in conditions in which myocardial function can be normal or "supernormal" (e.g., mild hypertension or mild aortic stenosis). Therefore, with the exception of myocardial infarction, anthracycline cardiomyopathy (discussed later in this chapter), and myocarditis, in which dilated cardiomyopathy follows an infectious process, the morphologic abnormalities present in dilated cardiomyopathy appear to be a consequence of the initial myocardial injury and are not responsible for the abnormal cardiac function. These observations indicate that the basic abnormality in most myopathic, noninfarcted, noninfiltrated hearts is functional rather than structural.

DILATED CARDIOMYOPATHIES WITH UNIQUE STRUCTURAL FEATURES

Certain dilated cardiomyopathies have unique structural features that can be recognized in terms of morphologic features and therefore detected in vivo by endomyocardial biopsy. These conditions include anthracycline cardiomyopathy, myocarditis, sarcoidosis, hemochromatosis, Chagas' disease, and amyloidosis. Many of the infiltrative types, such as amyloidosis and hemochromatosis, may have initial symptoms of predominant diastolic dysfunction and restrictive cardiomyopathy, but there is usually some degree of abnormal systolic function. Because some of these conditions may be amenable to medical therapy—such as iron unloading for hemochromatosis, cytotoxic/colchicine therapy for amyloidosis, steroid therapy for sarcoidosis, and various forms of immunosuppression for myocarditis—it behooves the clinician to be acutely aware of these relatively uncommon conditions.

Anthracycline cardiomyopathy is a representative form of dilated cardiomyopathy with unique morphologic and ultrastructural features. Anthracyclines are an extremely valuable class of antitumor agents; the prototype agent, doxorubicin, is the mainstay of the chemotherapeutic treatment of lymphomas, breast cancer, sarcomas, and many other forms of cancer. A unique adverse effect of anthracyclines, however, is a dose-related vacuolation of myocardial cells that ultimately leads to complete loss of myofibrils. Although there is a direct relationship between the amount of cardiotoxic insult administered (anthracycline dose) and the amount of damage produced, there is substantial individual variability in the dose–response curve. The morphologic abnormality, which can be semiquantitatively graded by examination of endomyocardial biopsy specimens, not surprisingly produces a severity-related adverse effect on systolic pump function. Because the lesion can be graded semiquantitatively and because cardiac function can be studied at the time of endomyocardial biopsy, anthracycline cardiomyopathy creates an opportunity to examine prospectively the structure–function relationship of a diffuse myocardial process in the intact human heart. [Figure 74.1](#) illustrates examples of anthracycline cardiomyopathy, graded as mild (grade 1), moderate (grade 2), or severe (grade 3). The Billingham classification of anthracycline cardiomyopathy also includes grades 1.5 and 2.5. In grade 3, more than 35% of the total number of cells are involved; in grade 2, 16% to 25% of the cells are involved; and in grade 1, fewer than 5% of the cells are affected.

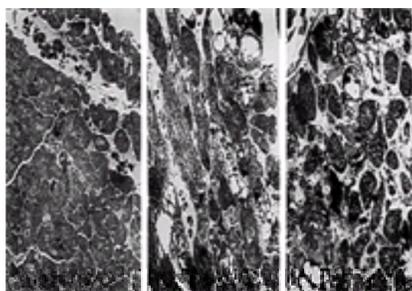

FIGURE 74.1. Examples of anthracycline cardiomyopathy. Left to right: grade 1 (mild), grade 2 (moderate), and grade 3 (severe). Arrows designate vacuolating cells that evidence myofibrillar dropout. (From Bristow MR. Toxic cardiomyopathy due to doxorubicin. *Hosp Pract* 1982;17:106, with permission.)

If one examines the development of functional abnormalities relative to the degree of anthracycline change, as judged by the Billingham scale, there appears to be little or no change until a grade 2 abnormality is achieved—that is, until some 20% of the cells are involved. At that point, cardiac dysfunction begins to appear in most patients, and this dysfunction grows rapidly in degree as the anthracycline score rises to 2.5 and 3. Therefore, for anthracycline cardiomyopathy, the structure–function relationship in the intact human heart consists of little change until 20% of the cells are affected and then a rapidly progressive development of cardiac dysfunction as 25% to 35% of the cells become abnormal. The relationship is nonlinear, indicating that small amounts of damage can be tolerated by the heart, either because compensatory changes are invoked or because of an inherent reserve capacity to tolerate myocardial cell loss. Beyond a critical percentage of cellular involvement (about 25%), however, severe heart failure develops rapidly. This fundamental relationship is probably the reason that many patients appear to experience heart failure “suddenly.” In most cases, the underlying disease process did not develop suddenly; rather, compensatory mechanisms were supporting cardiac function through the early phases of disease progression.

In most other types of myocardial disease, it is difficult to correlate structure and function, probably because observable structural changes have little to do with what is producing the cardiac dysfunction. This is apparently the case with idiopathic dilated cardiomyopathy with respect to hypertrophy/fibrosis, as described, and also may be the case for some of the infiltrative processes that can lead to cardiac dysfunction, such as myocarditis. In myocarditis and cardiac allograft rejection (which resembles myocarditis in morphologic features), there often is a disparity between the amount of infiltrate observed on histologic examination and the degree of cardiac dysfunction. In both situations, large amounts of lymphocytic infiltrate can be well tolerated in many cases, whereas in other cases a small amount of infiltrate may be associated with marked ventricular dysfunction. For the purely infiltrative processes of cardiac amyloidosis and hemochromatosis, a better correlation between structural abnormality and degree of dysfunction may exist, because the infiltrating substance causes abnormal function strictly through a replacement process. In the case of infiltration of the heart with T lymphocytes, however, processes other than pure infiltration (e.g., the local production of cytokines) most likely produce the cardiac dysfunction.

In postinfarction cardiomyopathy, it seems obvious that the symptoms are related to myocardial infarction—that is, the replacement of viable myocardium by nonfunctioning scar tissue. The situation is much more complicated than that, however, because postinfarction cardiomyopathy is seen often in patients who survive a myocardial infarct or one or more coronary artery bypass operations and then remain stable for months or years before showing evidence of heart failure. In these patients, it is possible to speculate that the initial insult was a relatively large infarct, involving 10% to 20% of the myocardium, which was initially reasonably well tolerated because of endogenous compensatory mechanisms. In time, however, the noninfarcted myocardium may fall victim to these compensatory changes, to the extent that normally or supernormally contracting viable muscle ultimately becomes myopathic.

Alternatively, a series of silent ischemic events may progressively damage viable myocardium. The fact that biochemical and morphologic changes present in noninfarcted areas of the heart in patients with postinfarction cardiomyopathy are myopathic in nature and similar to those found in idiopathic dilated cardiomyopathy suggests the former explanation in most cases. This scenario typically follows a large anterior infarct in the distribution of the left anterior descending coronary artery, but it may follow occlusion of any large epicardial artery with a large myocardial distribution. Finally, the fact that clinical stability usually ensues in patients who survive infarction but is followed in a certain subset of patients by the later development of heart failure suggests that the responsible progressive myopathic process may be subject to interventional strategies similar to those currently undergoing trial in the context of idiopathic dilated cardiomyopathy.

PATHOGENESIS

A case can be made for dividing the pathogenesis of myocardial disease into initial and delayed components. By the initial component, we mean the pathogenetic mechanism that accounted for the original impairment of intrinsic contractile function. Various types of initial myocardial injury known to account for dilated cardiomyopathy are shown in [Table 74.1](#). Within this large number of possibilities, however, there may be only a limited number of cellular or molecular mechanisms of action by which injury is effected. Some of them include direct toxic effects, such as those produced by release of cardiac norepinephrine and histamine; free radical formation; direct perturbation of membranes; and release of toxic cytokines.

The most recent advances in molecular genetics suggest that the disease is caused by altered cytoskeletal proteins, at least in a subset of cases. The discovery of mutations of dystrophin and cardiac actin in the human disease and of delta-sarcoglycan in the cardiomyopathic Syrian hamster, causing dilated cardiomyopathy, supports the hypothesis of a defect of force transmission from the sarcomere to the extracellular matrix.

Additionally, myocardial damage may be produced indirectly when myocardial oxygen demand exceeds the ability of the coronary circulation to supply it, leading to exhaustion of energy stores. Factors contributing to this situation are hypertrophy, increased wall stress, and reduced coronary flow. It is conceivable that these conditions lead to relative ischemia, which ultimately damages the highly aerobically dependent myocardium. The best-understood initial, indirect type of damage is from abrupt interruption of coronary flow, which causes myocardial infarction through a metabolic process involving abrupt withdrawal of blood supply. Relative ischemia due to inadequate coronary reserve in dilated cardiomyopathy also would be responsible for delayed cardiac damage. Ultimately, regardless of the type of damage, cardiac cell death probably results from cellular calcium overload, a relatively late-stage phenomenon that produces irreversible cytotoxicity.

Because it may be difficult or impossible to anticipate and prevent most cases of initial myocardial injury, a more likely focus for interventional strategies is in the delayed type of cardiac damage that appears to be responsible for the progressive nature of most forms of myocardial disease. Here the strong suspicion is that neurohumoral factors are playing a harmful role, as discussed earlier. It is highly likely that antagonism or elimination of adrenergic, renin-angiotensin-aldosterone, and vasopressin compensatory mechanisms ultimately afford some degree of protection against progression in myocardial disease and lead to stability or improvement in significant numbers of patients. As discussed later, however, these experimental approaches are still theoretical and have not undergone thorough evaluation. It also is likely that additional harmful compensatory mechanisms of action will continue to be elucidated as heart failure is more thoroughly investigated.

In addition to providing an accessible avenue for intervention, the concept of a delayed type of cardiac damage in myocardial disease is attractive because it is based on factors that are part of well-defined physiologic systems, about which much is known and toward which pharmacologic therapy can be targeted. As the full pathophysiologic picture of heart failure is elucidated in the ensuing decades, secondary prevention strategies in myocardial disease undoubtedly will become increasingly common.

NATURAL HISTORY

The natural history of dilated cardiomyopathy is relatively independent of cause, and the prognosis generally is thought to be poor. Data on prognosis, however, are derived mostly from series of patients from tertiary referral centers, where the patient is usually in an advanced stage of the disease at the time when he or she is first seen. When the population of patients referred to a tertiary referral center is examined, the natural history of dilated cardiomyopathy of unknown cause (idiopathic dilated cardiomyopathy) includes approximately a 30% 1-year mortality rate and a 60% 5-year mortality rate. If postinfarction cardiomyopathy is examined, the survival is perhaps slightly worse, presumably because of the additive adverse effects of the ischemic process. Overall, when one looks at the population of patients referred to tertiary centers, the natural history of dilated cardiomyopathy and heart failure is as bad as or worse than that for many forms of cancer.

Patients with dilated cardiomyopathy die of four general processes. The first two are the most common (more than 80% of patients), whereas the last two are less common. The two most common causes of death are sudden death from arrhythmia and complications related generally to progressive pump dysfunction; in published series, the incidence rates of these two causes of death are usually fairly evenly distributed. Sudden death in the context of cardiomyopathy is particularly frustrating to the clinician, inasmuch as it may occur in a patient who is completely stable and without any antecedent in the form of increased arrhythmic activity. Progressive pump dysfunction can develop either slowly (over years) or rapidly (over weeks to months). The third general category of cause of death in cardiomyopathy covers medical complications related to the underlying disease process, such as embolic stroke, pulmonary embolism, or pneumonia. The fourth category includes deaths unrelated to the underlying disease process.

A number of factors have been shown to correlate with poor prognosis in dilated cardiomyopathy, including a particularly bad ejection fraction or hemodynamics, the presence of high-grade arrhythmia, and the degree of activation of the sympathetic nervous system. With regard to the degree of myocardial dysfunction, it is perhaps surprising that there is not a good overall correlation between hemodynamic indexes and outcome. Arrhythmia quantification correlates even more poorly with outcome; in fact, in some studies there has been no correlation. The best single predictor of outcome in dilated cardiomyopathy or heart failure, in general, is the degree of activation of the sympathetic nervous system, though the correlation is imperfect in this case as well.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is defined as severe diastolic dysfunction resulting in altered filling characteristics of the left ventricle, in the context of normal or minimally abnormal systolic function. On echocardiograms, the left ventricular chamber size is normal; however, the walls of the left and right ventricles are thickened, and there is usually associated left atrial enlargement. The hemodynamic abnormalities of restrictive cardiomyopathy are so characteristic that they must be identified before the disease process can be classified as restrictive. The cardiac index is usually normal or slightly low, with a normal or near-normal ejection fraction. The left and right ventricular filling pressures are elevated and may be nearly equal. The ventricular pressure tracings show a dip—plateau configuration that also is found in constrictive pericarditis. In fact, hemodynamic abnormalities in these two states are so similar that it may be difficult to differentiate constrictive pericarditis from restrictive cardiomyopathy. In restrictive cardiomyopathy, however, the left ventricular filling pressures tend to be slightly higher than the right, and that can usually be augmented by rapid volume expansion or exercise. Additional features that can help distinguish restriction from constriction are increased wall thickness on echocardiography in restrictive cardiomyopathy but normal thickness in constrictive pericarditis and thickened pericardium on echocardiography or computed tomography in constrictive pericarditis but normal thickness with restrictive cardiomyopathy. Finally, endomyocardial biopsy is useful in helping discriminate restriction from constriction, because it usually shows more serious interstitial fibrosis or an infiltrative process in restriction.

MORPHOLOGY

Some common causes of restrictive cardiomyopathy are listed in [Table 74.3](#). These pathophysiologic abnormalities result from a multitude of causes, such as infiltration of the myocardium by an abnormal protein (amyloidosis), inflammatory cells (acute viral myocarditis), or heavy metals (hemosiderosis). In these conditions, the myocytes are unable to “relax” or increase in length during diastole; hence, restrictive physiologic features develop. If the endocardium is thickened as a result of fibrosis (endomyocardial fibrosis) or infiltrated (hypereosinophilic syndromes), similar hemodynamic abnormalities may arise. For example, restrictive cardiomyopathy caused by increased endomyocardial fibrosis recently has been reported in association with the anorectic agent fenfluramine. Because the histopathologic abnormalities differ with origin, endomyocardial biopsy is indicated. Recently, patients with nonspecific histologic characteristics showing interstitial myocardial fibrosis have been identified and classified as having idiopathic restrictive cardiomyopathy.

Direct
Toxic
Methysergide
Anorectic agents
Radiation
Infectious: viral myocarditis
Infiltration: endomyocardial fibrosis
Genetic
Idiopathic
Indirect
Infiltration
Sarcoid
Hemosiderosis
Amyloidosis
Glycogen storage disease

TABLE 74.3. INITIAL CAUSES OF RESTRICTIVE CARDIOMYOPATHY

PATHOGENESIS

When a systemic disorder is known, the pathogenesis of the restrictive cardiomyopathy is contingent on the severity of this systemic disease. Early in amyloid heart disease, abnormalities may be confined to conduction disturbances and subtle changes in diastolic function. As abnormal protein is deposited in greater quantities, the conduction disturbance worsens, the electrocardiographic voltage decreases, and diastolic function begins to be compromised. Similarly, in hemosiderosis, the severity of the hemodynamic abnormality is contingent on the degree of iron deposition, and the reversibility is dependent on the degree of secondary fibrosis. In patients in whom no morphologic cause can be identified (idiopathic), the physiologic abnormalities may or may not progress. Forms of genetic transmission of the disease have been reported. One of them is characterized by desmin deposition; restrictive cardiomyopathy with severe conduction defects, sometimes associated with ventricular wall thickening; and myopathy. The disorder is caused by mutations of desmin or of *CRYAB* genes, which encode a molecular chaperon for desmin. Finally, cardiac amyloidosis can be caused by mutation of transthyretin.

NATURAL HISTORY

In general, the natural history of restrictive cardiomyopathy depends on the cause. Amyloidosis, a disease for which no definitive cure has been established, has a poor prognosis when symptomatic restrictive cardiomyopathy develops. Studies in renal amyloid patients, however, suggest that when a light chain is identified (AL, or primary amyloidosis) the combination of steroids and colchicine at least retards the progression of the disease. Longitudinal studies in patients with cardiac amyloid have not been completed, so the effect on the deposition of amyloid protein in the myocardium is unknown. Hemosiderosis is a potentially reversible process if severe myocardial fibrosis has not developed, and removal of iron by phlebotomy and chelation (desferoxamine) has resulted in substantial hemodynamic improvement. In the hypereosinophilic syndromes, eradication of the source of the eosinophilia may retard the progression of the disease, and, in selected cases, surgery (endocardial resection) has resulted in physiologic improvement. When the restrictive cardiomyopathy is idiopathic, the long-term survival may be quite good (in excess of 10 years).

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy, also known as idiopathic hypertrophic subaortic stenosis, has a prognosis that generally is better than the other two major classes. The definition, as strictly applied, is a hypertrophic left ventricle with disproportionate septal hypertrophy, normal or supernormal systolic function, but varying degrees of diastolic dysfunction. The disproportionate septal hypertrophy may lead to a measurable outflow-tract obstruction, and the mitral valve apparatus may be abnormal as well, leading to mitral regurgitation. Characteristic echocardiographic abnormalities include asymmetric septal hypertrophy and systolic anterior motion of the mitral valve. On catheterization, an outflow-tract gradient may be present at rest or may be provoked by isoproterenol or specialized maneuvers. At a functional level, hypertrophic cardiomyopathy tends to overlap with both restrictive and dilated cardiomyopathy. Systolic function sometimes becomes abnormal in hypertrophic cardiomyopathy, combined with chamber dilatation, and often it is difficult to differentiate a hypertrophic, restricted ventricle from the disproportionately septally hypertrophied ventricle of hypertrophic cardiomyopathy.

MORPHOLOGY

The classic morphologic abnormality in hypertrophic cardiomyopathy is myocardial cellular disarray with disorganization of the normally parallel-distributed myocardial cells, and myofibrillar disarray with disorganization of the contractile elements themselves ([Figure 74.2](#)). Myocardial cell and myofibrillar disarray can be found not only in the left ventricle but also in the right ventricle and even in the skeletal muscle.

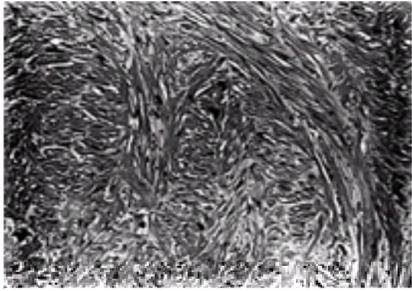

FIGURE 74.2. Myocardial cellular and myofibrillar disarray in hypertrophic cardiomyopathy. (From Tazelaar H, Billingham M. The surgical pathology of hypertrophic cardiomyopathy. *Arch Pathol Lab Med* 1987;111:257, with permission.)

PATHOGENESIS

Advances in the knowledge of the molecular defects underlying hypertrophic cardiomyopathy indicate that the disease is caused by mutations in genes that encode proteins of the sarcomere. The b-cardiac myosin heavy chain gene (chromosome 14) represents about 35% of cases, a-tropomyosin (chromosome 15) makes up less than 5%, troponin T (chromosome 1) accounts for about 15%, myosin-binding protein C (chromosome 11) comprises 15%, and essential (chromosome 3) and regulatory myosin light chain (chromosome 12) account for less than 1%. Mutations in the cardiac troponin I gene also have been identified (chromosome 19). Finally, a familial form of hypertrophic cardiomyopathy with Wolff-Parkinson-White syndrome has been mapped to chromosome 7, but the specific gene affected has not yet been identified. Mutations in genes encoding b-cardiac myosin heavy chain, a-tropomyosin, and troponin T are associated with myofibrillar disarray and the abnormal mechanical properties that characterize the disease. Despite these findings at the DNA level, it remains to be determined how contractile protein mutations can be transduced into the abnormal structure and function of the heart observed in this disease.

NATURAL HISTORY

The natural history of hypertrophic cardiomyopathy, in general, is better than that of dilated or restrictive cardiomyopathy, with a mortality rate of about 4% per year. Death usually occurs suddenly, presumably because of ventricular arrhythmia. Progression to severe, intractable heart failure based on abnormal diastolic function or progression to systolic dysfunction can and does occur, but this is a less common cause of demise.

Because abnormalities in diastolic function account for most initial symptoms in hypertrophic cardiomyopathy and because arrhythmia is the most common cause of death, it would seem likely that medications designed to improve ventricular compliance or antiarrhythmic agents might favorably influence natural history. Nevertheless, there has been no definitive documentation of any favorable effect on natural history, either by agents that improve diastolic compliance (calcium antagonists) or by antiarrhythmic agents. The genotype appears to modify the risk of heart failure and sudden death. Some myosin mutations are benign, whereas others are associated with premature death. Mutations of cardiac troponin T are also characterized by lowered life expectancy.

RIGHT VENTRICULAR CARDIOMYOPATHY

Right ventricular cardiomyopathy (or arrhythmogenic right ventricular dysplasia) is a heart muscle disease of unknown cause that is characterized by dilatation and/or aneurysmal bulges of the right ventricle in the absence of significant left ventricular involvement. The most common clinical manifestation is the presence of ventricular arrhythmia, ranging from symptomatic ventricular premature beats to ventricular tachycardia. Sudden cardiac death may occur. Right ventricular dysplasia is frequently characterized by inverted T waves in the right precordial leads (beyond V₁ over the age of 12) on electrocardiogram and by ventricular arrhythmia with left bundle-branch block configuration.

MORPHOLOGY

Characteristic of the disease is the fibro-fatty infiltration of the right ventricular myocardium. The left ventricle is usually normal or not severely involved, except in the advanced stages of the disease. The echocardiogram is extremely useful in detecting right ventricular enlargement or wall-motion abnormalities that would confirm the diagnosis of arrhythmogenic right ventricular dysplasia. Right ventricular angiography is also used for the quantification of right ventricular dimensions, contractility, and regional wall motion. Magnetic resonance imaging has the advantage of showing not only right ventricular anatomy but also tissue characterization. This technique can differentiate the fatty infiltration of the right ventricular wall, seen as a white area, compared with the gray color of the normal myocardium.

PATHOLOGY

A definitive (gold standard) diagnosis of right ventricular dysplasia is based on histologic evidence of transmural fibro-fatty replacement of right ventricular myocardium (Fig. 74.3). Histologic signs of myocarditis can be present. Nevertheless, endomyocardial biopsy lacks sensitivity, owing to the segmental nature of the disease, and specificity, owing to the normal presence of adipose tissue islands in the right ventricle. The diagnosis relies on the clinical findings of structural, functional, and electrophysiologic abnormalities that are caused by the underlying histologic changes.

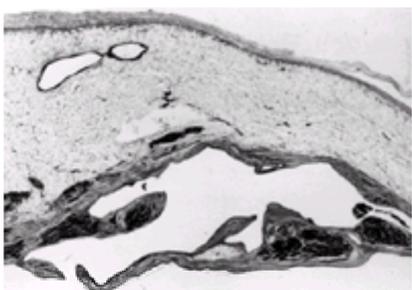

FIGURE 74.3. Histologic section of the right ventricular free wall from a patient with right ventricular dysplasia, showing the replacement of the muscle component by fatty tissue and by a thin layer of subendocardial connective tissue.

PATHOGENESIS

Right ventricular dysplasia has a genetic basis in at least 30% of patients. No gene has been identified so far, but several disease loci have been mapped, on chromosome 1, 2, and 3 and two on chromosome 14. Disease transmission is usually autosomal dominant. In a rare form identified on a Greek island (Naxos syndrome), transmission is autosomal recessive, and heart disease is associated with woolly hair and diffuse nonepidermiolytic palmoplantar keratoderma. This form has been mapped on chromosome 17. It remains unclear whether the genetic background predisposes to a degenerative disease with atrophy and fibro-fatty replacement of the right ventricular myocardium or whether the inflammatory cells found in about 25% of cases indicate an infection or, possibly, genetically determined immune pathogenesis.

NATURAL HISTORY

Right ventricular dysplasia shows a wide variability in clinical expression. The disease can be clinically silent and accidentally discovered at a very advanced age. It has been recognized as a frequent cause of sudden death, particularly in young persons. Finally, the disease can progress to left ventricular involvement, with right and left heart failure mimicking dilated cardiomyopathy.

DIAGNOSTIC WORKUP OF PATIENTS WITH SUSPECTED MYOCARDIAL DISEASE

Regardless of how it is classified, myocardial disease has nonspecific initial symptoms, referable to the heart. These may include signs and symptoms of congestive heart failure (including both congestive and low-output symptoms), chest pain, or arrhythmia. It is important to remember that because of the nonlinear structure–function relationship in dilated cardiomyopathy, overt symptoms and signs appear only after considerable damage has been done, giving the appearance that the damage has developed suddenly. In addition to a history and physical examination with careful elucidation of important factors, such as family history, alcohol or drug intake, recent history of a flulike illness, and history of abnormal physical examination findings or cardiac test results, the routine screening evaluation should include an electrocardiogram and an echocardiogram.

The electrocardiogram may provide clues to myocardial disease, such as conduction delays, an infarct or pseudoinfarct pattern, arrhythmia, or abnormal voltage. An echocardiogram is the easiest way to obtain definitive information about systolic function; it also provides information on the status of the pericardium and the cardiac valves. Also detectable on echocardiography are asymmetric septal hypertrophy and systolic anterior motion of the mitral valve (both signs of hypertrophic cardiomyopathy) as well as certain tissue-signature findings that may suggest an infiltrative process (granular sparkling in amyloid). If a patient is found to have systolic dysfunction and dilated cardiomyopathy, in most cases it is advisable to proceed with definitive invasive cardiac testing, including coronary angiography and endomyocardial biopsy, if these tests are available. In apparent cases of idiopathic dilated cardiomyopathy based strictly on clinical data, some other diagnosis is made by combining these two procedures in 5% to 10% of the cases. That is, myocarditis, some other infiltrative cardiomyopathy, or coronary artery disease may be detected, all of which may change the course of therapy. Consequently, it is important to obtain definitive information on all patients.

Finally, the identification of a genetic form of transmission in a significant proportion of patients with cardiomyopathies suggests the need for family screening. This is justified by the increased risk of disease in the relatives of patients, by the availability of sensitive noninvasive screening methods (in particular echocardiography), by the possibility of early diagnosis and prevention of complications, and by the growing availability of molecular diagnostic techniques. The identification of the molecular basis represents the first step toward a specific therapy for these disorders.

TREATMENT OF MYOCARDIAL DISEASE

Treatment of myocardial disease depends on the specific type of abnormality and its severity. The treatment of most types of myocardial disease, however, can be discussed in terms of general principles, as outlined in the following sections.

SPECIFIC THERAPY

Specific, targeted therapy should be the goal of treatment in all patients with myocardial disease, though, in actuality, this goal is achieved in only a small percentage of patients. The objective is to identify something that potentially can be corrected definitively and then to make that correction. In this category would be forms of myocardial disease and heart failure resulting from valvular heart disease that may respond to correction of the mechanical abnormality, such as aortic stenosis; sarcoidosis, which may improve with steroid therapy; hemochromatosis, which may be remedied by iron unloading; and hypertrophic cardiomyopathy refractory to medical management, which may be corrected by myectomy with or without mitral valve replacement. Patients with moderately severe left ventricular dysfunction and coronary artery lesions amenable to revascularization (in the rare case where the myocardium may be “hibernating” from lack of blood flow) are also possible candidates for specific therapy.

NONSPECIFIC MEDICAL THERAPY

For patients in whom definitive, specific therapy is not possible, nonspecific, symptomatic therapy is the only option. This therapy may consist of no therapy at all, a diuretic for congestive symptoms, the addition of digoxin and afterload reduction for more advanced congestive or low output symptoms, or inhibitors of the renin-angiotensin and adrenergic systems to favorably affect remodeling and lower mortality in dilated cardiomyopathies, or antiarrhythmic therapy for symptomatic arrhythmias. In hypertrophic cardiomyopathy, and possibly in some forms of restrictive cardiomyopathy, therapy to facilitate diastolic function can be attempted. Nonspecific, symptomatic therapy is indicated for patients with myocardial disease who have New York Heart Association class II or III symptoms, with no disability or mild disability, and in whom the prognosis is still relatively good (mortality rate less than 20% per year). Further details of the therapeutic approach to the patient with congestive heart failure are discussed in [Chapter 66](#).

DEFINITIVE THERAPY

When patients show signs of major disability (New York Heart Association class III or IV) or are at high risk of dying (estimated mortality rate more than 20% per year) for other reasons, definitive therapy in the form of cardiac replacement should be considered and performed if the subject meets eligibility criteria. Cardiac transplantation has emerged as a readily available, relatively straightforward procedure that offers even high-risk patients a high probability (more than 80%) of surviving 1 year and a better than 70% probability of surviving 5 years. [Figure 74.4](#) shows the patient survival rate in the Utah Cardiac Transplant Program compared with the average survival rates calculated from five different natural history studies of dilated cardiomyopathy; it can be seen that survival is dramatically improved with cardiac transplantation. Moreover, after transplantation, patients lead an essentially normal life with excellent functional capacity.

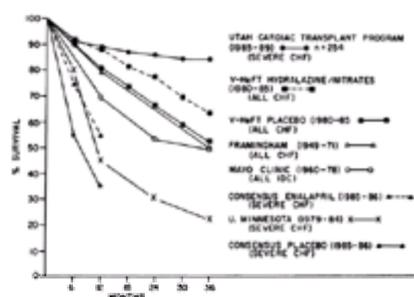

FIGURE 74.4. Survival in a cardiac transplant population (n = 254) with severe, end-stage heart failure due to myocardial disease versus survival in patients with symptomatic treatment or no treatment for heart failure.

The problem with cardiac transplantation is that the number of donors is limited, probably at an upper limit of 4,000 to 5,000 per year. If 250,000 patients in the United States have myocardial disease (probably an underestimate) and, conservatively speaking, one-fourth of them would benefit from cardiac transplantation, there is a potential donor-recipient mismatch of 1:10. This lifesaving procedure therefore is not available to all patients who could benefit from it. Obviously, medical approaches need to be developed that reverse or stabilize the generally unfavorable natural history of myocardial disease.

RENIN-ANGIOTENSIN SYSTEM INHIBITORS IN DILATED CARDIOMYOPATHIES

Controlled trials with angiotensin-converting enzyme (ACE) inhibitors (enalapril) in dilated cardiomyopathies have confirmed a modest decline in mortality rates. The

reason behind this decrease in mortality rates and ACE inhibition is not known, although an improvement in the neurohumoral profile and reduction in left ventricular size, leading to an improved myocardial oxygen demand-supply relationship, have been postulated. Recently the addition of the aldosterone antagonist spironolactone has been shown to confer additional survival benefit to subjects with dilated cardiomyopathies (the RALES Trial). Further discussion of the use of renin-angiotensin system inhibitors in subjects with heart failure from primary or secondary cardiomyopathies can be found in [Chapter 66](#).

b-BLOCKING AGENTS IN DILATED CARDIOMYOPATHIES

Because cardiac adrenergic drive is activated in the failing human heart and this sustained activation has multiple potential deleterious effects, it has been postulated that b-blocking agents can favorably affect outcome in dilated cardiomyopathies. Indeed, as observed first in small uncontrolled trials and then later in placebo-controlled medium sized trials, b-blockers consistently improve left ventricular function and attenuate or reverse the remodeling process in subjects with nonischemic or ischemic dilated cardiomyopathies. Recently the b-blocking agents carvedilol, bisoprolol, and metoprolol have been shown to substantially reduce mortality in subjects with mild to moderate heart failure from dilated cardiomyopathies. Thus b-blocker therapy in this myocardial disease phenotype has been established. Further discussion of the use of b-blocking agents in subjects with heart failure from primary or secondary cardiomyopathies can be found in [Chapter 66](#).

IMMUNOSUPPRESSION FOR MYOCARDITIS

Uncontrolled trials have demonstrated temporally related improvement in cardiac function after the use of immunosuppressive agents, with concomitant improvement in mononuclear infiltrate on endomyocardial biopsy. Spontaneous improvement also may occur in myocarditis, however, and it is unclear whether immunosuppressive therapy is warranted based on controlled clinical trials. It is clear that immunosuppressive therapy should not be applied generally to patients with idiopathic dilated cardiomyopathy.

CYTOTOXIC/COLCHICINE THERAPY FOR CARDIAC AMYLOID

Evidence suggests that tissue deposition by amyloid may be reversed by using alkylating agents and steroids or colchicine. Although this approach has undergone only limited trials in cardiac amyloid, it is a possible interventional strategy in this relatively common disease that has an otherwise dismal prognosis. Such an approach should be considered unproved, however, and there is the need for a controlled clinical trial to address the question of efficacy and the risks and benefits.

ANTIARRHYTHMIC THERAPY IN CARDIOMYOPATHIES

Because nearly all antiarrhythmic agents depress cardiac function and because most of them carry a high potential for being proarrhythmic in patients with myocardial disease, routine use of antiarrhythmic agents cannot be recommended in this group of patients. In general, antiarrhythmic therapy should be reserved for patients with a family history of sudden death, those with sustained ventricular tachycardia, or those with symptomatic arrhythmias. In such subjects amiodarone and sotalol are the only agents that have established an adequate safety profile, perhaps because both are Type III antiarrhythmics with b-blocking properties. Finally, the use of implantable defibrillators in selected individuals within the above-described clinical settings clearly has efficacy, but is expensive and, as a result, somewhat controversial.

CHAPTER 75: TUMORS OF THE HEART

JOEL S. RAICHLEN, MARTIN G. AND ST. JOHN SUTTON

[Diagnostic Imaging Modalities](#)
[Primary Cardiac Tumors](#)
[Treatment and Prognosis](#)

Tumors affecting the heart and pericardium are relatively rare, but their identification is extremely important because they may have disastrous clinical consequences that can be prevented or relieved by surgical resection. Unfortunately, most cardiac tumors are clinically silent and those that are not produce a wide variety of nonspecific signs and symptoms. In the past, cardiac tumors were interesting anomalies rarely diagnosed before death. With the introduction of cardiac catheterization, angiographic techniques provided the first means of diagnosing cardiac tumors during life. The development of M-mode echocardiography permitted the noninvasive detection of cardiac masses, but its sensitivity was low; angiography was generally required to assess the size and location of cardiac masses. In the 1980s contrast angiography was largely replaced by two-dimensional echocardiography as the diagnostic method of choice. Today, the diagnosis of cardiac tumors has been enhanced further by the development of transesophageal echocardiography, computed tomography, and magnetic resonance imaging. Guided by this information, elective surgical exploration can be performed for cardiac tumors without the need for invasive studies. The timely removal of cardiac tumors can be curative for most benign tumors and palliative for malignant tumors.

CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Cardiac tumors are detected in only 5% to 10% of patients because they rarely produce symptoms; when they do so, they are nonspecific and do not suggest the diagnosis. Symptoms, if any, are usually related to the size or the location of the tumor. The clinical manifestations of cardiac tumors result from mass effects, tissue infiltration, embolism, or systemic or immune responses to the tumor or its breakdown products ([Table 75.1](#)).

Specific Manifestations	Clinical Consequences
Mass effects	Mass effects
Obstruction to inflow/outflow	Hypertensive hypertension
Obstruction of valves	Signs and symptoms of valvular disease
Mechanical distortion of valves	Signs and symptoms of valvular regurgitation
Mechanical obstruction of outflow	Myocardial infarction, thromboembolism
Obstruction to inflow/outflow	Stroke, angina, acute peripheral edema, or pulmonary/congestive heart failure
	Tumor, paraneoplastic syndrome, embolism, pulmonary edema
Infiltration	Infiltration
Coronary artery	Obstruction, vascular aneurysm
Aortic valve	Chronic pericarditis, myocardial infarction
Systemic artery	Myocardial chest pain, pulmonary hypertension
	Acute myocardial infarction, peripheral ischemic events
Infiltration	Infiltration
Infiltration of ventricular myocardium	Regional dysfunction, congestive heart failure
Infiltration of atrial or ventricular tissue	Local or ventricular tachyarrhythmias
Infiltration of the conduction system	Heart block, sudden death
Pericardial infiltration or compression	Myocardial chest pain, constrictive pericarditis, pericardial effusion, cardiac tamponade
Tumor-mediated effects	Tumor-mediated effects
Systemic or immune response to tumor or breakdown products, or serum proteins	Constitutional symptoms, left-sided heart failure, hepatomegaly, splenomegaly, thrombocytopenia, leukopenia, polycythemia, elevated erythrocyte sedimentation rate (ESR), hyperparathyroidism
Locally damaged by tumor motion	

TABLE 75.1. CLINICAL PRESENTATIONS OF CARDIAC TUMORS

MASS EFFECTS

Clinical signs and symptoms resulting from mass effects occur when tumors protrude into the inflow or outflow tracts of the right or left heart chambers, interfering with blood flow ([Fig. 75.1A](#)). Minor degrees of obstruction create heart murmurs. As tumors enlarge sufficiently to produce major obstruction to blood flow, they may give rise to frank heart failure. Tumors affecting the right heart chambers can partially or totally obstruct systemic venous return, causing superior vena cava syndrome with facial and upper-extremity edema. Obstruction of drainage from the inferior vena cava or to the egress of blood from the right heart chambers is associated with peripheral edema, hepatomegaly, ascites, and dyspnea on exertion owing to an inability to increase cardiac output. Slowly growing tumors of the left heart chambers may impede diastolic filling, resulting in dyspnea and pulmonary hypertension mimicking the symptom complex of mitral stenosis.

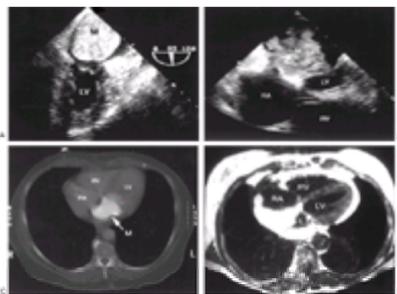

FIGURE 75.1. Imaging of primary tumors. **A:** Transesophageal echocardiogram showing a large myxoma (M) filling the left atrium of the heart. **B:** Transesophageal echocardiogram showing a large left atrial myxoma (M) with a surface made up of irregular projections. **C:** Computed tomographic (CT) scan of the heart showing a densely calcified myxoma (M) filling the left atrium. **D:** T1-weighted electrocardiography-gated magnetic resonance image (MRI) showing lipomatous hypertrophy of the interatrial septum that is contiguous with the epicardial fat surrounding the atria. Note that the tissue intensity is similar to that of the epicardial fat surrounding the ventricles and the subcutaneous fat. L, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Cardiac tumors that interfere with atrioventricular or semilunar valve function do so by mass effect or by distortion of the fibrous skeleton of the heart. They cause valvular regurgitation or, less frequently, stenosis, along with their associated murmurs. Severe disruption of mitral valve function can lead to orthopnea, paroxysmal nocturnal dyspnea, or pulmonary edema. Obstruction to aortic outflow can result in chest pain, syncope, or congestive heart failure. Mobile intracardiac tumors—most commonly atrial myxoma—occasionally generate a tumor plop as the forward motion of the tumor is arrested. Depending on the location of mobile tumors, the auscultatory findings may change with body position—murmurs will increase in the upright position and decrease or disappear in the supine position.

EMBOLISM

Many tumors are friable, with irregular, fibrillated surfaces that predispose to in situ thrombus formation and embolization ([Fig. 75.1B](#)). Systemic embolization from left-sided heart tumors may occlude local blood flow and become evident as strokes, transient cerebral ischemic attacks, or seizures from emboli to the brain; as acute abdominal pain from infarction of intra-abdominal or retroperitoneal organs; or as sudden onset of extremity ischemia from peripheral emboli. Coronary artery embolism is rare and is associated with the acute onset of chest pain and electrocardiographic findings suggesting myocardial ischemia or necrosis. Embolization from right-sided heart tumors into the pulmonary circulation may also cause acute chest pain, with or without hemoptysis, and pleural effusions on chest radiography when it is associated with pulmonary infarction.

MYOCARDIAL INFILTRATION

Tumor infiltration of the myocardium or pericardium may cause a wide spectrum of clinical and electrocardiographic findings. Infiltration of the atrial or ventricular myocardium or adjacent pericardium may result in tachyarrhythmias as well as nonspecific ST-T wave abnormalities on the resting 12-lead electrocardiogram, indicating altered myocardial repolarization. Other electrocardiographic findings that may be caused by tumor infiltration of the myocardium include reduced QRS voltage, left or right atrial enlargement, and left or right ventricular hypertrophy. Bundle-branch block or varying degrees of heart block may result from infiltration of conduction tissue. Advancing infiltration of the myocardium ([Fig. 75.2A](#)) results in regional dyssynergia, followed by clinical evidence of contractile dysfunction and, finally, progressive heart failure. Pericardial infiltration initially may take the form of friction rubs, effusions that can produce cardiac tamponade, or pericardial encasement and clinical signs of constrictive pericarditis.

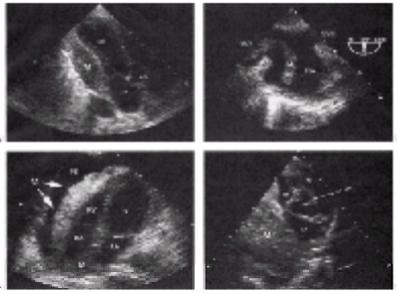

FIGURE 75.2. Metastatic tumors. **A:** Transthoracic echocardiogram showing a metastatic lung carcinoma (M) infiltrating the inferior wall of the left ventricle (LV). **B:** Transesophageal echocardiogram showing tumor mass (M) from a renal cell carcinoma that extends through the inferior vena cava (IVC) and into the right atrium (RA). **C:** Transthoracic echocardiogram showing a pericardial effusion (PE) associated with extensive epicardial metastases (arrows) from a metastatic melanoma (M) that also infiltrates the region of the interatrial septum. **D:** Transthoracic echocardiogram showing a large metastatic sarcoma compressing the right atrium (RA) and the left atrium (LA). AO, aorta; AV, aortic valve; RV, right ventricle; SVC, superior vena cava.

CONSTITUTIONAL SYMPTOMS

Tumors may be associated with such nonspecific symptoms as fever, malaise, arthralgia, polymyositis, Raynaud's phenomenon, weight loss, and cachexia. Hematologic and hepatic abnormalities include anemia, polycythemia, thrombocytopenia, thrombocytosis, leukocytosis, hypergammaglobulinemia, elevated erythrocyte sedimentation rate, and elevations of hepatic transaminases and alkaline phosphatase levels. These abnormal hematologic and biochemical findings are believed to result from immune responses to the tumor and its breakdown products, to mechanical damage to blood cells and serum proteins by tumor motion, or to tumor secretion products. The combination of these constitutional symptoms, hematologic abnormalities, and cardiac murmurs can mimic bacterial endocarditis. The diagnosis of cardiac tumors from the constellation of nonspecific signs and symptoms described here depends largely upon the clinician's level of awareness and vigilance. If the presence of a cardiac tumor is even a remote possibility, noninvasive imaging is mandatory to establish the diagnosis and to evaluate the characteristics of the tumor.

DIAGNOSTIC IMAGING MODALITIES

CHEST ROENTGENOGRAM

Chest radiography was the first clinical diagnostic technique to suggest the presence of cardiac tumors. Its usefulness was related to its ability to identify intracardiac calcification. Otherwise, chest radiography is of limited diagnostic value, because the cardiac silhouette is frequently normal even in the face of large cardiac tumors. One notable exception is benign pericardial cyst, which frequently appears as a well-defined, round or ovoid mass with sharply circumscribed, smooth borders in the right or, less frequently, the left cardiophrenic angle. Pericardial cysts lie along the cardiac silhouette in all projections, in the cardiophrenic angle in 90% of cases, and adjacent to the left or right atrium in 10% of cases.

ANGIOCARDIOGRAPHY

Tumors appear as filling defects on contrast angiograms and deform or encroach on the lumina of the cardiac chambers or the great vessels entering or leaving the heart. Rarely, arteriography will show evidence of tumor circulation in the form of discrete vessels or as a diffuse blush of dye. Angiography largely has been superseded by the current capabilities of noninvasive imaging techniques and is rarely employed today in the diagnostic evaluation of suspected cardiac tumors.

ECHOCARDIOGRAPHY

Two-dimensional echocardiography was the first diagnostic tool to provide complete images of cardiac tumors. The ability of transthoracic and/or transesophageal echocardiography to make the heart visible in multiple planes allows for determination of the size, location, shape, attachments, and mobility of cardiac masses and their anatomic relationship to surrounding structures. The accuracy with which the specific site of attachment can be determined makes it the only imaging study necessary before surgical excision in the majority of cases. When histologic diagnosis is required, the high-resolution images of the cardiac chambers provided by transesophageal echocardiography can be used to help guide transvascular biopsy. When right atrial tumors are present, imaging of the superior and inferior vena cava must be performed, to ensure that primary tumors do not arise within them and that metastatic tumors do not extend from them into the right atrium ([Fig. 75.2B](#)). This is particularly important when surgical resection is contemplated, because such involvement may interfere with the placement of central lines or with caval cannulation for cardiopulmonary bypass.

Echocardiography plays an important role in the evaluation of tumors extending from or infiltrating the myocardium. While tumors of moderate size are easily distinguished from adjacent myocardium, small sessile or intramural tumors are more difficult to detect. The presence of a tumor is suggested by differences in echocardiographic intensity compared with the surrounding myocardium and by the identification of areas with asymmetric thickening, especially when they are associated with hypokinetic wall motion.

Echocardiography is the diagnostic study of choice for identifying tumors originating on cardiac valves. When transthoracic echocardiograms do not adequately depict these structures, transesophageal echocardiography should be used, since it provides high-resolution images of the mitral, aortic, and tricuspid valves. When tumors obstruct cardiac valves or the inflow or outflow regions of cardiac chambers, conventional Doppler echocardiography can provide estimates of the pressure gradients generated as blood passes around the obstructing mass. When tumors disrupt the function of valves, color-flow Doppler echocardiography is useful for assessing the severity of valvular regurgitation.

COMPUTED TOMOGRAPHY

Computed tomographic radiologic imaging techniques are unencumbered by the chest wall, ribs, and lungs that surround the heart. The motion of the heart limits the diagnostic usefulness of conventional computed tomography (CT) imaging of small, mobile, or valvular tumors. Motion artifacts can be limited with more rapid acquisition techniques, such as spiral CT or ultrafast (cine) CT. CT scans are extremely useful in diagnosing cardiac tumors that infiltrate the pericardium, the great vessels, and the tissue surrounding the heart. The relative heterogeneity of the tissue making up the tumors can be characterized, as can its overall radiodensity, which can be compared with that of muscle and subcutaneous fat. CT is also useful in pinpointing the presence of calcifications within tumor masses ([Fig. 75.1C](#)). The primary usefulness of CT imaging for cardiac tumors resides in its ability to determine the extent of any myocardial, pericardial, and mediastinal extension of cardiac tumors.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) provides tomographic views of the heart, great vessels, mediastinum, lungs, and chest wall. By using differences between static tissue and flowing blood and differences in soft-tissue contrast, this technique makes possible the assessment of the extent of tumor invasion into great vessels, the myocardium, the pericardium, and the surrounding tissues. MRI has advantages over CT in the absence of ionizing radiation, the general lack of contrast requirement, and the ability to acquire several orthogonal or oblique projections directly. MRI is also useful for tissue characterization, particularly in differentiating lipomatous tumors with signal intensities similar to subcutaneous fat from thrombi, myxoma, or other soft-tissue tumors (Fig. 75.1D). Although this technique can also suggest the relative homogeneity of a tumor, tissue characterization by MRI cannot distinguish between benign and malignant tumors.

PRIMARY CARDIAC TUMORS

Primary tumors of the heart are rare; their prevalence in autopsy series ranges from 0.0017 to 0.33%. Today, when two-dimensional echocardiography serves as a screening test in the evaluation of many diverse clinical symptom complexes, it is increasingly common for cardiac tumors to be unexpected findings on clinical echocardiograms. When a primary tumor is identified, its classification is aided by knowledge of the distribution and relative incidence of tumors found in the heart (Table 75.2).

Primary Benign Tumors (2-4% of cardiac tumors)		Other Sites in the Heart	
Myxoma	60-90%	Left atrial septum - right atrium - ventricle	
Fibrous xanthoma	1-2%	Left atrial septum - right atrium	
Lipoma	1-2%	Throughout the heart	
Hemangioma	1-2%	Left atrium - right atrium	
Endothelial papilloma	1-2%	Throughout the heart	
		Arteriovenous malformation	

Primary Malignant Tumors (0-1% of cardiac tumors)		Other Sites in the Heart	
Angiosarcoma	10-15%	Right atrium	
Myxosarcoma	10-15%	Throughout the heart	
Fibrosarcoma	1-2%	Left atrial septum	
Liposarcoma	1-2%	Right or left atrium	
Leiomyosarcoma	1-2%	Myxoma in left atrium	
Endothelial papilloma	1-2%	Myxoma in left atrium	
Osteosarcoma	1-2%	Left atrium	

Secondary malignant tumors (20-30% of cardiac tumors)		Sites of Metastasis	
Lung carcinoma	50-60%	Myxosarcoma - liposarcoma - hemangiosarcoma	
Breast carcinoma	10-15%	Myxosarcoma - liposarcoma	
Liver carcinoma	10-15%	Hemangiosarcoma	
Colorectal carcinoma	10-15%	Hemangiosarcoma - lymphatic - direct extension	
Prostate carcinoma	10-15%	Hemangiosarcoma	
Renal carcinoma	10-15%	Myxosarcoma - hemangiosarcoma	

TABLE 75.2. DISTRIBUTION OF CARDIAC TUMORS IN ADULTS

BENIGN CARDIAC TUMORS

In large series, roughly 80% of primary cardiac tumors are benign (range, 60% to 90%). The majority of benign cardiac tumors are myxomas, which predominate in adults aged 30 to 60 years, with a 3:1 female predominance. The majority of cases occur sporadically, while about 7% are familial, inherited as an autosomal dominant trait. In a series of 130 myxoma patients, 65% had initial symptoms of valvular heart disease, 36% had embolic phenomena, 5% experienced sudden death, 4% had pericarditis, 3% had myocardial infarction, and 2% had fever of unknown origin. Only 16% of patients were asymptomatic.

Myxomas can develop anywhere within the heart, though the majority are found in the atria. More than 80% are discovered in the left atrium (Fig. 75.1), and most of the remainder are in the right atrium. Less than 2% of myxomas arise in the ventricles; rare cases have been reported in the valve or the inferior vena cava. Occasionally, there can be several myxomas; in this case, biatrial involvement is most common. The findings of several tumors and ventricular involvement are more common in the context of familial myxomas.

For the majority of cardiac myxomas, surgical resection is curative. The size of the tumor and its site of attachment are important in planning the surgical approach. Approximately 90% of myxomas are attached to the interatrial septum in the region of the fossa ovalis. They may be pedunculated or sessile, with a relatively broad base of attachment. They are frequently polypoid and friable, with a gelatinous, mucoid appearance associated with areas of hemorrhage and superficial thrombosis. Their surfaces may have frondlike excrescences (Fig. 75.1B), or they may be smooth and firm (Fig. 75.1A). The echocardiographic appearance of atrial myxomas correlates with the tumor characteristics on surgical inspection. Tumors that appear compliant and deformable are usually gelatinous, papillary, and friable, while those that appear nondeformable are more likely to be firm, smooth, and nonfriable. These differences are important, in that the former group of tumors has a greater frequency of embolization.

The second most common benign cardiac tumor is papillary fibroelastoma. Although these tumors can develop anywhere in the heart, 90% are found on the valves—the aortic and mitral valves more often than the tricuspid and pulmonic valves. Although valvular tumors are usually solitary and asymptomatic, papillary fibroelastomas can sometimes be found several at a time and have been associated with embolization. One study of 56 primary valve tumors found that 93% were benign. Papillary fibroelastomas were the most common histologic type, accounting for 73% of tumors; myxomas were found in 9% and fibromas in 7%. In that study, 53% of mitral valve tumors and 19% of aortic valve tumors produced serious neurologic symptoms or sudden death. In contrast, another study of 42 papillary fibroelastomas found that 93% manifested no symptoms attributable to the tumor.

The remaining benign cardiac tumors are very uncommon. Lipomas are sessile or polypoid tumors that originate in the subepicardium or subendocardium or in an intramuscular location. They are typically encapsulated, they may appear singly or several at a time, and they occur throughout the heart and pericardium. Lipomas are distinguished from lipomatous hypertrophy of the interatrial septum, which represents nonencapsulated adipose tissue that involves the interatrial septum and is in continuity with epicardial fat. In histologic features, both represent homogeneous accumulations of mature fat cells that can be identified by their tissue signature on CT or MR images (Fig. 75.1D).

Fibromas are more common in children than adults, are almost always single, and develop within the ventricular myocardium, most frequently in the septum or the left ventricular free wall. They are firm tumors that may compress surrounding structures. These benign tumors have been resected from the apex or ventricular free wall, but those involving the interventricular septum are frequently inoperable.

Hemangiomas are composed of proliferations of endothelial cells that form blood-filled channels that can create a so-called tumor blush on coronary arteriography. They can arise anywhere in the heart. Endodermal heterotopia (formerly thought to be mesothelioma) involving the conduction tissue is made up of nests of cells that arise in the region of the atrioventricular node. Although these tumors are benign in histologic features, they typically cause complete heart block and have been associated with ventricular fibrillation. They are the most common primary tumor associated with sudden death, followed closely by fibromas.

Rhabdomyomas are the most common tumors among pediatric patients but are exceedingly rare in adults. These tumors usually appear in groups deeply embedded in the right or left ventricular wall. They may regress completely, such that surgery is recommended only for refractory arrhythmias or critical hemodynamic compromise. Rhabdomyomas are found in 58% of children and 18% of adults with tuberous sclerosis, which is a complex of congenital anomalies inherited as an autosomal dominant trait. Teratomas are even more rare adult tumors that are more frequently found in young patients. They are extracardiac intrapericardial tumors that contain cysts and generally arise from the base of the heart.

PRIMARY MALIGNANT TUMORS

Although primary benign tumors in adults usually develop in the left atrium, primary malignant tumors are more often found in the right atrium. More than 80% of primary malignant neoplasms are sarcomas, making them the second most common type of primary cardiac tumor. The most prevalent primary malignant tumor is angiosarcoma, which is characterized by malignant cells that form vascular channels. These tumors occur throughout adulthood, at mean ages of 40 to 50 years. They are two to three times more common in men. Some 60% to 70% arise in the right atrium. They are aggressive tumors that rapidly expand into the adjacent myocardium and pericardium and frequently metastasize to the lungs and mediastinal lymph nodes.

The malignant cells in rhabdomyosarcoma have features of striated muscle. These tumors have similar incidence rates in all adult age groups and are slightly more prevalent in men. They are found throughout the chambers of the heart and pericardium. Fibrosarcomas, osteosarcomas, and leiomyosarcomas are less common malignant tumors that most frequently develop within the left atrium. Malignant fibrous histiocytoma involves fibroblasts and pleomorphic histiocytoid cells. These

tumors have an age at onset similar to that of angiosarcomas, but they exhibit no gender predominance. Over 80% occur in the left atrium, most often on the posterior wall, where they can obstruct pulmonary veins or the mitral valve or cause mitral regurgitation. Malignant mesotheliomas are multicentric tumors that arise from the visceral or parietal pericardium. They may become quite large and compress the great vessels as they enter or leave the heart. In general, these tumors diffusely affect the pericardium and may encase the heart, though they rarely invade the myocardium.

METASTATIC CARDIAC TUMORS

In autopsy series, cardiac metastases have been reported 20 to 40 times more often than primary cardiac tumors; recent estimates suggest that they may occur more than 100 times more frequently. An average of 10% of patients with metastatic malignant disease have myocardial metastases, and another 5% show signs of involvement limited to the pericardium. Cardiac involvement is found in 19% of patients with lung metastases and only 2.7% of patients without lung involvement. Factors suggested to explain this relatively low incidence of cardiac metastasis include mechanical damage of blood-borne metastatic cells as they are deformed by myocardial contraction, metabolic peculiarities of striated muscle, rapid coronary blood flow, and restricted lymphatic connections that are predominantly directed away from the heart, thus requiring metastasis via that route to progress against the direction of lymphatic flow.

Almost all types of malignant tumors have been found to metastasize to the heart; the most common is carcinoma of the lung. In decreasing order, the next most prevalent cancers found to metastasize to the heart are carcinoma of the breast, leukemia, lymphoma, and malignant melanoma. Melanomas are the most likely malignancies to involve the heart; metastases are found in more than 50% of cases in most autopsy series. Cardiac involvement is also found in up to half of all patients with leukemia, one-fourth of patients with bronchogenic carcinoma, and one-fifth of patients with breast carcinoma or lymphoma.

Metastatic tumors of the heart may take the form of intramyocardial masses ([Fig. 75.2A](#)), intracavitary masses ([Fig. 75.2B](#)), masses extending from the epicardial surface of the heart into pericardial effusions ([Fig. 75.2C](#)), or extracardiac masses that surround and/or compress chambers of the heart ([Fig. 75.2D](#)). When metastatic tumor involves cardiac chambers, the right side of the heart is more frequently involved than the left. In right atrial metastases, it is important to examine the inferior vena cava, to assess venous extension from the kidney, liver, or other abdominal organ ([Fig. 75.2B](#)).

When metastatic disease reaches the heart by direct extension, as in carcinomas of the lung, breast, and esophagus, it usually is associated with diffuse pericardial involvement. Other routes for cardiac metastases include embolic hematogenous spread, as in malignant melanomas and leukemias, and spread via lymphatic channels, as in breast carcinomas and lymphomas. In more than half of patients with cardiac metastasis from lung cancer, the primary tumor is distant from the heart. In these cases, metastasis occurs via lymphatic spread or, less often, by a hematogenous pathway. Lymphatic spread is the most typical route of metastasis in the context of malignant pericardial effusions. Metastases from lung and breast carcinomas may affect the pericardium without obvious cardiac involvement, while melanoma and leukemia usually metastasize to the heart with or without pericardial involvement.

Cardiac metastases to the pericardium may be associated with signs and symptoms of acute pericarditis, constrictive pericarditis, or pericardial effusions that can progress to cardiac tamponade. Pericardial metastases may preclude operative intervention in otherwise resectable noncardiac tumors. Metastatic involvement of the pericardium may take the form of irregularly appearing nodules attached to the visceral or parietal pericardium ([Fig. 75.2C](#)). In the context of externally compressing masses, diffuse pericardial thickening may be evident. In a patient with a known primary malignancy, echocardiographic evidence of discrete epicardial masses that move with the cardiac cycle and protrude into a pericardial effusion is highly suggestive of pericardial metastases.

TREATMENT AND PROGNOSIS

The recognition of cardiac tumors is important because of the potentially devastating consequences of embolic phenomena and hemodynamic obstruction. Unfortunately, most tumors of the heart metastasize from other organs. Early detection of primary tumors allows for surgical resection, which is frequently curative of benign neoplasms and may prolong survival in patients with malignant ones. Although aggressively debulking primary malignant tumors may retard their dissemination, such operations are only palliative. Postoperative irradiation occasionally is useful in shrinking tumor masses and transiently alleviating symptoms, whereas adjuvant chemotherapy is not often of benefit. Orthotopic cardiac transplantation offers the opportunity of completely removing unresectable tumors. Thus far, it has achieved only limited success in a small number of cases.

In metastatic disease, therapy should be focused on the specific type of tumor and on the clinical manifestations. Cardiac side effects of the malignant growths should be vigorously treated, including medical therapy of heart failure and pacemaker insertion for symptomatic heart block. Hemodynamically significant effusions warrant pericardiocentesis, which may have to be performed repeatedly or require placement of a pericardial-pleural window to obviate life-threatening cardiac tamponade. Reaccumulation of effusions can be prevented by instilling tetracycline, chemotherapeutic agents, or radioisotopes. Excision should be considered for resectable intracavitary tumors causing obstruction or peripheral emboli, particularly when extension and growth of the primary tumor is thought to be under control. Other therapeutic tools should be selected on a tumor-specific basis, such as hormonal and chemotherapy for patients with effusions associated with breast cancer and radiation therapy for pericardial disease in patients with leukemia or lymphoma. With few exceptions, the prognosis remains poor in patients with primary or secondary malignant tumors of the heart.

CHAPTER 76: CARDIAC ARRHYTHMIAS

BRADLEY P. KNIGHT, DOUGLAS P. ZIPES AND FRED MORADY

[Sinus Rhythms](#)
[Atrial Rhythm Disturbances](#)
[Preexcitation Syndrome](#)
[Ventricular Arrhythmias](#)
[Heart Block](#)

Cardiac arrhythmias are disorders of the normal heart rhythm. Most frequently, they create palpitations, which consist of an awareness of the heartbeat—usually because of a ventricular contraction that has greater strength than normal, a pause in the normal heart rhythm, extra beats, or combinations of these factors. Less commonly, cardiac rhythm disturbances can produce syncope, near-syncope, angina, congestive heart failure, or death. The ability of patients to perceive palpitations varies greatly. Some patients recognize a slight shortening of the cardiac cycle, whereas others are unaware of episodes of ventricular tachycardia. Some patients complain of palpitations even though they are documented to have sinus rhythm.

Cardiac arrhythmias are caused by a single heartbeat or series of heartbeats that are too slow (bradycardia) or too fast (tachycardia). They can originate in the specialized conduction system, including the sinus and atrioventricular (AV) nodes, His bundle, and Purkinje fibers, or they can originate from atrial or ventricular muscle. In this chapter, cardiac arrhythmias are discussed in relation to their anatomical site of origin. A summary of the pertinent characteristics of arrhythmias is given in [Table 76.1](#).

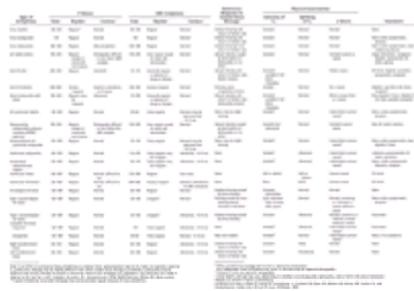

TABLE 76.1. ARRHYTHMIA CHARACTERISTICS

An arrhythmia feature must be distinguished from an arrhythmia diagnosis. For example, AV dissociation is present when the atria and the ventricles beat independently. It is never a primary disturbance of rhythm, but is the result of an underlying disturbance. When discussing AV dissociation, it must be stated that “AV dissociation is present and is caused by...” and then the cause responsible for independent atrial and ventricular discharge must be given.

Artifact deserves early mention in a chapter on arrhythmias. Electrocardiographic artifacts are generated by a variety of sources, including patient movement and electromagnetic interference, and can be confused with arrhythmias. Artifact is best recognized by the presence of a baseline rhythm “buried in” or “marching through” a recording ([Fig. 76.1](#)). A high index of suspicion and awareness of the common occurrence of electrocardiographic artifact is required to avoid misdiagnosing artifact as an arrhythmia.

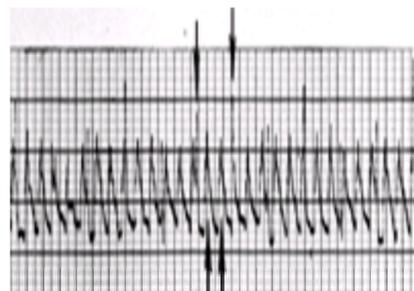

FIGURE 76.1. Artifact mimicking tachycardia. The patient, being monitored on a coronary care unit, brushed his teeth with an electric toothbrush and generated a regular artifact that mimicked a ventricular tachycardia (*upright arrows*). However, the patient's QRS complex (*inverted arrows*) can be seen clearly.

SINUS RHYTHMS

NORMAL SINUS RHYTHM

Sinus discharge at rates of 60 to 100 beat per minute (faster in infants and children) is defined as normal sinus rhythm. The P wave is upright in leads II, III, and aVF and is negative in lead aVR. The P wave can be negative in lead V₁ and sometimes V₂ but is positive in V₃ through V₆. The PR interval exceeds 120 msec. The sinus rate is decreased by vagal stimulation and increased by sympathetic stimulation. Vagal stimulation is dominant at the sinus node; therefore, during simultaneous maximal vagal and sympathetic stimulation, the sinus rate decreases.

SINUS TACHYCARDIA

Sinus tachycardia is present when the sinus rate exceeds 100 beats per minute, usually not exceeding 180 beats per minute in the adult. The maximal sinus rate achieved during strenuous physical activity decreases with age. Sinus tachycardia has a gradual onset and termination, and the P-wave contour can become more peaked and of larger amplitude. It is important to note that carotid sinus massage or other vagal maneuvers result in gradual and transient slowing of sinus tachycardia ([Table 76.1](#)).

Although chronic sinus tachycardia has been described in otherwise healthy persons and is called *inappropriate sinus tachycardia*, sinus tachycardia most frequently results from physiologic or pathophysiologic stresses, such as fever, hypotension, congestive heart failure, or thyrotoxicosis. Its presence should prompt a search for underlying causes. Nonprescription drugs such as decongestants, which contain catecholamines, or alcohol, nicotine, and caffeine can produce sinus tachycardia.

Sinus tachycardia uncommonly is a primary disorder, and therapy focuses on potential causes. The uncommon patient with primary chronic sinus tachycardia may

need drug, surgical, or ablative therapy to treat the sinus tachycardia directly.

SINUS BRADYCARDIA

Sinus bradycardia is present when the sinus discharge rate is less than 60 beats per minute. P waves have a normal contour and the PR interval exceeds 120 msec. Excessive vagal or decreased sympathetic tone and anatomical or electrophysiologic abnormalities in the sinus node can cause sinus bradycardia. It is often present in healthy young adults, particularly in athletes, and during sleep. Myxedema, hypothermia, vasovagal reactions, and drugs such as lithium, amiodarone, b-adrenergic blocking agents, and calcium channel blockers can produce sinus bradycardia. Most commonly, it is a benign arrhythmia, and treatment is usually not necessary. Transiently symptomatic sinus bradycardia can be treated with drugs such as atropine or isoproterenol, or with temporary pacing. Chronic symptomatic sinus bradycardia typically requires pacemaker therapy.

SINUS ARRHYTHMIA AND WANDERING PACEMAKER

Sinus arrhythmia is characterized by a phasic variation in sinus cycle length, usually exceeding 120 msec from the maximum to the minimum change in the cycle length. P-wave contour as a rule remains fairly constant, as does the PR interval. Sinus arrhythmia has a respiratory and nonrespiratory form. *Ventriculophasic sinus arrhythmia* occurs when the ventricular rate is slow, such as during complete AV block, and is characterized by shorter PP cycles for the two P waves that flank a QRS complex and by longer PP cycles for the two P waves that do not include a QRS complex between them. Such changes probably result from the influence of the autonomic nervous system responding to changes produced by the ventricular stroke volume.

Wandering pacemaker is a variant of sinus arrhythmia and is diagnosed when there is a cyclic increase in the RR interval, a PR interval that gradually shortens and may become less than 120 msec, and when a change in the P wave contour that often becomes negative in leads I or II or is lost within the inscription of the QRS complex ([Fig. 76.2](#)). As the pacemaker shifts back to the sinus node, these changes may occur in reverse.

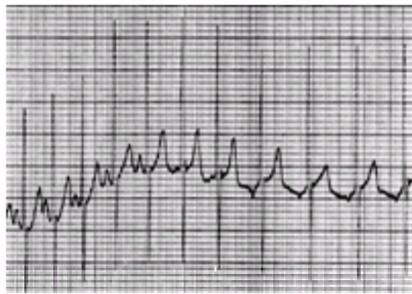

FIGURE 76.2. Wandering pacemaker, monitor lead. Progressive sinus slowing occurs as the P wave becomes isoelectric initially and then negative in the terminal portion of the ECG recording. The P wave once again became positive and varied repetitively in this cyclic manner (not shown).

Sinus arrhythmia and wandering pacemaker often happen in the very young, particularly in athletes, and probably result from heightened vagal tone. If the patient has no symptoms, treatment is not necessary. For the rare symptomatic patient, the treatment approach is the same as in sinus bradycardia.

SINUS PAUSE OR SINUS ARREST

Sinus pause or sinus arrest is diagnosed when a pause in the sinus rhythm occurs, the duration of which does not equal a multiple of the basic PP interval ([Fig. 76.3](#)). Anatomical disruption of the sinus node by ischemia or infarction, degenerative fibrotic changes, the effects of drugs, and excessive vagal tone all can produce a sinus pause or sinus arrest. Sinus pauses can occur after termination of atrial fibrillation in patients with sick sinus syndrome ([Fig. 76.4](#)). The arrhythmia may have no clinical significance by itself if latent pacemakers discharge to prevent ventricular asystole. Treatment is as for sinus bradycardia.

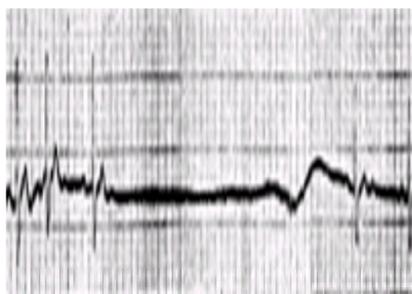

FIGURE 76.3. Sinus pause or sinus arrest, monitor lead. Initial slight sinus slowing is followed by sinus arrest with a junctional escape beat (next to last QRS complex) after almost 8 seconds of asystole. During this time, the patient developed near-syncope. Why other pacemakers did not discharge during that interval is unclear.

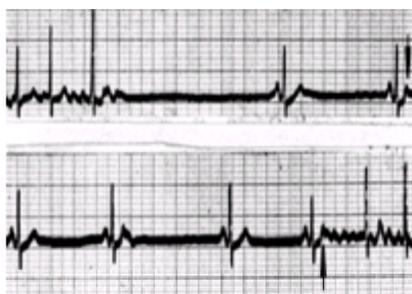

FIGURE 76.4. Sick sinus syndrome, monitor lead. Atrial flutter-fibrillation abruptly terminates and is followed by a slightly irregular sinus bradycardia with intermittent premature atrial complexes (*inverted arrow*). One of these premature atrial complexes (*upright arrow*) reinitiates the atrial flutter-fibrillation.

SINOATRIAL EXIT BLOCK

Sinoatrial (SA) exit block results when a pause in the PP interval occurs which is equal to a multiple of the basic PP interval. Electrophysiologically, SA exit block

results when the sinus node discharges but the impulse is blocked from propagating to the atrium. The SA exit block can be type I, during which the PP interval progressively shortens before the pause, and the duration of the pause is less than two PP cycles (see type I Wenckebach second-degree AV heart block), or type II, in which the pause equals two, three, or four normal PP cycles. First-degree SA exit block cannot be recognized electrocardiographically because SA nodal discharge cannot be recorded with the scalar electrocardiogram (ECG). Third-degree SA exit block can present as the complete absence of P waves and mimic sinus arrest. Causes and treatment are the same as for sinus bradycardia.

SINUS NODAL REENTRY

Reentry within the sinus node or involving a part of the sinus node can result in a supraventricular tachycardia with rates of 80 to 200 beats per minute, averaging 130 to 140 beats per minute. During tachycardia, P waves resemble the sinus P wave, and the PR interval is related to the tachycardia rate, usually producing a long RP interval and a shorter PR interval. AV block can occur with persistence of the tachycardia, a hallmark of a tachycardia occurring in the atrium and not requiring participation of the ventricle. Vagal maneuvers can slow and then abruptly terminate the tachycardia. Sinus nodal reentry may account for 1% of cases of symptomatic paroxysmal supraventricular tachycardia. β -Adrenergic blocking agents, calcium channel blockers, or digitalis may be effective therapy.

ATRIAL RHYTHM DISTURBANCES

PREMATURE ATRIAL COMPLEXES

Premature atrial complexes manifest as a premature P wave morphologically different from the sinus P wave. Premature P waves superimposed on the preceding T wave can be difficult to recognize. When such a premature atrial complex blocks in the AV junction before reaching the ventricle, it can be misinterpreted as a sinus pause.

Usually, a premature atrial complex discharges the sinus node and is followed by a *noncompensatory* pause. On occasion, the premature atrial complex can initiate an aberrantly conducted QRS complex, usually with a right bundle-branch-block contour. Premature atrial complexes can occur in normal persons and can be provoked by drugs, alcohol, caffeine, and tobacco. Premature atrial complexes as a rule do not require therapy, but when they do because of symptoms or precipitation of tachycardias, treatment with digitalis, propranolol, or verapamil may be useful. On occasion, class IA drugs or amiodarone may be tried.

ATRIAL FLUTTER

Atrial flutter is recognized electrocardiographically as sawtooth-shaped atrial complexes, usually at rates of 250 to 350 beats per minute (most often 300 beats per minute), with a 2:1 ventricular response in untreated persons (Fig. 76.5). The flutter waves commonly are negative in leads II, III, aVF, and V₁, and if the AV conduction ratio remains constant, the ventricular rhythm is regular. A varying ratio of conducted beats produces an irregular ventricular rhythm. The classic or type I atrial flutter usually has a rate of 300 beats per minute, whereas type II flutter is faster at 350 to 450 beats per minute. Reentry is the most probable cause of atrial flutter with a counterclockwise macro (large) right atrial circuit due to the impulse traveling cephalad up the right atrial septum and caudad down the right atrial free wall when the flutter waves are negative in II, III, and aVF. When the circuit is in an opposite direction, the flutter waves can be positive or negative. Atrial flutter usually is associated with underlying heart disease, such as rheumatic or ischemic heart disease or cardiomyopathy.

FIGURE 76.5. Atrial flutter. **A:** Relatively slow atrial flutter (200 beats per minute) due to the effects of amiodarone. **B:** Atrial flutter (*arrows*) is difficult to recognize. A long-short cycle sequence initiates functional right bundle-branch block (see section on aberration). **C:** Atrial flutter that is difficult to recognize in lead I (*left*) but obvious when the recording is switched to lead II (*right*). **D:** ECG of a 16-year-old patient with a rapid atrial flutter (*arrows*) induced with physical exertion. Because of an uncontrollable ventricular response, the patient despite his young age, underwent atrioventricular junctional ablation to modify atrioventricular conduction. **E:** Monitor strip showing conversion of atrial flutter to sinus rhythm during an infusion of ibutilide.

Synchronous direct-current (DC) cardioversion is usually the initial treatment of choice. Rapid atrial pacing can effectively terminate atrial flutter in most patients. Pharmacologic therapy is directed at slowing the ventricular response. If atrial flutter persists, class IA, IC, or III drugs can be tried (Fig. 76.5). Before class I drugs are given, the ventricular rate must be slowed.

Prevention of recurrent atrial flutter is as outlined for prevention of recurrent atrial fibrillation. Radiofrequency catheter ablation can be effective in eliminating typical atrial flutter (Fig. 76.5). If recurrences cannot be prevented, therapy is directed toward controlling the ventricular rate.

ATRIAL FIBRILLATION

Atrial fibrillation is the most common sustained arrhythmia, and its incidence increases with age. Atrial fibrillation is characterized by totally disorganized atrial depolarization without effective atrial contraction and is most commonly sustained by multiple atrial wavelets of reentry.

Accurate recognition of atrial fibrillation is important because of its high morbidity. Atrial fibrillation appears as small, irregular baseline undulations of varying amplitude and morphology, called F waves, at a rate of 350 to 600 per minute (Fig. 76.6). Many of the fibrillatory impulses are blocked in the AV node, which accounts for the irregular ventricular rhythm. Atrial fibrillation should not be confused with multifocal atrial tachycardia, which is also "irregularly irregular" but has discrete atrial beats separated by isoelectric periods. Regularization and slowing of the rhythm can occur with heart block and digitalis toxicity. A rapid ventricular response results in less irregularity and can lead to a misdiagnosis of paroxysmal supraventricular tachycardia (Fig. 76.6). In the untreated person with normal AV conduction, the ventricular rate usually is 100 to 160 beats per minute. Conversion of atrial fibrillation to atrial flutter is accompanied by a slowing of the atrial rate, but an increase in the ventricular rate, because fewer impulses block in the AV node. It is easier to slow the ventricular rate during atrial fibrillation than during atrial flutter, because the increased concealed conduction makes it easier to produce AV block.

FIGURE 76.6. Atrial fibrillation. **A:** Atrial fibrillation and a slow ventricular response to digitalis therapy are noted. **B:** Monitor strip showing atrial fibrillation with a rapid ventricular response. The irregularity is less obvious when the ventricular rate is rapid but the rhythm is not as regular as paroxysmal supraventricular tachycardia. This patient was unnecessarily treated with adenosine. **C:** Atrial fibrillation with complete atrioventricular block and a wide QRS escape. **D:** Atrial fibrillation in a patient with Wolff-Parkinson-White syndrome. The negative delta wave in lead V_1 is consistent with a right-sided accessory pathway. Although atrial activity cannot be seen, the rapid, irregular, wide QRS complexes, with rates exceeding 300 beats per minute at times, interspersed with normal QRS complexes, support the diagnosis of atrial fibrillation with conduction to the ventricle over an accessory pathway.

Atrial fibrillation commonly occurs in patients with hypertension, rheumatic heart disease, atrial septal defect, cardiomyopathy, coronary heart disease, and thyrotoxicosis and in those who have undergone cardiac surgery, but it can be present in patients without structural heart disease, so-called lone atrial fibrillation. The patient who has atrial fibrillation for the first time should be evaluated for precipitating causes.

The therapeutic objective is to slow the ventricular rate and then to restore atrial systole. If acute cardiovascular decompensation has occurred, electrical cardioversion is the initial treatment of choice. Otherwise, drugs that slow the ventricular response can be used. Sometimes digitalis must be combined with a b-blocker or calcium channel blocker. Digitalis is less effective during exercise. Adequacy of ventricular rate control must be assessed both at rest and with activity. Inadequate rate control can lead to a tachycardia-induced cardiomyopathy. Creation of complete heart block using radiofrequency ablation followed by implantation of a pacemaker is a useful option for patients with medically refractory rapid ventricular rates during atrial fibrillation. This procedure can significantly improve symptoms related to rapid rates but does not restore sinus rhythm. Therefore, continuation of anticoagulation is usually required to prevent thromboembolism.

Conversion to sinus rhythm should be considered in patients with atrial fibrillation when it is likely that sinus rhythm will remain for a relatively long time period, when symptoms are present, or when the ventricular rate cannot be controlled. Electrical cardioversion with a DC shock is the most effective cardioversion technique and can be performed on an outpatient basis. A variety of oral and intravenous drugs are also useful for cardioversion. Pharmacologic cardioversion should be performed while the patient is monitored in the hospital when structural heart disease is present. Intravenous ibutilide is more effective than procainamide. Amiodarone is ineffective at converting atrial fibrillation.

The strongest predictor of recurrent atrial fibrillation is the duration of atrial fibrillation before cardioversion. Atrial fibrillation is more likely to be long-standing in patients with left atrial enlargement. Antiarrhythmic drugs help maintain sinus rhythm. However, sodium channel blockers such as quinidine and flecainide can increase mortality due to proarrhythmia when used chronically in patients with significant underlying structural heart disease. Although not approved by the Food and Drug Administration (FDA) for the treatment of atrial fibrillation, amiodarone effectively prevents recurrences and is relatively safe to use in patients with ventricular dysfunction.

Nonpharmacologic techniques are being developed to manage atrial fibrillation. The Maze and Corridor operations involve open-heart surgery in which surgical incisions are strategically placed in the atria to interrupt atrial fibrillation by preventing reentry. Special catheters are being tested to accomplish this procedure using a transvenous endocardial approach. A subset of patients with apparent atrial fibrillation has a rapidly firing atrial tachycardia arising from the pulmonary veins, resulting in fibrillatory conduction. These patients tend to have frequent uniform premature atrial depolarizations and focal ablation in one of the pulmonary veins can be curative. Implantable transvenous atrial defibrillators permit out-of-hospital conversion for patients who require frequent cardioversion. Multisite atrial pacing may reduce the number of tachycardia episodes in patients with paroxysmal atrial fibrillation.

Patients with chronic atrial fibrillation have an increased risk for stroke. Risk factors include hypertension, rheumatic heart disease, diabetes, history of previous stroke or transient ischemic attack, left atrial enlargement, coronary artery disease, history of congestive heart failure, significant valvular heart disease, and age greater than 65 years. Long-term anticoagulation with warfarin is necessary in patients who are predisposed to the development of emboli. Aspirin can be effective in some patients. Electrical cardioversion and pharmacologic cardioversion are associated with atrial contractile dysfunction (stunning) and thrombus formation. Therefore, short-term anticoagulation before and after cardioversion is necessary in all patients with persistent atrial fibrillation for more than 2 days or of uncertain duration unless a contraindication is present. Absence of a left atrial thrombus by a transesophageal echocardiogram permits safe cardioversion without prior anticoagulation. However, cardioversion must be performed after heparin is started and must be followed by warfarin for 4 weeks.

ATRIAL TACHYCARDIA

Atrial tachycardia can be due to enhanced atrial automaticity, reentry or to triggered activity. In either, AV block can exist without affecting the tachycardia. The atrial rate usually is 150 to 200 beats per minute. The atrial rate can be slightly irregular, and characteristic isoelectric intervals between P waves usually are present ([Fig. 76.7](#)). Vagal maneuvers usually do not terminate the tachycardia, even though they may produce transient AV nodal block.

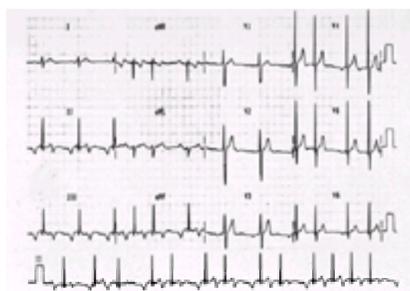

FIGURE 76.7. Atrial tachycardia with varying atrioventricular (AV) nodal block is seen in the 12-lead ECG. Predominantly 2:1, 3:2, and 5:4 AV block is apparent in the lead II rhythm strip (*bottom*).

Atrial tachycardia occurs most commonly in patients with structural heart disease such as coronary artery disease or cor pulmonale or in patients after congenital heart surgery or digitalis intoxication. If digitalis is not the cause, it may be given, as may a slow channel blocker or b-blocker drug, to slow the ventricular response. Recurrent atrial tachycardia can be controlled with antiarrhythmic drugs and can often be cured with catheter ablation.

CHAOTIC ATRIAL TACHYCARDIA

Chaotic, or multifocal, atrial tachycardia is characterized electrocardiographically by atrial rates of 100 to 130 beats per minute, marked variation in P-wave morphology, and irregular PP intervals ([Fig. 76.8](#)). Usually, at least three P-wave morphologies are noted. This tachycardia occurs frequently in patients with pulmonary disease. Digitalis appears to be an unusual cause, but theophylline administration has been implicated. Therapy is directed primarily at the underlying disease, and antiarrhythmic agents often are ineffective in slowing either the atrial rate or the ventricular response. Potassium and magnesium replacement may suppress the tachycardia. Propranolol should be avoided in patients with bronchospastic disease.

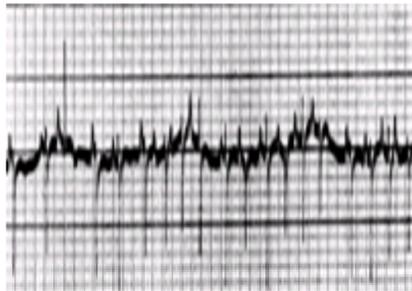

FIGURE 76.8. Chaotic atrial tachycardia. Lead II illustrates frequent premature atrial complexes with multiple morphologies, at times conducting with aberration and often with a prolonged PR interval.

ATRIOVENTRICULAR JUNCTIONAL ESCAPE BEATS

Latent pacemakers are automatic fibers that are prevented from initiating depolarization by a pacemaker, such as the sinus node, that possesses a more rapid rate of firing and keeps them depolarized. Latent pacemakers are found in some parts of the atrium, AV node–His bundle area, and Purkinje system. A latent pacemaker can become the dominant pacemaker by increasing its rate of discharge or by default during bradycardia.

An AV junctional escape beat occurring by default is characterized by a normal QRS complex at a cycle length longer than the normal PP interval with absent, retrograde, fusion, or sinus P waves that do not conduct to the ventricle. This rhythm may be completely normal, and patients most often are asymptomatic.

ATRIOVENTRICULAR JUNCTIONAL RHYTHM

If the AV junctional escape beats continue, the rhythm is called an AV junctional rhythm and is at the inherent rate of the AV junctional tissue of 35 to 60 beats per minute (Fig. 76.9). The ECG displays a normally conducted QRS complex that may conduct retrogradely to the atrium or may occur independently of atrial discharge, producing AV dissociation. Treatment of patients with AV junctional escape beats or AV junctional rhythm usually is not necessary but, if required, can be achieved with drugs that increase the discharge rate of the sinus node and improve AV conduction. Pacing rarely is required.

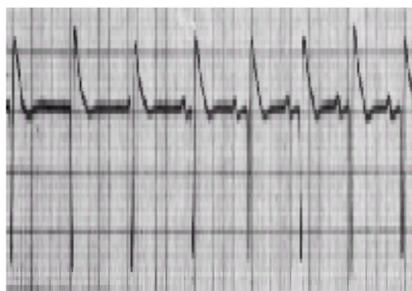

FIGURE 76.9. Atrioventricular (AV) junctional rhythm. Sinus bradycardia permits the escape of an AV junctional rhythm (*left*: 48 beats per minute) until the sinus rate speeds sufficiently to again control the rhythm (*middle*). First-degree AV block is present.

PREMATURE ATRIOVENTRICULAR JUNCTIONAL COMPLEXES

Premature AV junctional complexes are characterized by a premature supraventricular QRS complex with or without conduction to the atrium. A retrograde P wave can occur before, during, or after the QRS complex, or a nonconducted sinus P wave may occur (Fig. 76.10).

FIGURE 76.10. Premature atrioventricular (AV) junctional complexes are noted in leads aVF and V₅ (onset indicated by dark circles in ladder diagram). They do not block the subsequent sinus impulse, which conducts with a prolonged PR interval. Hence, the premature AV junctional complexes are called interpolated.

NONPAROXYSMAL ATRIOVENTRICULAR JUNCTIONAL TACHYCARDIA

Nonparoxysmal AV junctional tachycardia usually is characterized by a gradual onset and termination of a supraventricular tachycardia at rates commonly between 70 and 130 beats per minute. Although accepted terminology confers the label of tachycardia to rates exceeding 100 beats per minute, the term nonparoxysmal AV junctional tachycardia has been applied to this rhythm because rates exceeding 60 beats per minute represent, in effect, a tachycardia for the AV junctional tissue.

Nonparoxysmal AV junctional tachycardia occurs most commonly in association with underlying heart disease (inferior myocardial infarction [MI] or myocarditis, after open-heart surgery, or from excessive digitalis). The last of these can produce the ECG manifestations of junctional exit block, usually of the Wenckebach type. The clinical features vary, depending on the rate of arrhythmia and the underlying cause and severity of the heart disease. Nonparoxysmal AV junctional tachycardia can occur in otherwise healthy persons without symptoms, or it can occur at rapid rates and result in heart failure. It is especially important to recognize slowing and regularization of the ventricular rhythm in patients with atrial fibrillation as being caused by nonparoxysmal AV junctional tachycardia and as a possible early sign of digitalis intoxication.

Generally, monitoring and attention to the underlying heart disease usually are all that are required. The arrhythmia usually abates spontaneously. If the cardiovascular status is compromised, digitalis, slow channel blockers, or b-blockers can be considered. Digitalis may be a cause, and, if so, it should be

discontinued. Rarely, catheter ablation is indicated.

ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

AV nodal reentry is characterized by a regular tachycardia with a QRS complex of supraventricular origin, usually at rates between 150 and 250 beats per minute (commonly 180 to 200 beats per minute in adults), sudden onset, and sudden termination. The development of unidirectional block in the AV nodal region is due to the presence of tissues with disparate electrophysiologic properties.

Because anterograde conduction to the ventricle usually occurs over a slowly conducting AV nodal pathway and retrograde conduction occurs over a more rapidly conducting pathway, at the onset of tachycardia the atrial complex blocks in the fast pathway anterogradely, travels to the ventricle over the slow pathway, and returns to the atrium over the previously blocked fast pathway, with the reentry circuit using the two approaches to the AV node ([Fig. 76.11](#)). A premature atrial complex that conducts with a long PR interval commonly precipitates AV nodal reentry. The retrograde P wave occurs at the onset or just after the termination of the QRS complex in most cases ([Fig. 76.11](#)).

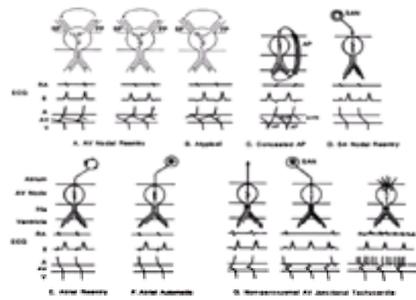

FIGURE 76.11. Diagrammatic representation of various supraventricular tachycardias. In the top portion of each example, a schematic diagram of the presumed anatomical pathways is drawn; in the bottom half, the ECG presentation and the explanatory ladder diagram are depicted. **A:** Atrioventricular (AV) nodal reentry. In the left example, reentrant excitation is drawn with retrograde atrial activity occurring simultaneously with ventricular activity because of anterograde conduction over the slow AV nodal pathway and retrograde conduction over the fast AV nodal pathway. In the right example, atrial activity occurs slightly later than ventricular activity because of retrograde conduction delay. **B:** Atypical AV nodal reentry due to anterograde conduction over a fast AV nodal pathway and retrograde conduction over a slow AV nodal pathway. **C:** Concealed accessory pathway. Reciprocating tachycardia due to anterograde conduction over the AV node and retrograde conduction over the accessory pathway. Retrograde P waves occur after the QRS complex. **D:** Sinus nodal reentry. The tachycardia is due to reentry within the sinus node, which then conducts to the rest of the heart. **E:** Atrial reentry. Tachycardia is due to reentry within the atrium, which then conducts to the rest of the heart. **F:** Automatic atrial tachycardia. Tachycardia is due to automatic discharge in the atrium, which then conducts to the rest of the heart; it is difficult to distinguish from atrial reentry. **G:** Nonparoxysmal AV junctional tachycardia. Various presentations of this tachycardia are depicted with retrograde atrial capture, AV dissociation with the sinus node in control of the atria, and AV dissociation with atrial fibrillation. (From Zipes DP. Specific arrhythmias: diagnosis and treatment. In: Braunwald E, ed. *Heart disease: a textbook of cardiovascular medicine*, third ed. Philadelphia: WB Saunders, 1996, with permission.)

Less frequently, anterograde conduction proceeds over the fast pathway and retrograde conduction over the slow pathway, producing the unusual form of AV nodal reentry. In this instance, the retrograde P wave precedes the following QRS complex at a relatively short AV interval, producing a long ventriculoatrial interval ([Fig. 76.11](#)).

AV nodal reentry occurs commonly in patients without structural heart disease and produces a constellation of symptoms ranging from palpitations, nervousness, and anxiety to angina, heart failure, and syncope, depending on the duration and rate of the tachycardia and the presence of structural heart disease. Initial hypotension during tachycardia may evoke a sympathetic response that increases blood pressure and in turn causes a rise in vagal tone that may terminate the tachycardia. The prognosis for patients without heart disease usually is good.

Termination of AV nodal reentrant supraventricular tachycardia initially involves vagal maneuvers, including carotid sinus massage, Valsalva's and Muller's maneuvers, gagging, and, on occasion, exposure of the face to ice water. The drug of first choice is intravenous adenosine (a vagomimetic drug), followed by diltiazem or verapamil or by a short-acting β -blocker such as esmolol. Prevention of recurrences may be more difficult to achieve than termination of the acute episode. Radiofrequency catheter ablation of the slow pathway usually is the initial treatment of choice in symptomatic patients with frequent recurrences because of the high success rate (about 95%), low risk (less than 2%), and effective elimination of future recurrences. AV nodal blocking drugs are most often the initial drugs of choice.

PREEXCITATION SYNDROME

Preexcitation conduction occurs when the atrial impulse activates the whole or some part of the ventricle or when the ventricular impulse activates the whole or some part of the atrium, earlier than would be expected if the impulse traveled through the normal specific conduction system only. In Wolff–Parkinson–White syndrome (preexcitation syndrome), muscular connections composed of working myocardial fibers exist outside the specialized conducting tissue, connecting atrium, and ventricle. They are named *accessory AV pathways* or *connections*, are commonly called *Kent bundles*, and are responsible for the most common variety of preexcitation. When the atrial impulse activates the ventricle over the accessory pathway, three ECG changes result ([Fig. 76.12](#)): (a) the PR interval is less than 120 msec during sinus rhythm; (b) the QRS complex duration exceeds 120 msec with a slurred, slowly rising onset of the QRS in some leads (delta wave) and usually a normal terminal QRS portion; and (c) secondary ST-T wave changes occur with T waves that usually are directed opposite to the major delta wave and QRS vectors. The term Wolff–Parkinson–White or preexcitation syndrome is used when the patient has symptoms due to tachyarrhythmias. The anomalous complexes can mask or mimic other cardiac abnormalities such as MI ([Chapter 73](#)).

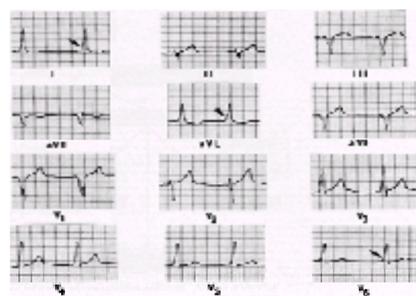

FIGURE 76.12. of a patient with preexcitation and an accessory pathway located in the right posteroseptal region.

During the electrophysiologic study, a variety of pacing techniques are used to localize the position of the accessory pathway and its role in the tachycardia ([Chapter 88](#)). Careful analysis of the ECG can localize the accessory pathway to one of four major sites ([Fig. 76.13](#)).

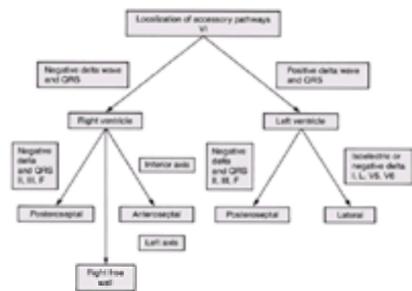

FIGURE 76.13. Electrocardiogram analysis of the sites of accessory pathways in Wolff-Parkinson-White syndrome.

Because the Kent bundle usually has a longer refractory period during longer cycle lengths than does the AV node, despite the fact that it has more rapid conduction, a premature atrial complex can occur sufficiently early to block anterogradely in the accessory pathway and conduct to the ventricle only over the normal AV node–His bundle pathway. The resultant QRS complex is normal and allows the impulse to return to the atrium over the accessory pathway and initiate the most common type of reciprocating tachycardia, called *orthodromic*. Because the atria may be activated eccentrically (i.e., in a manner other than the normal retrograde activation sequence, starting at the low right atrial septum as in AV nodal reentry), the retrograde P wave may have an unusual contour.

Some accessory pathways are capable only of retrograde conduction. The presence of an accessory pathway that conducts only retrogradely is not apparent by analysis of the scalar ECG during sinus rhythm because the ventricle is not preexcited. Therefore, the ECG manifestations of Wolff–Parkinson–White syndrome are absent, and the accessory pathway is said to be concealed. However, the patient still can have orthodromic reciprocating tachycardia that is identical in appearance to the same tachycardia occurring in a patient who has an accessory pathway capable of bidirectional conduction (Fig. 76.14). The presence of concealed accessory pathways is estimated to account for about 30% of patients with a supraventricular tachycardia referred for electrophysiologic evaluation.

FIGURE 76.14. Schematic diagram of tachycardias associated with accessory pathways. **A:** Orthodromic tachycardia with anterograde conduction over the AV node–His bundle route and retrograde conduction over the accessory pathway (left-sided for this example, as depicted by left atrial activation preceding right atrial activation). **B:** Orthodromic tachycardia and ipsilateral functional bundle-branch block. The impulse must activate the contralateral ventricle, cross the septum, and enter the accessory pathway, making the ventriculoatrial conduction time longer. **C:** Antidromic tachycardia with anterograde conduction over the accessory pathway and retrograde conduction over the AV node–His bundle. **D:** Orthodromic tachycardia with a slowly conducting accessory pathway. **E:** Atrial fibrillation with the accessory pathway as a bystander. **F:** Anterograde conduction over a portion of the AV node and a nodoventricular pathway and retrograde conduction over the AV node. AVN, atrioventricular node; LA, left atrium; RA, right atrium. (From Zipes DP. Specific arrhythmias: diagnosis and treatment. In: Braunwald E, ed. *Heart disease: text book of cardiovascular medicine*, third ed. Philadelphia: WB Saunders, 1988, with permission.)

Less commonly, the tachycardia can be antidromic, during which anterograde conduction occurs over the accessory pathway and retrograde conduction occurs over the AV node. The resultant QRS complex is abnormal, owing to total ventricular activation over the accessory pathway (Fig. 76.14). In all patients who have reciprocating tachycardias in which one of the limbs of the tachycardia involves the AV node, vagal maneuvers produce a response similar to that in AV nodal reentry.

About 5% of patients have multiple accessory pathways, and, on occasion, tachycardia can result from anterograde conduction over one accessory pathway and retrograde conduction over the other. An incessant form of orthodromic tachycardia occurs with a long ventriculoatrial interval because of a posteroseptal accessory pathway that conducts very slowly, possibly because it has a long, tortuous route. It is called the *permanent form of junctional tachycardia*. An accessory pathway may also be a “bystander” uninvolved in the mechanism responsible for the tachycardia. SA nodal reentry, AV nodal reentry, atrial tachycardia, atrial flutter or atrial fibrillation that conducts to the ventricle over the accessory pathway does not require the accessory pathway for maintenance of the tachycardia (Fig. 76.14). About 15% to 30% of patients have atrial fibrillation, and 5% have atrial flutter.

The reported prevalence of preexcitation syndrome averages about 1.5 per 1,000 (0.15%), but it is higher in relatives of patients who have Wolff–Parkinson–White syndrome. The acquisition of an accessory pathway is probably congenital. Left-sided pathways are more common than right-sided pathways. Wolff–Parkinson–White syndrome is found in all age groups, with a higher prevalence in men and a decrease in prevalence with age, possibly because of loss of preexcitation. Most adults with preexcitation syndrome have normal hearts, although a variety of acquired and congenital cardiac defects have been reported to be associated with Wolff–Parkinson–White syndrome, most commonly Ebstein’s anomaly.

The prognosis for patients with preexcitation syndrome is excellent for those without tachycardia or an associated cardiac abnormality. In most patients with tachycardia, the prognosis is good, but sudden death does occur rarely. Intermittent preexcitation during sinus rhythm or loss of preexcitation after intravenous administration of a class 1 antiarrhythmic agent or with exercise suggests that the refractory period of the accessory pathway is long and the patient is not at risk for the development of a rapid ventricular rate if atrial flutter or fibrillation occurs. Exceptions to these safeguards can be present, however. In the patient without tachycardia, no therapy is indicated. For the patient with recurrent episodes of tachycardia, pharmacologic, electrical, or surgical therapy can be considered. Termination of the acute episode of orthodromic reciprocating tachycardia characterized by a normal QRS complex should be approached as for AV nodal reentry.

For atrial flutter or atrial fibrillation, drugs that prolong refractoriness in the accessory pathway, often coupled with drugs that prolong AV nodal refractoriness, must be used. In some patients with very rapid ventricular rates, electrical cardioversion should be the initial treatment of choice. Verapamil and lidocaine may increase the ventricular rate during atrial fibrillation in a patient with Wolff–Parkinson–White syndrome, and intravenous verapamil can precipitate ventricular fibrillation. Because verapamil usually is not effective in patients with ventricular tachycardia, a reasonable rule is that intravenous administration of verapamil is contraindicated in any patient with a wide QRS tachycardia. The presence of atrial fibrillation in patients with a concealed accessory pathway should not present a greater therapeutic challenge than it does in patients who do not have an accessory pathway, because anterograde AV conduction occurs only over the AV node.

As in AV nodal reentry, radiofrequency catheter ablation usually is the initial treatment of choice for the symptomatic patient because it eliminates conduction over the accessory pathway (success rate 95%) with minimal complications (less than 2%) and provides a cure of the tachycardia. Surgery rarely is done any longer. Drugs to prevent recurrences are chosen to prolong conduction time or refractoriness in the AV node, the accessory pathway, or both. Digitalis actually can shorten refractoriness in the accessory pathway in some patients and speed the ventricular response during atrial fibrillation.

VENTRICULAR ARRHYTHMIAS

PREMATURE VENTRICULAR COMPLEXES

Premature occurrence of a QRS complex that is bizarre in shape and has a duration usually exceeding the dominant QRS complex (typically greater than 120 msec) characterizes a premature ventricular complex (Fig. 76.15). A large T wave opposite in direction to the major deflection of the QRS complex also is present. A premature P wave does not precede the QRS complex, but a sinus P wave that occurs at its expected time can be present. Because an aberrantly conducted supraventricular complex can mimic the manifestations of a premature ventricular complex, diagnosis of the latter cannot be made unequivocally from the scalar ECG. Most commonly, the premature ventricular complex does not discharge the atria and sinus node because the wave fronts from the anterograde impulse conducted from the sinus node and the retrograde impulse conducted from the premature ventricular complex collide at the AV junction. Therefore, a fully compensatory pause usually follows a premature ventricular complex. That is, the RR interval produced by two sinus-initiated QRS complexes flanking the premature ventricular complex equals twice the normally conducted RR interval. If the premature ventricular complex conducts retrogradely to the atrium and resets the sinus node, a noncompensatory pause occurs. If the sinus impulse is able to conduct to the ventricle despite the premature ventricular complex, the latter is called *interpolated*.

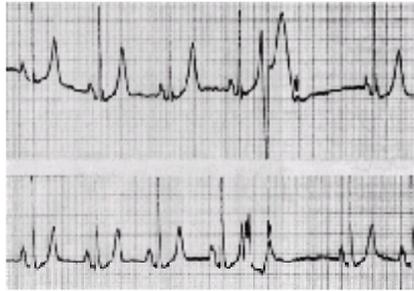

FIGURE 76.15. Multiform premature ventricular complexes. Premature ventricular complexes with different contours occur at a very short coupling interval. The sinus P wave (arrow) occurs on time and is blocked because of a refractory AV junction from the premature ventricular complex. A compensatory pause is present.

The term *bigeminy* refers to pairs of complexes and indicates a normal and a premature complex; *trigeminy* indicates a premature complex following two normal beats; *quadrigeminy* is a premature complex following three normal beats. A *pair* or a *couplet* refers to two successive premature ventricular complexes, whereas three successive premature ventricular complexes are called a *triple*. Arbitrarily, three or more successive premature ventricular complexes are termed *ventricular tachycardia*. Premature ventricular complexes can have different contours and often are called *multifocal*. More properly, they should be called *multiform*, *polymorphic*, or *pleomorphic*, because it is not known whether multiple foci are discharging or whether conduction of the impulse originating from one site is merely changing.

The prevalence of premature ventricular complexes increases with age. Symptoms may be those of palpitations or discomfort in the neck or chest because of the greater than normal contractile force of the postextrasystolic beat or the feeling that the heart has stopped during the long pause after the premature ventricular complex. Exercise, sleep, or other activities can increase or decrease the number of premature ventricular complexes. Premature ventricular complexes occur in association with a variety of stimuli and can be produced by direct mechanical, electrical, and chemical stimulation of the myocardium. Coronary disease, myocarditis, a variety of medications, electrolyte imbalance, tension states, caffeine, tobacco, alcohol, and autonomic stimulation all can provoke premature ventricular complexes.

The importance of premature ventricular complexes varies, depending on the clinical setting. In the absence of underlying heart disease, premature ventricular complexes have little significance and treatment is not indicated. The presence of premature ventricular complexes and complex ventricular arrhythmias in apparently healthy middle-aged men is associated with an increased incidence of coronary heart disease and a greater risk of subsequent death. It has not been demonstrated that these arrhythmias actually precipitate sudden death in these patients, and they may be simply a marker of heart disease. In a study of patients with asymptomatic ventricular arrhythmias after MI, treatment with flecainide and encainide *increased* mortality 2.5 times compared with the placebo group (Cardiac Arrhythmias Suppression Trial). If ventricular arrhythmias are not associated with structural heart disease, these patients do not have an increased incidence of sudden cardiac death.

Treatment of patients with premature ventricular complexes most often is not indicated, except for the uncommon patient in whom those premature ventricular complexes produce intolerable palpitations. Treatment in general is as for ventricular tachycardia. Premature ventricular complexes in patients with structurally normal hearts often arise from the right ventricular outflow tract and can be treated with radiofrequency ablation.

VENTRICULAR PARASYSTOLE

Parasystole refers to a cardiac arrhythmia characterized electrocardiographically by four basic features: a varying coupling interval between the ectopic or parasystolic complex and the dominant complex, which usually is sinus initiated; a common minimal time interval between manifest interectopic parasystolic intervals, with the longer interectopic intervals being a multiple of this minimal interval; fusion complexes because of the variable intervals between the parasystolic and dominant rhythms; and the presence of the parasystolic impulse whenever the cardiac chamber is excitable (Fig. 76.16). The analogy commonly invoked to represent parasystole is the behavior of a fixed-rate pacemaker. Parasystole can occur in the sinus and AV nodes, atrium and ventricle, and AV junction. Its mechanism presumably is attributable to the regular discharge from an automatic focus that is independent of, and protected from, discharge by the dominant cardiac rhythm.

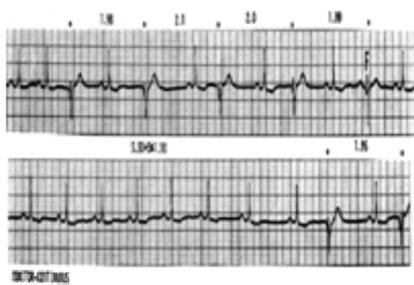

FIGURE 76.16. Ventricular parasystole. Premature ventricular complexes (dots above tracing) occur at regular intervals of about 1.98 seconds. The long pause without a premature ventricular complex is 9.9 seconds long, which equals five parasystolic intervals. Note varying intervals and a fusion complex (F).

VENTRICULAR TACHYCARDIA

Ventricular tachycardia arises distal to the bifurcation of the His bundle in the specialized conduction system, the ventricular muscle, or combinations of both tissues. Ventricular tachycardia is diagnosed when three or more premature ventricular complexes occur in a row. Ventricular tachycardia can be sustained, defined arbitrarily in electrophysiologic studies as lasting longer than 30 seconds or requiring termination because of hemodynamic collapse, or nonsustained, in which case it stops spontaneously in less than 30 seconds. AV dissociation may be present, during which atrial activity is independent of the ventricular tachycardia, or the atria may be captured retrogradely by the ventricles, in which case AV dissociation is not present (Fig. 76.17). QRS complexes may exhibit a uniform or monomorphic contour (Fig. 76.18), or they may vary (multiform, polymorphic, pleomorphic; Fig. 76.19).

FIGURE 76.17. Ventricular tachycardia with retrograde atrial capture. A late premature ventricular complex (*upright arrow*) initiates a short episode of ventricular tachycardia with retrograde atrial capture (*inverted arrow*).

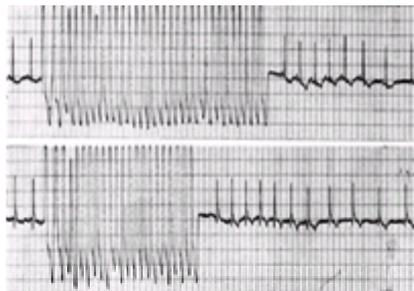

FIGURE 76.18. Monomorphic ventricular tachycardia. A relatively late premature ventricular complex initiates two short episodes of monomorphic ventricular tachycardia. After cessation of the ventricular tachycardia, the atrial rate increases for a short time, probably because of sympathetic discharge provoked by the hypotension resulting from the rapid ventricular tachycardia.

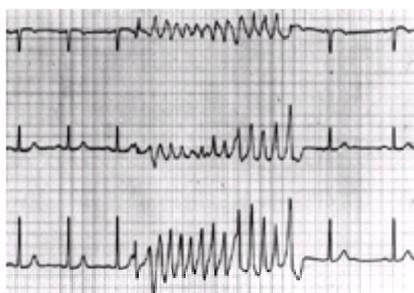

FIGURE 76.19. Polymorphic ventricular tachycardia. A premature ventricular complex occurring in the T wave provokes a short episode of polymorphic ventricular tachycardia. Leads from top to bottom recorded simultaneously are V₁, II, and V₅.

Ventricular complexes with bizarre configuration or prolonged duration indicate only that conduction through the ventricle is abnormal, and such complexes can occur during supraventricular rhythms as a result of preexisting bundle-branch block, aberrant conduction during incomplete recovery of repolarization (functional; see [Fig. 76.5](#)), conduction over accessory pathways ([Fig. 76.12](#)), and several other conditions. These complexes do not necessarily indicate the origin of impulse formation or the reason for the abnormal conduction; therefore, the ECG distinction between supraventricular tachycardia with aberration and ventricular tachycardia may be difficult ([Table 76.2](#)).

Supports Supraventricular
Slowing or termination by increased vagal tone
Onset with premature P wave
RP interval = 100 msec
P and QRS rate and rhythm linked to suggest ventricular activation depends on atrial discharge (eg, 2:1 AV block)
Long—short cycle sequence
QRS identical to known supraventricular conduction (eg, preexisting bundle-branch block)
Supports Ventricular
Fusion beats
Capture beats
AV dissociation
P and QRS rate and rhythm linked to suggest atrial activation depends on ventricular discharge (eg, 2:1 VA block)
Compensatory pause
Left axis deviation
QRS duration > 140 msec
Specific QRS contours
<small>AV, atrioventricular; VA, ventriculoatrial.</small>

TABLE 76.2. DIFFERENTIAL DIAGNOSIS OF WIDE QRS TACHYCARDIAS

The presence of fusion beats and capture beats provides maximum support for the diagnosis of ventricular tachycardia ([Fig. 76.20](#)). Fusion beats indicate activation of the ventricle from two different foci, implying that one of the foci has a ventricular origin. Discharge of the ventricle by the supraventricular rhythm, with a normal configuration of the captured QRS complex at an interval shorter than the wide QRS tachycardia, indicates that the captured beat has a supraventricular origin and suggests that the wide QRS complex tachycardia is of ventricular origin.

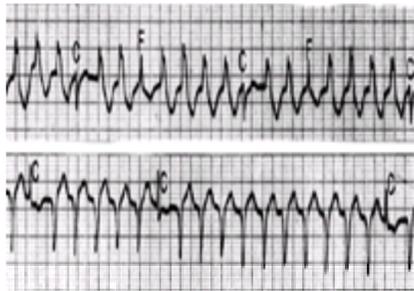

FIGURE 76.20. Ventricular tachycardia with fusion beats (F) and capture beats (C). Atrial activity is not clearly seen, but atrioventricular dissociation is likely. Note normalization of capture beats and blend of normal beats and ventricular tachycardia to create fusion beats. **Top**, lead V₁; **bottom**, lead II.

Analysis of specific QRS contours can be helpful in the diagnosis of ventricular tachycardia ([Table 76.2](#)). During ventricular tachycardia with a right bundle-branch-block appearance, (a) the QRS complex is monophasic or biphasic in V₁, with an initial deflection different from the sinus-initiated QRS complex; (b) the amplitude of the R wave in V₁ exceeds the R'; (c) a small R wave and large S wave or a QS pattern may be present in V₆; and (d) the QRS duration exceeds 140 msec. With a ventricular tachycardia that has a left bundle-branch-block contour, the axis may be rightward, with negative deflections deeper in V₁ than in V₆; a broad, prolonged (greater than 40 msec) R wave may be present in V₁ and V₃; and a small qR or QS pattern may be observed in V₆. A QRS complex that is similar in V₁ through V₆, either all negative or all positive, favors a ventricular origin. An upright QRS complex in V₁ through V₆ may occur, however, because of conduction over a left-sided accessory pathway.

ABERRANCY VERSUS VENTRICULAR TACHYCARDIA

Electrocardiographic features characterizing supraventricular arrhythmia with aberrancy include consistent onset of the tachycardia with a premature P wave; a very short (less than 100 msec) RP interval; a QRS configuration that is the same as that which occurs from known supraventricular conduction at similar rates; linkage of P and QRS rates and rhythms, suggesting that ventricular activation depends on atrial discharge; and slowing or termination of the tachycardia by vagal maneuvers. Uncommonly, vagal maneuvers may terminate a ventricular tachycardia.

Supraventricular beats with aberrancy often have a triphasic pattern in V₁, an initial vector of the abnormal complex similar to that of the normally conducted beats, and a wide QRS complex that terminates a short cycle that follows a long cycle (long-short cycle sequence; [Fig. 76.5](#)). During atrial fibrillation, fixed coupling, short coupling intervals, a long pause after the abnormal beat, and runs of bigeminy rather than a consecutive series of abnormal complexes all favor a ventricular origin of the premature complex rather than a supraventricular origin with aberrancy. In the presence of preexisting bundle-branch block, a wide QRS tachycardia with a contour different from that which occurs during sinus rhythm probably is a ventricular tachycardia. A grossly irregular wide QRS tachycardia with ventricular rates faster than 200 beats per minute should raise the possibility of atrial fibrillation with conduction over an accessory pathway ([Fig. 76.6](#)). At times, a supraventricular tachycardia can induce a ventricular tachycardia.

When an accurate differential diagnosis between supraventricular tachycardia with aberrancy and ventricular tachycardia cannot be made, one must rely on sound clinical judgment, use of the ECG as only one of several helpful ancillary tests. For example, a wide QRS tachycardia occurring for the first time in a middle-aged man with a history of a previous MI has a greater than 90% chance of being a ventricular tachycardia rather than a supraventricular tachycardia with aberrancy. Rarely, a ventricular tachycardia produces a QRS complex with duration of less than 120 msec, probably when it arises close to the His bundle in the fascicles.

The rate of the ventricular tachycardia, its duration, and the presence of associated heart disease or peripheral vascular disease all help determine the symptoms occurring from the ventricular tachycardia. In addition, the location of impulse formation and, therefore, the way in which the depolarization waves spread across the myocardium may be important. Physical findings vary ([Table 76.1](#)).

Ischemic heart disease is the most common cause of ventricular tachycardia, the next being cardiomyopathy, followed by a variety of other causes. Ventricular tachycardia and ventricular fibrillation are responsible for most sudden cardiac deaths. When ventricular tachycardia is recorded in ambulatory patients, it most often starts with a late premature ventricular complex. Short runs of ventricular tachycardia consisting of three or four complexes after MI indicate an increased risk of mortality. Left ventricular dysfunction and ventricular arrhythmias are independently related to mortality risk in the 2 years after MI. Studies are ongoing to identify high-risk patients who might benefit from implantation of a prophylactic cardiac defibrillator.

Termination of the acute episode of ventricular tachycardia depends on the clinical circumstances. Ventricular tachycardia that does not cause hemodynamic decompensation can be treated medically with intravenous lidocaine. Intravenous procainamide or bretylium can be administered next. Intravenous procainamide usually is more effective than intravenous lidocaine. Amiodarone is effective when given intravenously and has recently been approved for this route of administration. Contributing factors such as hypokalemia, ischemia, hypomagnesemia, and extreme bradycardia should be considered and corrected, if present.

If pharmacologic therapy is unsuccessful or if the patient has hemodynamic decompensation with hypotension, shock, angina, congestive heart failure, or symptoms of cerebral hypoperfusion, prompt direct-current electrical cardioversion is indicated. A synchronized shock of 10 to 50 J often is successful. Digitalis-induced ventricular tachycardia is best treated pharmacologically. Striking the patient's chest, sometimes called *thump version*, may terminate ventricular tachycardia by mechanically inducing a premature ventricular complex that presumably interrupts the reentrant pathway. Competitive pacing similarly can terminate ventricular tachycardia. However, these procedures incur the risk of accelerating the tachycardia to ventricular flutter or ventricular fibrillation.

Recurrent episodes usually are treated with class I drugs, sotalol, or amiodarone. Propranolol may be useful when fast sinus rates or ischemia contribute to the induction of ventricular tachycardia. Combinations of drugs with different mechanisms of action can be successful when single drugs fail and allow the use of low doses of both agents rather than higher, toxic doses of one drug. Implantable defibrillators have been shown to be more effective in improving survival compared with antiarrhythmic drugs in patients who have experienced a cardiac arrest or sustained ventricular tachycardia. For selected patients, surgery or radiofrequency catheter ablation may be indicated.

Management of ventricular tachycardia with a polymorphic pattern is influenced by whether the QT interval is prolonged. If it is, the ventricular tachycardia may be torsades de pointes, which is treated effectively by accelerating the ventricular rate, usually with pacing. In addition, intravenous magnesium or isoproterenol (used cautiously to increase the rate) successfully has suppressed acquired torsades de pointes. Class IA and possibly classes IC and III antiarrhythmic agents may increase the abnormally prolonged QT interval and worsen the arrhythmia. Class IB drugs may be tried cautiously if the QT interval already is prolonged. When the QT interval is normal, polymorphic ventricular tachycardia is treated as ordinary ventricular tachycardia. For patients with the idiopathic long QT syndrome, β -adrenoreceptor blockade is suggested. For patients who continue to have syncope, left-sided cervicothoracic sympathetic ganglionectomy that interrupts the stellate ganglia and the first three or four thoracic ganglia may be helpful. Implantation of an automatic implantable cardioverter-defibrillator may be advised.

SPECIFIC TYPES OF VENTRICULAR TACHYCARDIA

Fairly specific types of ventricular tachycardia can be identified on the basis of a constellation of distinctive ECG and electrophysiologic features or from a specific set of clinical events.

ACCELERATED IDIOVENTRICULAR RHYTHM

During accelerated idioventricular rhythm, the ventricular rate usually is fairly similar to the sinus rate and ranges between 60 and 110 beats per minute ([Fig. 76.21](#)). Fusion beats and capture beats are common as control of the cardiac rhythm passes between the sinus rhythm and the accelerated idioventricular rhythm. The rhythm terminates as the dominant sinus rhythm accelerates or the ectopic ventricular rhythm slows. The ventricular rhythm can be regular or irregular and

occasionally shows sudden doubling, suggesting the presence of exit block. Enhanced automaticity is a probable mechanism.

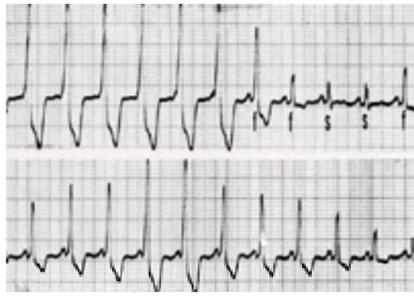

FIGURE 76.21. Accelerated idioventricular rhythm. Gradual speeding of the sinus rate results in fusion beats (i) and finally complete sinus capture (s), as the idioventricular rhythm focus and sinus node vie for control of the cardiac rhythm.

Accelerated idioventricular rhythm primarily occurs in patients with structural heart disease (e.g., acute MI) or digitalis toxicity. Its presence has been used to indicate that coronary reperfusion has been accomplished. Usually, no therapy is required.

TORSADES DE POINTES

The term torsades de pointes refers to a ventricular tachycardia characterized by QRS complexes of changing amplitude that appear to twist about the isoelectric line and occur at rates of 200 to 250 beats per minute (Fig. 76.22). The term connotes a syndrome, not simply an ECG description of the QRS complex, with prolonged QT intervals usually exceeding 500 msec. During the ventricular tachycardia, the peaks of the QRS complexes appear successively on one side and then the other of the isoelectric baseline, giving the typical twisting appearance with continuous and progressive changes in QRS contour and amplitude. Long-short QRS cycle sequences commonly precede the onset of torsades de pointes, which often stops spontaneously with a progressive prolongation of cycle lengths and larger and more distinctly formed QRS complexes, but can degenerate into ventricular fibrillation.

FIGURE 76.22. Long QTU syndrome with torsades de pointes. After two sinus-initiated complexes with obvious QTU prolongation caused by amiodarone, a polymorphic ventricular tachycardia ensues that exhibits the typical contour (not shown) of torsades de pointes.

Ventricular tachycardias that are similar morphologically to torsades de pointes but occur in patients without QT interval prolongation should be classified as polymorphic ventricular tachycardias rather than torsades de pointes. The distinction has important therapeutic implications. The most common predisposing factors to the development of torsades de pointes include severe bradycardia, potassium depletion, and class IA and IC antiarrhythmic drugs. Therapy is as described earlier.

LONG QT SYNDROME

The long QT syndrome is characterized by the presence of a prolonged QT interval (usually the corrected QT interval is greater than 500 msec) and often an abnormal U wave (Fig. 76.22). Afterdepolarizations may be important and related to the prolonged, notched, bifid, and sinusoidal T waves that occur. Ventricular tachycardia, commonly of the torsades de pointes variety, occurs.

The syndrome can be divided into a primary or idiopathic group caused by a congenital, often familial, disorder that occasionally is associated with deafness, and an acquired group caused by various drugs (e.g., class IA, IC, and III antiarrhythmic agents, phenothiazines, tricyclic antidepressants, non-sedating antihistamines), metabolic abnormalities (e.g., hypokalemia), the liquid protein diet and starvation, central nervous system lesions, autonomic nervous system dysfunction, coronary artery disease with MI, and other disturbances.

Patients with congenital long QT syndrome who are at increased risk for sudden cardiac death include those who have family members who died suddenly at an early age and those who have experienced syncope. ECGs should be obtained for all family members when the proband has symptoms. Genetic abnormalities have been established for this syndrome.

BIDIRECTIONAL VENTRICULAR TACHYCARDIA

Bidirectional ventricular tachycardia is an uncommon ventricular tachycardia characterized by QRS complexes with a right bundle-branch-block pattern, alternating polarity in the frontal plane from -60 degrees to -90 degrees and +120 degrees to +130 degrees, and a regular rhythm. The ventricular rate is between 140 and 200 beats per minute. It occurs commonly, but not exclusively, as a manifestation of digitalis excess, typically in older patients and in patients with severe myocardial disease.

IDIOPATHIC VENTRICULAR TACHYARRHYTHMIAS

Idiopathic ventricular fibrillation may occur in about 1% of all cases of out-of-hospital ventricular fibrillation, affecting mostly men and those in middle age. The cardiovascular evaluation is normal except for the arrhythmia. The natural history is incompletely known, but recurrences are common. Antiarrhythmic drugs and implantable defibrillators are useful therapeutic choices. Some patients have right bundle-branch block and ST-segment elevation. The arrhythmia at times is an early manifestation of a developing cardiomyopathy or arrhythmogenic right ventricular dysplasia, at least in some patients.

Idiopathic ventricular tachycardias with monomorphic contours can be divided into at least three types. Two types, paroxysmal ventricular tachycardia and repetitive monomorphic ventricular tachycardia (Fig. 76.23), appear to originate from the region of the right ventricular outflow tract. Right ventricular outflow tract ventricular tachycardias have a characteristic ECG appearance of left bundle-branch-block contour in V_1 and an inferior axis in the frontal plane. A third type is left septal ventricular tachycardia that arises in the left posterior septum and sometimes is called a *fascicular tachycardia*. The prognosis for most patients is good. Radiofrequency catheter ablation effectively eliminates these focal tachycardias in symptomatic patients. In others, antiarrhythmic drugs are effective.

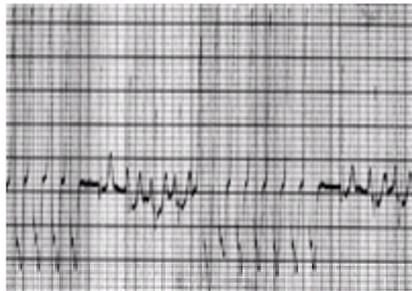

FIGURE 76.23. Repetitive monomorphic ventricular tachycardia. Short bursts of ventricular tachycardia are interrupted by sinus impulses.

BUNDLE-BRANCH REENTRANT VENTRICULAR TACHYCARDIA

Reentry over the bundle branches appears to be responsible for yet another type of ventricular tachycardia. Retrograde conduction over the left bundle-branch system and anterograde conduction over the right bundle branch create a QRS complex with a left bundle-branch-block contour, a frontal plane axis of about +30 degrees, and an HV interval that equals or exceeds that of the normally conducted QRS complex. It is more prevalent in patients with dilated cardiomyopathy. Therapy is as indicated for ventricular tachycardia. Creation of bundle-branch block by catheter ablation can eliminate the tachycardia.

VENTRICULAR FLUTTER AND VENTRICULAR FIBRILLATION

Ventricular flutter and ventricular fibrillation represent severe derangements of the heartbeat that usually lead to death within 3 to 5 minutes unless they are terminated. Ventricular flutter presents as a sine wave in appearance with regular, large oscillations occurring at a rate of 150 to 300 beats per minute (usually around 200 beats per minute; [Fig. 76.24](#)). The distinction between rapid ventricular tachycardia and ventricular flutter may be difficult and usually is of academic interest only. Ventricular fibrillation is recognized by the presence of irregular undulations of varying contour and amplitude without distinct QRS complexes, ST segments, or T waves ([Fig. 76.24](#)). On occasion, the fibrillatory waves are so small as to simulate asystole.

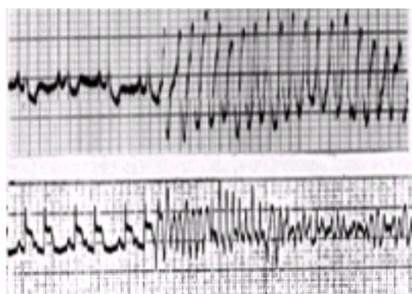

FIGURE 76.24. Ventricular flutter and ventricular fibrillation. In the top electrocardiographic recording, ventricular flutter begins and progresses to ventricular fibrillation (not shown) in this monitor lead. In the bottom recording (lead II), ST-segment elevation indicates the presence of acute inferior myocardial infarction. A 3:2 Wenckebach atrioventricular block is present. A premature ventricular complex initiates ventricular fibrillation.

Ventricular flutter or ventricular fibrillation promptly results in faintness followed by loss of consciousness, seizures, apnea, and death. Ventricular fibrillation most commonly occurs in association with coronary artery disease and as a terminal event. It may occur during antiarrhythmic drug administration, hypoxia, ischemia, atrial fibrillation, and rapid ventricular rates in Wolff–Parkinson–White syndrome, after electric shock is administered during cardioversion, or accidentally by improperly grounded equipment.

Ventricular fibrillation probably is responsible for more than 75% of sudden cardiac deaths, with bradycardia and asystole accounting for the remainder. Slow heart rates as a cause of cardiac arrest are associated with a worse prognosis than is ventricular fibrillation. Only 20% to 30% of patients resuscitated from cardiac arrest have acute transmural MIs. Those in whom transmural MIs develop have a recurrence rate of ventricular fibrillation of only 2% at 1 year. Those patients in whom MIs do not evolve have a much higher recurrence rate of ventricular fibrillation. Predictors of death for resuscitated patients include reduced ejection fraction, abnormal wall motion, history of congestive heart failure, history of MI but no acute event, and presence of ventricular arrhythmias.

Immediate nonsynchronized DC electrical shock with 200 to 360 J is mandatory treatment. Cardiopulmonary resuscitation is used only until defibrillator equipment can be applied. *Time should not be wasted with cardiopulmonary resuscitation maneuvers if electrical defibrillation can be done promptly.* After reversion of the arrhythmia to normal sinus rhythm, it is essential to monitor the rhythm continuously and to institute measures to prevent a recurrence. If artificial ventilation is necessary, it is accomplished adequately with a tightly fitting mask and an Ambu bag. Too often, precious time is lost in attempts at intubation by unskilled personnel. A search for conditions contributing to the initiation of the arrhythmia should be made and treated if possible.

HEART BLOCK

Heart block is a disturbance of impulse conduction that can occur at any site, but is recognized commonly between the sinus node and atrium (SA block), between the atrium and ventricle (AV block), or within the ventricles (intraventricular or bundle-branch block). During AV block, the block can occur in the AV node (between the atrial and His deflections), within the His bundle (producing an H and H'), or distal to the His bundle (between the His bundle and ventricular deflections). Heart block must be distinguished from interference, which is a normal phenomenon characterized by block of an impulse as a result of physiologic refractoriness from a preceding impulse.

FIRST-DEGREE ATRIOVENTRICULAR BLOCK

During first-degree AV block, the PR interval exceeds 200 msec in the adult, but all P waves conduct to the ventricles. The prolonged PR interval can result from conduction delay in the AV node (AH interval), in the His–Purkinje system (HV interval), or at both sites. Occasionally, intra-atrial or intrahisian conduction delay results in PR prolongation. If the QRS complex is normal, the AV delay almost always resides in the AV node, rarely within the His bundle itself. If the QRS complex exhibits a bundle-branch-block pattern, conduction delay can be within the AV node or the His–Purkinje system.

SECOND-DEGREE ATRIOVENTRICULAR BLOCK

Second-degree AV block is divided into type I and type II, as described earlier. In both instances, the AV block is intermittent and usually repetitive. During type I AV block with a regular PP interval, progressive PR interval prolongation precedes the nonconducted P wave ([Fig. 76.25](#)). The increment in PR interval conduction delay decreases after the first cycle, resulting in a PR interval that increases but at a decreasing rate, and an RR interval that progressively decreases ([Fig. 76.26](#)). This classic AV Wenckebach structure occurs in less than 50% of the spontaneous clinical examples of type I Wenckebach AV nodal block. During type II AV block, the PR interval remains constant before the nonconducted P wave ([Fig. 76.27](#)).

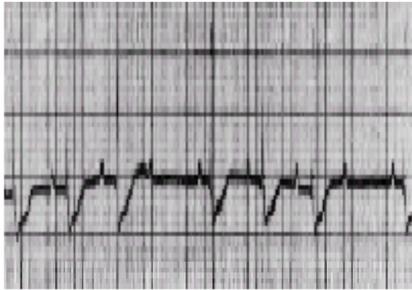

FIGURE 76.25. Type I (Wenckebach) second-degree atrioventricular block. A regular 4:3 conduction ratio is present.

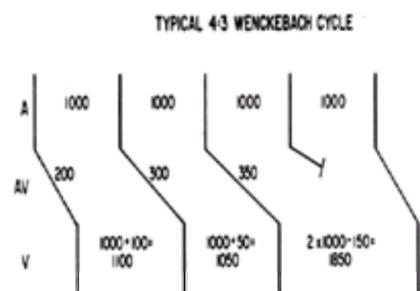

FIGURE 76.26. Diagrammatic representation of a 4:3 Wenckebach cycle. The sinus cycle length is constant (1,000 msec). The increment in atrioventricular nodal conduction time decreases from 100 to 50 msec, resulting in a shortening of the RR intervals from 1,100 to 1,050 msec. The duration of the RR cycles encompassing the blocked P wave is twice the PP interval minus the increments in the PR intervals.

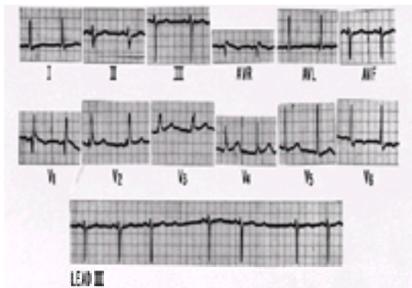

FIGURE 76.27. Type II second-degree atrioventricular (AV) block. Left-axis deviation and right bundle-branch block are present in this patient. Lead II illustrates sudden failure of AV conduction without antecedent PR prolongation.

If the QRS complex is normal, the block is more likely to be type I located in the AV node, whereas if a bundle-branch block is present, the block may be located in the AV node or the His–Purkinje system. Almost always, type II AV block occurs in the setting of a bundle-branch block.

As a rule, type I AV block is a more benign conduction disturbance, often not producing symptoms or requiring pacemaker therapy. It almost always occurs in the AV node, but it can occur at other sites. First-degree and type I second-degree AV block can occur in normal healthy persons, such as in well-trained athletes, and during sleep because of the increased vagal tone that occurs during rest ([Fig. 76.28](#)). Type II AV block usually is located in the His–Purkinje system and is associated more often with syncope, requiring pacemaker therapy. Type I AV block occurs more commonly during inferior MI, whereas type II AV block occurs more commonly during anterior MI, requiring temporary or permanent pacing, and is associated with a high rate of mortality, usually resulting from pump failure. Type I AV block during inferior MI is transient and does not require temporary pacing.

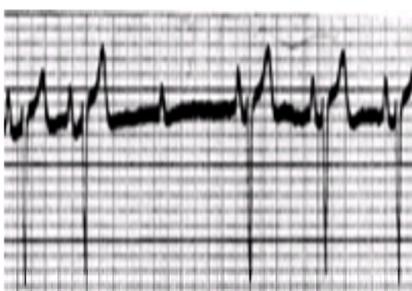

FIGURE 76.28. Vagal-induced type I second-degree atrioventricular block. The rhythm was recorded from a healthy 18-year-old woman during sleep. The PP interval lengthens, and a single P wave is blocked. This is consistent with an increase in vagal tone during sleep and would not be considered abnormal.

Two-to-one AV block ([Fig. 76.29](#)) and *high-grade AV block* (consecutive block of more than one P wave) can result from type I or type II AV block.

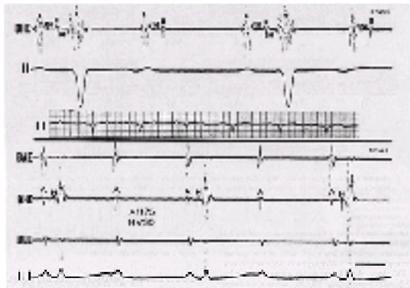

FIGURE 76.29. (Top) The electrocardiographic strip illustrates 2:1 atrioventricular block. From the His bundle recording, it is obvious that the block occurs distal to the His bundle recording site. The bundle of His-ventricular interval is prolonged (80 msec). (**Bottom**) The 2:1 atrioventricular block evident in lead III is proximal to the His bundle recording site. All intervals are normal. Time line, bottom right, 200 msec. *BAE*, bipolar right atrial electrogram; *BEE*, bipolar esophageal electrogram; *BHE*, bipolar His electrogram. (From Zipes DP. Second degree atrioventricular block. *Circulation* 1979;60:465, with permission of the American Heart Association.).

COMPLETE ATRIOVENTRICULAR BLOCK

Complete AV block occurs when no atrial activity conducts to the ventricles, and therefore independent pacemakers control the atria and ventricles. Complete AV block is one type of complete AV dissociation. The ventricular focus usually is located just below the region of block. When complete AV block results from block at the level of the AV node (usually congenital), the QRS complex is normal and the ventricular rate usually is 40 to 60 beats per minute. Atropine and exercise increase the ventricular rate. Acquired complete AV block occurs most commonly distal to the bundle of His because of trifascicular conduction disturbance. The QRS complexes are abnormal, and the ventricular rate usually is less than 40 beats per minute, with no change after atropine or exercise ([Fig. 76.30](#)).

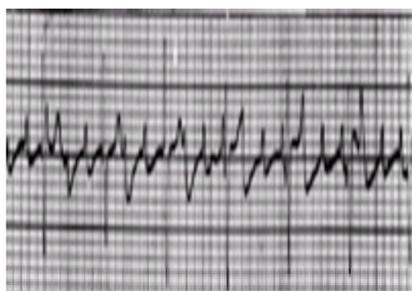

FIGURE 76.30. Acquired complete atrioventricular (AV) block. Tracing recorded in an elderly man with syncope illustrates complete AV block and a ventricular escape rate at about 38 beats per minute. No significant increase in the ventricular escape rate occurred with activity. The patient was treated with permanent pacemaker implantation.

A lengthy list of diverse causes can produce AV block, including surgery, electrolyte disturbances, endocarditis, tumors, rheumatoid nodules, calcific aortic stenosis, infiltrative processes, drug toxicity, coronary artery disease, and degenerative processes. In children, the most common cause is congenital, with block occurring at the AV node. Anti-Ro-negative antibodies in the maternal sera of patients with congenital complete AV block raise the possibility that placentally transmitted antibodies play a role. Children most often have no symptoms, but those in whom symptoms develop may require pacemaker implantation. For short-term therapy, vagolytic agents such as atropine or sympathomimetic agents such as isoproterenol may be used. Patients with acquired His-Purkinje block usually are symptomatic from Adams-Stokes syncope and require pacemaker implantation.

AORTIC STENOSIS

DEFINITION

Aortic stenosis implies obstruction to left ventricular outflow due to a fixed anatomical abnormality of the aortic valve. Valvular aortic stenosis should be distinguished from nonvalvular forms of left ventricular outflow obstruction, including congenital supra- and subvalvular stenosis, and dynamic subvalvular left ventricular outflow obstruction in hypertrophic obstructive cardiomyopathy.

The normal aortic valve area is 3.0 to 4.0 cm². Aortic stenosis is not usually of hemodynamic significance until the valve area is reduced to 25% of normal. It is clinically useful to categorize aortic stenosis as mild, moderate, or severe based on transvalvular gradients and valve area. In general, aortic stenosis is mild when valve area is more than 1.5 to 3.0 cm², moderate when valve area is more than 1.0 to 1.5 cm², and severe when ≤ 1.0 cm². With normal cardiac output, severe aortic stenosis is usually associated with a mean transvalvular pressure gradient ≥ 50 mm Hg. However, there are limitations in the ability to categorize the severity of aortic stenosis based on gradients and estimated valve area. Transvalvular gradients are affected by flow, so patients may have low gradients despite severe aortic stenosis if there is left ventricular systolic dysfunction. Although valve area is independent of flow, there is considerable overlap based on body size; a valve area of 1.0 cm² may be adequate in a smaller patient but representative of significant stenosis in a larger patient. Because therapeutic decisions typically are based on the presence of symptoms in the setting of significant aortic stenosis, categorization of disease as mild, moderate, or severe is of lesser clinical importance.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

In adults, aortic stenosis may be congenital, rheumatic, or senile degenerative (calcific) in origin. Congenital aortic stenosis is much more common in men than women. Although usually associated with a bicuspid aortic valve, other abnormalities such as unicuspid and quadricuspid valves are less commonly present. Bicuspid valves may be true bicuspid valves, with two leaflets and two sinuses of Valsalva or "false" bicuspid valves, with three sinuses of Valsalva and a raphe in one of the valve leaflets, suggesting incomplete commissural development. Rheumatic aortic stenosis may occur in isolation, although it is seen more commonly in conjunction with rheumatic mitral valve disease. Degenerative aortic stenosis occurs exclusively in older adults, with progressive leaflet calcification. Pathology specimens of bicuspid aortic valve and rheumatic aortic stenosis are shown in [Figure 77.1](#) and [Figure 77.2](#), respectively.

FIGURE 77.1. Bicuspid aortic valve with leaflet calcification. There are two sinuses of Valsalva and two symmetric cusps with no raphe.

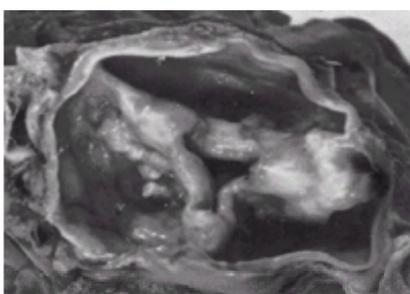

FIGURE 77.2. Rheumatic aortic valve stenosis in an elderly man. Commissural fusion and nodular calcification of the cusps are seen.

PATHOGENESIS

Lesion Pathogenesis

The pathogenesis of the valve lesion in aortic stenosis varies by cause. In congenital aortic stenosis, an abnormal valve is present from birth. However, whereas unicuspid valves can demonstrate significant stenosis from birth, hemodynamically important stenosis associated with most bicuspid valves usually occurs later. Years of mild obstruction and turbulent flow lead to fibrosis, calcification, and rigidity of the valve with subsequent decrease in orifice area. Poststenotic dilation of the ascending aorta is common with congenitally abnormal aortic valves, and associated aortic dissection may occur. In rheumatic disease, aortic stenosis typically manifests years after rheumatic fever. Progressive scarring and adhesion between commissures lead to commissural fusion and a decrease in orifice area. Calcification of the valve may be heavy, especially among older patients. Mild aortic regurgitation is commonly present. Senile calcific aortic stenosis is a gradual, degenerative process, and the progression from a normal aortic valve to stenosis is not fully understood. In general, cusp flexion over years results in calcification and aortic sclerosis, which in some patients may be associated with progressive calcification and stenosis. Although calcification occurs in both rheumatic and degenerative aortic stenosis, calcification occurs from the commissures toward the base in rheumatic disease and from the base toward the commissures in degenerative disease. The association between senile calcific aortic stenosis and risk factors for coronary artery and peripheral vascular disease suggests that this may be another form of vascular atherosclerosis.

Hemodynamic Pathogenesis

The common hemodynamic lesion in all forms of aortic stenosis is fixed obstruction to left ventricular outflow. Left ventricular hypertrophy occurs as a compensatory mechanism to maintain left ventricular wall stress in the setting of increased afterload. Left ventricular systolic function at rest is preserved late into the course of disease, although diastolic function may be impaired owing to the increase in left ventricular mass. Cardiac output may fail to increase with exertion in severe disease. Late in the course of aortic stenosis, left ventricular hypertrophy is no longer able to compensate for increased afterload, and the left ventricle dilates with subsequent development of systolic dysfunction.

CLINICAL FINDINGS

History

There is a long latent period before the development of symptoms, during which outflow obstruction and a compensatory increase in left ventricular mass occur. The three classic symptoms associated with aortic stenosis are dyspnea, angina pectoris, and syncope. Dyspnea occurs secondary to increases in left ventricular diastolic, left atrial, and pulmonary venous pressures. Angina pectoris occurs without coronary artery disease resulting from increased oxygen demand from increased left ventricular mass and elevated intracavitary pressures in the setting of a fixed blood supply and from decreased coronary flow due to progressive outflow obstruction. Approximately 50% of patients with senile calcific aortic stenosis and angina pectoris have concomitant coronary artery disease. Syncope may be caused by peripheral vasodilation with exertion, with an increase in peripheral oxygen requirement in the setting of a fixed cardiac output. In addition, syncope at rest or with effort may be due to development of a tachyarrhythmia compromising cardiac output.

Late in the course of disease, a decrease in cardiac output results in congestive heart failure, with symptoms of fatigue, weakness, and peripheral cyanosis. Peripheral edema, hepatomegaly, and ascites may occur as a result of right ventricular failure secondary to pulmonary hypertension. Atrial fibrillation is a late manifestation of pure aortic stenosis, and its presence without other symptoms of advanced disease should suggest the possibility of concomitant mitral valve disease.

During the period in which patients are asymptomatic, mortality is extremely low. However, with the onset of symptoms, prognosis is poor and average survival without intervention is between 2 and 3 years, with the worst prognosis noted among patients with symptoms of congestive heart failure. Sudden death has been reported among patients with severe aortic stenosis and no symptoms of dyspnea, angina, or syncope. However, the incidence is extremely low and the weight of evidence suggests that patients develop typical symptoms of aortic stenosis before a morbid event.

Physical Findings

The classic physical finding of aortic stenosis is *pulsus tardus et parvus*, a delayed and prolonged arterial pulse of diminished intensity, caused by sustained ejection of blood across the stenotic valve. A prominent anacrotic notch is noted in the ascending limb of the arterial pulse. The pulse contour is typically assessed in the carotid artery. However, rigidity of the carotid arterial wall in older patients may transmit a vigorous pulse that does not accurately reflect central arterial pressure, and assessment of the brachial arterial pulse contour may be more appropriate.

Palpation of the precordium may reveal lateral and inferior displacement of the left ventricular apical impulse because of left ventricular hypertrophy, with a sustained apical impulse and palpable S_4 . On auscultation, S_1 is normal. A systolic ejection click may be audible if the valve has not become completely immobile. The aortic component of S_2 is diminished. An S_4 is usually audible and an S_3 may be heard in a patient with congestive heart failure. The classic murmur of aortic stenosis is a harsh, low-pitched, crescendo–decrescendo systolic ejection murmur, which radiates from the base of the heart into the carotids.

Aortic stenosis is distinguished from aortic sclerosis by the abnormal arterial pulse contour and by the murmur peaking in the latter half of systole. Increasing severity of aortic stenosis is associated with the anacrotic notch occurring earlier in systole, progressive delay of the arterial upstroke, and the development of a precordial thrill. On auscultation, there is a progressive decrease in the aortic component of S_2 , and the murmur peaks progressively later in systole and encompasses S_2 . End-stage aortic stenosis may be associated with a softer murmur owing to decreasing cardiac output.

LABORATORY FINDINGS

Electrocardiogram and Chest Radiograph

The electrocardiogram (ECG) is neither sensitive nor specific for aortic stenosis, but it may show evidence of left atrial enlargement or left ventricular hypertrophy. Similarly, the chest radiograph may remain normal or may show increased size of the cardiac silhouette or evidence of left ventricular hypertrophy. Calcific deposits in the aortic valve can be seen, but their absence on chest radiograph does not preclude calcification of the valve.

Echocardiography and Doppler Imaging

Echocardiography and Doppler imaging are indispensable in the diagnosis and serial assessment of aortic stenosis. These techniques provide an accurate, noninvasive, low-cost, and widely available means to establish the presence, severity, and cause of aortic stenosis; the presence of concomitant valve lesions; and assessment of left ventricular size, mass, and systolic function. Echocardiographic imaging reveals anatomical abnormalities associated with the aortic valve, and a normal aortic valve on echocardiography precludes the presence of aortic stenosis. Left ventricular size, mass, and systolic function can be assessed serially for change. Doppler techniques provide an accurate means for the serial assessment of stenosis severity, with determination of peak instantaneous and mean transvalvular pressure gradients and estimation of valve orifice area based on the continuity equation and orifice planimetry. Transesophageal echocardiography allows additional assessment of valve anatomy for determination of the cause of stenosis. In addition, transesophageal imaging allows assessment of the ascending aorta, including the number of sinuses of Valsalva and the degree and location of poststenotic dilation, both of which impact surgical options for aortic valve replacement.

Cardiac Catheterization

Hemodynamic assessment during cardiac catheterization allows determination of peak-to-peak and mean transvalvular gradients and calculation of the stenotic orifice area using the Gorlin equation. An example of pressure tracings in a patient with aortic stenosis is shown in [Figure 77.3](#). Because the hemodynamic assessment of aortic stenosis can usually be obtained using echocardiography and Doppler, cardiac catheterization for assessment of stenosis severity should be reserved for patients in whom there is a discrepancy between clinical and echocardiographic data. Coronary angiography allows assessment of coronary anatomy among patients with suspicion of coronary artery disease in whom surgical intervention is planned.

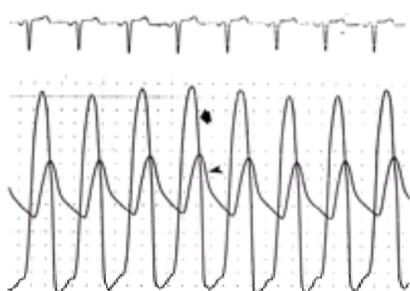

FIGURE 77.3. Simultaneous pressure tracings of left ventricle (*arrow*) and ascending aorta (*smaller arrowhead*) in patient with aortic stenosis. Systolic pressure of

ascending aorta (101/59 mm Hg) is diminished and delayed in upstroke compared with that of left ventricle (155/2 mm Hg).

Exercise Testing

Exercise testing has been used with caution, if at all, in patients with significant aortic stenosis because of potential risks, as well as limited diagnostic accuracy for detecting coronary artery disease in the setting of aortic stenosis. Exercise testing is generally not recommended in symptomatic patients with evidence of severe aortic stenosis. However, exercise and pharmacologic stress testing may be useful in some patients. In asymptomatic patients with severe aortic stenosis, exercise testing may identify patients with limited exercise capacity and may provoke symptoms or signs that were not previously reported. In addition, exercise testing may be beneficial in patients with left ventricular systolic dysfunction and evidence of only moderate or mild aortic stenosis. Because gradients are dependent on flow, patients with severe aortic stenosis and low cardiac output have only moderately increased gradients, and it may be difficult to distinguish these patients from others with impaired left ventricular systolic function and only mild or moderate aortic stenosis. Although orifice area is independent of flow, the formulas used to calculate it are known to lose accuracy in low flow states, and calculated orifice area may be low in both groups. Among such patients, it may be useful to assess gradients and orifice area during exercise or dobutamine stress, when cardiac output is increased. When performed, stress testing should be directly supervised by a physician, with careful and frequent assessment of systolic blood pressure. Stress should be terminated for symptoms of angina, dyspnea or light-headedness, or if blood pressure falls.

OPTIMAL MANAGEMENT

Medical Therapy

All patients with aortic stenosis should receive appropriate antibiotic prophylaxis. There is no suitable medical therapy for the hemodynamic lesion of aortic stenosis. In addition, nitrates, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and diuretics, used to treat symptoms of angina pectoris and congestive heart failure, may cause untoward hemodynamic changes in patients with aortic stenosis. Because left ventricular afterload is increased by the stenotic aortic valve, it is not reduced by medications that affect peripheral afterload. However, the hypertrophied left ventricle is reliant on preload for adequate filling, and a decrease in peripheral vascular tone may also decrease left ventricular filling and cardiac output with consequent hemodynamic collapse. Furthermore, medical therapy does not improve the poor prognosis associated with symptomatic aortic stenosis. Therefore, medications such as ACE inhibitors should be avoided in patients with severe aortic stenosis, and nitrates and diuretics should be used with caution. Considerations for medical therapy in aortic stenosis and other valve lesions are summarized in [Table 77.1](#)

Lesion	Goal of Therapy	Medical Intervention
Aortic stenosis	Avoid increase in preload, peripheral afterload	Avoid over diuresis, afterload reducing therapy, negative inotropic agents
Aortic regurgitation, acute	Reduce afterload	Diuretics Nitroglycerin or nitroprusside
	Therapy for pulmonary edema	Diuretics
	Maintain increased heart rate	β-adrenergic agents or temporary cardiac pacing
Aortic regurgitation, chronic	Decrease systolic blood pressure	Medication therapy with nitroglycerin, ACE inhibitor
Mitral stenosis	Control heart rate	Negative chronotropic β-adrenergic or calcium channel antagonists
	Therapy for pulmonary congestion	Saline restriction, diuretics
	Reduce thromboembolic risk	Warfarin if atrial fibrillation or prior embolism
Mitral regurgitation, acute	Reduce afterload and preload	Nitroglycerin (with inotropic agent if hypotensive), diuretics, intra-aortic balloon counterpulsation
Mitral regurgitation, chronic		Afterload reduction not tested for long-term therapy

ACE, angiotensin-converting enzyme.
*General considerations for therapy are prophylaxis against infective endocarditis and prophylaxis against thrombotic fever.

TABLE 77.1. MEDICAL THERAPY IN PATIENTS SEVERE AORTIC AND MITRAL VALVE DISEASE

Aortic Valve Replacement

Symptomatic patients with significant aortic stenosis should undergo consideration for surgical aortic valve replacement. In patients with aortic stenosis and symptoms of angina pectoris, syncope, or congestive heart failure, aortic valve replacement is associated with symptomatic improvement and increased survival. Left ventricular systolic dysfunction should not preclude consideration for surgical intervention. In the absence of significant comorbid conditions, aortic valve replacement is indicated for virtually all symptomatic patients with aortic stenosis. Aortic valve replacement is also indicated in patients with severe aortic stenosis undergoing coronary artery bypass surgery, surgery on other heart valves, or surgery on the aorta.

Surgical reconstructive procedures for the aortic valve have more limited application than for the mitral valve and are appropriate only for certain congenital aortic valve lesions without significant calcification. Mechanical prostheses have advantages of favorable hemodynamic profile and durability but require long-term anticoagulation because of thrombogenicity. Although stented heterografts do not require anticoagulation, their use is limited by durability and suboptimal hemodynamics associated with smaller prosthesis sizes. Allograft prostheses and the Ross procedure, a “switch” operation in which the normal pulmonic valve is implanted in the aortic position and replaced with a pulmonic allograft, are important alternatives for some younger patients requiring aortic valve replacement, although technical requirements and availability limit their more widespread use. Stentless tissue heterografts offer a new alternative for aortic valve replacement, with advantages of favorable hemodynamics and no requirement for anticoagulation. Considerations for surgical management of aortic stenosis and other valve lesions are summarized in [Table 77.2](#).

Lesion	Intervention	Indications
Aortic stenosis	Aortic valve replacement	Symptoms of angina pectoris, syncope or heart failure
	Percutaneous balloon valvotomy	Undergoing coronary bypass surgery or surgery on other heart valve or thoracic aorta
		Alternative to valve replacement in selected young patients with congenital aortic stenosis
Aortic regurgitation	Aortic valve replacement	Refractive therapy or temporary measure before aortic valve replacement
		Symptoms of angina pectoris or congestive heart failure
		Left ventricular systolic dysfunction (ejection fraction <50% at rest or marked left ventricular dilation [end-diastolic diameter >75 mm or end-systolic diameter >50 mm])
Mitral stenosis	Mitral valve replacement	Undergoing coronary bypass surgery or surgery on other heart valve or thoracic aorta
		Symptoms of heart failure, if not good candidate for percutaneous balloon valvotomy
	Percutaneous balloon valvotomy	If available, with favorable valve morphology and absence of left atrial thrombus or significant mitral regurgitation
Mitral regurgitation	Mitral valve replacement	Symptoms of heart failure
		Left ventricular systolic dysfunction (ejection fraction <40% at rest and end-systolic diameter >40 mm)
	Mitral valve repair	If available with favorable valve morphology and indication for valve replacement
		Some asymptomatic patients with progressive left ventricular dilation, new atrial fibrillation, new-onset mitral regurgitation
		Ischemic mitral regurgitation undergoing coronary artery bypass grafting

TABLE 77.2. SURGICAL AND PERCUTANEOUS INTERVENTION IN PATIENTS WITH SEVERE AORTIC AND MITRAL VALVE DISEASE

Aortic Balloon Valvotomy

In adolescents and young adults, aortic balloon valvotomy plays an important role in delaying or preventing the need for valve replacement surgery. In older adults, balloon valvotomy plays a very limited role in the therapy of aortic stenosis. Although the procedure results in moderate early improvement in transvalvular gradients, the orifice area rarely exceeds 1.0 cm² following the procedure. Restenosis of the valve occurs within 6 to 12 months in most patients, and nearly 10% of patients experience periprocedural complications such as stroke and vascular complications. Aortic balloon valvotomy may be useful palliative therapy in selected patients

with severe, symptomatic aortic stenosis in whom comorbid diseases preclude surgical intervention, among some patients with severe aortic stenosis who require urgent noncardiac surgery, and as a temporizing measure to improve hemodynamics before aortic valve replacement in unstable patients with decompensated congestive heart failure and a prohibitive acute risk of surgery.

Elderly Patients

Because there is no suitable alternative therapy, including aortic balloon valvotomy, aortic valve surgery should be considered in all symptomatic patients with aortic stenosis, regardless of age. Although the operative risk of aortic valve surgery is higher among elderly than younger patients, the surgical procedure is feasible and successful surgery improves survival among elderly patients to that which is normal for their age.

Asymptomatic Patients

Patients with mild aortic stenosis should undergo periodic evaluation including assessment for the development of symptoms and echocardiography with Doppler imaging to evaluate for change in left ventricular size, mass, or function. Asymptomatic patients with moderate or severe aortic stenosis should undergo periodic evaluation more frequently. Patients should be made aware of the importance of angina pectoris, dyspnea, and syncope or presyncope and should promptly report the onset of symptoms.

AORTIC REGURGITATION

DEFINITION

Acute and chronic aortic regurgitation are conditions of left ventricular volume overload caused by incompetence of the aortic valve. As with other forms of valvular heart disease, the severity of aortic regurgitation occurs as a continuum, and the hemodynamic impact of the lesion is affected by factors in addition to regurgitant volume. The severity of aortic regurgitation is defined by its features on Doppler imaging and at cardiac catheterization. However, no gold standard exists against which to judge lesion severity, and overlap occurs between categories. Descriptions of severity are therefore best used in context with other clinical data.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

In general, aortic regurgitation is caused by congenital or acquired abnormalities of the aortic valve or by acquired abnormalities of the aortic root that affect the competence of the aortic valve. Congenital causes of aortic regurgitation include bicuspid aortic valve and fenestrations of the valve cusps. Acquired abnormalities of the aortic valve can be due to rheumatic disease, hypertensive and atherosclerotic diseases, infective endocarditis, and nonpenetrating trauma. Diseases of the ascending aorta can result in aortic regurgitation, including aortic aneurysm and aneurysm of the sinus of Valsalva, cystic medial necrosis with or without other features of Marfan's syndrome, connective tissue diseases including Reiter's syndrome and ankylosing spondylitis, luetic (syphilitic) aortitis, and aortic dissection. Finally, dysfunction of an aortic valve prosthesis can result in aortic regurgitation.

PATHOGENESIS

Lesion Pathogenesis

The pathogenesis of the lesions responsible for aortic regurgitation varies according to the cause of disease. In congenitally bicuspid aortic valve, turbulent flow due to mild stenosis leads over years to fibrosis and calcification of the cusps, which can result in moderate and rarely severe aortic regurgitation. Bicuspid aortic valve frequently leads to combined aortic stenosis and regurgitation, but severe aortic regurgitation in the setting of bicuspid aortic valve usually implies a secondary process such as infective endocarditis. Aortic valve fenestrations are present at birth and can cause mild or moderate regurgitation.

Rheumatic aortic valve disease occurs years after rheumatic fever. Progressive thickening and retraction of the cusps result in incomplete coaptation and aortic regurgitation. Rheumatic aortic regurgitation typically occurs with some degree of aortic stenosis. Although rheumatic aortic valve disease can occur in isolation, it is more common with concomitant mitral valve disease. Hypertensive and atherosclerotic diseases can cause focal aortic valve calcification and scarring as well as dilation of the aortic root with resultant aortic regurgitation. Although the high prevalence of the underlying diseases makes these causes of aortic regurgitation common, it is usually only mild in severity. Infective endocarditis can cause aortic regurgitation of any severity. Infection of the valve tissue results in a continuum of destructive processes, from leaflet perforation to leaflet flail and leaflet destruction. Rupture of a paravalvular abscess complicating aortic valve endocarditis can lead to a fistula between the ascending aorta and the left ventricle. The degree of valve destruction is influenced by the destructiveness of the organism, chronicity of infection, and host factors. Because the mechanism of regurgitation in infective endocarditis usually relates to destruction of valve tissue, aortic regurgitation usually persists after successful treatment of the infection. Rarely, aortic regurgitation during endocarditis is caused by mechanical interference of a vegetation with normal leaflet coaptation but without significant tissue destruction, and regurgitation may improve or even resolve completely after treatment. Any preexisting congenital or acquired valve lesion can serve as a nidus for infection, and a rapid change in regurgitation severity should raise the possibility of superimposed infective endocarditis. Nonpenetrating trauma can result in avulsion of one or more valve cusps, leading to significant aortic regurgitation.

Diseases of the aortic root can also affect the competence of the aortic valve. Aneurysmal dilation of the aortic root can lead to dilation of the aortic annulus with incomplete leaflet coaptation and aortic regurgitation. Cystic medial necrosis, usually associated with Marfan syndrome, causes characteristic dilation of the sinuses of Valsalva with effacement of the sinotubular junction and aortic regurgitation. Cystic medial necrosis can also occur without other manifestations of Marfan syndrome. Luetic (syphilitic) aortitis is now extremely rare but causes heavy calcification of the aortic root and aortic regurgitation. Aortic dissection can be associated with aortic regurgitation with or without associated aortic aneurysm. Prolapse of the dissection flap through the aortic valve can directly interfere with valve closure and cause aortic regurgitation.

Most mechanical valve prostheses have a small amount of associated regurgitation during normal function, and mild aortic regurgitation is an anticipated finding. Dysfunction of a mechanical prosthesis can result in more significant regurgitation. Bioprosthetic valves typically fail with calcification and fracture of a valve leaflet, resulting in significant regurgitation. Paravalvular regurgitation can occur with both mechanical and tissue prostheses. Severe paravalvular regurgitation suggests partial dehiscence of the prosthesis, caused by either endocarditis or mechanical suture failure.

Hemodynamic Pathogenesis

The initial hemodynamic lesion with both acute and chronic aortic regurgitation is left ventricular volume overload. When chronic, the left ventricle compensates with gradual chamber dilation. Ejection fraction remains normal at rest until late in the disease, and increased left ventricular end diastolic volume permits increased stroke volume and normal forward cardiac output. Systolic hypertension results in a pressure overload component of chronic aortic regurgitation. Increased left ventricular volume causes increased wall tension, and compensatory hypertrophy leads to markedly increased left ventricular mass. The increased left ventricular mass associated with aortic regurgitation occurs with normal or mildly increased wall thickness and significant chamber dilation, whereas hypertrophy in aortic stenosis occurs with markedly increased wall thickness and normal chamber diameter.

Chronic aortic regurgitation is generally tolerated for years without symptoms. Although left ventricular ejection fraction remains normal at rest until late in the course of disease, augmentation with exercise is impaired earlier. Left ventricular end-diastolic pressure is elevated and with severe regurgitation equilibrates with diastolic aortic pressure. Eventually, left ventricular ejection fraction at rest declines as dilation and hypertrophy are unable to compensate for the combined volume and pressure overload, and many patients first note symptoms of dyspnea. Myocardial ischemia occurs in patients with advanced aortic regurgitation because of increased myocardial oxygen demand due to increased left ventricular diameter, stroke volume, and mass and because of decreased oxygen availability due to low perfusion pressure and an eventual decrease in cardiac output.

Acute severe aortic regurgitation results in left ventricular volume overload, but without time for left ventricular dilation, tachycardia is the only compensatory mechanism to maintain forward cardiac output. Left ventricular end-diastolic and left atrial pressures increase rapidly, with pulmonary venous congestion. Unlike chronic aortic regurgitation, acute severe aortic regurgitation is poorly tolerated. Without compensatory chamber dilation, tachycardia alone is usually insufficient to maintain forward cardiac output, and patients frequently present with pulmonary edema and shock.

CLINICAL FINDINGS

History

Patients with chronic aortic regurgitation usually remain asymptomatic for years or decades. Early symptoms include a sensation pounding in the chest, palpitations, or head pounding. Exertional dyspnea may be the first manifestation of left ventricular decompensation, with later development of orthopnea and paroxysmal nocturnal dyspnea. Symptoms of more advanced disease include angina pectoris, which may be nocturnal, and eventually symptoms of right-sided congestive heart failure with ascites and peripheral edema. Asymptomatic patients with severe aortic regurgitation and decreased left ventricular systolic function usually develop symptoms within 3 to 3 years. Sudden death among patients with compensated severe aortic regurgitation has been reported but appears to be rare, occurring with an incidence of less than 0.2% per year. Left ventricular systolic dysfunction and marked left ventricular dilation are associated with a worse prognosis, even if patients remain asymptomatic. Prognosis worsens with the onset of symptoms; mortality rate is estimated to be more than 10% per year among patients with severe aortic regurgitation and angina pectoris and more than 20% per year among patients with symptoms of congestive heart failure.

Acute severe aortic regurgitation usually occurs in the setting of infective endocarditis or acute aortic dissection or, more rarely, after blunt chest trauma. Patients typically exhibit symptoms referable to the underlying disease, including fever with infective endocarditis, and chest or back pain with aortic dissection. Acute severe aortic regurgitation is poorly tolerated and patients frequently present with pulmonary edema or cardiogenic shock.

Physical Findings

Most physical findings associated with severe aortic regurgitation reflect the combination of increased stroke volume and widened pulse pressure. Physical findings can be extensive, and there may be no other single lesion in medicine so rich with associated eponyms. In general appearance, patients can exhibit a bobbing motion of the torso or the head (de Musset's sign) synchronous with the heartbeat. Systolic pulsation of the uvula may be visible (Müller's sign). Arterial pulses are unusually prominent, with exaggerated systolic distention and exaggerated diastolic collapse on palpation (water-hammer or Corrigan's pulse). Palpation of the carotid arteries reveals a bisferiens, or double-peaking pulse. Capillary pulsation is visible in the nail beds when the distal nail is softly compressed (Quincke's pulse). Auscultation of large arteries may reveal a brief, loud systolic (pistol shot) sound. Auscultation of the femoral artery reveals booming systolic and diastolic sounds (Traube's sign); light pressure of the stethoscope proximally reveals a systolic murmur, with a diastolic murmur with pressure distally (Duroziez's sign). The systolic blood pressure is elevated, and the diastolic blood pressure is often very low, revealing a wide pulse pressure.

The left ventricular apical impulse is enlarged and displaced owing to left ventricular enlargement, and may be visible. A systolic thrill may be evident along the base of the heart or in the carotids, caused by the large left ventricular stroke volume. On auscultation, the aortic component of S_2 may be diminished or absent. The murmur of aortic regurgitation is a high-pitched, blowing decrescendo diastolic murmur, loudest at the left or right upper sternal border. Held end-expiration with the patient upright and leaning forward and the stethoscope diaphragm held firmly against the chest aid in the auscultation of soft murmurs of aortic regurgitation. The murmur may radiate to the cardiac apex (Austin Flint murmur), with a low-pitched diastolic rumble that mimics mitral stenosis. A systolic ejection murmur, often louder and more easily heard than the diastolic murmur, is due to large stroke volume and does not necessarily imply aortic stenosis.

Many of the typical physical findings associated with chronic aortic regurgitation are absent in patients with acute aortic regurgitation. Because the left ventricle is not dilated in acute aortic regurgitation, stroke volume is not increased, pulse pressure is not widened, and the associated peripheral arterial manifestations are absent. Although chronic severe aortic regurgitation can usually be diagnosed on physical examination, the detection of acute severe regurgitation is less reliable.

LABORATORY FINDINGS

Electrocardiogram and Chest Radiograph

Neither the ECG nor the chest radiograph is accurate in the detection or estimation of severity of aortic regurgitation. The ECG may reveal evidence of left ventricular hypertrophy or interventricular conduction delay. The chest radiograph may reveal cardiomegaly, dilation of the aortic root, or evidence of pulmonary venous congestion.

Echocardiography and Doppler Imaging

Echocardiography is indicated in patients with suspected aortic regurgitation to confirm the presence and to establish the severity and cause of aortic regurgitation. The dimensions, mass, and systolic function of the left ventricle should be determined, as well as the size and anatomy of the aortic root. Because absolute and subsequent change in left ventricular dimensions directly affect management, accurate quantification is important both at baseline and on subsequent examinations.

Transthoracic imaging allows assessment of aortic valve morphology and may establish the cause of aortic regurgitation with evidence of congenital abnormalities or findings suggestive of infective endocarditis. The proximal 2 to 3 cm of ascending aorta can usually be visualized. Aortic regurgitation is suggested by diastolic fluttering of the mitral valve; acute severe regurgitation is associated with premature closure of the mitral valve. Doppler imaging allows reliable detection and semiquantification of aortic regurgitation. Aortic regurgitation severity is estimated by the size of the regurgitant jet, as well as deceleration characteristics of regurgitant flow. Diastolic flow reversal in the descending aorta suggests severe aortic regurgitation. Transesophageal echocardiographic imaging allows optimal assessment of aortic valve morphology as well as definitive assessment of anatomy of the aorta, including assessment for aortic dissection. An example of bicuspid aortic valve on transesophageal echocardiography is shown in [Figure 77.4](#), and associated aortic dilation and aortic regurgitation are shown in [Figure 77.5](#). Transesophageal imaging is indicated to assess prosthetic valve dysfunction.

FIGURE 77.4. Transesophageal echocardiogram in patient with bicuspid aortic valve. Three sinuses of Valsalva and leaflet raphe (*arrow*) suggest incomplete commissural development. *LA*, left atrium; *RA*, right atrium.

FIGURE 77.5. Transesophageal echocardiogram demonstrating aortic regurgitation in patient with bicuspid aortic valve. Dilation of tubular portion of ascending aorta is present. Ao, ascending aorta; LA, left atrium; LV, left ventricle.

Radionuclide Angiography

Radionuclide angiography is a useful noninvasive means for assessment of left ventricular size and function if these data are not available on echocardiographic imaging or if there is discordance between clinical data and data from echocardiographic imaging.

Exercise Testing

Exercise testing is useful to assess functional capacity and symptoms in patients with significant aortic regurgitation and equivocal symptoms. Change in left ventricular ejection fraction with exercise has been used as an indication for surgical intervention, although no definitive data support the incremental diagnostic or prognostic value.

Cardiac Catheterization

Cardiac catheterization with coronary angiography allows assessment of coronary anatomy among patients at risk for coronary artery disease in whom surgical intervention is planned. Aortic regurgitation severity and aortic root size can be assessed with root angiography, although these data are usually available with noninvasive testing.

OPTIMAL MANAGEMENT

Medical Therapy

Patients with aortic regurgitation should receive appropriate antibiotic prophylaxis. Patients with chronic mild or moderate aortic regurgitation do not benefit from any other form of medical therapy. However, asymptomatic patients with chronic severe aortic regurgitation benefit from long-term vasodilating therapy with nifedipine or possibly ACE inhibitors. Therapy appears to delay the need for aortic valve replacement and results in improved left ventricular size and function after surgery. Therapy should be limited to patients with systolic hypertension, and dose should be titrated upward until systolic blood pressure decreases or side effects develop. Medical therapy is not an alternative to surgery for symptomatic or asymptomatic patients with severe aortic regurgitation and decreased left ventricular systolic function. Asymptomatic patients with moderate or severe aortic regurgitation are able to participate in normal physical activity, including mild intensity exercise, although weight lifting and other isometric exercises should be avoided.

Patients with acute severe aortic regurgitation typically suffer hemodynamic compromise with pulmonary edema and cardiogenic shock. Medical therapy should be directed at aggressive afterload reduction with intravenous nitroprusside or nitroglycerin. Diuretics are useful in the management of pulmonary edema. Because regurgitant volume decreases with a shorter diastolic interval and because diastolic interval decreases with increasing heart rate, maintaining a rapid heart rate using β -agonists or temporary cardiac pacing is useful among patients with acute severe aortic regurgitation and hemodynamic compromise. Intra-aortic balloon counterpulsation is contraindicated.

Serial Testing

Asymptomatic patients with aortic regurgitation and normal left ventricular systolic function should be followed up for evidence of angina or heart failure and for change in left ventricular size and function. Patients with mild aortic regurgitation should be followed up with periodic medical history and physical examination, with additional testing if symptoms develop or if physical examination suggests progression of disease. Patients with moderate or severe aortic regurgitation should undergo serial follow-up, including history, physical examination, and echocardiographic imaging. Patients with chronic, stable aortic regurgitation should be evaluated every 6 to 12 months. Follow-up should be more frequent if there is evidence of left ventricular chamber dilation.

Aortic Valve Replacement

Aortic valve replacement is indicated for patients with severe aortic regurgitation and symptoms of angina or heart failure. In addition, aortic valve replacement is indicated for asymptomatic patients with severe aortic regurgitation and either left ventricular systolic dysfunction (ejection fraction less than 50% at rest) or marked left ventricular dilation (end-diastolic diameter more than 75 mm or end-systolic diameter greater than 55 mm). The risk of surgery increases with progressive left ventricular systolic dysfunction, although functional status and prognosis are improved with aortic valve replacement despite preexisting severe left ventricular systolic dysfunction. Patients with severe aortic regurgitation who require coronary artery bypass grafting or surgery on other heart valves or on the thoracic aorta should also undergo aortic valve replacement.

MITRAL STENOSIS

DEFINITION

Mitral stenosis implies valvular obstruction to left ventricular inflow. Nonvalvular causes of left ventricular inflow obstruction include congenital abnormalities not usually encountered in an adult population, and obstruction due to left atrial tumor or ball thrombus. The normal mitral valve area is 4.0 to 5.0 cm². Symptoms occur with exercise or tachycardia when the valve area is approximately 2.0 to 2.5 cm²; symptoms at rest usually do not occur until the valve area is \leq 1.5 cm². In general, mitral stenosis is considered mild if mean pressure gradient is less than 5 mm Hg and valve area is more than 1.5 cm².

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

Mitral stenosis in adults is predominantly of rheumatic origin. Women are affected more often than men. The mitral valve is the most common site of rheumatic valve disease, which may occur in isolation or with concomitant rheumatic involvement of other valves. Heavy mitral annular calcification can extend into the mitral orifice and lead to functional mitral stenosis, most often encountered in elderly persons and in patients with underlying conditions that lead to ectopic calcification. Congenital mitral stenosis is rarely encountered in an adult population and distinguished by "arcade" or "parachute" deformities of the papillary muscles and chordae tendineae.

PATHOGENESIS

Lesion Pathogenesis

Rheumatic mitral stenosis typically manifests years after rheumatic fever, although many patients are unaware of the episode of rheumatic fever. Progressive fibrosis and scarring of the mitral leaflets occur, with the pathologic process extending from the leaflet commissures toward the bases. The chordae tendineae and submitral apparatus are often involved, with scarring and retraction. Calcification of the mitral apparatus is variable, and prominent calcification is more commonly seen in older patients. The anatomy of mitral stenosis forms a continuum, with variable degrees of leaflet and submitral thickening, rigidity, retraction, and calcification. Although mitral stenosis with pliable, noncalcified leaflets is common in developing countries, most patients with mitral stenosis in the United States and other Western countries present late after rheumatic fever with extensive valvular and subvalvular calcification. Nonrheumatic stenosis due to mitral annular calcification occurs with progression from the annulus toward the commissures, whereas rheumatic disease progresses from the commissures to the annulus.

Hemodynamic Pathogenesis

Obstruction to left ventricular inflow causes left atrial dilation and hypertension and resultant pulmonary venous hypertension. Pulmonary arteriolar and capillary vasoconstriction protect against pulmonary edema, although increased pulmonary vascular resistance exacerbates pulmonary arterial and right ventricular hypertension and causes right ventricular hypertrophy. Pulmonary hypertension can be severe late in the course of mitral stenosis, with eventual right ventricular systolic dysfunction. Because the diastolic interval shortens with increased heart rate, left ventricular filling is further compromised in patients with mitral stenosis and tachycardia. Sinus tachycardia, precipitated by physical or emotional stress, results in worsened left atrial hypertension, decreased left ventricular filling, and lower cardiac output. In addition, left atrial dilation predisposes to atrial fibrillation and other supraventricular tachyarrhythmias; the associated rapid ventricular response is poorly tolerated symptomatically and hemodynamically.

The hemodynamics and clinical expression of mitral stenosis are altered by the coincident occurrence of secundum atrial septal defect (Lutembacher's syndrome). The left atrium is decompressed by the atrial septal defect, and left atrial and pulmonary hypertension are attenuated. However, lower driving pressure across the stenotic mitral valve further impairs left ventricular filling. In addition, the presence of mitral stenosis exaggerates volume overload of the right ventricle and pulmonary circulation. In general, low systemic output replaces pulmonary edema among patients with the combination of mitral stenosis and atrial septal defect.

CLINICAL FINDINGS

History

Rheumatic mitral stenosis is a chronic and insidious disease in which the first symptoms typically occur decades after an episode of rheumatic fever that may have been unrecognized or may be no longer recalled. There is usually another long period during which symptoms of mitral stenosis are present but not debilitating. However, once debilitating symptoms occur, usually with associated pulmonary hypertension, prognosis is poor. Whereas 10-year survival rate is more than 80% in patients with mitral stenosis but no symptoms or mild symptoms, it falls to 0% to 15% in patients with debilitating symptoms, and estimated survival is less than 3 years among unoperated patients with advanced mitral stenosis and severe pulmonary hypertension. Among patients with advanced mitral stenosis, mortality is due to progressive heart failure, systemic embolization, pulmonary embolization, and infection.

Early symptoms of mitral stenosis consist of fatigue or dyspnea precipitated by events with associated tachycardia, including strenuous physical exercise, emotional stress, fever, pregnancy, or surgery. Dyspnea may be associated with cough. Later, dyspnea occurs with less strenuous activity and eventually at rest, with eventual development of paroxysmal nocturnal dyspnea and orthopnea that are associated with pulmonary edema and production of frothy, pink sputum. Patients may note palpitations due to atrial or ventricular ectopic beats, paroxysmal atrial tachycardia, or atrial fibrillation. Dyspnea typically worsens with both sinus tachycardia and with tachyarrhythmias owing to the shortened diastolic interval. Hemoptysis is a late symptom, caused by rupture of small bronchial vessels in the setting of significant pulmonary hypertension. Peripheral edema, ascites, and pleural effusion occur late and are caused by right ventricular failure.

The left atrium can become markedly enlarged, and systemic arterial emboli occur secondary to stasis and clotting in the dilated left atrium. Left atrial thrombi may occur in patients in sinus rhythm; the development of atrial fibrillation further increases the risk of thrombus formation. Pulmonary emboli are a late manifestation of mitral stenosis and can be debilitating or fatal.

Physical Findings

Changes in general appearance occur only with advanced mitral stenosis, with evidence of malar flushing due to peripheral cyanosis. Neck vein distention occurs caused by right ventricular failure, and jugular venous a waves are prominent in patients in sinus rhythm with tricuspid regurgitation or right ventricular hypertension but are absent with atrial fibrillation. Palpation of the precordium reveals a right ventricular lift or tap at the left sternal border. S_1 may be palpable, whereas the left ventricular apical impulse is diminished or nonpalpable. A diastolic thrill may be appreciable at the left ventricular apex with the patient in the left lateral decubitus position.

Auscultation reveals accentuation of S_1 in patients with pliable mitral leaflets and an increase in the pulmonic component of S_2 in patients with pulmonary hypertension. The classic high-pitched opening snap occurs 50 to 120 msec after the aortic component of S_2 in patients with a noncalcified valve. A low-pitched diastolic rumble occurs after the opening snap, loudest at the left ventricular apex using light application of the stethoscope bell and the patient in the left lateral decubitus position. The murmur intensity increases with simple exercises such as leg lifts or sit-ups. Presystolic accentuation occurs in sinus rhythm. More severe mitral stenosis is associated with longer duration of the diastolic rumble and decrease in the time between the aortic component of S_2 and the opening snap. The murmur of mitral stenosis is differentiated from an Austin Flint murmur of aortic regurgitation by the presence of an opening snap and increased intensity of S_1 .

Late signs of mitral stenosis include congestion due to right ventricular failure, with hepatomegaly, ascites, pleural effusion, and peripheral edema. Pulmonary hypertension is associated with the Graham Steell murmur, a blowing diastolic murmur at the right upper sternal border caused by pulmonic insufficiency, and a murmur of tricuspid regurgitation. Murmurs of aortic or mitral regurgitation or both occur with concomitant valve disease.

LABORATORY FINDINGS

Electrocardiogram and Chest Radiograph

Mitral stenosis is associated with "P mitrale" on ECG, with broadened, notched P waves in the inferior leads due to left atrial enlargement. Atrial fibrillation is common. Pulmonary hypertension is associated with right axis deviation and right ventricular hypertrophy. The chest radiograph is associated with classic findings. Left atrial and pulmonary venous hypertension result in apical redistribution and prominent vascularity in the lung parenchyma, with interstitial edema and peribronchial and perivascular cuffing. Edema in the interlobular septa results in Kerley's B lines, horizontal lines at the lung bases extending to the pleural surfaces. With more advanced disease, there may be pulmonary edema and pleural effusions. Fine, diffuse interstitial nodularity may occur due to hemosiderin deposits after recurrent episodes of hemoptysis. The cardiac silhouette reveals prominent pulmonary arteries. Left atrial enlargement results in straightening of the left heart border and splayed bronchi with elevation of the left mainstem bronchus.

Echocardiography and Doppler Imaging

M-mode echocardiography reveals classic findings associated with mitral stenosis, including thickening of the mitral leaflets with decreased excursion, decreased E-F slope, and anterior motion of the posterior leaflet. Two-dimensional imaging reveals variable degrees of thickening and calcification of the mitral leaflets and submitral apparatus. There is a characteristic "doming" or "hockey stick" appearance when the leaflets remain pliable. An example of mitral stenosis with pliable leaflets is shown in [Figure 77.6](#). When thickening and calcification are more advanced, the mitral valve appears as a solid, calcified mass. The left atrium is enlarged and, in the presence of pulmonary hypertension, there is right ventricular enlargement and hypertrophy. The severity of mitral stenosis is established by Doppler-derived transvalvular pressure gradients, and estimation of orifice area using planimetry on two-dimensional imaging or pressure half-time of transmitral Doppler. Tricuspid regurgitation velocity provides an estimate of right ventricular systolic pressure. Color-flow Doppler imaging is useful to assess the presence and severity of associated mitral or aortic regurgitation. Transesophageal imaging is invaluable in the assessment for thrombi within the body or appendage of the left atrium.

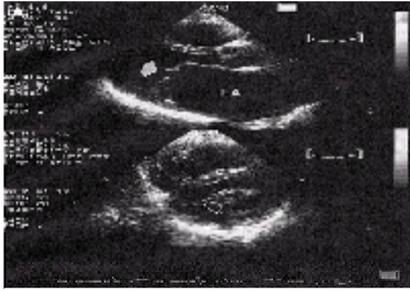

FIGURE 77.6. Transthoracic echocardiogram of patient with rheumatic mitral stenosis. Upper panel shows restricted but pliable leaflets (*arrow*) with doming. Lower panel shows diminished valve orifice *en face* (*open arrow*). LA, left atrium.

Cardiac Catheterization

Invasive techniques usually add little to the anatomical, functional, and hemodynamic information available on echocardiographic and Doppler imaging. Stenosis severity and pulmonary arterial pressures should be assessed at catheterization if right ventricular pressure is elevated out of proportion to stenosis severity on echocardiography or if there is a discrepancy between severity of symptoms and disease on noninvasive imaging. Coronary anatomy should be assessed before surgery in patients with risk factors for coronary artery disease.

Exercise Testing

Exercise testing with Doppler imaging is useful among patients with symptoms of dyspnea or fatigue and evidence of only mild or moderate mitral stenosis at rest. Because early symptoms of mitral stenosis are precipitated by tachycardia, exercise may reveal a sharp increase in transvalvular pressure gradients and right ventricular systolic pressure in patients with functionally significant stenosis but only modest abnormalities at rest.

OPTIMAL MANAGEMENT

Medical Therapy

Patients should receive prophylaxis against endocarditis. In addition, patients with a history of rheumatic fever or evidence of rheumatic valve disease should receive secondary prophylaxis against recurrent infection, usually with monthly intramuscular injections of 1.2 million U of benzathine penicillin G. Patients in sinus rhythm with exertional symptoms at rapid heart rate may benefit from rate control using β - or calcium channel blocking agents. Salt restriction and diuretic therapy are useful if there is dyspnea due to pulmonary congestion. Although medical therapy may be useful in patients with mild symptoms of mitral stenosis, surgical or percutaneous intervention is indicated among patients with severe mitral stenosis and more advanced symptoms or with evidence of significant pulmonary hypertension complicating mitral stenosis.

Patients with mitral stenosis are at risk of systemic embolization. Risk is further increased with advanced age, atrial fibrillation, or history of embolic event. Patients with mitral stenosis and either atrial fibrillation or history of embolization should receive long-term anticoagulation therapy. Long-term anticoagulation is more controversial among patients with mitral stenosis and neither atrial fibrillation nor prior embolic event, but should be considered if mitral stenosis is moderate or severe or if the left atrium is significantly enlarged.

Atrial Fibrillation

Atrial fibrillation is a common complication of mitral stenosis and may exacerbate symptoms owing to both loss of atrial contraction and associated tachycardia. For many patients, the diagnosis of mitral stenosis is first made only after the occurrence of atrial fibrillation. Atrial fibrillation increases the risk of thromboembolism. Acute therapy consists of anticoagulation and rate control. Electrical cardioversion should be performed for hemodynamic instability. Elective cardioversion should be performed weighing the risks of atrial fibrillation, including tolerance of symptoms and risk of thromboembolism, against the likelihood of successful cardioversion and long-term maintenance of sinus rhythm, impacted by the chronicity of atrial fibrillation, and degree of left atrial dilation. Patients should be anticoagulated during and for ≥ 3 weeks after cardioversion to reduce the risk of systemic embolization, and for ≥ 3 weeks before cardioversion unless no left atrial thrombus is established on transesophageal echocardiography.

Percutaneous and Surgical Valvotomy

Percutaneous balloon valvotomy results in acute decrease in transvalvular gradient and increase in orifice area in most patients, with good long-term results in some. Echocardiographic imaging identifies patients with favorable valve morphology based on leaflet mobility, absence of leaflet thickening and calcification, and relative sparing of the subvalvular apparatus. In general, the procedure results in a 50% to 60% decrease in pressure gradients and an increase in valve area from about 1.0 to 2.0 cm². Event-free survival, with freedom from death, mitral valve replacement, and another valvotomy, is 50% to 60% at 3 to 7 years and 80% to 90% among patients with the most favorable valve morphology. Acute procedural complications include severe mitral regurgitation in 2% to 10% of patients and persistent, hemodynamically significant atrial septal defect in less than 5% to 12%, with lesser risks of embolic events, myocardial infarction, and left ventricular perforation. Success is greater and procedural risks lower when performed in patients selected for optimal valve morphology and in centers with high procedural volume. Relative contraindications include left atrial thrombus and preexisting moderate or severe mitral regurgitation.

Among appropriately selected patients, there is no difference in hemodynamics, functional improvement, or procedural complications between percutaneous balloon mitral valvotomy and open surgical commissurotomy on either early and later follow-up. Either procedure may delay or avoid mitral valve replacement. Percutaneous balloon mitral valvotomy may be the procedure of choice in appropriate centers with skilled operators for selected patients with favorable valve morphology and absence of both significant mitral regurgitation and left atrial thrombus. Percutaneous balloon valvotomy may be an especially attractive alternative to surgery in young women who wish to bear children, in whom warfarin is contraindicated and tissue prostheses have limited durability.

Mitral Valve Surgery

Intervention is indicated for patients with moderate or severe mitral stenosis and intolerable symptoms, presence of pulmonary hypertension regardless of symptoms, or recurrent thromboembolism despite adequate anticoagulation. Open commissurotomy provides good results in selected patients with mitral stenosis. Patients with significant fibrosis and calcification of the mitral leaflets or with more advanced subvalvular fusion are less likely to have a successful result with either percutaneous balloon valvotomy or open surgical commissurotomy. Mitral valve replacement is indicated for patients who require intervention for mitral stenosis but who are not good candidates for percutaneous valvotomy or open commissurotomy.

The decision of prosthesis type for individual patients begins with an assessment of the relative risks and benefits of each choice. Mechanical prostheses have greater durability but significant thrombogenicity, whereas tissue prostheses have lower thrombogenicity and no independent requirement for anticoagulation but more limited durability. Mechanical prostheses in the mitral position have greater thrombotic risk than those in the aortic position due to the larger orifice area and lower velocity blood flow crossing the prosthesis.

MITRAL REGURGITATION

DEFINITION

Mitral regurgitation occurs as an acute or chronic process of left ventricular volume overload due to incompetence of the mitral valve, with blood ejected from the left ventricle into both the low-pressure left atrium and the high-pressure aorta. Trivial amounts of mitral regurgitation are physiologic and normal. Pathologic amounts of mitral regurgitation are typically graded by the size of the regurgitant jet alone or relative to the size of the left atrium. As with aortic regurgitation, semiquantification of mitral regurgitation severity on both noninvasive and invasive testing uses arbitrary criteria, and overlap occurs between categories. Regurgitant volume and regurgitant fraction can be quantified using invasive and noninvasive techniques but are of limited clinical importance.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

The mitral apparatus is a complex structure comprising the leaflets, annulus, chordae tendineae, papillary muscles, and, in some respects, the entire left ventricle. Disease or geometric change involving any of these structures can result in mitral regurgitation. Regurgitation caused by abnormal leaflet anatomy can be due to congenital or rheumatic disease, myxomatous degeneration, connective tissue diseases, and infective endocarditis. Congenitally cleft anterior leaflet usually occurs as part of an endocardial cushion defect with associated primum atrial septal defect, paramembranous ventricular septal defect, and abnormalities of the tricuspid valve; regurgitation is present from a young age. Connective tissue diseases associated with mitral regurgitation include systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, and scleroderma. Valvular involvement in connective tissue diseases is variable; about 50% of patients with systemic lupus erythematosus have detectable mitral regurgitation, and approximately 25% have significant regurgitation. Myxomatous degeneration (mitral valve prolapse) is discussed separately.

Ischemic mitral regurgitation is caused by incomplete mitral leaflet coaptation due to ischemic changes in left ventricular geometry or function and restricted leaflet motion. Sufficient myocardial ischemia can cause transient mitral regurgitation. Any myopathic process that causes left ventricular dilation can cause mitral regurgitation by a similar mechanism, with restricted leaflet motion and incomplete leaflet coaptation. Dysfunction of mechanical and bioprosthetic valves can also lead to regurgitation. Small amounts of paraprosthetic regurgitation are common; larger paravalvular leaks can cause significant regurgitation, often with associated hemolysis. Acute severe mitral regurgitation is caused by infective endocarditis, acute myocardial infarction with papillary muscle rupture or retraction, or prosthetic valve dysfunction.

PATHOGENESIS

Lesion Pathogenesis

Rheumatic disease of the mitral valve usually occurs years after rheumatic fever and may occur with concomitant mitral stenosis or rheumatic involvement of the aortic or tricuspid valve. The leaflets and subvalvular apparatus are typically involved. Mitral annular calcification predominantly occurs in older patients and in patients with conditions associated with ectopic calcification, including patients with end-stage renal failure. Although a common cause of mitral regurgitation, it is not usually severe. Infective endocarditis results in mitral regurgitation caused by destruction of leaflet tissue, submitral structures, or, more rarely, mechanical interference with valve function caused by a vegetation. Coronary artery disease causes mitral regurgitation based on papillary muscle ischemia or infarction with scarring and retraction. Papillary muscle rupture can complicate a small, otherwise hemodynamically well-tolerated myocardial infarction, usually involving the right coronary artery or, less often, the left circumflex artery. Mild mitral regurgitation is a normal finding associated with most mechanical prostheses. Dysfunction of a mechanical prosthetic valve can cause more significant regurgitation, and fracture of a calcified tissue prosthesis results in acute regurgitation. Paravalvular regurgitation of any severity can occur with either mechanical or tissue prostheses owing to annular calcification, infection, or suture failure.

Any myopathic process can be associated with secondary mitral regurgitation caused by left ventricular dilation and incomplete leaflet coaptation. A vicious cycle develops in which the left ventricular volume overload of mitral regurgitation adds to the volume overload of the underlying myopathic process. Progressive left ventricular dilation and progressive mitral regurgitation result in a scenario in which “mitral regurgitation begets mitral regurgitation.”

Hemodynamic Pathogenesis

Mitral regurgitation results in left ventricular volume overload with left ventricular ejection into both the high-impedance aorta and the compliant, low-impedance left atrium. In chronic mitral regurgitation, left atrial dilation maintains low left atrial and pulmonary venous pressures. Forward cardiac output is maintained by compensatory left ventricular dilation with increases in left ventricular end-diastolic volume, ejection fraction, and stroke volume. Patients typically remain entirely asymptomatic during this phase of compensated mitral regurgitation, which may last for years. However, prolonged left ventricular volume overload eventually leads to left ventricular systolic dysfunction and pulmonary congestion, with increasing left ventricular end systolic volume and decreasing ejection fraction and forward cardiac output. Because left ventricular emptying does not rely on overcoming high aortic pressure, left ventricular stroke volume remains elevated and ejection fraction remains within the normal range despite progressive systolic dysfunction. Late in the course of disease, left ventricular ejection fraction falls below normal.

In acute severe mitral regurgitation, limited left atrial distensibility leads to acutely increased left atrial and pulmonary venous pressures and pulmonary edema. Although the increased preload associated with acute severe mitral regurgitation results in a modest increase in total left ventricular stroke volume, the absence of compensatory left ventricular dilation results in reduced forward stroke volume and forward cardiac output.

CLINICAL FINDINGS

History

Patients with chronic mitral regurgitation remain asymptomatic for an extended period. Later, patients develop symptoms of fatigue and exertional dyspnea, followed by more overt symptoms of congestive heart failure, including orthopnea and paroxysmal dyspnea. Symptoms are typically insidious at onset, and patients frequently fail to recognize the gradual fatigue and subtle exercise limitations associated with chronic severe mitral regurgitation. In distinction, patients with acute severe mitral regurgitation are almost always symptomatic, with fulminant symptoms of pulmonary edema.

Physical Findings

Patients with chronic severe mitral regurgitation often have a hyperactive precordium and displacement of the left ventricular apical impulse due to left ventricular enlargement. A late systolic left parasternal lift due to left atrial expansion may be present, which, in conjunction with an apical heave, results in a rocking motion of the precordium. An apical systolic thrill may be evident. S_1 is usually normal, although it may be encompassed by the systolic murmur and difficult to appreciate. An S_3 is often present and not necessarily indicative of ventricular failure. The classic murmur of mitral regurgitation is a loud, blowing holosystolic murmur that may obliterate S_1 and S_2 . The murmur is usually loudest at the apex with radiation to the axilla or to the back, although it is often audible throughout the precordium. Mitral regurgitation caused by leaflet flail is usually eccentric, and the murmur associated with posterior leaflet flail radiates anteriorly to the left sternal border. The large volume of blood crossing the mitral valve in diastole causes turbulent flow in patients with severe regurgitation, causing a diastolic rumble despite absence of mitral stenosis.

The systolic murmur associated with acute severe mitral regurgitation may be decrescendo rather than holosystolic because of early equilibration of left atrial and left ventricular pressures in the setting of a normal-sized left atrium. The apical left ventricular impulse is not displaced. S_3 and S_4 are common.

LABORATORY FINDINGS

Electrocardiogram and Chest Radiograph

The ECG and chest radiograph may reveal evidence of left atrial or left ventricular enlargement in patients with chronic mitral regurgitation. Later, the ECG may disclose atrial fibrillation.

Echocardiography and Doppler Imaging

Echocardiographic imaging allows assessment of left atrial and left ventricular size and systolic function. Mitral valve anatomy can usually be seen sufficiently to allow

assessment of the underlying cause of mitral regurgitation. Examples of incomplete mitral leaflet coaptation and valve perforation due to infective endocarditis are shown in [Figure 77.7](#) and [Figure 77.8](#), respectively. Transesophageal echocardiography provides superb visualization of mitral valve anatomy and almost always allows sufficient visualization to define the cause of regurgitation. Left ventricular wall motion abnormalities associated with coronary artery disease may be evident. However, a small wall motion abnormality accompanying papillary muscle rupture complicating a small myocardial infarction may be obscured by the hyperdynamic left ventricle associated with acute severe mitral regurgitation. Color-flow Doppler imaging allows semiquantitative assessment of mitral regurgitation severity and jet characteristics that may help with determination of cause of regurgitation. Evidence of concomitant valve disease or pulmonary hypertension also may be evident. Among patients with chronic mitral regurgitation, accurate quantitative assessment of left ventricular size and systolic function are important as a baseline with which future studies are compared.

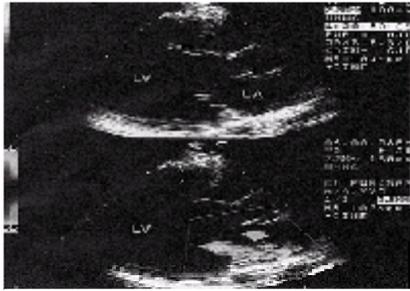

FIGURE 77.7. Transthoracic echocardiogram of patient with dilated cardiomyopathy and mitral regurgitation (*arrow*). There is incomplete mitral leaflet coaptation owing to left ventricular and mitral annular dilation. LA, left atrium; LV, left ventricle.

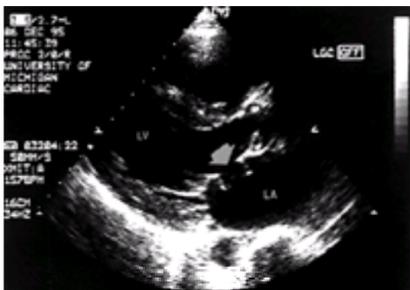

FIGURE 77.8. Transthoracic echocardiogram demonstrating large anterior mitral leaflet perforation (*arrow*) in patient with infective endocarditis. Severe mitral regurgitation was present. LA, left atrium; LV, left ventricle.

Cardiac Catheterization

Left ventriculography allows assessment of left ventricular ejection fraction and semiquantitative assessment of mitral regurgitation severity, both of which are usually available using noninvasive imaging. Cardiac catheterization is useful for assessment of coronary anatomy in patients at risk for coronary disease who are undergoing mitral valve surgery and among patients with suspicion for ischemic cause of mitral regurgitation.

Exercise Testing

Mitral regurgitation is a dynamic lesion and, especially in the setting of ischemic mitral regurgitation, severity can worsen with exercise. Although exercise testing is not contributory in most patients, stress testing with Doppler imaging may be useful among patients with exertional symptoms and only mild or moderate mitral regurgitation at rest.

OPTIMAL MANAGEMENT

Medical Therapy

The goal of medical therapy for acute severe mitral regurgitation is to decrease the severity of mitral regurgitation and thereby increase forward cardiac output and minimize pulmonary venous congestion. Nitroprusside decreases afterload and results in lower regurgitant volume and increased forward cardiac output. Nitroprusside is useful alone in normotensive patients with acute severe mitral regurgitation, or in combination with an inotropic agent in patients with hypotension. Intra-aortic balloon counterpulsation is a useful adjunct in patients with acute severe mitral regurgitation and hypotension or pulmonary edema, resulting in decreased afterload, decreased regurgitant volume, and increased forward cardiac output.

As with other patients with valvular heart disease, appropriate antibiotic prophylaxis should be used among patients with chronic mitral regurgitation. Although afterload reducing agents may decrease the severity of mitral regurgitation and are advocated by some for asymptomatic patients with chronic severe mitral regurgitation, the benefits of long-term therapy have not been tested.

Serial Testing

Asymptomatic patients with mild mitral regurgitation and normal left ventricular systolic function should undergo periodic assessment, including history and physical examination on approximately a yearly basis. After the initial documentation of mild mitral regurgitation, echocardiographic imaging should be repeated if there are new symptoms or evidence on physical examination of worsened regurgitation. Patients with moderate mitral regurgitation should undergo yearly assessment, including history, physical examination, and echocardiographic imaging to assess for new symptoms or signs of heart failure and to monitor left ventricular size and function. Asymptomatic patients with severe mitral regurgitation should undergo history, physical examination, and echocardiography every six to 12 months, with more frequent testing if symptoms develop or if there is progressive left ventricular dilation or decreasing left ventricular systolic function on echocardiography. Establishing accurate baseline measures of left ventricular size and ejection fraction are important for future comparison.

Because preoperative left ventricular systolic function is an important predictor of postoperative survival, patients should be referred for surgical intervention before the onset of left ventricular systolic dysfunction. Ejection fraction overestimates left ventricular systolic function in patients with mitral regurgitation because blood is also ejected into the low-impedance left atrium; the ejection fraction remains in the normal range after the onset of systolic dysfunction.

Mitral Valve Surgery

Alternatives for mitral valve surgery include mitral valve repair and mitral valve replacement with or without chordal preservation. Mitral valve replacement without chordal preservation results in loss of ventricular systolic shortening and lower postoperative left ventricular systolic function, functional class, and survival. Mitral valve repair minimizes the use of prosthetic material, thus obviating the need for long-term anticoagulation and reducing the risk of endocarditis. Repair is often associated with more favorable hemodynamics compared with valve replacement, and there is no risk of prosthetic valve failure. However, mitral repair is a more technically demanding procedure requiring substantial surgical skill and expertise, and it may not be feasible for all valves. Intraoperative echocardiography is used to

assess the adequacy of repair. Despite a more technically demanding procedure with longer extracorporeal circulation times, mitral valve repair is associated with lower operative and subsequent mortality compared with valve replacement. Mitral valve repair should be considered the surgical procedure of choice if valve morphology is amenable to reconstruction and if appropriate surgical expertise is available.

Mitral valve surgery is indicated for patients with severe mitral regurgitation and either symptoms of heart failure or evidence of left ventricular systolic dysfunction, defined as left ventricular ejection fraction less than 60% or left ventricular end-systolic diameter ≥ 45 mm. Although severe left ventricular systolic dysfunction before surgery is associated with increased operative and later mortality, symptomatic patients should nonetheless undergo consideration for surgical intervention. Some asymptomatic patients with normal left ventricular systolic function may benefit from early surgical intervention with the goal of preventing the sequelae of chronic mitral regurgitation, if there is a good likelihood of successful valve repair. Asymptomatic patients with severe mitral regurgitation and progressive left ventricular dilation or with atrial fibrillation of recent onset, and patients with new severe mitral regurgitation should be considered for mitral repair.

MITRAL VALVE PROLAPSE

DEFINITION

Mitral valve prolapse is a fairly common syndrome of myxomatous degeneration of the mitral valve leading to redundant leaflets and elongation of chordae tendineae. Patients with mitral valve prolapse syndrome have a propensity to premature valve degeneration with chordal rupture, leaflet flail, and mitral regurgitation. Other features of the syndrome include atypical chest pain, palpitations due to atrial and ventricular arrhythmias, and possibly panic attacks. In distinction, isolated prolapse of a normal mitral valve can be seen on echocardiography in some patients with no propensity to valve degeneration or regurgitation, and mitral valve prolapse may be incorrectly diagnosed. Normal mitral valve leaflets can prolapse into the left atrium in the setting of volume depletion or hyperdynamic left ventricle. On echocardiography, the diagnosis of mitral valve prolapse should be reserved for patients with evidence of prolapse and leaflet thickening or mitral regurgitation, or prolapse with coaptation of the mitral leaflets on the left atrial side of the annulus.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

Mitral valve prolapse occurs in 2% to 6% of the adult population and is found in more women than men. However, sequelae of mitral valve prolapse, including surgery for mitral regurgitation, appear to be more common in men who carry the diagnosis than in women. Presentation is usually in young adulthood, with evidence of an autosomal dominant inheritance pattern. Mitral valve prolapse is associated with connective tissue diseases, and most patients with Marfan syndrome have mitral valve prolapse. There is an increased incidence of atrial septal aneurysm and secundum atrial septal defect among patients with mitral valve prolapse. Left ventricular dilation can mask the presence of mitral valve prolapse. Patients with Marfan syndrome and chronic severe aortic regurgitation may not have echocardiographic evidence of mitral valve prolapse or mitral regurgitation until after aortic valve replacement and subsequent remodeling of the left ventricle. Increased intravascular volume during the second and third trimesters of pregnancy may similarly minimize prolapse, with fewer associated symptoms and reduced severity of mitral regurgitation.

PATHOGENESIS

Mitral valve prolapse can be diagnosed as an incidental finding on either physical examination or echocardiographic imaging. Myxomatous degeneration of the mitral valve and submitral apparatus can lead to rupture of chordae tendineae. Mitral regurgitation due to mitral valve prolapse may be gradually progressive or may worsen acutely with chordal rupture and leaflet flail.

CLINICAL FINDINGS

History

Patients with mitral valve prolapse can remain asymptomatic and never develop any sequelae of the syndrome. Some patients have symptoms of palpitations or atypical, nonexertional chest pain. Palpitations are due to isolated ectopic beats, supraventricular tachycardia, or, more rarely, ventricular arrhythmias. Sudden cardiac death associated with mitral valve prolapse is rare and presumably related to ventricular arrhythmias. The association between mitral valve prolapse and transient ischemic attacks is controversial, as is the association between mitral valve prolapse and panic attacks. The risk of endocarditis is increased among patients with mitral valve prolapse, especially if there is mitral regurgitation or myxomatous degeneration. Symptoms associated with acute and chronic mitral regurgitation are as previously described.

Physical Findings

Patients with mitral valve prolapse can have a classic appearance of thin body habitus. There is an association between mitral valve prolapse and pectus excavatum and straight back. Auscultation reveals one or more high-pitched mid-to-late systolic nonejection clicks. If there is mitral regurgitation without leaflet flail, the murmur begins in systole after the click. Mitral regurgitation and the associated murmur are holosystolic in patients with flail leaflet. The timing of clicks and intensity of the murmur are affected by left ventricular volume. Maneuvers such as squatting, which increase left ventricular volume, result in clicks later in systole and a murmur of lesser intensity, whereas maneuvers such as standing, which decrease left ventricular volume, result in clicks earlier in systole and a murmur of louder intensity.

LABORATORY FINDINGS

Echocardiography and Doppler imaging are extremely useful in the diagnosis and assessment of mitral valve prolapse. Because of the saddle shape of the mitral annulus, the normal mitral valve can appear to prolapse into the left atrium in some imaging planes, and the diagnosis of mitral valve prolapse should rely on the parasternal long-axis view rather than an apical window. Echocardiographic evidence of myxomatous degeneration includes leaflet thickening, annular dilation, and chordal elongation. Doppler imaging allows detection and semiquantification of mitral regurgitation. To avoid inappropriate diagnosis, caution should be used when there is limited echocardiographic evidence of mitral valve prolapse and absence of leaflet thickening, annular dilation, chordal elongation, or mitral regurgitation. Mitral regurgitation associated with mitral valve prolapse with or without leaflet flail is usually eccentric. Jet eccentricity can lead to suboptimal visualization on transthoracic imaging and underestimation of regurgitation severity. Transesophageal imaging should be used if there is poor visualization of valve anatomy or suspicion of significant mitral regurgitation that is not well demonstrated on transthoracic imaging. Examples of mitral valve prolapse on transthoracic echocardiography and flail mitral leaflet on transesophageal imaging are shown in [Figure 77.9](#) and [Figure 77.10](#), respectively.

FIGURE 77.9. Transthoracic echocardiogram in patient with mitral valve prolapse. Upper panel demonstrates prolapse of posterior mitral valve leaflet (*arrow*) behind the plane of the mitral annulus. Lower panel demonstrates associated mitral regurgitation (*open arrow*). LA, left atrium; LV, left ventricle.

FIGURE 77.10. Transesophageal echocardiogram demonstrating flail anterior mitral valve leaflet (*arrow*) complicating mitral valve prolapse. Severe mitral regurgitation was present. *LA*, left atrium; *LV*, left ventricle.

OPTIMAL MANAGEMENT

Patients with mitral valve prolapse and either leaflet thickening on echocardiography or mitral regurgitation based on a murmur or on Doppler imaging should receive appropriate antibiotic prophylaxis for prevention of infective endocarditis. Asymptomatic patients require no additional therapy for mitral valve prolapse. Patients should undergo periodic follow-up with history and physical examination, and echocardiographic imaging if there is evidence of mitral regurgitation.

Patients with palpitations usually require no medical therapy other than reassurance. β -adrenergic antagonists are useful for symptomatic relief. Continuous or event-activated ECG monitoring is useful among patients with recurrent or protracted episodes of palpitations. Patients with focal neurologic events who are in sinus rhythm and have no left atrial thrombus should receive antiplatelet therapy with aspirin. Long-term anticoagulation therapy with warfarin is recommended for patients with no contraindication who either have suffered a stroke or have recurrent transient ischemic attacks while receiving aspirin. Timing of surgery for mitral regurgitation follows the same guidelines as described previously. Early surgical intervention should be considered if valve repair is likely.

TRICUSPID VALVE DISEASE

DEFINITION

Tricuspid stenosis is obstruction to right ventricular inflow due to an anatomical abnormality of the tricuspid valve. Tricuspid regurgitation is incompetence of the tricuspid valve, resulting in ejection of blood from the right ventricle into both the pulmonary artery and the right atrium. Small amounts of tricuspid regurgitation are common and should be considered normal. Semiquantification of tricuspid regurgitation is based on the size of the regurgitant jet relative to the size of the right atrium.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

Primary abnormalities of the tricuspid valve occur far less often than secondary abnormalities. Primary abnormalities include rheumatic disease, infective endocarditis, carcinoid heart disease, and abnormalities caused by anorectic drugs. Congenital abnormalities of the tricuspid valve include Ebstein's anomaly, tricuspid atresia, involvement in endocardial cushion defect, and other complex congenital lesions and are relatively uncommon in an adult population. Rheumatic disease of the tricuspid valve causes stenosis, regurgitation, or both and is almost always seen in conjunction with involvement of other valves. Approximately 5% of patients with rheumatic mitral valve disease also have involvement of the tricuspid valve. Right-sided endocarditis involving the tricuspid valve, especially common in intravenous drug abusers, causes tissue destruction and significant regurgitation. Carcinoid involvement of the tricuspid valve results in characteristic rigidity of the leaflets. Anorectic drugs are discussed below. Secondary tricuspid regurgitation occurs commonly in association with diseases that cause either right ventricular enlargement or pulmonary artery hypertension.

PATHOGENESIS

Tricuspid stenosis results in increased right atrial pressure, with passive congestion of the systemic venous circulation and hepatomegaly, pleural effusion, ascites, and peripheral edema. Tricuspid regurgitation results in right ventricular volume overload, which, similar to mitral regurgitation, is well tolerated for an extended period.

CLINICAL FINDINGS

Isolated tricuspid valve disease rarely results in significant symptoms. Chronic right ventricular volume overload associated with severe tricuspid regurgitation can eventually cause right ventricular systolic dysfunction. Patients with tricuspid stenosis have jugular venous distension and giant a waves generated by systolic contraction of the right atrium against the stenotic tricuspid valve. Auscultation reveals an opening snap and diastolic murmur similar to mitral stenosis, but distinguished by location at the left sternal border and augmentation with inspiration. Tricuspid regurgitation produces jugular *c-v* waves and a pulsatile liver with hepatojugular reflux. Auscultation reveals a holosystolic murmur along the left sternal border, increasing in intensity with inspiration. Both tricuspid stenosis and tricuspid regurgitation result in systemic venous congestion with hepatomegaly, pleural effusion, ascites, and peripheral edema.

LABORATORY FINDINGS

In tricuspid stenosis, the ECG may show evidence of right atrial enlargement with peaked P waves in the inferior leads. The right atrium is enlarged on chest radiograph in both tricuspid stenosis and tricuspid regurgitation. Echocardiography reveals thickened, restricted tricuspid leaflets in tricuspid stenosis and may reveal evidence of underlying valvular pathology including rheumatic disease, endocarditis or carcinoid, or the cause of secondary regurgitation. Doppler imaging is useful for quantification of transvalvular gradient in tricuspid stenosis and for semiquantitative assessment of tricuspid regurgitation. Minimal or mild tricuspid regurgitation is common on echocardiography with Doppler imaging and should be considered a normal finding. The presence of tricuspid regurgitation allows estimation of right ventricular systolic pressure from the velocity of the regurgitant jet, which correlates well with pulmonary arterial systolic pressure in the absence of pulmonic stenosis.

OPTIMAL MANAGEMENT

Therapy of secondary tricuspid regurgitation involves treatment of the underlying disease. Systemic venous congestion can be treated with salt restriction and diuretics. Digoxin may be useful if there is right ventricular systolic dysfunction. Surgical alternatives for tricuspid regurgitation include tricuspid valve repair or replacement. Similar to mitral repair, reconstruction is preferable, if feasible. Mechanical prostheses in the tricuspid position have a relatively high rate of thrombosis, and a bioprosthesis is usually preferable.

PULMONIC VALVE DISEASE

DEFINITION

Pulmonic stenosis is valvular obstruction to right ventricular outflow. Pulmonic regurgitation is incompetence of the pulmonic valve with resultant right ventricular volume overload.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

Isolated pulmonic valve disease is rare. Pulmonic stenosis is nearly always congenital; rare causes include rheumatic disease and involvement in carcinoid syndrome.

Small amounts of pulmonic regurgitation are normal. Pathologic pulmonic regurgitation can be caused by rheumatic disease, infective endocarditis, carcinoid disease, or anorectic drugs. Rheumatic involvement of the pulmonic valve is rare and almost exclusively seen in association with rheumatic involvement of other valves. Right-sided endocarditis can involve the pulmonic valve, although isolated pulmonic valve endocarditis is unusual. Significant pulmonic regurgitation is most commonly caused by pulmonary arterial dilation secondary to pulmonary hypertension.

PATHOGENESIS

Pulmonic stenosis results in right ventricular hypertension and right ventricular hypertrophy, although the presence of pulmonic stenosis protects the pulmonary vasculature from increased pressures. Congenital valvular pulmonic stenosis is often accompanied by infundibular right ventricular hypertrophy with secondary subvalvular outflow obstruction. Pulmonic regurgitation is well tolerated for extended periods. Chronic severe pulmonic regurgitation may lead to right ventricular dilation and eventual systolic dysfunction.

CLINICAL FINDINGS

Patients with mild or moderate pulmonic stenosis are usually asymptomatic. Severe pulmonic stenosis is associated with symptoms of fatigue and exertional dyspnea. Patients with pulmonic regurgitation are also typically asymptomatic, although chronic severe regurgitation can eventually lead to right ventricular failure with hepatomegaly, pleural effusion, ascites, and peripheral edema. The murmur associated with pulmonic stenosis is a high-pitched systolic crescendo-decrescendo murmur distinguished from aortic stenosis by location at the left upper sternal border, increase with inspiration, and continuation beyond the aortic component of S₂. The Graham Steell murmur of pulmonic regurgitation is a soft, decrescendo diastolic murmur at the left upper sternal border.

LABORATORY FINDINGS

Echocardiography and Doppler imaging allow accurate assessment of transvalvular pulmonic gradients and semiquantification of pulmonic regurgitation. Minimal or mild pulmonic regurgitation are common findings on echocardiographic imaging and should be considered normal. The anatomy of the pulmonic valve is often visible on transthoracic echocardiography; transesophageal imaging may be useful for additional interrogation.

OPTIMAL MANAGEMENT

Congenital pulmonic stenosis may be amenable to percutaneous balloon valvotomy. Surgical alternatives include commissurotomy and pulmonic valve replacement using mechanical, heterograft, or allograft prostheses. Pulmonic regurgitation usually requires no specific medical therapy. In pulmonic regurgitation due to pulmonary hypertension, therapy is aimed at treatment of the underlying disease.

VALVE DISEASE ASSOCIATED WITH ANORECTIC DRUGS

DEFINITION

An association has been suggested between acquired valvular heart disease and the anorectic drugs dexfenfluramine and fenfluramine with or without phentermine, which led to the voluntary withdrawal of both dexfenfluramine and fenfluramine in the United States. The observed lesions include thickening of right-sided heart valves, similar to that observed in carcinoid syndrome, and unusual thickening of left-sided valves with associated regurgitation.

ETIOLOGY, INCIDENCE, AND EPIDEMIOLOGY

The incidence of acquired valve disease associated with anorectic drug use is not known. However, risk appears to be associated with duration of therapy. By some estimates, up to 30% of patients who received dexfenfluramine or fenfluramine and phentermine for 6 to 24 months had echocardiographic evidence of significant aortic or mitral regurgitation. The concentration of valve disease in specific geographic locations raises the possibility that additional factors may have contributed to the development of disease.

PATHOGENESIS

Some of the patients who developed valve disease had echocardiographic and histopathologic findings similar to those observed in patients with carcinoid heart disease. The action of the involved anorectic medications as serotonin-releasing agents raises the possibility that the valve lesions occurred as a result of exposure to increased levels of serotonin, although this hypothesis has not been tested.

CLINICAL FINDINGS

Most patients with echocardiographic evidence of regurgitation were asymptomatic. Some patients presented with murmur on physical examination or with symptoms of fatigue referable to the underlying valve lesions. Because valve lesions associated with anorectic drug use occur in a population of patients with substantial obesity, physical findings may be limited.

LABORATORY FINDINGS

Echocardiographic and Doppler imaging demonstrate thickening of one or more valves with associated regurgitation. As previously noted, in some reports the echocardiographic appearance of affected valves resembles those observed in patients with carcinoid heart disease.

OPTIMAL MANAGEMENT

Screening for valvular heart disease among patients who received anorectic drugs should include history and careful physical examination. Echocardiographic imaging should be used if there is evidence of valve disease based on presence of symptoms, heart murmur, or other clinical findings or if body habitus precludes adequate auscultation. In addition, echocardiographic imaging should be considered for patients who are at risk of cardiac involvement in whom a procedure is anticipated that would require antibiotic prophylaxis in the setting of significant valve disease. The specific regurgitant valve lesions are treated as previously outlined.

CHAPTER 78: CONGENITAL HEART DISEASE IN THE ADULT

TOMAS RYAN AND J. KEVIN HARRISON

[General Approach to the Patient](#)
[Common and Uncommon Congenital Heart Diseases: Natural Survival Patterns](#)
[Postoperative Congenital Heart Disease](#)
[Medical Management Issues](#)

Congenital heart diseases are those cardiac malformations present at birth. Traditionally, the care of patients with these disorders—even those who survived to adulthood—was provided by pediatricians and pediatric cardiologists. In recent years, it has become increasingly common for internists and “adult” cardiologists to assume the care of these patients as they grow older. Several factors are responsible for this trend.

An estimated more than 500,000 adult patients in the United States have congenital heart disease. Of the 25,000 infants born with congenital heart disease every year, about 85% are now expected to reach adulthood. As this population continues to grow—in number, complexity, and age—the need for ongoing specialized cardiac care will expand. With aging, the health care requirements of these patients will change as acquired medical problems compound the congenital ones. It is neither feasible nor appropriate to expect the pediatric physician to assume this responsibility throughout the patient’s adult life. Training programs and specialized clinics are some examples of recent efforts to address this need.

Various factors have contributed to this growing population of older patients with congenital heart diseases. Perhaps most important are the improvements and innovations in the surgical management of young patients. Over the past several decades, these developments have had a profound impact on survival patterns. The variety and complexity of surgical options have grown so that relatively few lesions remain inaccessible to the surgeon. Despite these often extraordinary advances, few patients can be considered “cured,” and most require ongoing cardiac care.

In addition, improvements in cardiac catheterization now allow more accurate diagnoses for patients with congenital heart disease. Percutaneous therapeutic options now exist for some patients who would have previously required surgery.

We can conclude the following: the number of adults with congenital heart disease will continue to grow; most of these patients will undergo palliative or reparative surgery but will require ongoing specialized medical care to provide access to new developments in therapy; and the assessment and management of these patients will become increasingly complex over time.

This chapter focuses on the diagnosis and management of adults with congenital heart disease. Problems unique to older patients, such as those related to pregnancy, are discussed. Only lesions with expected adult survival are covered, and emphasis is placed on the malformations encountered most frequently. Because most adult patients will undergo some form of surgery, postoperative evaluation and management are also stressed. In addition, the final section of the chapter describes some of the newer percutaneous therapeutic options that exist for specific congenital cardiac problems.

GENERAL APPROACH TO THE PATIENT

Adults with congenital heart disease may be categorized as having either a natural or an unnatural history. *Natural history* refers to the unoperated condition and includes patients presenting for the first time, those with mild or well-tolerated lesions who have not required intervention, and those who have been considered inoperable or have declined surgical repair. With the increasing availability of accurate diagnostic tools, relatively few patients remain undiagnosed until adulthood. As a result, the population of adult patients with a natural history is shrinking, and most have either mild, simple lesions or very advanced and inoperable defects.

Unnatural history refers to disease whose course has been altered by an intervention, usually surgical. In these patients, a diagnosis has been established and either palliation or repair has been previously performed. In many patients, many procedures have been done over a span of decades, often at different institutions. Unless an up-to-date medical record is available, a major challenge for the physician is to determine the underlying condition and what has been done to alter it. These patients now make up the largest group of patients followed up in most adult congenital heart disease clinics.

The initial evaluation of the adult patient with known or suspected congenital heart disease is greatly facilitated by a thorough review of the medical record. A complete history and physical examination, electrocardiogram (ECG), chest radiograph, and, in most cases, an echocardiogram should be performed. Laboratory studies often include a complete blood count, iron studies, measurement of electrolytes, urea nitrogen, and creatinine, and uric acid and clotting tests. This battery of diagnostic studies provides most of the information needed for a complete initial assessment.

A multidisciplinary approach is recommended for the long-term management of these patients. The involvement of both pediatric and adult cardiologists has several advantages. The array of medical problems encountered in these young patients often includes both congenital and acquired conditions. Input from the different subspecialists is ideal in these situations. The presence of the two cardiologists also facilitates the smooth transfer of care from the pediatric to the adult cardiologist. Other key members of the health care team may include the cardiovascular surgeon, obstetrician, hematologist, geneticist, and nurse specialist.

COMMON AND UNCOMMON CONGENITAL HEART DISEASES: NATURAL SURVIVAL PATTERNS

AORTIC VALVE DISEASE

A congenitally malformed aortic valve that is stenotic at birth is usually either unicuspid or dysplastic. More commonly, the valve is bicuspid and functionally normal at birth but becomes increasingly regurgitant or stenotic in the third or fourth decade. Calcification is rare until later in life. Other forms of left ventricular outflow tract obstruction, including subvalvular and supra-ventricular aortic stenosis, account for less than 20% of all cases in most series.

Symptoms of aortic stenosis include syncope, exertional dyspnea, and chest pain. Sudden death is uncommon in children. In young patients, the presence of an early systolic ejection sound or “click” is useful to distinguish the valvular from subvalvular and supra-ventricular forms. The associated systolic ejection murmur, present in almost all patients, is of limited value in assessing severity. In a young patient, evidence of left ventricular hypertrophy on the ECG suggests severe aortic stenosis.

The natural history of congenital aortic valve disease varies. The eventual need for aortic valve replacement is directly related to the severity of stenosis at the time of presentation. In young adults with a nonstenotic bicuspid aortic valve, progression to significant stenosis is rare. Ongoing surveillance is necessary to detect the development of aortic regurgitation or endocarditis. Echocardiography is a useful adjunct to the physical examination for this purpose. If mild stenosis is present, progression can occur, and about 20% of patients eventually require intervention. If moderate stenosis is present, up to 50% progress to severe stenosis and ultimately need surgery.

Many young adult patients with congenital aortic stenosis have undergone valvotomy in childhood, and the natural history of these patients is especially unpredictable. In one large multicenter registry, about one-third of these patients required aortic valve replacement after 20 years. The indication for surgery was either progressive stenosis, in the majority, or severe regurgitation. Longitudinal follow-up, usually on an annual basis, is recommended in these young patients. To assess the severity of aortic valve disease, echocardiography is most often used for serial evaluation.

PULMONIC STENOSIS

In 80% of cases, obstruction of right ventricular outflow occurs at the level of the pulmonary valve. The valve may be dysplastic, resulting in severe stenosis and often heart failure in infancy, or it may be tricuspid, with thickening and partial fusion of the leaflets, producing a conical or dome-shaped structure. An atrial septal defect (ASD) often accompanies this lesion. Pulmonic stenosis leads to elevated right ventricular pressure and subsequent hypertrophy, which may produce an element of subvalvular obstruction ([Fig. 78.1](#)). A systolic, crescendo–decrescendo murmur is generally present from birth, and the diagnosis is rarely overlooked. Symptoms such as fatigue or exertional dyspnea are uncommon until early adulthood and correlate poorly with the gradient. Cyanosis suggests severe stenosis in association with

right-to-left shunting through an ASD or patent foramen ovale. Right ventricular failure is a late development. If the stenosis is severe, balloon or surgical valvotomy is undertaken in childhood, usually with excellent results.

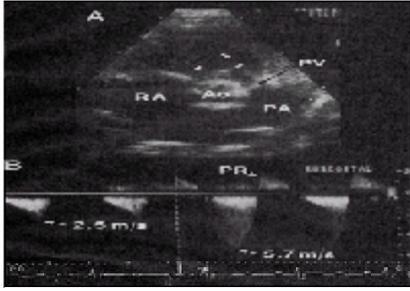

FIGURE 78.1. Two-dimensional echocardiogram (A) and Doppler recording (B) from a patient with both subvalvular and valvular pulmonic stenosis. In the short-axis view (A), right ventricular hypertrophy and infundibular narrowing are apparent (arrowheads). The pulmonic valve (PV) is thickened. In B, Doppler demonstrates both subvalvular and valvular obstruction. A dynamic subvalvular gradient of about 25 mm Hg (left) and a maximum gradient at the level of the valve of 130 mm Hg (right) are noted. Pulmonic regurgitation (PR) is also present. Ao, aorta; RA, right atrium; PA, pulmonary artery. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994:365, with permission.)

The diagnosis of pulmonic stenosis can be confidently made at the bedside. A long and late-peaking systolic ejection murmur heard best at the upper left sternal border indicates significant stenosis. Other indicators of severe stenosis include a soft and very delayed pulmonary closure sound, a right-sided fourth heart sound, and a substernal lift due to right ventricular hypertrophy and dilation.

The adult with pulmonic stenosis has a relatively favorable prognosis. Significant progression is uncommon, so mild to moderate pulmonic stenosis can be managed conservatively. If obstruction is severe or if symptoms accompany moderate pulmonic stenosis, intervention is indicated. In most institutions, percutaneous balloon valvotomy is preferred in both children and adults with valvular stenosis. The procedure is less successful for dysplastic valves. Recurrent stenosis rarely occurs and iatrogenic pulmonic regurgitation is usually mild. Persistent right ventricular dysfunction, probably due to myocardial fibrosis, may occur despite successful repair, especially in older patients. The long-term significance of this requires further study. In most cases, however, adequate valvotomy is associated with relief of symptoms and improved exercise capacity.

ATRIAL SEPTAL DEFECT

ASDs are classified on the basis of the location of the defect within the septum. The most common type, a secundum ASD, involves the primum portion of the atrial septum and is often encountered in adults. Because of the paucity of symptoms in childhood and the often subtle or unremarkable physical findings, the diagnosis is delayed until adulthood in many patients. With age, the decrease in left ventricular compliance causes elevation of the left atrial pressure and increased left-to-right shunting through the ASD. Thus, for a given ASD size, greater shunting and right ventricular volume overload occurs with age. This increase in the volume load on the right heart may lead to atrial arrhythmias, exercise intolerance, or frank right-sided congestive heart failure, bringing the adult patient with a previously unrecognized ASD to medical attention. Thus, by the third or fourth decade symptoms are common—usually dyspnea, fatigue, or palpitations. Other presentations in adults include peripheral or central nervous system (CNS) emboli due to paradoxical embolism.

Unrepaired primum ASDs are uncommon in adults. These defects involve the most apical portion of the atrial septum at the insertion of the atrioventricular valve leaflets, which are usually structurally abnormal, most often exhibiting a cleft anterior mitral leaflet. Even after surgical repair, many patients continue to have atrioventricular valve regurgitation. These patients require serial echocardiographic reevaluation. Some eventually require reoperation to prevent ventricular dysfunction and congestive failure.

Venous ASDs are less common than secundum defects and often lead to symptoms in adulthood. Venous ASDs involve the superior vena cava–right atrium junction and are truly defects in the floor of the superior vena cava. The right upper pulmonary vein normally travels just posterior to the superior vena cava at this point; the floor of the superior vena cava serves as the “roof” of the right upper lobe pulmonary vein. A venous defect in the floor of the superior vena cava–right atrium junction “unroofs” the right upper lobe pulmonary vein, which preferentially drains into the lower pressure right atrial chamber. Some speak of this as anomalous pulmonary venous drainage but the right upper lobe pulmonary vein is not anomalously located, and its drainage is correctly rerouted to the left atrium by surgical closure of the venous defect in the floor of the superior vena cava.

Note that echocardiography, and transesophageal echocardiography in particular, has revolutionized our diagnostic ability to define ASDs in adults. ASDs result in a left-to-right shunt and right ventricular volume overload. Congestive heart failure can develop due to right ventricular failure, manifested by an elevated right ventricular diastolic pressure. Atrial fibrillation is a common late complication, but severe pulmonary vascular disease and pulmonary hypertension are rare. As previously described, symptoms may develop or worsen if left ventricular compliance decreases (e.g., due to hypertension or coronary artery disease), thereby augmenting left-to-right shunting.

Physical findings may be subtle. A fixed and widely split second heart sound is characteristic. The basal systolic ejection murmur is due to increased flow across the pulmonary valve (not due to flow through the defect). Mitral regurgitation may be secondary to mitral valve prolapse in secundum defects or may be due to a cleft mitral leaflet in the case of primum defects. The chest radiograph demonstrates an enlarged right heart and increased pulmonary vascularity (Fig. 78.2). The ECG often reveals incomplete right bundle-branch block. A normal or rightward frontal plane axis suggests a secundum ASD (Fig. 78.3); left axis deviation is characteristic of primum defects (Fig. 78.4). Echocardiography is diagnostic and permits assessment of the location and size of the defect (Fig. 78.5). Associated findings and an estimate of right heart pressure can also be determined noninvasively in most patients.

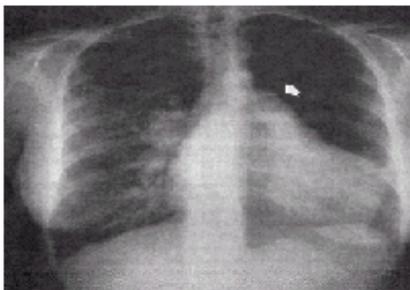

FIGURE 78.2. Chest radiograph from a 28-year-old woman with secundum atrial septal defect. The heart, particularly the right ventricle, is enlarged. The pulmonary artery (arrow) is dilated. Pulmonary vascularity is increased.

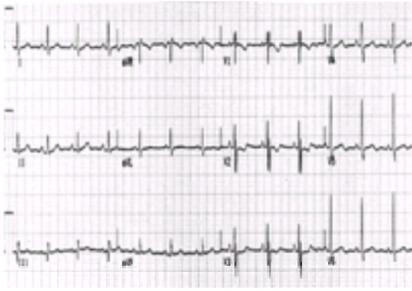

FIGURE 78.3. Electrocardiogram from a patient with secundum atrial septal defect. There is sinus rhythm and incomplete right bundle-branch block. The frontal plane QRS axis is about +30 degrees.

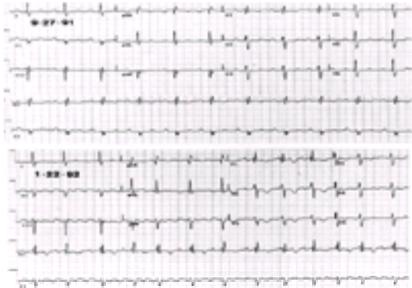

FIGURE 78.4. Serial electrocardiograms from a patient with primum atrial septal defect and mitral regurgitation. The top tracing was recorded before surgical repair. There is sinus rhythm with first-degree atrioventricular block, left-axis deviation, and incomplete right bundle-branch block. The lower tracing was recorded soon after surgical repair. Atrial flutter is noted.

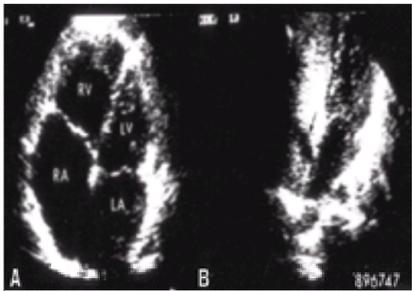

FIGURE 78.5. Two-dimensional echocardiogram from a patient with a large secundum atrial septal defect. **A:** A dilated right atrium (RA) and right ventricle (RV) are demonstrated, as well as echo dropout in the area of the atrial septum. **B:** Injection of agitated saline through a peripheral vein results in negative contrast effect within the right atrium (arrow). This finding is diagnostic of left-to-right shunting through the atrial septal defect. LA, left atrium; LV, left ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

In adults with symptoms, surgical repair should be recommended unless there is severe pulmonary vascular disease. If surgery is performed in young adults, the outlook is excellent, and long-term survival is better than in older patients who undergo repair. If surgery is undertaken later in life, the patient may still benefit; this advantage of surgical therapy seems to be maintained even in elderly patients and those with moderate pulmonary hypertension (pulmonary vascular resistance ≤ 5 Wood units). The management of asymptomatic adults remains controversial. Repair has traditionally been recommended if the left-to-right shunt ratio exceeds 1.5 or 2 to 1. Currently, closure is often recommended in young adults with evidence of right ventricular volume overload based on echocardiography (i.e., right ventricular dilation and paradoxical septal motion). Closure of smaller ASDs, now often detected by transesophageal echocardiography, remains controversial.

Other causes of right heart, right atrium, and right ventricle enlargement in adults include partial anomalous pulmonary venous connection, either with or without an associated ASD. Abnormal congenital development of the pulmonary veins, allowing part of the pulmonary venous drainage to return to the right heart, physiologically causes left-to-right shunting and right ventricular volume overload. In contrast to that which occurs with ASDs, this shunt is fixed and does not tend to increase with age. These patients are often asymptomatic. Those with large shunt volumes may develop symptoms of palpitations, dyspnea on exertion, and fatigue similar to ASD patients as right ventricular compliance deteriorates. Surgical correction for symptomatic patients is feasible and is most often performed by creating a baffle redirecting the anomalous pulmonary venous return. Such a baffle along the floor of the cava and right atrium can be continued to the atrial septum, where, either through a congenital or surgically created ASD, the pulmonary venous return is redirected properly into the left atrium.

PATENT DUCTUS ARTERIOSUS

Persistent patency of the ductus arteriosus is common in children but uncommon in adults. Risk factors for this condition include female gender, maternal rubella, and birth at high altitude. If the ductus does not close spontaneously within the first 2 months of life, it will probably remain patent. This results in a left-to-right shunt, the magnitude of which depends on the size of the channel and the pressure gradient between the aorta and the main pulmonary artery. Blood pressure measurement typically finds wide pulse pressure, with a low diastolic pressure. A typical continuous machinery-like murmur is present at the upper left sternal border, and often there is evidence of left ventricular volume overload, with cardiomegaly and hyperdynamic pulses. The murmur is often heard best below the left clavicle, but it radiates widely and can be easily heard in the back. With the development of pulmonary vascular disease, the diastolic component shortens and becomes softer.

The adult who escaped detection and surgical repair as a child is often symptomatic unless the ductus is small and restrictive. If the shunt is large, left heart failure usually develops in adolescence or early adulthood. Pulmonary hypertension and endocarditis are other important complications of this condition. If Eisenmenger's syndrome is present, an important differentiating point is the occurrence of clubbing and cyanosis distal to the site at which the shunt occurs (beyond the left subclavian artery). Thus, the feet and toes are affected, but the hands and fingers are spared.

Surgical closure of the patent ductus in children may be considered curative, but the decision to close a ductus in an adult is more complex. The presence of pulmonary vascular disease and the residual effects of chronic left ventricular volume overload must be taken into account. The procedure itself is also more difficult, primarily because of the calcification of the aortic end of the channel. Transcatheter closure of patent ducti is an alternative for selected adult patients and is discussed in more detail later.

VENTRICULAR SEPTAL DEFECT

Defects of the ventricular septum vary considerably in size and location. All, however, have a left-to-right shunt, the magnitude of which depends on the size of the

defect and the pulmonary vascular resistance. The most common type involves the region around the membranous septum. Muscular or trabecular defects can occur anywhere within the muscular portion of the septum and may be multiple (Fig. 78.6). An important feature of peri-membranous and trabecular ventricular septal defects is their propensity for spontaneous closure (Fig. 78.7). This occurs more commonly with small defects and is rare after adolescence. Atrioventricular canal-type defects are usually large and affect the most posterior and basal part of the septum. They are often associated with a primum ASD and abnormalities of the atrioventricular valves. Supracristal defects are less common, are usually small, and involve the portion of the septum between the aortic and pulmonic annuli.

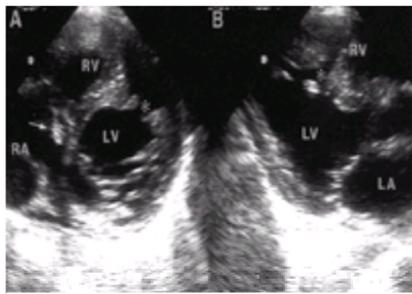

FIGURE 78.6. **A:** A short-axis view through the left ventricle in a patient with bacterial endocarditis complicating a trabecular ventricular septal defect (*). A large echogenic mass is attached to the atrial side of the septal leaflet of the tricuspid valve (arrow). **B:** The long-axis view demonstrates the ventricular septal defect (*) as a complex and irregular channel through the septum. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

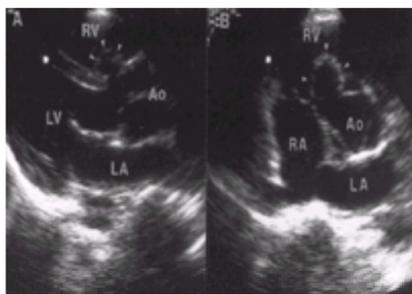

FIGURE 78.7. Two-dimensional echo-cardiograms from a patient with a peri-membranous ventricular septal defect. The defect has closed through formation of a large ventricular septal aneurysm (arrowheads). Doppler imaging confirmed a lack of blood flow through the aneurysm. On examination, the patient had no evidence of a residual ventricular septal defect, but significant aortic regurgitation was present. Ac, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Adults with ventricular septal defect usually have either a small, restrictive defect or a large, unrestrictive defect with elevated pulmonary vascular resistance (Eisenmenger's complex). Patients in the former group are often asymptomatic and present with a loud, harsh holosystolic murmur and associated thrill. Their prognosis is generally favorable, with a cumulative risk of endocarditis (Fig. 78.6) or progressive aortic regurgitation. Obstructive pulmonary vascular disease results in a diminished or reversed shunt and a poor long-term prognosis. This progression is associated with a gradual decrease in the intensity of the murmur. Thus, the disappearance of the murmur in an adult patient generally heralds the development of Eisenmenger's syndrome and should not be misinterpreted as a sign of spontaneous defect closure. In such patients, cyanosis and clubbing develop and exercise tolerance is invariably reduced. Characteristic findings on ECG and chest radiography accompany these changes (Fig. 78.8 and Fig. 78.9). The increase in pulmonary vascular resistance is usually fixed, and surgical repair is rarely an option.

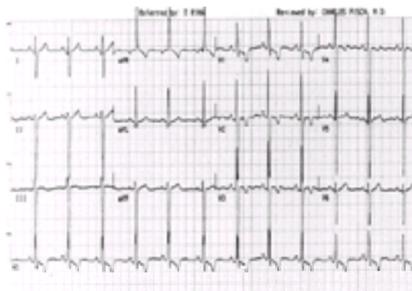

FIGURE 78.8. Electrocardiogram from a patient with complete atrioventricular canal defect and pulmonary hypertension. Sinus rhythm with a right-axis deviation and evidence of right ventricular hypertrophy are found.

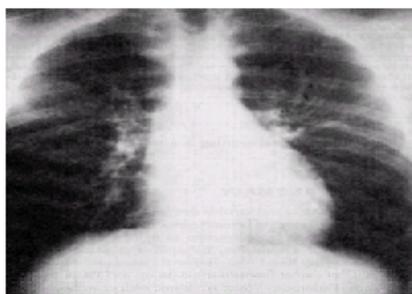

FIGURE 78.9. Chest radiograph from a 23-year-old man with ventricular septal defect. The heart is enlarged. There is evidence of increased pulmonary blood flow, and the pulmonary arteries are dilated (black arrows).

Management of the adult patient with a small, isolated ventricular septal defect must take into account the location of the defect, the pulmonary vascular resistance, the symptom status, and the presence or absence of associated findings, such as aortic regurgitation. Most patients with a small defect are asymptomatic and have

normal pulmonary artery pressure. In the Second Natural History Study of Congenital Heart Defects, the 20-year survival probability for patients with a small ventricular septal defect was over 90%, and 94% of these patients were in the New York Heart Association functional class I. Thus, surgical repair for adults with a small defect and normal pulmonary artery pressure is generally not recommended. The occasional patient with aortic regurgitation in association with a perimembranous or suprasternal defect would, in most institutions, be an exception to this rule. In these patients, surgical closure is often recommended to prevent further undermining of the aortic annulus and progressive regurgitation.

AORTIC COARCTATION

Coarctation of the aorta is characterized by a discrete, shelf-like narrowing of the descending aorta just distal to the origin of the left subclavian artery. As in other forms of left ventricular outflow tract obstruction, the elevation in ventricular pressure is proportional to the severity of the obstruction. In coarctation, however, this increase in pressure proximal to the narrowing is transmitted to the head and upper extremities. Hypertension in a young patient should always suggest the possibility of coarctation. Associated findings include a bicuspid aortic valve (in up to 50% of patients) and berry aneurysms of the circle of Willis.

If symptoms do not develop in infancy, most patients remain asymptomatic until adolescence or early adulthood. At that point, however, the outlook deteriorates dramatically if repair is not performed. By age 30, mortality rate approaches 50%. Death may be due to left heart failure, a ruptured cerebral aneurysm, endocarditis, or a dissecting aortic aneurysm. The diagnosis is often made when hypertension is discovered in a young patient. Diminished and delayed pulses in the lower extremities point to the diagnosis. A harsh systolic murmur is usually audible over the left chest posteriorly. The severity of the coarctation gradient may be estimated by measurement of the systolic blood pressure in the upper extremities compared with that of the lower extremities.

The coarctation can be imaged noninvasively with echocardiography ([Fig. 78.10](#)) or magnetic resonance imaging ([Fig. 78.11](#)). Echocardiography is useful to measure the pressure gradient across the obstruction and permits simultaneous assessment of associated findings, such as left ventricular hypertrophy or a bicuspid aortic valve.

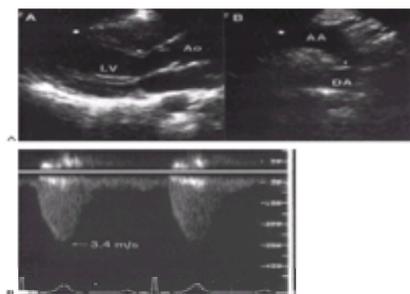

FIGURE 78.10. **A:** The long-axis view of a patient with a bicuspid aortic valve and aortic coarctation demonstrates a thickened aortic valve that domes mildly in systole. **B:** A suprasternal long-axis view of the aortic arch (AA) demonstrates a discrete, shelf-like narrowing (arrowhead) immediately distal to the origin of the arch vessels (arrows). The descending aorta (DA) beyond the coarctation is well visualized. **C:** Continuous wave Doppler recording of flow in the descending aorta reveals a maximal systolic pressure gradient of 46 mm Hg. The gradient diminishes rapidly, and there is little gradient during diastole. Ac, aorta; Lv, left ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

FIGURE 78.11. A magnetic resonance image of the heart in the coronal plane from a patient with aortic coarctation. Narrowing in the descending aorta is indicated by the arrowhead. The distal descending aorta is well visualized. The left ventricular outflow tract is indicated by the asterisk.

In most situations, the initial repair of coarctation is performed surgically. Even when the obstruction is eliminated, however, longevity is not returned to normal. Persistent hypertension and the small risk of stroke or aortic dissection adversely affect the long-term prognosis. Deterioration of a bicuspid aortic valve is also a possibility. For restenosis in adults, the procedure of balloon dilation and stenting is a reasonable alternative to reoperation.

EBSTEIN'S ANOMALY

Apical displacement and variable dysplasia of the tricuspid valve can have a broad range of hemodynamic consequences. Ebstein's anomaly may result in obstruction to right ventricular inflow, right ventricular dysfunction, tricuspid regurgitation, and reduced pulmonary blood flow. Important associated findings include ASD or patent foramen ovale (in up to 75% of patients) and Wolff–Parkinson–White syndrome with or without supraventricular tachyarrhythmias. The clinical course varies, depending on the severity of the deformity and the presence of associated lesions.

Adults with Ebstein's anomaly usually have presenting complaints of dyspnea and fatigue. Cyanosis is a poor prognostic sign and suggests right-to-left interatrial shunting. Tachyarrhythmias occur in about 25% of patients and may lead to syncope. Management depends on the morphology of the tricuspid valve and the extent of right ventricular hypoplasia. Surgical repair or replacement of the valve is often beneficial to relieve symptoms and eliminate shunting. Selection of the appropriate procedure is primarily made on the basis of echocardiographic findings. The long-term prognosis after repair varies and remains largely uncertain. However, optimal plastic repair is clearly associated with clinical improvement and relief of symptoms.

TETRALOGY OF FALLOT

By far the most common cyanotic congenital cardiac lesion seen in adults, tetralogy of Fallot is encountered in both the unoperated and the surgically repaired state. Although referred to as a “tetralogy” the primary abnormalities are the ventricular septal defect, which is usually large and subaortic, and the right ventricular outflow tract obstruction, which may occur at the valvular, subvalvular, or supra-valvular level. Right ventricular hypertrophy and the overriding aorta can be considered secondary. Depending on the severity of the right ventricular outflow obstruction, effects include variable degrees of right ventricular pressure elevation, reduced pulmonary blood flow, and bidirectional shunting.

The clinical presentation of a patient with tetralogy of Fallot depends primarily on the severity of pulmonic stenosis. If mild, the condition resembles that of a large ventricular septal defect, and cyanosis may not be present. If affected patients do not undergo surgical repair early, their condition progresses to elevated pulmonary resistance, pulmonary artery hypertension, and Eisenmenger's physiology. If severe pulmonic stenosis exists, marked cyanosis and reduced pulmonary blood flow are present early in life. The degree of shunting varies and depends on the balance between pulmonic stenosis and systemic vascular resistance. Cyanotic spells occur during infancy when right-to-left shunting increases. In children, compulsive squatting is classically observed in this condition, presumably an attempt by the child to

increase systemic vascular resistance and thereby reduce right-to-left shunting.

The second heart sound is single and loud. A right ventricular heave and palpable systolic thrill are usually present. The ejection murmur is helpful to assess the severity of the pulmonic stenosis. A long, late-peaking murmur suggests severe obstruction. The absence of a murmur may indicate pulmonary atresia. Chest radiography demonstrates right ventricular enlargement and a small main pulmonary artery (Fig. 78.12). The pulmonary vascular markings indicate the magnitude of the decrease in pulmonary blood flow. In about 25% of patients, a right-sided aortic arch is present. Echocardiography is useful and permits assessment of essentially all the salient features of tetralogy (Fig. 78.13).

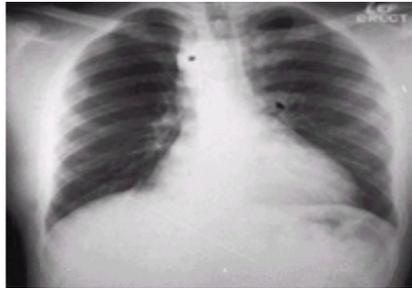

FIGURE 78.12. Chest radiograph from an 18-year-old man with tetralogy of Fallot. The proximal pulmonary artery is small (black arrowhead), and the pulmonary vascularity is decreased. The aortic arch is on the right side (*).

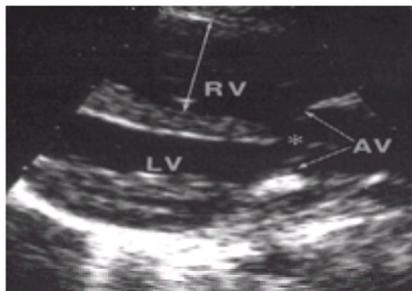

FIGURE 78.13. Long-axis view from a patient with tetralogy of Fallot demonstrates a dilated right ventricle (RV), an overriding aorta (AV), and a subaortic ventricular septal defect (*). Right ventricular hypertrophy, the other feature of tetralogy of Fallot, is not well illustrated in this image. LV, left ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

LEVOTRANSPOSITION OF THE GREAT ARTERIES

Congenitally corrected, or levo (*L*), transposition of the great arteries is characterized by ventricular inversion with ventriculoarterial discordance. Thus, the right-sided left ventricle receives the systemic venous blood and pumps it to the pulmonary artery. The left-sided right ventricle receives the pulmonary venous blood and pumps it to the aorta (Fig. 78.14). Circulatory integrity is maintained, but the roles of the two pumping chambers are reversed, forcing the morphologic right ventricle to function as the systemic pumping chamber. Progressive ventricular dysfunction leading to heart failure is a variable and often late event. The clinical consequences of *L*-transposition are primarily the result of the ventricular inversion, as well as the presence or absence of associated anomalies. These include atrioventricular conduction system abnormalities leading to complete heart block, ventricular septal defect, subvalvular pulmonic stenosis, and incompetence of the left-sided atrioventricular valve (the morphologic tricuspid valve resulting in functional mitral regurgitation).

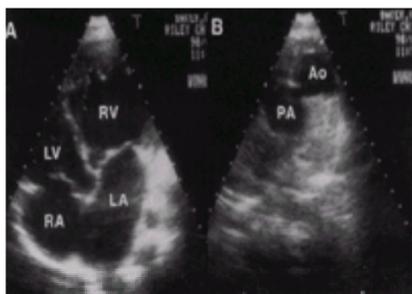

FIGURE 78.14. Apical four-chamber (A) and high parasternal short-axis (B) views from a patient with *L*-transposition of the great arteries. A: Ventricular inversion is demonstrated. The dilated and trabeculated right ventricle (RV) receives blood from the morphologic left atrium (LA). The displaced tricuspid valve is apical to the right-sided mitral valve. B: The two great arteries arise in parallel, and the aorta (Ao) is anterior and to the left of the pulmonary artery (PA). RA, right atrium; LV, left ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Patients with these associated lesions usually come to the attention of the physician early in life. However, if symptoms do not bring the patient to the physician, the correct diagnosis is often delayed until adulthood. Complete heart block, mitral regurgitation, or left heart failure may lead the patient to seek medical attention. Still, the diagnosis of *L*-transposition is often missed.

Treatment depends on the associated anomalies. Among patients with left heart failure, medical therapy should be instituted. The use of afterload reduction (usually with angiotensin-converting enzyme inhibitors) for treatment of asymptomatic systemic ventricular dysfunction is often used, although the benefit has not been proved. Subvalvular pulmonic stenosis is really a clinical issue unless it is severe, because the morphologic left ventricle ejects to the pulmonary artery. For symptomatic complete heart block, dual-chamber pacing is usually recommended. Surgical treatment of ventricular septal defect or atrioventricular valve regurgitation may also be necessary.

POSTOPERATIVE CONGENITAL HEART DISEASE

An increasing proportion of adults with congenital heart disease have undergone some form of surgical repair. Included in this heterogeneous group are those with a simple malformation, such as patent ductus arteriosus (PDA), which was corrected at a young age; those with a more complex lesion, such as tetralogy of Fallot, which was successfully repaired; and those in whom only a palliative procedure, such as a Blalock–Taussig shunt, has been performed. Regardless of the simplicity of the underlying lesion or the degree of surgical success, few patients with congenital heart disease can truly be considered “cured,” and most require ongoing

surveillance and treatment.

Despite the extraordinary developments over the past few decades in congenital cardiac surgery, most affected young patients are left with residua, anatomical defects left uncorrected or partially corrected by the surgery, or sequelae, abnormalities caused by or resulting from the procedure. Proper diagnosis and management of these patients require a thorough knowledge of the underlying cardiac condition as well as the date and type of intervention. The clinician should also anticipate the potential residua and sequelae that might be encountered and should consider the possible need for further surgical intervention.

SYSTEMIC-TO-PULMONARY ARTERY SHUNTS

Palliation for complex congenital heart disease characterized by inadequate pulmonary blood flow (e.g., tetralogy of Fallot) often involves creation of a vascular connection between the systemic arterial or systemic venous circulation and the pulmonary arteries. These relatively simple surgical procedures are generally effective, resulting in reduced symptoms and improved oxygenation in most patients. Several variations of this type of shunt have been developed over the years. One of the most effective involves a direct end-to-side anastomosis between the subclavian artery and the ipsilateral pulmonary artery (the Blalock–Taussig shunt). The degree of palliation depends on the magnitude of shunt flow. If the connection is too small, there is no meaningful increase in pulmonary blood flow and thus arterial oxygen content. If the connection is large and nonrestrictive and permits transmission of systemic pressures to the pulmonary circuit, pulmonary vascular obstructive disease may be the late result.

Another form of systemic-to-pulmonary artery connection, the Glenn shunt, creates an end-to-end connection between the superior vena cava and the right pulmonary artery. A late complication of this operation is the development of pulmonary arteriovenous fistulae in the right lower lung. These pulmonary arteriovenous malformations are small and typically diffuse in the right lower lung, and they result in cyanosis. The reason for their development is not known. Often these shunts are disconnected at the time of more definitive surgery. Their anastomotic sites may leave stenosis in the pulmonary arteries, contributing to late obstruction to pulmonary blood flow.

ATRIAL SEPTAL DEFECT

The long-term outlook for the patient with an isolated secundum ASD who underwent patch repair as a child is excellent. Survival is similar to that of age-matched normal subjects; a decrease in right ventricular size occurs in most of the patients, and reoperation is rarely necessary. The risk of endocarditis in these patients is thought to be negligible. The results in patients operated later in life are slightly less gratifying. In this group, preoperatively pulmonary vascular resistance is a major determinant of outcome. A significant improvement in symptoms is also less likely in the presence of preoperative pulmonary hypertension. The most common late complication in the adult patient is the development of atrial fibrillation. This is estimated to occur in up to 50% of patients who undergo repair beyond age 40 and is an important cause of late morbidity.

TETRALOGY OF FALLOT

Surgical correction of tetralogy of Fallot, when performed early in life, is associated with a markedly improved prognosis; many affected young patients are now reaching adulthood. Residual problems include recurrent right ventricular outflow tract obstruction, right ventricular failure, and severe pulmonic regurgitation. Repair previously included a two-stage process. A palliative systemic-to-pulmonary artery shunt was first created, followed by intracardiac repair at age 1 to 2 years. Definitive surgery involves closure of the ventricular septal defect and relief of the right ventricular outflow obstruction, either by patch enlargement of the outflow tract or repair or replacement of the pulmonary valve. An external right ventricle-to-pulmonary artery conduit or homograft is occasionally required.

Surgical success is the rule in most patients, with the benefits extending through 10 to 20 years of follow-up. Long-term complications include recurrent right ventricular outflow tract obstruction (requiring reoperation in about 15% of patients), severe pulmonic regurgitation, right ventricular failure, advanced heart block, and ventricular dysrhythmias. Left ventricular dysfunction is a late complication that occurs most often in patients who undergo repair later in life. Sudden death, probably secondary to ventricular tachyarrhythmias, also occurs.

D-TRANSPOSITION OF THE GREAT ARTERIES

The surgical management of dextro- or D-transposition of the great arteries has changed in the past decade. Since the early 1960s, an intra-atrial venous switch (the Mustard or Senning operation) was the procedure of choice for transposition. By redirecting venous return at the atrial level, correction of transposition was achieved and 20-year survival rate was about 80% to 85% (Fig. 78.15). With this approach, however, the morphologic right ventricle continued to function as the systemic ventricle. An abnormal response to exercise and a progressive decrease in systolic function were common, thereby accounting for most of the late morbidity and mortality. Atrial dysrhythmias, sinus node dysfunction, atrioventricular block, and sudden death were important late electrophysiologic complications in this type of repair.

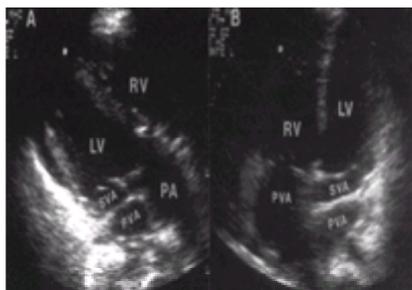

FIGURE 78.15. A: A long-axis view from a patient following an intra-atrial baffle procedure for D transposition of the great arteries. The baffle is easily visualized as a linear structure dividing the atria into a systemic venous atrium (SVA) and a pulmonary venous atrium (PVA). **B:** The apical four-chamber view again shows the baffle and the orientation of the atria. LV, left ventricle; PA, pulmonary artery; RV, right ventricle. (From Feigenbaum H. *Echocardiography*, fifth ed. Philadelphia: Lea & Febiger, 1994, with permission.)

In the past decade, intra-atrial repair has gradually been replaced by the arterial switch procedure. This operation is now feasible for infants and children. An important advantage of this approach is the restoration of the normal ventricular arrangement by transferring systemic ventricular function to the morphologic left ventricle.

FONTAN PROCEDURE

The original Fontan operation, used for repair of tricuspid atresia, involved the creation of a direct connection between the right atrium and pulmonary artery. In bypassing the rudimentary right ventricle, the procedure maintained separation between the systemic and pulmonary circuits and provided nonpulsatile flow of caval blood to the lungs. Several modifications of the operation have subsequently been developed, and the Fontan surgery is now applied to an increasing number of malformations (e.g., single ventricle with pulmonic stenosis) in which two ventricle repairs are not possible. Recently reported long-term results have been very positive. In properly selected patients, this procedure can result in a marked improvement in symptoms. Survival rate at 5 years approaches 90%, and most patients remain in functional class I or II. Complications include persistent pericardial and pleural effusions, atrial tachyarrhythmias, pulmonary arteriovenous fistulas, and protein-losing enteropathy.

Fontan repair is now being applied to adults, many of whom had undergone previous palliative shunt procedures. Careful selection of candidates for this surgery is critical. The primary predictors of success are adequate systemic ventricular function as defined by left ventricular end-diastolic pressure of less than 10 mm Hg, the

presence of sinus rhythm, the absence of atrioventricular valve regurgitation, and the absence of increased pulmonary vascular resistance.

MEDICAL MANAGEMENT ISSUES

DYSRHYTHMIAS

The management of dysrhythmias is becoming an increasingly important component in the overall care of adults with congenital heart disease. Certain categories of patients, both before and after surgery, are at particular risk for specific rhythm disturbances. For example, Ebstein's anomaly is frequently associated with Wolff–Parkinson–White syndrome and atrial tachyarrhythmias. In patients with β -transposition of the great arteries, atrioventricular block is common, with a 2% annual risk of developing complete heart block.

Postoperative dysrhythmias are common, reflecting both the underlying malformation and the type of surgical repair. The overall risk increases with the patient's age, the complexity of the lesion, and the severity of ventricular dysfunction. For example, age is an important determinant of likelihood of developing atrial fibrillation or flutter after repair of secundum ASD (Fig. 78.4). Among patients who have undergone a Fontan procedure, decreased ventricular function predisposes to the development of supraventricular dysrhythmias.

Certain types of repair are associated with particular rhythm abnormalities. The Mustard operation for transposition of the great arteries involves the creation of an intra-atrial baffle. Sinus node dysfunction and atrioventricular block are late complications and tend to be progressive. Patients also exhibit an abnormal chronotropic response to exercise. Sudden death occurs in about 5% of patients after Mustard repair. A documented episode of atrial flutter appears to be a marker for increased risk, but the actual mechanism of sudden death is unknown. Both atrial tachyarrhythmias and bradycardia have been implicated, but prevention remains a challenge.

Surgical closure of ventricular septal defect carries a risk of conduction system damage. Right bundle-branch block is a common finding after repair, and transient complete heart block occurs in up to 25% of patients. Persistent complete heart block is present in 1% to 10% of patients, who are at increased risk of sudden death. Pacemaker placement is indicated in most of these patients.

Patients who have undergone repair of tetralogy of Fallot often exhibit right bundle-branch block. More important, however, is risk of sudden death late after repair, which occurs in up to 5% of patients. In most patients, the primary cause is thought to be ventricular tachyarrhythmias. Risk factors include older age at time of surgery, elevated right ventricular systolic pressure (more than 60 mm Hg), and premature ventricular complexes during monitoring. Ventricular arrhythmias in this group are more common in those with significant residual right ventricular outflow tract obstruction with associated severe pulmonary valve insufficiency. These factors taken together suggest that prolonged or severe right ventricular pressure overload is the underlying cause of serious dysrhythmic complications.

CYANOTIC CONGENITAL HEART DISEASE

Tissue hypoxia leads to a rise in erythropoietin production and a resultant increase in red blood cell mass. If this in turn causes an adequate increase in tissue oxygen delivery, erythropoietin release stabilizes and an equilibrium is established at a higher hematocrit level. This condition is called *compensated erythrocytosis*. In some patients, however, an equilibrium state is not achieved and continued expansion of the red cell mass occurs; this has detrimental effects on oxygen delivery, partly because of increased blood viscosity. This condition is referred to as *decompensated erythrocytosis*.

Patients with compensated erythrocytosis have an elevated but stable hematocrit and may be considered iron replete. They exhibit few if any symptoms of hyperviscosity and rarely benefit from phlebotomy. Patients with decompensated erythrocytosis often have significant symptoms of hyperviscosity such as fatigue, headache, visual disturbance, or nightmares. The clinical picture may be complicated by iron deficiency and the creation of microspherocytes (often secondary to phlebotomy). These cells are more rigid than normal erythrocytes, further contributing to the increased blood viscosity.

These conditions are often mismanaged. The risk of thrombotic stroke in adults with cyanotic congenital heart disease is low and is unrelated to the hematocrit level or iron stores. Thus, therapeutic phlebotomy performed to reduce the risk of stroke is unwarranted. Phlebotomy should be considered only after dehydration is excluded and should be reserved for patients with symptomatic hyperviscosity and a hematocrit level above 65%. Withdrawal of 500 mL of blood should be followed by replacement with a similar volume of saline or colloid. As noted previously, repeated phlebotomy may cause iron deficiency and microspherocytes and thereby worsen symptoms. Routine monitoring for iron stores is mandatory, and iron replacement, when indicated, should be done cautiously, usually at a dose of 325 mg per day of ferrous sulfate with biweekly measurements of hematocrits and frequent reevaluation of iron stores.

Many patients with cyanotic congenital heart disease also exhibit defects in hemostasis. In most patients, the bleeding tendency is mild and manifests as easy bruising, epistaxis, or petechiae. Less often, recurrent hemoptysis occurs that may be life threatening. Evaluation of the prothrombin time and activated partial thromboplastin time and deficiencies in the various coagulation factors suggest defects in both the intrinsic and extrinsic coagulation systems. Mild thrombocytopenia and abnormal platelet function also contribute to the bleeding and bruising problems. The use of aspirin, heparin, or nonsteroidal anti-inflammatory agents can aggravate these conditions and should be avoided in these patients. The severity of the bleeding disorder associated with trauma or surgical procedures generally correlates with the hematocrit level. To reduce the operative risk, hemostasis can be temporarily improved by lowering the hematocrit level to 60% to 65%.

INFECTIVE ENDOCARDITIS

The risk of endocarditis in congenital heart disease depends on three factors: the type and severity of the cardiac malformation; whether or not the patient has undergone surgical intervention; and the presence of bacteremia. Lesions that predispose to infection are those associated with a turbulent, high-velocity jet that impacts on an endothelial surface. Thus, a restrictive ventricular septal defect with a left-to-right jet impinging on the septal leaflet of the tricuspid valve poses a greater risk than a large secundum ASD that is not associated with a jet lesion. Surgical status also influences the relative risk. In some cases, such as ligation of a PDA, surgery substantially lowers the patient's risk. Other surgical devices, such as valved conduit, significantly increase the potential for infection.

Patients can be categorized as having low, intermediate, or high risk based on the underlying lesion and surgical status. Low-risk conditions include secundum ASD, mild pulmonic stenosis, and anomalous pulmonary venous connection. Certain repaired lesions are also considered low risk; these include secundum atrial or ventricular septal defect following patch repair, ligated PDA, repaired tetralogy of Fallot (without a prosthetic valve), and Fontan surgery. Intermediate risk conditions include both unoperated and operated lesions; examples are left-sided valvular regurgitation, bicuspid aortic valve, aortic coarctation, unoperated ventricular septal defect and PDA, and nonvalved conduits (either intracardiac or external). With the highest risk are patients with valved conduits or mechanical prosthetic valves and those with a previous episode of infective endocarditis.

Prevention of endocarditis involves antibiotic prophylaxis and ensuring good personal and dental hygiene. Guidelines developed by the American Heart Association serve as the basis for antibiotic prophylaxis, and these recommendations should be reinforced on a regular basis during clinic visits. The pocket-sized card provided by the association is a convenient and effective way to emphasize the importance of these guidelines. Other measures that help to prevent endocarditis include good general hygiene practices, meticulous skin and dental care, and avoidance of certain female contraceptive devices. All patients with congenital heart disease should be encouraged to undergo twice-yearly dental visits for cleaning and prophylaxis.

PREGNANCY AND CONGENITAL HEART DISEASE

Because of the improvements in medical and surgical management, pregnancy among women with congenital heart disease is becoming increasingly possible. To counsel and manage these patients properly, it is essential to understand the hemodynamic changes associated with normal pregnancy. This condition is often described as a hyperdynamic state with superimposed volume overload. Blood volume and cardiac output increase significantly during pregnancy. The rise in cardiac output is due to increased contractility and heart rate. Despite these alterations, blood pressure changes little, primarily owing to a fall in peripheral vascular resistance. During labor and delivery, fluctuations in intravascular volume, stroke volume, and blood pressure occur. Vaginal delivery is usually associated with a loss of about 500 mL of blood, which partially compensates for the gestational hypervolemia.

Management of women with congenital heart disease ideally begins before conception and focuses on the safety and advisability of pregnancy. If pregnancy is contraindicated (see following text), safe methods of contraception should be presented. The risk of pregnancy to mother and fetus must be covered in detail. This discussion should also include the potential risks of medications and diagnostic procedures. For example, warfarin should not be used during the early stages of pregnancy, and women who are chronically anticoagulated should be switched to heparin before conception. Finally, the risk of heart disease in the offspring should

be discussed.

Despite these concerns, there are relatively few congenital malformations in which pregnancy is contraindicated. In general, the most important determinants of outcome are the presence and severity of pulmonary vascular disease and the mother's functional class. Pulmonary hypertension, regardless of the underlying cause, poses a high risk to the mother and a low likelihood of a successful pregnancy. Thus, the presence of Eisenmenger's physiology is widely regarded as a contraindication to pregnancy. Significant heart failure also greatly increases the likelihood of a poor outcome. Mortality in pregnant women with New York Heart Association functional class III or IV is about 7%. Other conditions in which pregnancy should be avoided include severe and symptomatic aortic stenosis, Marfan's syndrome with a dilated aortic root, uncorrected cyanotic heart disease, and unrepaired aortic coarctation. Pregnant women with Marfan's syndrome and an aortic root diameter greater than 40 mm are at risk for aortic rupture. Likewise, coarctation of the aorta during pregnancy has also been associated with rupture, dissection, or stroke. Placental blood flow is also significantly reduced in this condition.

In contrast, most patients with acyanotic congenital heart disease bear the demands of pregnancy with few problems. Those with uncomplicated left-to-right shunts generally do well. If the shunt is large, there is an increased risk of congestive heart failure; if the shunt is reversed, pregnancy should be avoided. In patients with repaired shunt lesions, pregnancy is well tolerated with little additional risk. Isolated ASD is one of the most common conditions and is well tolerated despite the gestational increase in blood volume. With advancing age, however, the possibility of dysrhythmias or paradoxical emboli increases.

Among patients with valvular disease, regurgitant lesions generally fare better than stenotic ones. Severe aortic stenosis often becomes unstable during pregnancy, resulting in heart failure or dysrhythmias. Likewise, severe mitral stenosis is poorly tolerated during pregnancy, often resulting in congestive heart failure, atrial fibrillation, or hemoptysis. In contrast, pulmonic stenosis is better tolerated, even if severe. Because of the decrease in systemic vascular resistance during pregnancy, the severity of left-sided valvular regurgitation rarely worsens and may instead physiologically decrease in severity during pregnancy.

Among the complex forms of disease, unrepaired tetralogy of Fallot is still occasionally encountered in pregnant women. In most, the possibility of clinical deterioration can be anticipated. Because of the hemodynamic changes, right-to-left shunting usually increases, with an associated worsening of cyanosis. Fluctuations during labor and delivery pose an additional risk, occasionally leading to syncope or death. Conversely, in patients who have undergone successful intracardiac repair, the expected risks (with the exception of endocarditis) are substantially less.

EXERCISE AND ACTIVITY RESTRICTIONS

Specific recommendations regarding restriction of activity in adolescents and young adults with congenital heart disease depend on several issues. Although strenuous exercise in certain patients may predispose them to complications or even sudden death, most patients can safely engage in a variety of activities. The overall risk of serious complications is low, and there are few data that demonstrate that a specific activity actually predisposes to sudden death and that avoiding that activity would prolong life. Guidelines take into account the specific cardiac lesion, the type and intensity of exercise, the risk of body collision, and the patient's overall fitness. Certain aspects of the patient's history, such as prior syncope or known dysrhythmias, are also important.

Activities may be categorized as having both a static and a dynamic component. Exercises with a high static component include strenuous isometric activity such as weightlifting or wrestling. Dynamic, or isotonic, activities involve repetitive muscle movements with relatively little developed force (e.g., walking, jogging, low-impact aerobics, cycling). Most activities have an element of both, such as downhill skiing. Recommendations have been published regarding the classification of competitive sports and the relative risks of each to persons with various types of heart disease. For example, athletes with uncomplicated ASD without pulmonary hypertension may participate in all competitive sports. If pulmonary arterial pressure is elevated, only low-dynamic, low-static activities (e.g., golf and bowling) are permitted. In patients with Eisenmenger's physiology, participation in sports is discouraged.

Patients who have undergone repair of complex congenital heart disease constitute a heterogeneous group. For example, after repair of tetralogy of Fallot, patients may be permitted to engage in all forms of sports, provided that the right heart pressure is near normal, that no residual shunting exists, and no significant dysrhythmias have been demonstrated. Patients with right ventricular hypertension or significant right ventricular volume overload should be restricted to low-intensity sports. In addition to the history and physical examination, exercise testing, echocardiography, and ambulatory ECG monitoring are helpful to evaluate these issues.

Adult patients with transposition who have undergone a Mustard or Senning repair usually have limited exercise capacity owing to abnormal systemic ventricular function. The ability of the systemic ventricle to respond to the demands of exercise is blunted, and the risk of exercise-induced dysrhythmias may be increased. For these reasons, patients should be restricted to low- to moderate-intensity exercise of limited duration.

Patients who have undergone Fontan repair for palliation of complex heart disease often experience a marked improvement in functional capacity and a subsequent desire to participate in vigorous exercise. Despite the symptomatic improvement, exercise is usually limited by a reduced cardiac output at rest and during exercise. Most of these patients can safely participate in low-intensity activities if ventricular function is preserved and the presence of significant dysrhythmias has been excluded.

INTERVENTIONAL CARDIAC CATHETERIZATION

Cardiac catheterization has long been a vital diagnostic tool for patients with congenital heart disease. Improvements in digital radiographic imaging, radiographic contrast agents, combined uses of catheterization, cardiac anesthesia, and echocardiography, as well as the direct advances in percutaneous interventional technology, have led to the improved techniques of percutaneous intervention for congenital heart disease. The dream of nonsurgical correction of some of the less complex forms of congenital heart disease has now become a reality for selected individuals.

Percutaneous intervention can also palliate certain congenital heart disorders, thereby postponing the need for surgery. Such interventions can also be combined with surgery in some cases to make the surgery less risky and more effective.

Percutaneous catheter-based intervention to treat patients with congenital heart disease began three decades ago. In 1966, Rashkind described balloon septostomy to treat infants with transposition of the great vessels. This section is an overview of some of these catheter-based interventions for congenital heart disease, which continue to actively evolve.

PERCUTANEOUS TREATMENT OF CONGENITAL VALVULAR DISEASE

One of the most effective and widely accepted percutaneous congenital interventions is that of balloon valvotomy for treatment of persons with pulmonary valvular stenosis. This technique was described in 1982. Indications for the procedure in children and adults include symptomatic valvular pulmonary stenosis, causing chest pain, palpitations, or dyspnea. In addition, asymptomatic persons with severe stenosis, manifested by peak gradients greater than 50 mm Hg, are usually offered balloon valvotomy to prevent late sequelae such as right heart failure.

Classic congenital pulmonary valve stenosis is most easily defined in the lateral radiographic projection during contrast angiography of the right ventricular outflow tract and main pulmonary artery ([Fig. 78.16](#)). The systolic doming of the pulmonary valve leaflets and the dilation of the main pulmonary artery just cephalad of the valve defines this disorder. Balloon catheters are selected to dilate the valve to about 1.2 times the size of the measured annulus.

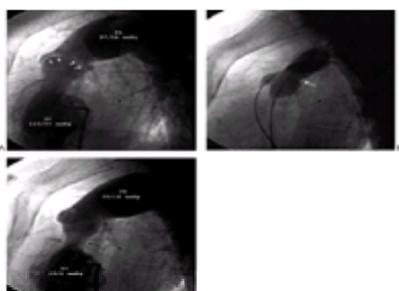

FIGURE 78.16. A: Right ventricular angiogram in the lateral projection in a patient with classic congenital pulmonary valvular stenosis. The systolic doming of the stenotic pulmonary valve leaflets is highlighted by the white arrows. Also note the supra-annular dilation of the main pulmonary artery, which is characteristic of this disorder. The peak-to-peak gradient is 118 mm Hg. **B:** Dilation of the valvular pulmonic stenosis using the double-balloon technique. **C:** Lateral angiographic view of the right ventricular outflow tract after balloon dilation of the pulmonary valve stenosis. Note the lack of systolic doming of the valve leaflets and improved leaflet orifice. A small gradient of 15 mm Hg persists immediately after the procedure, which was localized to the mild narrowing of the right ventricular outflow tract (*black arrows*).

This technique is associated with excellent results and carries a very low complication rate. Immediately after valve dilation, there is usually a dramatic reduction in the transvalvular gradient. Some gradient, between the right ventricle and pulmonary artery, typically about 30 mm Hg, often persists immediately after balloon dilation. This is usually due to right ventricular infundibular narrowing, from the underlying right ventricular hypertrophy, which results in some subvalvular right ventricular outflow tract gradient after relief of the valvular stenosis. This outflow gradient regresses in follow-up, and the long-term echocardiographic and clinical results of the procedure are excellent. Pulmonary valve insufficiency has not been a clinical problem in follow-up and appears to be less severe than that seen previously with surgical pulmonary valvotomy. Less ideal cases of valvular pulmonary stenosis, in patients with dysplastic valves, can still be effectively dilated percutaneously in many persons. These valves, occurring as isolated problems or in association with Noonan's syndrome, consist of thickened fused leaflet tissue. They can be recognized on the lateral angiographic images of the right ventricular outflow tract as thickened leaflet tissue, lacking the domed appearance in systole and also lacking the supra-annular dilation of the main pulmonary artery. The results of balloon dilation are less ideal and uniform in this group, although many experience effective relief of pulmonary stenosis. Those who are not improved require surgical treatment.

Congenital aortic stenosis in adults is less well suited for percutaneous treatment than is pulmonary valve stenosis. In children with congenital aortic stenosis and in selected young adults with bicuspid aortic stenosis, percutaneous balloon valvotomy has been found to offer effective palliative treatment, postponing the need for valve replacement surgery. In children, balloon valvotomy has been shown to have palliative effects similar to what is seen with surgical valvotomy. In adults, however, the results are less encouraging. Even by the third and fourth decade of life, bicuspid aortic valves are less pliable and are often calcified. These calcified valves are usually not improved significantly by balloon dilation, and restenosis rates are high. Adults with aortic stenosis are usually most effectively treated by valve replacement surgery.

In those suitable for percutaneous balloon aortic valvuloplasty, the procedure is usually performed by way of the femoral artery using retrograde crossing of the stenotic aortic valve. In infants and small children, a venous, prograde approach across the atrial septum may be preferred to avoid femoral artery trauma. After crossing the stenotic aortic valve with a guidewire, a balloon catheter equal in size to the measured diameter of the aortic annulus is positioned. Unlike the pulmonary annulus, over-dilation of the aortic annulus is to be avoided in an attempt to avoid aortic annular disruption and aortic valve insufficiency. Complications of the procedure include femoral artery injury or occlusion. Less common but important complications include the creation of severe valvular regurgitation, heart block, myocardial infarction, stroke, and death. In general, although balloon aortic valvuloplasty plays a palliative role in congenital aortic stenosis in children, surgical valve replacement remains the treatment of choice for most adults with congenital aortic stenosis. Congenital mitral valve stenosis is distinctly uncommon and typically responds poorly to balloon dilation. Commissure fusion causing rheumatic mitral valve stenosis in adults responds extremely well to balloon dilation; however, congenital mitral stenosis is usually not improved. Causes of congenital mitral stenosis include supra-annular stricture, a hypoplastic annulus, fibrotic fused leaflet tissue, and abnormal chordal or papillary muscle architecture. These anatomical anomalies respond poorly to balloon dilation, usually not improving the severity of mitral stenosis and often causing leaflet tearing leading to severe mitral regurgitation. Thus, adult patients with congenital mitral valve stenosis, with rare exception, are best treated by surgical valve replacement.

COARCTATION

The treatment of coarctation of the aorta remains controversial. Balloon dilation is effective in reducing the trans-stenotic gradient. Potential complications of the procedure, however, include femoral artery damage and more serious complications such as dissection of the aorta at the dilation site, resulting in acute rupture or late aneurysm formation. Intravascular ultrasonography and stenting of the coarctation site hold promise for limiting these serious complications and improving the hemodynamic results by preventing vascular recoil. Intravascular ultrasonography is important in these procedures in identifying dissections in the wall of the aorta that are often not seen by aortography. Intravascular stenting of the aorta using Palmaz stents has shown excellent early results. Discrete coarctations, especially recurrent coarctation after previous surgery, are ideal indications for percutaneous intervention. Patients who have had previous coarctation surgery have greater risks from repeat surgical intervention. In addition, the periaortic fibrosis in these persons provides an increased margin of safety for percutaneous dilation and stenting.

PULMONARY ARTERY STENOSIS

Balloon dilation of the pulmonary arteries in patients with peripheral pulmonary artery stenosis is the procedure of choice. Peripheral pulmonary artery stenosis may occur as an isolated disorder or may be associated with tetralogy of Fallot, maternal rubella syndrome, or Williams syndrome ([Fig. 78.17](#)). Peripheral pulmonary artery stenosis may also occur as a late sequela of previous systemic-to-pulmonary artery shunt surgery. With the exception of the most proximal pulmonary artery lesions, these lesions are not surgically accessible.

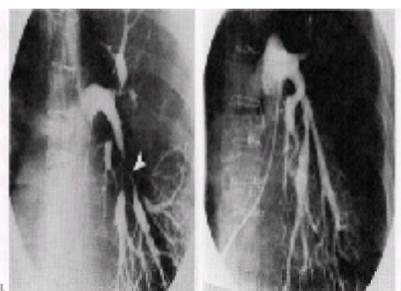

FIGURE 78.17. A: Left pulmonary arteriogram in the anteroposterior (AP) view showing severe peripheral pulmonary artery stenosis, causing severe pulmonary hypertension. **B:** Left pulmonary arteriogram in the AP view 1 year after stenting the left lower lobe pulmonary artery. Three Palmaz stents were used; 2 P308 “kissing” stents in the lower branches and a P188 stent in the more proximal, posteromedial branch. Pulmonary artery systolic pressures improved from 100 mm Hg to 40 mm Hg after stenting of both pulmonary arteries, resulting in marked improvement of exercise tolerance.

Recoil of the dilated pulmonary artery segment is common after balloon angioplasty alone. Stenting of pulmonary artery stenosis has therefore largely replaced balloon dilation. Long delivery sheaths and improved guidewires have made deployment of Palmaz stents to even distal segments of the pulmonary vasculature feasible.

The greatest risks of pulmonary artery stenting are over-dilation, dissection, and rupture of the pulmonary artery segment, which are fortunately rare occurrences. Minor dissections often seal and are self-limited, causing small amounts of hemoptysis. This is particularly true in patients who do not have pulmonary hypertension. Life-threatening bleeding may be treated by coil closure of the pulmonary artery branch involved, or they may require surgical intervention.

In addition to pulmonary hemorrhage, a unique and uncommon complication of pulmonary artery stenting is pulmonary edema in the lung distal to the stented segment. This is more likely to occur in patients with severe stenosis and high central pulmonary artery pressure. After relief of the stenosis in these patients, high blood flow rates in the stented segment may cause focal pulmonary edema. This complication, if it occurs, does so within the first 48 hours of the procedure.

Supportive care allows resolution of the edema, which usually occurs over the next week.

Stent thrombosis has not been a problem with pulmonary artery stenting owing to the large vessel diameters and high flow rates involved. Aspirin (325 mg per day) is usually prescribed for a period of 3 months.

Procedural success rates have been good, and late clinical and angiographic follow-up has demonstrated excellent long-term results. Follow-up angiography typically reveals some neointimal hyperplasia within the stented segment, but significant restenosis is distinctly uncommon.

PATENT DUCTUS ARTERIOSUS

Percutaneous closure of PDA is now possible for many patients. Closure of PDAs is generally recommended in adults to reduce the risk of endocarditis and left heart failure.

Catheterization-based closure of PDAs was described in the 1970s. Devices, however, remained suboptimal and percutaneous closure remained limited. In 1991, the use of vascular occlusion coils was described for closure of PDAs. Over the last several years, refinements of this coil occlusion technique have made percutaneous closure more successful. Improvements include the use of detachable coils and coil occlusion bags (Fig. 78.18). The anatomy of the PDA influences the success rate of percutaneous closure. Narrow ducts (less than 4 mm in diameter), with lengths that exceed the diameter, are ideal for coil closure.

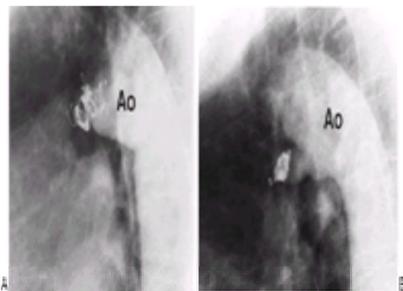

FIGURE 78.18. A: Aortography (Ao) in the lateral projection after coil closure of a patent ductus arteriosus. **B:** Aortography in the lateral view after closure of a patent ductus using a Gianturco–Griffka vascular occlusion coil bag.

Coil embolization is a risk of the procedure. Most embolization is to the pulmonary artery, and most can be percutaneously retrieved using snare techniques and are of no clinical consequence. Percutaneous closure of PDAs is especially advantageous in adult patients for whom surgical closure carries higher risk because of comorbid illnesses and calcified, friable tissue in the region of the ductus.

Coil occlusion techniques are useful in other situations as well. They can be used to occlude systemic-to-pulmonary collateral vessels in patients with Eisenmenger's syndrome and other congenital conditions limiting pulmonary blood flow, when these collaterals are responsible for hemoptysis. This coil occlusion technique can also be used to close coronary–cameral fistulas, as well as other abnormal vascular connections such as anomalous pulmonary venous drainage when dual drainage to the left atrium coexists (Fig. 78.19).

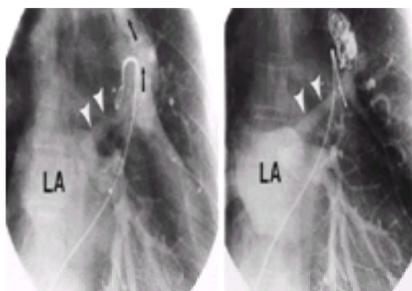

FIGURE 78.19. A: Levophase left pulmonary artery angiogram in the anteroposterior (AP) projection demonstrating anomalous pulmonary venous return of the left upper lung draining to the innominate vein (black arrows). Dual, normal drainage via a smaller pulmonary vein to the left atrium (LA) is also seen (white arrowheads). **B:** Levophase left pulmonary arteriogram in the AP projection demonstrating normal left upper lobe pulmonary venous drainage after coil closure of the anomalous pulmonary venous return. A coil matrix is seen, which was deployed to occlude the vertical vein draining the left upper lobe anomalously to the right side of the heart. Note the persistence of the normal left upper lobe pulmonary venous drainage (white arrowheads) to the left atrium.

ATRIAL SEPTAL DEFECTS

Perhaps the most exciting area of current investigation is in the area of percutaneous techniques for closure of secundum ASD. Attempts at nonsurgical closure for ASDs is not new. Hufnagel and Gillespie first described such an attempt in 1959. In the 1970s and 1980s, several devices were tested, of which the best known and most widely used was the clamshell device. This device proved promising but was eventually redesigned because of late wire fractures seen in the radial arms of the device.

Several devices are under active investigation in the United States and Europe. These include the Angel Wings device, the Amplatzer device, the Cardioseal device, the Sideris button occluder, and the AS-DOS device. These devices are designed for catheterization-based closure of secundum ASDs. They are best suited for use in patients with moderate-sized or smaller defects, which have an adequate rim of remaining atrial septal tissue surrounding the defect to which the device may adhere. These devices can also be used to close patent foramen ovals in patients with presumed paradoxical emboli or orthodeoxia.

The Amplatzer, Cardioseal, and Angel Wings devices are perhaps the most encouraging devices currently being studied. Although structurally unique, these devices, share similar delivery and implantation features. They are placed across the atrial septum into the left atrium using a sheathed delivery catheter that is inserted percutaneously into the femoral vein. The left atrial portion of the devices are then deployed, and the catheter is withdrawn slightly to seat this portion of the device against the left side of the atrial septum. Once properly positioned, the right atrial portion of the device is deployed to secure the device in place. The position of the device is confirmed before its final release from the delivery catheter. These procedures are generally performed under general anesthesia. Continuous transesophageal echocardiographic monitoring, as well as fluoroscopy, is vital to ensure optimal device positioning.

Potential risks of percutaneous ASD closure include device embolization, incomplete ASD closure, atrial arrhythmias, thrombus formation on the device with subsequent embolization, and damage to surrounding structures, such as the atrial free walls, atrioventricular valves, and pulmonary veins. These complications have been very uncommon in the recent clinical trials, and procedural success rates have been about 90%.

Two- to three-year follow-up is now available for these devices, and most patients have been shown to have complete occlusion of the ASD and have had excellent

clinical outcomes (Fig. 78.20). Some devices are used with a temporary period of anticoagulation with warfarin, whereas others are used with just aspirin.

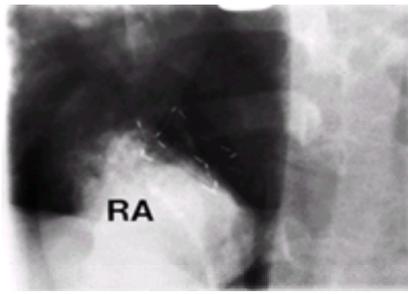

FIGURE 78.20. Right atrial angiogram in the left anterior oblique projection, with cranial angulation, following percutaneous closure of a secundum atrial septal defect using an Angel Wings device. The square wire framework, made of nitinol, is radiographically visible. Each nitinol frame supports a dacron square; the squares are sewn together in the center of the fabric.

In summation, percutaneous treatments for adults with congenital heart disease is in an exciting era of evolution. Improvements in catheterization techniques and new interventional devices have made selected forms of congenital heart defects treatable in the catheterization laboratory, in some cases postponing the need for surgery and in others eliminating the need for surgery altogether.

CHAPTER 79: PERICARDIAL DISEASES

E. WILLIAM HANCOCK

[Acute Pericarditis](#)
[Pericardial Effusion](#)
[Constrictive Pericarditis](#)
[Specific Forms of Pericardial Disease](#)

The diseases that involve the pericardium have many causes, but the pathologic and clinical features of many types of pericardial disease are similar despite the diverse causes. These diseases represent the response of the pericardium to injury. There are three broad pericardial syndromes: acute pericarditis, pericardial effusion, and constrictive pericarditis.

ACUTE PERICARDITIS

ETIOLOGY

Most instances of acute pericarditis are of unknown origin and are assumed to be infections caused by unidentified viral agents. The attribution of idiopathic acute pericarditis to viral infection is based largely on the clinical similarity of idiopathic cases to the many fewer cases of documented viral cause. Bacterial pericarditis, although relatively rare, occasionally occurs as a primary infection but is more often associated with sepsis, pneumonia, thoracic surgery, trauma, or suppression of a patient's immune responses.

Tuberculous pericarditis is common in many parts of the world and tends to become chronic and to cause tamponade or constriction of the heart. Many other mycobacterial, fungal, and parasitic agents also cause pericarditis.

Many cases of acute pericarditis are noninfective and occur in such conditions as postsurgery (postcardiotomy) syndrome, connective tissue disease, renal failure, radiation, administration of various drugs, or trauma. Many of the noninfective cases probably have a common mechanism related to the nonspecific reaction of the pericardium to injury. The inflammatory response may be mediated by an immunologic reaction. Complicating viral infection may also play a role. Noninfective pericarditis often has relatively little true inflammatory component but consists predominantly of deposits of fibrin on the visceral and parietal surfaces of the pericardium.

CLINICAL FINDINGS

Idiopathic or viral acute pericarditis is often preceded by a low-grade fever, sore throat, and muscular aches. Anterior chest pain, however, is usually the first and most characteristic symptom of the pericarditis itself. The chest pain of pericarditis is classically substernal and pleuritic. It is often sudden in onset and severe and can simulate the chest pain of acute myocardial infarction (MI). The pleuritic component is the most important feature that distinguishes pericardial pain from ischemic chest pain. Other distinguishing features are listed in [Table 79.1](#).

Acute Pericarditis	Acute Myocardial Infarction
Worse in inspiration	Not affected by breathing
Partially relieved by sitting up	Not affected by position
Radiation, if any, to left shoulder and back	Radiation to jaw, left arm
Not relieved by nitroglycerin	Often relieved by nitroglycerin

TABLE 79.1. DIFFERENCES BETWEEN THE CHARACTERISTIC CHEST PAIN OF ACUTE PERICARDITIS AND THAT OF ACUTE MYOCARDIAL INFARCTION

The pericardial friction rub is the most distinctive physical sign of acute pericarditis. Definite pericardial friction rubs have both systolic and diastolic components, and the classic friction rub has three components. The systolic and early diastolic components give a to-and-fro character, and the third component in late diastole due to atrial contraction, adds a highly distinctive element that is virtually pathognomonic of pericarditis. Pericardial friction rubs are best heard with the diaphragm of the stethoscope firmly applied, with the patient in the sitting position, and with breathing suspended in expiration.

LABORATORY FINDINGS

The characteristic abnormalities on electrocardiogram (ECG) in acute pericarditis are ST-segment elevation and PQ-segment depression ([Fig. 79.1](#)). These abnormalities reflect subepicardial inflammation of the ventricles and the atria, respectively. ST elevation due to acute pericarditis is usually generalized and present in multiple leads, with the exception of leads aVR and V₁. In some patients, leads III and aVL (when they are cavity leads) also fail to show ST elevation. The ST-segment elevation of acute pericarditis differs from that of acute MI in its diffuse nature and the lack of reciprocal ST-segment depression in noncavity leads. It can be differentiated from the normal variant ST-segment elevation, often termed *early repolarization*, chiefly by the amplitude of the T waves, which tend to be taller compared with the degree of ST-segment elevation, and by absence of PQ segment depression in the normal variant pattern. Depression of the PQ segment is comparable to elevation of the ST segment in its sensitivity and specificity for acute pericarditis.

FIGURE 79.1. Electrocardiogram in a patient with acute pericarditis. ST-segment elevation and PQ-segment depression are seen in many leads. The T wave is low compared with the level of ST-segment elevation.

The serum levels of enzymes, such as creatine kinase, which are used in the diagnosis of acute MI usually remain normal during episodes of acute pericarditis. Moderate rises may occur, however, when a significant degree of myocarditis accompanies the pericarditis. Often, the erythrocyte sedimentation rate and the white blood cell count are elevated.

NATURAL HISTORY

Idiopathic or viral acute pericarditis is a self-limited syndrome in most cases, with a very low probability of permanent adverse effects. A few cases progress to subacute and chronic constrictive pericarditis; usually these patients had a subacute onset of pericarditis initially, were more severely ill during the active phase, and showed pericardial effusion and often pneumonitis and pleuritis with pleural effusion in addition to pericarditis.

A few patients follow a course of relapsing or recurrent acute pericarditis over months or years. The recurrent episodes are usually benign, although the symptoms are distressing. Cardiac tamponade and constrictive pericarditis are unlikely to develop even after numerous relapses of acute pericarditis. These patients are more likely to require treatment with adrenal corticosteroids, which often prevents relapses but also results in hyperadrenocorticism and a liability to corticosteroid withdrawal symptoms.

OPTIMAL MANAGEMENT

The initial diagnostic studies in patients with a clear clinical presentation of acute pericarditis should focus primarily on ruling out a bacterial infection. Cultures of the blood and other sites are indicated when the degree of fever and leukocytosis and the severity of the clinical illness suggest purulent pericarditis as a reasonable possibility. Studies for viral infection are usually not indicated, because the yield is low and the results are usually not useful in management. The tuberculin skin test is usually indicated. When cardiac tamponade is absent, pericardiocentesis done purely for diagnostic studies on the fluid is not indicated unless strong clues point to an infective or neoplastic cause.

After the initial workup, it is usually wise to perform screening tests for rheumatic diseases, such as assays for the rheumatoid factor and the fluorescent antinuclear antibody. A plain chest radiograph usually provides clues to the diagnosis of lung cancer, the most common cause of neoplastic disease presenting as apparently primary pericardial disease.

Treatment of nonspecific acute pericarditis is directed primarily at short-term relief of symptoms. After initial relief of the severe pain with analgesics such as codeine or morphine, it is usually best to prescribe aspirin as an analgesic and anti-inflammatory agent, in doses of 4 to 6 g per day for at least 1 week. Other nonsteroidal anti-inflammatory drugs are more expensive and not necessarily superior to aspirin for the treatment of acute pericarditis. Adrenal corticosteroids, such as prednisone in doses of 60 mg per day rapidly tapering and discontinued after 1 to 2 weeks, are more effective than aspirin and are sometimes indicated in severe cases of acute pericarditis. However, corticosteroids should be avoided, if possible, because of the difficulty in withdrawing them later.

The best solution to the problem of corticosteroid dependency is a very gradual tapering of the corticosteroid dose, over as long as 6 to 12 months, accompanied by the use of nonsteroidal anti-inflammatory drugs and other supportive therapy. Colchicine, 1 mg per day given for at least 1 year, is helpful in preventing episodes of recurrent pericarditis in some patients.

PERICARDIAL EFFUSION

The pericardial space normally contains 20 to 30 mL of fluid that is a transudate of plasma. Pericardial effusion is an abnormal increase in the amount of such fluid and may be either a transudate or an exudate. The fluid is often bloody or is virtually equivalent to whole blood, as in trauma, rupture of acute MI, or coagulation defects. Special forms of pericardial effusion occur rarely. One such form is chylous effusion resulting from communication of the thoracic duct with the pericardial space. Another is cholesterol effusion, a form of chronic pericardial effusion in which lipoproteins have become gradually concentrated, probably because of their slower reabsorption.

Pericardial effusion often occurs as a part of a general increase in extracellular fluid volume, as in congestive heart failure and nephrotic syndrome. It also occurs as a feature of virtually any form of pericardial disease; in many of these instances, the pericardial effusion is the essential presenting feature.

The clinical importance of pericardial effusion is primarily related to the degree of compression of the heart that it may produce. The pressure in the pericardial space normally equals the intrapleural pressure, being about equal to the atmospheric pressure but becoming negative with inspiration. When a pericardial effusion develops rapidly, as in traumatic hemopericardium, the pericardium has very little elasticity and the pressure in the pericardial space rises steeply with as little as 200 mL of fluid. The layers of collagen that largely make up the parietal pericardium are wavy, however, and can stretch over time. Thus, a slowly developing pericardial effusion, as in myxedema, for example, can reach a volume as large as 2,000 mL without elevating the intrapericardial fluid pressure significantly.

CARDIAC TAMPONADE

Cardiac tamponade is caused by an abnormally increased pressure within a pericardial effusion that compresses the heart and impedes its filling in diastole. The term "tamponade" is sometimes used in a more restricted sense to refer to a condition of "compromised circulation," that is, hypotension or diminished blood flow to the vital organs. Such a condition is better referred to as *decompensated tamponade*, because it represents only the most severe stage of a graded process.

PATHOGENESIS

As pericardial fluid accumulates, the intrapericardial pressure begins to rise and soon approaches the level of the central venous pressure. From this point, the two pressures rise together, so that in cardiac tamponade of even moderate degree, the central venous pressure (and the jugular venous pressure) can be taken as a close approximation of the intrapericardial pressure. As the intrapericardial pressure rises still further, the right-sided cardiac chambers are compressed. Reduction in volume of the left-sided chambers follows, initially because of reduced output of the right side of the heart secondary to compression, and later as a result of compression of the left-sided chambers. In severe tamponade, all the cardiac chambers are reduced (50% or more) in volume.

Reduction of cardiac filling is followed by reduction in stroke volume. Cardiac output is maintained by tachycardia initially, but becomes reduced later. Arterial pressure is maintained by vasoconstriction in early phases, but it also falls in later stages.

Cardiac tamponade alters the phasic pattern of venous return to the heart during the cardiac cycle. Venous return occurs mainly during systole, when the heart is smallest and least compressed. However, the compression of the heart that exists throughout the cardiac cycle reduces or eliminates the surge of rapid filling in early diastole that occurs both normally and in constrictive pericarditis. This is reflected in the waveform of the venous pulse, which in cardiac tamponade is characterized by a prominent systolic (x) descent and by absence of the normal (y) descent in early diastole. Venous pressure usually varies only slightly with respiration. Kussmaul's sign (increased venous pressure in inspiration) is seen in some cases of constrictive pericarditis but does not occur in uncomplicated cardiac tamponade.

Paradoxical pulse (an abnormal fall in arterial systolic pressure with inspiration) is characteristic of cardiac tamponade ([Fig. 79.2](#)). Paradoxical pulse results from an interplay of several factors, including the depth of intrathoracic pressure excursions with breathing. The principal factor, however, is the increased degree of interdependence of the volume of the right and left ventricles. Because both are contained within a relatively fixed overall volume imposed by the tense pericardial effusion, the increase in right ventricular volume with inspiration is accompanied by a greater than normal reduction in the volume of the left ventricle.

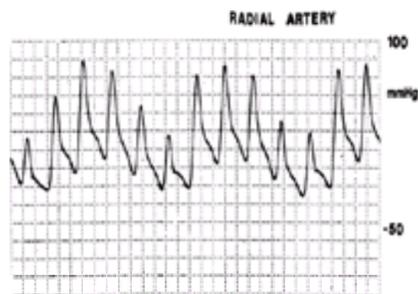

FIGURE 79.2. Radial artery pressure recording showing a paradoxical pulse. The systolic pressure falls by 15 to 20 mm Hg with inspiration. The diastolic pressure varies less. The fall in pulse pressure with inspiration reflects a fall in stroke volume.

CLINICAL FINDINGS

Very acute tamponade occurs most frequently on the basis of acute hemopericardium, caused by such conditions as closed chest or penetrating trauma, complications of cardiac catheterization, postoperative hemorrhage in cardiac surgical patients, acute dissection of the ascending aorta, or rupture of the heart in acute MI. Sudden hypotension is the hallmark of these cases. Paradoxical pulse is expected but may be undetected because of difficulty in obtaining the blood pressure. Venous pressure elevation is also expected but is often difficult to detect because the relative depletion of intravascular volume is accompanied by constriction of the superficial veins.

Patients with cardiac tamponade associated with medical conditions, such as idiopathic or infective pericarditis, neoplasm, renal failure, or rheumatic diseases, usually present in a less acute manner. The principal symptom is dyspnea, which occurs despite clear lungs. Pleural effusion is often associated and contributes to the dyspnea. Pericardial pain is often absent, and peripheral edema is frequently absent. Jugular venous pressure is nearly always elevated, however, and this is often the key finding in suggesting the diagnosis. The external jugular veins may not be visibly distended because of venoconstriction, but the internal jugular pulsations are seen above the level of the clavicle in the sitting position, usually up to the angle of the jaw.

The other key finding is the paradoxical pulse, which should be sought first by simple palpation and then assessed with the sphygmomanometer. A respiratory variation of 10 mm Hg is a convenient dividing line between normal and abnormal respiratory variation in arterial systolic pressure. Direct arterial pressure recordings are likely to show more variation, usually 15 mm Hg or more in clear instances of cardiac tamponade.

LABORATORY FINDINGS

The ECG in cardiac tamponade often shows low amplitude of the complexes, but this reflects the insulating or short-circuiting effect of the pericardial effusion rather than tamponade itself. Beat-to-beat alternation in the amplitude of the QRS complexes (electrical alternans) occurs in a few cases of cardiac tamponade and is a relatively specific sign. Electrical alternans in pericardial effusion essentially reflects a beat-to-beat change in QRS axis, because the heart swings from one position to another within the pericardial space on successive heartbeats. It is particularly characteristic of neoplastic pericardial effusion, probably because neoplastic effusions are often large effusions with serous fluid and free of adhesions within the pericardial space.

Chest radiographs are expected to show enlargement of the cardiomeastinal silhouette in subacute or chronic pericardial effusion with tamponade, although in very acute cases this may not be evident. The contour of the cardiomeastinal silhouette in pericardial effusion is not sufficiently distinctive for this to be reliable in diagnosis. The plain film may show lucencies, known as *pericardial fat lines*, caused by pericardial fluid adjacent to the epicardial fat, as a sign of pericardial effusion.

Echocardiography is the most valuable diagnostic procedure for the detection of pericardial effusion, demonstrating an echo-free space around the heart ([Fig. 79.3](#); see also [Chapter 85](#)). Pericardial effusion can also be demonstrated by other imaging techniques, such as computed tomography (CT) of the chest, magnetic resonance imaging (MRI), radionuclide scans, and contrast angiography, but these methods are more expensive and less convenient than echocardiography. Echocardiographic signs that suggest tamponade include a reduction in the diameter of the right ventricle, an abnormal degree of inward movement (collapse) of the free wall of the right atrium and right ventricle in early diastole, and an abnormal fullness of the inferior vena cava. Echocardiography also shows the exaggerated phasic changes in volume of the right and left ventricle with respiration and Doppler recordings of mitral and tricuspid flow velocity that are related to paradoxical pulse.

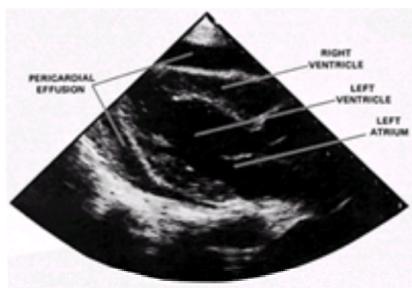

FIGURE 79.3. Two-dimensional echocardiogram showing pericardial effusion in a long-axis parasternal view. A prominent echo-free space is present both anterior to the right ventricle and posterior to the left ventricle. There is little fluid posterior to the left atrium because the space is limited by the attachments of the pulmonary veins.

OPTIMAL MANAGEMENT

Although the circulation may be supported temporarily by infusion of fluid, with cautious use of dopamine or isoproterenol, the only consistently effective treatment for cardiac tamponade is to remove the pericardial fluid. Removal of the pericardial fluid is indicated if the patient has symptoms or has reduction of arterial pressure, elevation of venous pressure to more than about 10 mm Hg, or a prominent paradoxical pulse. Pericardial fluid can be removed either by needle pericardiocentesis or by one of several surgical procedures. Surgical drainage is more certain to be effective and also provides a biopsy of the pericardium. Pericardiocentesis is less traumatic and is a superior method when physiologic assessment is an important objective of the procedure. Needle pericardiocentesis can be supplemented by balloon pericardiostomy in patients who have recurrent tamponade.

When compression of the heart is due solely to fluid under increased pressure, removal of the fluid leads to an immediate fall in venous pressure, a rise in arterial pressure and cardiac output, and near elimination of the paradoxical pulse. The central venous pressure may remain mildly elevated for 12 to 24 hours until a diuresis allows it to fall further. Occasionally, there is a constricting peel of tissue on the epicardial surface in addition to the pericardial effusion (effusive-constrictive pericarditis). In this case, the central venous pressure remains markedly elevated despite removal of the fluid, and a visceral pericardiectomy is required.

Localized cardiac tamponade occurs occasionally, usually in patients who are recovering from cardiac surgery. Fluid collects in a loculated area and compresses only a portion of the heart. The most common form of localized tamponade is caused by an anterior mediastinal hematoma that compresses the right atrium, simulating superior vena caval obstruction. A loculated pericardial effusion also may compress the left atrium selectively, causing pulmonary edema. Localized tamponade

usually requires surgical exploration, both to confirm the diagnosis and to evacuate the fluid.

CONSTRICTIVE PERICARDITIS

DEFINITION AND ETIOLOGY

In constrictive pericarditis the heart is compressed, or filling of the heart is limited, by solid tissue surrounding the heart. The solid tissue is usually scar tissue, but malignant solid tumors and organizing blood clot also can constrict the heart. Any of the causes of pericardial disease can produce sufficient scarring to result in constrictive pericarditis (Table 79.2). Most cases in developed countries are now idiopathic, rather than tuberculous, which was thought to be the most common cause in the past. Previous radiation therapy and cardiac surgery also have become common causes of constrictive pericarditis in the developed countries.

Common Causes	Rare Causes
Idiopathic	Bacterial infection
Radiation therapy (in developed countries)	Rheumatic diseases
Cardiac surgery (in developed countries)	Uremia/dialysis
Tuberculosis (in less developed countries)	Neoplasm
	Trauma
	Myocardial infarction

TABLE 79.2. CONSTRICTIVE PERICARDITIS

PATHOGENESIS

Because constriction is a subacute or chronic condition, the arterial pressure and cardiac output are usually well maintained by the compensatory control mechanisms of the circulation. Constrictive pericarditis acts more like a rigid shell around the heart than like a continuously imposed positive pressure on the heart. The heart is relatively little compressed at the beginning of diastole when its volume may be less than the volume of the rigid shell; therefore, the early diastolic inflow into the ventricles is not impeded. Filling becomes limited shortly into diastole when the volume of the heart reaches a critical level. Thus, the atrioventricular flow patterns and the associated pressure waveforms are different in constriction than in tamponade. Patients with constrictive pericarditis have a steep early diastolic descent in the venous pressure waveform, followed by a steep rise to a plateau level through the remainder of diastole. The ventricular pressure waveform shows the steep rise particularly well, with a dip-plateau or “square-root” waveform (Fig. 79.4).

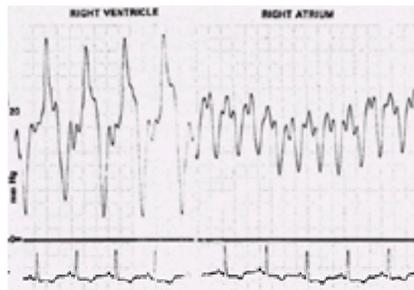

FIGURE 79.4. Pressure recordings in the right ventricle and right atrium in a patient with chronic constrictive pericarditis. Right ventricular pressure falls to a normal nadir in initial diastole but rises quickly to an elevated level for the remainder of diastole, producing a dip-plateau waveform (“square root” sign). Systolic (x) and diastolic (y) dips are both prominent in the right atrial pressure waveform (M or W waveform).

Constrictive pericarditis is not always like a rigid shell; it may be more elastic, with a hemodynamic pattern more like that of cardiac tamponade. There is a spectrum of cases between the rigid and elastic forms of constriction; the venous pressure waveform in many of them shows both prominent systolic and diastolic descents, assuming a W or M waveform. In occult constriction of the heart, the elevated filling pressures and abnormal pressure waveforms are seen only after additional intravascular volume has been infused.

CLINICAL FINDINGS

Patients with constrictive pericarditis usually have at least a mild degree of shortness of breath and impaired capacity for physical exertion. Edema of the ankles, ascites, enlargement of the liver due to congestion, and pleural effusion occur, singly or in any combination. Compared with patients with right-sided congestive heart failure caused by the common forms of heart disease, patients with constrictive pericarditis often have little or no ankle edema, probably because they are often younger and have better preserved skin and venous valves in the legs. Thus, many patients with constrictive pericarditis present primarily with ascites or hepatomegaly and are thought to have conditions such as cirrhosis of the liver or abdominal neoplasm. Others present primarily with pleural effusion and are thought to have conditions such as lung cancer or tuberculosis. The key to the differential diagnosis is to recognize the elevated jugular venous pressure during the physical examination.

Elevated jugular venous pressure is virtually a sine qua non for the diagnosis of constrictive pericarditis, unless there are specific conditions that prevent it from being recognized. The elevated venous pressure may be seen in either the external or the internal jugular veins. Unless the venous pressure is extremely high, the venous pulsation is also characteristic, showing a prominent brief dip in early diastole.

The cardiac impulse in constrictive pericarditis sometimes shows a retraction in systole and a prominent outward movement in early diastole. The latter is conspicuous enough in some patients to merit the term *diastolic heartbeat*. There is also an abnormal extra heart sound in early diastole, sometimes termed the *pericardial knock*. The sound is intermediate in both timing and character between a mitral opening snap and a typical third heart sound. Paradoxical pulse is not prominent in most patients with constrictive pericarditis.

LABORATORY FINDINGS

The ECG in patients with constrictive pericarditis is usually abnormal but not distinctive. Atrial fibrillation occurs frequently in long-standing cases, whereas those that are in sinus rhythm often show notched P waves with low amplitude, suggesting disease of the atrial myocardium. Most patients show mild nonspecific abnormalities of the T waves. QRS voltage is often relatively low.

The chest radiograph usually shows normal heart size and clear lungs, with little evidence of redistribution of pulmonary blood flow, in keeping with the level of pulmonary venous pressure, which is usually less than 20 mm Hg even in relatively severe cases. Calcification of the pericardium is seen in a few cases.

Echocardiographic images most often show that the size of the cardiac chambers, the systolic wall motion, and ventricular wall thickness all are normal. The ventricular septum usually shows an abnormal jerky motion in diastole. The pericardium usually appears thickened, but the limited resolution of echocardiography (about 1 mm) makes this a nonspecific finding. However, Doppler studies of the mitral and tricuspid flow velocities, as they vary with respiration, show distinctive exaggerations and are helpful in distinguishing constrictive pericarditis from restrictive cardiomyopathy.

CT and MRI have better resolution than echocardiography and provide more accurate assessment of the thickness of the pericardium. A normal thickness of the pericardium by MRI or CT gives substantial, although not complete, assurance that constriction is not present.

Cardiac catheterization is usually indicated when constrictive pericarditis is diagnosed, both to support the diagnosis and to indicate the severity of the constriction. The classic hemodynamic picture consists of diastolic pressures elevated to the same level in all chambers of the heart, with dip–plateau pressure waveforms in the right ventricle ([Fig. 79.3](#)).

Some patients with congestive heart failure, particularly those with amyloidosis or idiopathic restrictive cardiomyopathy, may have findings by cardiac catheterization and angiography that closely simulate those of constrictive pericarditis. Occasionally, a myocardial biopsy or even an exploratory thoracotomy is required for proof.

OPTIMAL MANAGEMENT

Surgical pericardiectomy is usually the only effective treatment and is indicated if the venous pressure is substantially elevated or if significant symptoms are attributable to the constriction. Pericardiectomy for constriction is essentially curative in most uncomplicated cases. However, it is often a difficult operation, with an operative mortality risk that is higher than that associated with coronary artery bypass surgery, for example. Constrictive pericarditis is occasionally spontaneously reversible when it develops in the wake of acute pericarditis. In other instances, constriction may be recognizable but may follow a clinically mild course, with the fluid retention controlled by diuretics alone, so that surgery may not be required.

SPECIFIC FORMS OF PERICARDIAL DISEASE

UREMIA/DIALYSIS

Pericarditis occurs in advanced renal failure, usually in the form of pericardial effusion with fibrinous deposits on the pericardial surfaces. Tamponade occurs rarely, but with no dialysis the pericarditis reflects an advanced stage of the uremic syndrome and a survival limited to weeks or months. A more important syndrome is the occurrence of pericarditis in patients who are on chronic maintenance dialysis. The genesis of dialysis pericarditis is unknown, because it occurs despite adequate dialysis. Pericardial effusion is usually the predominant manifestation, but chest pain, friction rub, and ECG indications of acute pericarditis also occur frequently.

Cardiac tamponade is difficult to recognize specifically in patients who are on dialysis, because of the hypertension, coronary artery disease, left ventricular failure, and fluid overload that are often associated. Tamponade caused by dialysis-related pericardial effusion often presents as an unexpected drop in arterial pressure during dialysis sessions.

Chest pain and other symptoms of pericardial inflammation may be treated symptomatically, as in idiopathic pericarditis. Corticosteroids may be used in severe cases, and some favor the instillation of triamcinolone, a nonabsorbable corticosteroid, into the pericardial space. Hemodynamic abnormalities severe enough to require intervention are best managed by pericardiocentesis or subxiphoid pericardiostomy, since recurrent tamponade is unusual and progression to constriction is rare.

RHEUMATIC DISEASES

Pericardial involvement in patients with rheumatoid arthritis usually occurs in association with other extra-articular involvement and with a positive serologic test for the rheumatoid factor. The effusive–constrictive pericarditis syndrome is particularly likely to develop in patients with rheumatoid arthritis. Pericarditis occurs eventually in most patients with long-standing systemic lupus erythematosus. It often develops during flare-ups as the syndrome of acute pericarditis. Corticosteroid therapy is more likely to be used in pericardial disease associated with rheumatic diseases than in other forms, but this is because of the indications for corticosteroids in controlling the basic disease process.

NEOPLASM

Neoplasms account for about 50% of the cases of cardiac tamponade among medical patients. Carcinomas of the breast and lung are the most common sources. Neoplastic pericardial disease is prone to cause large pericardial effusions, often with relatively little solid tumor involvement of the pericardium. The neoplasm often spreads from the mediastinal lymph nodes to the heart by way of the lymphatics, and lymphatic obstruction is probably a frequent contributing factor to the effusion.

In general, neoplastic pericardial effusion represents advanced cancer with a short life expectancy, a fact that tends to dictate a conservative approach. Patients with breast cancer that involves the pericardium, however, usually respond to chemotherapy and have a substantial period of survival. Also, pericardial effusion in a patient with neoplasm is not necessarily neoplastic; it may be due to previous radiation therapy, and there is also an increased incidence of idiopathic nonneoplastic pericardial effusion in patients with neoplasms. This tends to dictate an aggressive diagnostic approach, usually including cytologic study of the pericardial fluid. Cytologic study is highly likely to be positive if the involvement is that of breast or lung cancer; it is less likely to be positive in lymphomas and other neoplasms that less commonly metastasize to the pericardium.

Cardiac tamponade in neoplastic pericardial disease usually responds well to needle pericardiocentesis. Recurrence of effusion is relatively common and may require a partial pericardiectomy, but a substantial proportion of cases do not recur if a single tap is followed by several days of percutaneous catheter drainage.

PERICARDIAL DISEASE AFTER RADIATION THERAPY

Radiation therapy for neoplasms in the chest, especially Hodgkin's disease, is an important cause of pericardial disease. The pericardial disease can present as acute or subacute pericarditis, and the onset is months or years, sometimes many years, after the radiation therapy has been completed.

Pericardial disease is usually the most important aspect of the cardiac complications of irradiation, but myocardial fibrosis, coronary artery disease, conduction system disease, and valvular disease also occur in varying combinations in many patients. The differential diagnosis always includes recurrent neoplasm. In addition, radiation disease of the lungs and pleura is often associated and contributes to a complex clinical picture.

Pericardiectomy for radiation-related constrictive pericarditis should only be undertaken for strong indications, because of the added operative risk and often limited long-term results.

TUBERCULOUS PERICARDITIS

Infection of the pericardium by the tubercle bacillus is usually hematogenous and is not necessarily associated with active pulmonary tuberculosis. It may present as acute pericarditis but is more likely to have a subacute course with pericardial effusion. In the developed Western countries, where tuberculous pericarditis has become rare, a negative tuberculin skin test is usually sufficient to effectively exclude this diagnosis. Achieving a positive diagnosis is difficult, because the pericardial fluid is often negative for tubercle bacilli, both on smear and culture. Biopsy of the pericardium gives a higher proportion of positive results.

Antituberculous chemotherapy is often not sufficient to prevent tamponade or constriction in those with active tuberculous pericarditis. Pericardiocentesis is indicated when there is evidence of tamponade, and pericardiectomy is indicated when substantial constriction is demonstrated, regardless of the duration of chemotherapy.

PURULENT PERICARDITIS

Bacterial (purulent) pericarditis usually requires both antibiotic therapy and surgical drainage for a successful outcome. However, purulent pericarditis is likely to

progress to constriction within a short time, even when a needle pericardiocentesis or a subxiphoid pericardiostomy has been done. Therefore, a limited pericardial resection is usually indicated at the time the diagnosis is established. Selected cases, particularly those with relatively thin serous effusions, may be managed by antibiotics and catheter drainage alone.

PERICARDIAL DISEASE IN PATIENTS WITH AIDS

Pericardial disease occurs in about 20% of patients with AIDS, and about 25% of these have large pericardial effusions with cardiac tamponade. Many are idiopathic (apparently caused by the HIV itself), but about 50% are caused by bacterial or mycobacterial infection and about 10% by neoplasms such as lymphoma or Kaposi's sarcoma.

POSTCARDIOTOMY SYNDROME

The postcardiotomy syndrome is a syndrome of acute pericarditis that often occurs after cardiac surgery. The mechanism may involve a hypersensitivity reaction to blood, to products of damaged myocardium, to foreign material introduced at the time of surgery, or to viral infection. Pericardial effusion is common and tamponade occurs occasionally. The constrictive pericarditis that occurs after cardiac surgery is probably a late complication of the postcardiotomy syndrome.

PERICARDITIS AFTER MYOCARDIAL INFARCTION

Two types of pericarditis occur after MI. Both are characterized by the syndrome of acute pericarditis, often with some pericardial effusion and rarely with tamponade or constriction. The early form is a direct result of the acute myocardial necrosis and is particularly characteristic of large infarctions. It is seen less often than in the past, probably as a result of the beneficial effect of therapeutic reopening of the infarct-related artery in the early stage of acute MI. The late form of pericarditis after MI, occurring 1 to 2 weeks or more after the acute infarction, is known as *Dressler's syndrome*. It is clinically similar to the postcardiotomy syndrome and probably has a similar pathologic mechanism.

CONGENITAL ABSENCE OF THE PERICARDIUM

Congenital absence of the pericardium occurs occasionally, usually with absence of the left pericardium and rarely a total absence. The condition is generally unimportant, but it may be discovered in chest radiographs because the absence of the pericardium causes unusual prominence of the radiographic shadows of the structures along the left border of the heart shadow, especially the main pulmonary artery. Rarely symptoms and even death result from strangulated herniation of portions of the heart through a partial defect in the pericardium.

PERICARDIAL CYSTS

Pericardial cysts usually present as asymptomatic masses near the right or left pericardiophrenic angle in the chest radiograph. Most are probably congenital. If the differential diagnosis can be resolved noninvasively, surgery is not required.

[Clinical Features](#)
[Diagnosis](#)
[Optimal Management](#)
[Prognosis and Natural History](#)

NORMAL PULMONARY CIRCULATION

The pulmonary circulation is normally a high-flow, low-resistance circuit that is capable of accommodating the entire right ventricular output at a pressure that is one-fifth of the level in the systemic circulation. In contrast to the pressure-generator pumping properties of the left ventricle, the thin-walled right ventricle functions primarily as a flow-generator pump. Accordingly, the right ventricle is particularly sensitive to increases in its afterload.

The pulmonary vascular bed has a remarkable capacity to regulate its vascular tone and recruit unused vessels to adapt to physiologic changes. For example, the fourfold or greater increases in cardiac output that occur during maximal exercise are accepted by the normal pulmonary circulation with a minimal increase in pulmonary artery pressure. Similarly, regional decreases in alveolar ventilation and oxygen tension are associated with local vasoconstriction, which redistributes blood flow to adequately ventilated lung units to optimize ventilation–perfusion relations. This phenomenon, known as *hypoxic pulmonary vasoconstriction*, depends on the alveolar and to a lesser degree on the mixed venous oxygen tensions and is potentiated by hypercarbia and acidosis.

The initial phase of the hypoxic pressor response results from inhibition of pulmonary vascular smooth muscle K^+ channel conductance, leading to cellular depolarization and an influx of Ca^{2+} ions through voltage-gated calcium channels. Prolonged or intense pulmonary vasoconstriction leads to a remodeling of the pulmonary circulation, which includes a loss of distal vasculature, extension of smooth muscle into small, nonmuscularized pulmonary arterioles, intimal fibrosis, and, eventually, more severe degrees of vascular obstruction and obliteration. This process, possibly mediated by vascular growth factors, may be responsible for the progression of pulmonary hypertension in chronic hypoxic lung diseases and primary pulmonary hypertension. Evidence suggests that endothelium-derived substances may play an important modulating role in the responses of pulmonary vascular smooth muscle to hypoxia. In conditions such as chronic pulmonary thromboembolism, obstruction of a large component of the vascular surface area is the primary cause of the increased pulmonary artery pressure.

DEFINITIONS

The pressures in the normal pulmonary circulation are shown in [Figure 80.1](#). *Pulmonary hypertension* is defined as a mean pulmonary artery pressure exceeding 25 mm Hg at rest or 30 mm Hg during exercise. Although the term *cor pulmonale* is often equated with overt right-sided heart failure, it is best defined as pulmonary hypertension in the setting of chronic respiratory disease. Right-sided heart failure is a late manifestation of chronic pulmonary hypertension, and its presence should not be required to entertain the diagnosis of cor pulmonale.

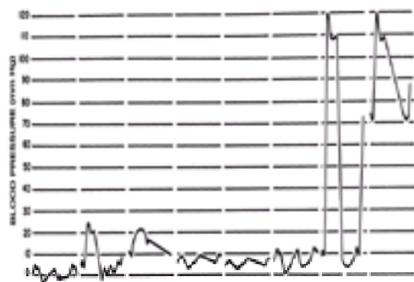

FIGURE 80.1. Pressures in the normal pulmonary circulation contrasted to those in the systemic circulation.

ETIOLOGY

The causes of pulmonary hypertension can be categorized according to the primary circulatory site of the pathophysiologic insult ([Table 80.1](#)). Postcapillary pulmonary hypertension is caused by obstruction of pulmonary venous return, which secondarily produces an increase in precapillary vascular pressure. Precapillary pulmonary hypertension is caused by constriction, obstruction, or obliteration of a substantial component of the pulmonary arterial tree. Although all conditions associated with precapillary pulmonary hypertension share similar hemodynamic profiles, the pathogenesis should be determined, and the approach to therapy should be individualized according to the cause.

Postcapillary
Left ventricular failure
Mitral valve disease
Aortic valve disease
Left atrial myxoma or thrombus
Pulmonary venoocclusive disease
Precapillary
Respiratory disorders
Parenchymal lung disease (obstructive, restrictive, or mixed)
Restrictive chest wall diseases
Sleep apnea and hypoventilation syndromes
High altitude disease
Occlusive pulmonary vascular disease (tumor, aic, amniotic fluid, intravenously injected foreign material, schistosomiasis)
Congenital heart disease
Intracardiac septal defects
Peripheral pulmonary stenosis
Pulmonary vasculitis
Primary pulmonary hypertension

TABLE 80.1. CLASSIFICATION OF PULMONARY HYPERTENSION BASED ON SITE OF PRIMARY INJURY

DISTURBANCES OF VENTILATION AND GAS EXCHANGE

The presence and severity of pulmonary hypertension in the setting of chronic respiratory diseases correlate with parameters indicating the degree of impairment in ventilation or gas exchange. For example, the lower the forced expiratory volume in 1 second (FEV_1) in patients with chronic obstructive pulmonary disease, the greater is the likelihood of pulmonary hypertension, particularly when the FEV_1 falls below 1 L. In patients with restrictive lung disease, a vital capacity below 50% of predicted has been correlated with elevations in pulmonary artery pressure.

The strongest correlations have been found with the degree of arterial hypoxemia. Patients with a P_{aO_2} value less than 55 mm Hg are likely to have pulmonary hypertension, and acidosis or hypercarbia may further contribute to this process.

PULMONARY THROMBOEMBOLISM

Although most patients who experience an acute pulmonary embolism do not have elevations in pulmonary artery pressure, massive embolism can produce vascular obstruction sufficient to raise pressure and cause cardiovascular collapse. Pulmonary hypertension can also be caused by recurrent small-vessel embolism. Most of these patients have never experienced a distinct “embolic event” that necessitated medical attention.

Large-vessel unresolved pulmonary embolism is a potentially treatable cause of chronic pulmonary hypertension. This entity is probably the result of an isolated, often subclinical, embolic event and should be considered in the differential diagnosis of unexplained pulmonary hypertension.

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension is a rare disease of unknown cause in which substantial and often extreme elevations in pulmonary artery pressure are seen with no known causative factors. This hypertension occurs more often in women, particularly in the childbearing years. A familial association has been found in some patients, which suggests an autosomal dominant mode of genetic transmission with incomplete penetrance, and recent efforts have localized the site of the genes responsible for familial primary pulmonary hypertension. Clinical and pathologic findings consistent with primary pulmonary hypertension have also been found increasingly frequently in patients with portal hypertension and spontaneous or surgically induced portal–systemic shunting. The mechanism responsible is unknown, but one theory suggests that vasotoxins, which are normally metabolized by the liver, reach the pulmonary circulation and induce vascular disease.

Primary pulmonary hypertension is characterized by a spectrum of vascular lesions, from medial hypertrophy of small pulmonary arteries and intimal proliferation of pulmonary arteries and arterioles to more severe destructive vascular abnormalities, such as plexiform lesions and fibrinoid necrosis ([Fig. 80.2](#)). Pulmonary veno-occlusive disease is characterized by obliterative changes in the pulmonary venules and secondary changes in the arterial bed.

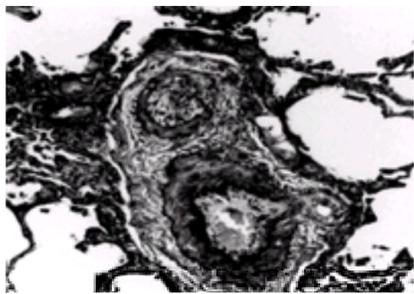

FIGURE 80.2. Pathologic features in the vessels of a patient with primary pulmonary hypertension. Shown are intimal fibrosis and medial hypertrophy in a small pulmonary artery.

PULMONARY HYPERTENSION DUE TO EXOGENOUS SUBSTANCES

A variety of exogenous substances can produce pulmonary hypertension. Drug abusers frequently inject foreign material intravenously, such as cotton fibers and talc, which may obstruct the circulation or induce a granulomatous reaction within the vessel wall and surrounding parenchyma. Inhaled cocaine use has also produced pulmonary vascular disease, presumably because of its potent vasoconstrictor effects. Tea made from the seeds of *Crotalaria fulva* (bush tea) and a herbal remedy from the seeds of *Crotalaria laburnoides* have been implicated in pulmonary vascular disease in several patients, and monocrotaline, an alkaloid derived from *Crotalaria*, has been shown to produce a necrotizing pulmonary arteritis in animal studies.

An epidemic of severe pulmonary hypertension in Europe between 1967 and 1968 coincided with the widespread use of aminorex, a diet suppressant structurally related to amphetamines. More recently, an association between the use of the anorexigens, fenfluramine and dexfenfluramine, which work by inhibiting the reuptake of serotonin in the brain, has been demonstrated in a case-controlled, prospective epidemiologic study. *Infection with HIV has been associated with the development of severe pulmonary hypertension*, which is similar pathologically to primary pulmonary hypertension. The mechanism responsible is uncertain, but the condition appears unrelated to the level of immunocompetence and may be present with no other signs of HIV infection.

CLINICAL FEATURES

The symptoms associated with pulmonary hypertension are usually nonspecific, and patients with chronic respiratory disease who develop cor pulmonale may present merely with a worsening of their previous symptoms. Exertional dyspnea, tachypnea, chest pain, and light-headedness are common and are related to the increased right ventricular work. The pulmonary vascular limitation is attributed to the inability to increase cardiac output, particularly during exercise. Syncope, pedal edema, and ascites are indicative of more critical impairments in right ventricular function. Hemoptysis, presumably caused by rupture of small vessels, occasionally occurs in patients with precapillary pulmonary hypertension, but it is more common in those with pulmonary venous hypertension. Hoarseness occurs with severe pulmonary hypertension and is caused by compression of the left recurrent laryngeal nerve by enlarged proximal pulmonary arteries. Raynaud's phenomenon may affect patients with connective tissue diseases or, on occasion, those with primary pulmonary hypertension.

DIAGNOSIS

PHYSICAL EXAMINATION

In addition to findings referable to the underlying diseases, the physical examination can provide important clues to the presence of pulmonary hypertension. Examination of the neck may show jugular venous distention and prominent cv waves, which are indicative of tricuspid insufficiency. Palpation of the precordium may reveal a parasternal lift or, in patients with hyperinflated lungs due to chronic obstructive airways disease, a prominent subxiphoid cardiac impulse. On auscultation, the pulmonic component of the second heart sound is loud, and a pulmonic ejection click may be found. Third and fourth heart sounds heard at the left parasternal region are found in right ventricular failure or severe pulmonary hypertension, respectively. The murmur of tricuspid insufficiency, a holosystolic murmur increasing with inspiration that is best heard along the lower left sternal border, is frequently audible as right ventricular dilation develops. The Graham Steell murmur of pulmonic insufficiency is heard as a diastolic blow at the left second intercostal space.

Examination of the abdomen may disclose tender hepatomegaly due to venous congestion or the pulsatile liver of tricuspid insufficiency. Ascites and edema may indicate overt right-sided heart failure in the absence of other potential causes, such as hypoalbuminemia. Digit clubbing is a common finding in patients with chronic obstructive lung disease, pulmonary fibrosis, cystic fibrosis, and congenital heart disease but is uncommon in other conditions causing pulmonary hypertension, such as primary pulmonary hypertension and thromboembolism.

LABORATORY TESTS

The diagnostic approach consists of two paths: establishing the presence and degree of pulmonary vascular disease and clarifying the cause. Some studies, particularly the more invasive procedures, may be useful for both objectives but are often not undertaken early in the evaluation of patients suspected of having

pulmonary hypertension because of the risks entailed.

Pulmonary function testing and arterial blood gas analysis are useful in detecting unsuspected or deteriorating chronic respiratory disease. Some investigators have suggested performing sleep studies, monitoring oxygen saturation noninvasively in patients with unexplained pulmonary hypertension to exclude sleep apnea or hypoventilation syndromes.

The electrocardiogram (ECG) usually shows evidence of right ventricular hypertrophy, with a frontal plane axis that is generally greater than 100 degrees and an R/S ratio in the right precordial leads (V_1 and V_2) of >1 , and S waves greater than 3 mm in leads V_5 and V_6 (Fig. 80.3). P pulmonale, defined as a P wave greater than 2.5 mm in amplitude in leads II, III, aVF, and V_1 or V_2 , is an insensitive marker for pulmonary hypertension, because it can be seen in patients with acute or chronic respiratory diseases in the absence of pulmonary hypertension.

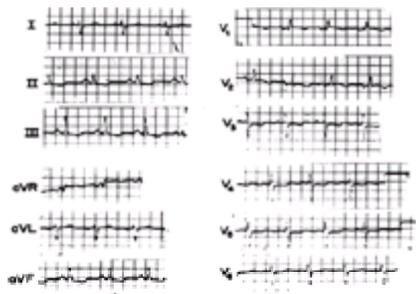

FIGURE 80.3. Electrocardiogram from a patient with primary pulmonary hypertension demonstrating changes of right ventricular hypertrophy.

Echocardiography is a useful noninvasive procedure for patients with suspected pulmonary hypertension. Chamber size and wall motion can be assessed, and the presence and severity of tricuspid and pulmonic insufficiency can be evaluated, particularly using Doppler techniques. Echocardiography may provide important information concerning mitral valve disease or left ventricular dysfunction. A right-to-left shunt may be determined using agitated saline or hydrogen peroxide injected intravenously and looking for bubbles traversing to the left side of the heart. Pulmonary artery systolic pressure may also be estimated by Doppler echocardiography, although these measurements are not consistently reliable.

Ventilation–perfusion lung scanning is a critical test in diagnosing the cause of pulmonary hypertension. Patients with recurrent or unresolved thromboembolism have multiple perfusion defects (Fig. 80.4), but the perfusion scan is qualitatively essentially normal for patients with primary pulmonary hypertension. Patients with pulmonary veno-occlusive disease may exhibit a mottled or patchy distribution on perfusion lung scanning. Although there are several anecdotal reports of fatalities during lung scanning of patients with pulmonary hypertension, this test can generally be performed safely and without substantial risk. Scanning of the brain or kidneys after intravenous injection of the tracer may provide evidence of an unsuspected intracardiac or intrapulmonary shunt (Fig. 80.5).

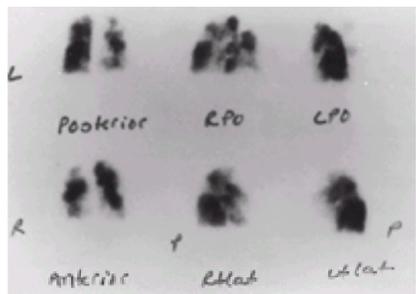

FIGURE 80.4. Perfusion lung scan from a patient with chronic thromboembolic pulmonary hypertension demonstrating multiple perfusion defects.

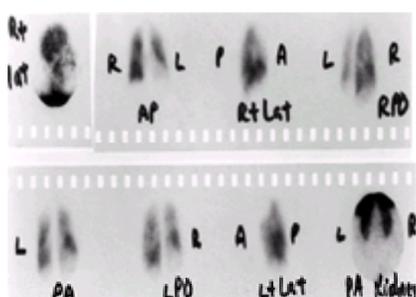

FIGURE 80.5. Perfusion lung scan from a patient with primary pulmonary hypertension demonstrating homogeneous perfusion. Right-to-left shunting through a patent foramen ovale resulted in the demonstration of tracer uptake in the head and kidneys.

Pulmonary arteriography should be performed for a patient with evidence of pulmonary hypertension who has an abnormal lung scan result to clarify the diagnosis and to determine the extent and site of a clot. Pulmonary arteriography carries increased risk in this setting, but it can be performed safely by using newer contrast materials with less osmotic properties and by performing selective studies with hand injections.

A positive test for antinuclear antibody, usually at a lower titer and in a nonspecific pattern, is obtained for about 25% of patients with primary pulmonary hypertension. An elevated hematocrit level in a patient with pulmonary hypertension should prompt consideration of hypoxemia due to chronic parenchymal lung disease, sleep apnea, or right-to-left shunting. Detailed coagulation studies should be performed for patients with recurrent or major unresolved thromboembolism to exclude antithrombin III, protein C, or protein S deficiencies or the presence of a circulating anticoagulant.

The role of open-lung biopsy in the evaluation of unexplained pulmonary hypertension remains controversial. Although open-lung biopsy can establish the presence of subclinical interstitial lung disease, pulmonary vasculitis, or small-vessel thromboembolism and can clarify the pathologic severity of pulmonary vascular disease, this procedure carries substantial risk in patients with pulmonary vascular disease who are fragile hemodynamically. Open-lung biopsy may be important in guiding appropriate therapy in patients in whom the cause of pulmonary hypertension is not clear on clinical grounds.

A clinical diagnosis of primary pulmonary hypertension can be made when pulmonary artery hypertension (mean pulmonary artery pressure 25 mm Hg at rest) exists in the absence of significant parenchymal lung disease, thromboembolic disease, congenital heart disease, left-sided valvular heart disease, or left ventricular dysfunction. Pulmonary veno-occlusive disease may be suspected in a patient who has a chest radiograph suggesting pulmonary edema with Kerley B lines, but

cardiac catheterization demonstrates pulmonary hypertension with a normal pulmonary artery wedge pressure.

OPTIMAL MANAGEMENT

TREATMENT OF UNDERLYING DISEASE

Pulmonary hypertension is a manifestation of a variety of disorders affecting the pulmonary circulation. Therapy should address the responsible factors, if possible. Therapeutic measures that improve ventilation and gas exchange, such as bronchodilators, mucolytics, corticosteroids, and respiratory stimulants, may secondarily improve the abnormalities in the pulmonary circulation in patients with parenchymal lung disease. Some bronchodilators, such as the theophylline derivatives and β_2 -agonists, also have modest pulmonary vasodilator and inotropic properties that may be beneficial.

Supplemental oxygen therapy can prolong life in hypoxemic patients with chronic obstructive pulmonary disease, although its hemodynamic effects are variable and frequently not dramatic. The maximal effects of oxygen on pulmonary hemodynamics may not be seen for several months after beginning therapy.

The criteria most frequently used for instituting supplemental oxygen therapy are a stable $\text{Pa O}_2 < 55$ mm Hg when breathing ambient air or a $\text{PaO}_2 < 60$ mm Hg with P pulmonale on the ECG, a hematocrit greater than 55%, or edema. Patients with documented exercise-induced hypoxemia may also benefit from oxygen therapy. Oxygen should be administered in a manner that raises the Pa O_2 to more than 60 mm Hg, and it should be used as continuously as possible. The flow rates should be increased at night for patients who experience desaturation during sleep.

Although most patients with primary pulmonary hypertension do not experience hemodynamic improvement with supplemental oxygen, they may notice symptomatic improvement, which may justify its expense and cumbersome nature.

CARDIAC GLYCOSIDES AND DIURETICS

The value of digitalis in the management of isolated right ventricular dysfunction appears limited. Digitalis toxicity occurs more frequently in patients with chronic respiratory disease, owing in part to the coexistent hypoxemia, endogenous and exogenous catecholamine excess, and hypokalemia with concomitant diuretic use. Digitalis may be useful for biventricular failure and for control of supraventricular tachyarrhythmias in the absence of reversible causes.

Because the right ventricle is sensitive to reductions in preload, diuretics should be used with caution in the setting of cor pulmonale. Small doses of oral furosemide (20 to 40 mg) should be given initially, with the dose increased as needed. In patients with ascites or anasarca that is refractory to furosemide, oral metolazone in initial doses of 2.5 to 5 mg has proved useful. Serum levels of electrolytes, particularly potassium and magnesium, should be monitored periodically when diuretics are administered.

PHLEBOTOMY

Polycythemia is common in patients with chronic hypoxemia and can result in hyperviscosity, which can further contribute to pulmonary hypertension. Supplemental oxygen therapy produces a fall in the hematocrit of patients with chronic obstructive pulmonary disease, although it may take months to occur. Isovolumic phlebotomy is recommended if the hematocrit exceeds 50%, because at this level, the decrease in oxygen carrying capacity produced by phlebotomy is offset by the increases in cardiac output and systemic oxygen delivery, which occur when the viscosity of blood is returned to normal.

ANTICOAGULATION

Unless contraindicated, patients with pulmonary hypertension due to thromboembolism and primary pulmonary hypertension should be treated with anticoagulants for life. The treatment of choice is warfarin, administered in doses sufficient to prolong the prothrombin time to an international normalized ratio of 2:3. Subcutaneous heparin, administered two or three times daily in doses sufficient to prolong the activated partial thromboplastin time to 1.5 times that of the control, may be as effective as warfarin in preventing recurrence and is associated with a lower incidence of bleeding complications.

The use of anticoagulants in other causes of pulmonary hypertension is controversial. The rationale for their use is based on the increased risk of a potentially fatal thromboembolism in patients with a compromised pulmonary vascular bed who are predisposed because they are frequently sedentary and have venous stasis and sluggish pulmonary blood flow. However, the risks of hemorrhagic complications may be increased in patients with the altered hepatic metabolism of warfarin because of right-sided heart failure. Serious adverse effects, including fatal hemoptysis, have been reported in patients with pulmonary hypertension treated with oral anticoagulants.

VASODILATORS

The rationale for the use of vasodilators in some forms of pulmonary hypertension is based on the pathologic findings of medial hypertrophy, implying active vasoconstriction in some forms of pulmonary hypertension, and on the demonstration that several systemic vasodilators exert similar effects in the pulmonary circulation in experimental models of pulmonary vasoconstriction. Because development of right-sided heart failure results from the increased right ventricular afterload produced by the elevations in pulmonary artery pressure, interventions that reduce afterload could improve right ventricular output.

A variety of vasodilators have been used to treat patients with pulmonary hypertension from diverse causes ([Table 80.2](#)). Substantial hemodynamic and symptomatic improvements have been reported for some patients with primary or secondary forms of pulmonary hypertension. Acute deterioration with hypotension, worsening hypoxemia, and death have also been reported. The mixed experience with this approach to therapy emphasizes the need for extreme caution and careful monitoring of cardiovascular dynamics and gas exchange if vasodilator administration is contemplated.

Agent	Trial Dosage	Plasma Half-Life	Long-Term Therapy
Nifedipine	10 mg tid initially; repeat once after 15-20 min ^a	3-4 h	10-40 mg PO 2 or 4 times daily or 40-160 mg of extended-release preparation once daily ^b
Diltiazem	30 mg PO ^a	3-5 h	30-60 mg PO 2 times daily or 90-270 mg of extended-release preparation once daily ^b
Adenosine	50 μ g/kg/min IV, increasing infusion by 50 μ g/kg/min every 2 min to a maximum of 200 μ g/kg/min	1-10 min	None
Nitro-glycerin	10-40 μ g/min IV	2-5 min	None
Prostaglandin ₁ (prostaglandin)	1-2 μ g/kg/min IV, increasing by 2 μ g/kg/min every 10-15 min	3-5 min	2-200 μ g/kg/min ^c
Prostaglandin ₂	0.02-0.04 μ g/kg/min IV	30 min	Under investigation

^aNot recommended for testing of acute responsiveness; doses are for initiation of oral therapy.
^bDoses of oral therapy should be adjusted based on individual needs and responses.

TABLE 80.2. VASODILATORS USED FOR PULMONARY HYPERTENSION

Because of the risks of protracted adverse effects when a vasodilator is administered to a patient with “fixed” pulmonary vascular disease, some researchers have advocated using potent, short-acting, titratable vasodilators administered intravenously or by inhalation to evaluate the initial responses to this form of therapy. Prostaglandin I_2 (PGI_2), which is now commercially available, has been used in this manner and may be useful in determining whether vasoreactivity exists. Patients who respond to infusion of PGI_2 with increases in cardiac output and decreases in pulmonary artery pressure or pulmonary vascular resistance seem to manifest similar responses when given orally active drugs. Other commercially available intravenous vasodilators such as adenosine, acetylcholine, and prostaglandin E_1 may be useful in a similar fashion, but experience with these drugs in this setting is limited. PGI_2 has also been used as a continuous intravenous infusion for the treatment

of severe pulmonary hypertension and may be particularly useful as a bridge to transplantation.

Inhaled nitric oxide (NO), the endothelium-derived relaxing factor, has been used to test vascular reactivity initially and to treat patients with severe pulmonary hypertension for brief periods. Inhaled NO is a fairly selective pulmonary vasodilator, because the molecule readily binds to hemoglobin in the pulmonary capillary bed, rendering it physiologically inactive.

The question about what constitutes a beneficial response to vasodilators is unresolved. Although most investigators agree that a substantial fall in pulmonary artery pressure accompanied by an increase in cardiac output is a beneficial response, this pattern is observed infrequently. More commonly, cardiac output increases while pulmonary artery pressure falls slightly or not at all. Because most patients who manifest an increased cardiac output with vasodilators notice improvement in symptoms, chronic therapy may still be warranted. The generally accepted contraindications to vasodilator therapy are symptomatic hypotension, an increase in pulmonary artery pressure, and a deterioration in gas exchange with worsening hypoxemia. This latter event is usually caused by a worsening ventilation-perfusion relation as blood flow increases to poorly ventilated lung units. In patients with right-to-left shunts, vasodilators can increase shunting if systemic vasodilation is greater than pulmonary vasodilation.

TRANSPLANTATION

Combined heart-lung transplantation has been performed successfully in patients with primary pulmonary hypertension or Eisenmenger's syndrome. The major limitations to more widespread application of this approach are the limited availability of suitable organs for transplantation and the limited access to the few centers with the expertise and resources to perform the operation. Additional problems include postsurgical complications, such as transplant rejection, increased susceptibility to opportunistic infections, and adverse effects attributable to immunosuppressant therapy. Bronchiolitis obliterans occurs in as many as 40% of patients after heart-lung transplantation and may be life threatening. Single- or double-lung transplantation has also been performed successfully in patients with pulmonary hypertension in whom right ventricular function was less severely impaired. The greater availability of lungs for transplantation, compared with heart-lung blocs, may make this approach more suitable for widespread applications in the future.

PROGNOSIS AND NATURAL HISTORY

Coexistent pulmonary hypertension in the setting of chronic respiratory disease is a poor prognostic sign, with death resulting from respiratory failure or combined cardiopulmonary decompensation commonly occurring within 3 to 5 years.

The median survival from the time of initial diagnosis in primary pulmonary hypertension is 2 to 3 years. Survival is related more to right-sided heart function than to the degree of pulmonary artery pressure elevation. A reduced cardiac output or symptoms indicative of an inability to increase cardiac output with activity, such as syncope, are ominous signs. Spontaneous remissions of primary pulmonary hypertension have been reported but appear to be unusual. Improved survival with oral vasodilator therapy or transplantation has not been evaluated in a prospective, multicenter study fashion, but continuous infusion of PGI₂ has been shown to improve survival in severely affected patients with primary pulmonary hypertension.

CHAPTER 81: VASCULAR MEDICINE

MARK A CREAGER AND MARIE GERHARD-HERMAN

[Arterial Disease](#)
[Specific Arterial Diseases](#)
[Arteriovenous Fistula](#)
[Venous Disease](#)
[Lymphatic Disease](#)

Vascular disease constitutes some of the most common causes of disability and death in Western society. Vascular medicine is a subspecialty of medicine that involves the treatment of disorders affecting arteries, veins, and lymphatics. This includes atherosclerosis of the peripheral arteries, arterial aneurysms, vasospastic diseases, venous thromboembolism, venous insufficiency, lymphedema, and the many disorders that predispose to these vascular diseases. In the field of vascular medicine, the vasculature is often thought of as a unique system, since the vessels supplying different organs share many structural and functional features. This concept, along with advances in vascular technology and interventions, has led to the growth of this field.

ARTERIAL DISEASE

Arteries are commonly described as large (elastic), medium (elastic and muscular), and small (muscular). Their main function is to deliver oxygenated blood to organs. All arteries are composed of intima, media, and adventitia. The intima, the innermost layer, is normally a thin layer composed of endothelial cells and bounded by the internal elastic lamina. Endothelial cells synthesize vasoactive factors that can relax and constrict blood vessels, as well as factors with anticoagulant and procoagulant activities. The smooth muscle cells of the media are bounded by the internal and external elastic lamina and regulate the tone of the vessels. The outermost layer is the connective tissue matrix of the adventitia, which contains both fibroblasts and smooth muscle cells. Arterial disease results from pathologic narrowing of the lumen, inappropriate vasoconstriction, and structural weakness of the media.

ARTERIAL OCCLUSIVE DISEASE

Symptomatic arterial occlusive disease generally occurs when the luminal diameter is reduced to half of the normal diameter. Acquired arterial stenoses and occlusion may be chronic or acute. Atherosclerosis is the most common cause of peripheral arterial disease. Other causes must be considered in persons without risk factors for atherosclerosis or with an unusual distribution of arterial occlusive disease. These include arteritides such as Takayasu's arteritis and giant cell arteritis, which may cause a localized inflammatory reaction that results in stenosis of upper and lower extremity vessels, the aorta, or visceral vessels. Other forms of vasculitis ([Chapter 181](#)) can also result in symptomatic arterial occlusive disease. Thromboangiitis obliterans, characterized by intimal inflammation and thrombosis, affects the distal arteries of the upper and lower extremities. Arterial occlusion also occurs as a consequence of embolism or thrombosis in situ. Emboli originating in the heart may travel to the aorta and lower extremities. Thrombosis can acutely develop in diseased arteries or occur in normal arteries in patients with some hypercoagulable states or with trauma. Coarctation of the aorta is a congenital cause of arterial narrowing due to hypoplastic growth in a localized area of the thoracic, or more rarely, abdominal, aorta.

PERIPHERAL ARTERIAL DISEASE

Atherosclerosis of the lower extremity causes symptoms in approximately 3% of persons over the age of 50. In contrast, over 25% of persons over age 70 have evidence of peripheral arterial disease by noninvasive testing. The prevalence of peripheral arterial disease is threefold greater when determined by noninvasive testing for arterial stenosis rather than by questionnaires regarding symptoms, consistent with the observation that two-thirds of affected persons are asymptomatic. The risk of peripheral atherosclerosis increases with the presence of known risk factors for atherosclerosis ([Table 81.1](#)). Ten percent of symptomatic patients have arterial stenoses limited to the aorta and iliac arteries, and the other 90% have diffuse disease extending to the femoral and tibioperoneal vessels. Patients with only aortoiliac disease tend to be younger and have a high incidence of cigarette smoking. Patients with more extensive disease are likely to be older or have diabetes.

Risk Factor	Relative Risk
Diabetes	3.0-4.0
Smoking	2.5-3.0
Hypertension	1.5-2.5
Cholesterol (each 10 mg/dL)	1.1
Age (q 10 yr)	1.6-2.4
Non white	1.3-3.4
Gender	1.0
Homocysteine	1.7-2.6

TABLE 81.1. ATHEROSCLEROSIS RISK FACTORS FOR PERIPHERAL ARTERY DISEASE

Many patients with mild degrees of peripheral arterial disease remain asymptomatic. Approximately 75% of patients with claudication remain stable with a proper risk factor modification program and exercise. The remaining 25% have progression of their symptoms. Of those with progressive disease, 1% to 10% eventually require a major amputation. The risk of progression is even greater in patients with diabetes, in whom there is a 17-fold increase in the risk of amputation. Peripheral atherosclerosis is one manifestation of systemic atherosclerosis, and affected persons are likely to have atherosclerosis affecting the coronary, carotid, and renal arteries as well. The risk of a cardiovascular event (myocardial infarction, cardiovascular death, and stroke) is increased six times in those with evidence of peripheral arterial occlusive disease on noninvasive testing. The 5-year survival rate is 44% for patients with severe peripheral atherosclerosis—that is, an ankle brachial index of 0.40.

CLINICAL FINDINGS IN PERIPHERAL ATHEROSCLEROSIS

The inability of blood flow to meet the metabolic demands of exercising muscle results in a symptom called *intermittent claudication*, in which the patient might describe discomfort, pain, cramping, or tiredness of the buttock, thigh, or calf, which occurs with exercise and is relieved with rest. Intermittent claudication should be distinguished from pseudoclaudication, which occurs from lumbar spine disease. In *pseudoclaudication*, leg pain may also occur with standing. Males develop vasculogenic impotence from inadequate pelvic blood flow. Limb-threatening ischemia with forefoot pain at rest, tissue ulceration, or gangrene can occur if the stenoses are so severe that the resting metabolic needs of the tissues are not met.

On physical examination, the patient usually has diminished lower extremity pulses. The femoral, popliteal, posterior tibial and dorsalis pedis pulses should be palpated, because the location of the abnormal pulse may provide an indication of the site of stenosis. For example, a normal femoral pulse but an abnormal popliteal pulse suggests stenosis in the superficial femoral artery. The femoral arteries should be auscultated for bruits providing evidence of stenosis.

With chronic severe disease, the patient may have hair loss, muscle atrophy, cool feet, and nail changes. Pallor occurs with leg elevation because perfusion decreases without the assistance of gravity. Dependent rubor occurs because the capillaries in the distal lower extremity are maximally vasodilated and therefore fill rapidly in the dependent position. Ulcers or gangrene can be present on the feet, particularly on the toes and heels, and often at sites of trauma or pressure from footwear when there is severe arterial insufficiency ([Fig. 81.1](#)).

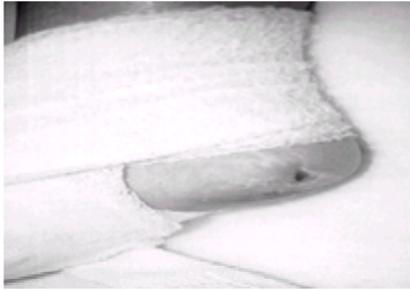

FIGURE 81.1. Arterial ulcer and peripheral arterial disease. Ulcers occur often at sites of pressure from footwear, such as at the heel.

TESTING FOR PERIPHERAL ARTERIAL DISEASE

The initial confirmation of peripheral atherosclerotic disease can be acquired noninvasively by determining the systolic blood pressure in the ankle and comparing it with the systolic blood pressure in the arm. Ankle systolic pressure is greater than or equal to arm pressure in the absence of arterial occlusive disease. Conversely, the ankle pressure is usually less than the highest brachial pressure in the presence of peripheral atherosclerosis, with an ankle brachial ratio of ≤ 0.90 considered abnormal. The ankle:brachial systolic pressure ratio is referred to as the *ankle brachial index*. More extensive information about the location of limb arterial occlusive disease is available through segmental systolic blood pressure measurements performed in the vascular laboratory. Blood pressure cuffs are placed on the proximal thigh, distal thigh, proximal calf, and above the ankle (Fig. 81.2). A Doppler probe is then placed over the dorsalis pedis or posterior tibial artery to determine systolic blood pressures at these cuff locations by listening for the onset of flow when a cuff previously inflated to suprasystolic pressures is deflated. A pressure drop of 20 mm Hg indicates the presence of significant stenosis between the two adjacent levels. Pulse volume recordings (PVR) may also indicate the presence of stenoses. A normal PVR resembles a blood pressure waveform, whereas that distal to a stenosis has a delayed upstroke and diminished amplitude. Doppler waveforms can also be recorded at each level by pulse wave Doppler using duplex ultrasound (Fig. 81.3). When stenosis is present, there is a triphasic waveform proximal to the stenosis to a biphasic or monophasic pattern beyond the stenosis. When pulse wave Doppler waveforms are determined along the length of the artery, an increase in the peak systolic velocity is seen at the site of stenosis. The segmental pressure measurements may be normal at rest and should be repeated after exercise if the clinical suspicion of peripheral arterial disease is high. A precipitous and sustained drop in ankle pressures occurs after exercise in patients with peripheral arterial disease.

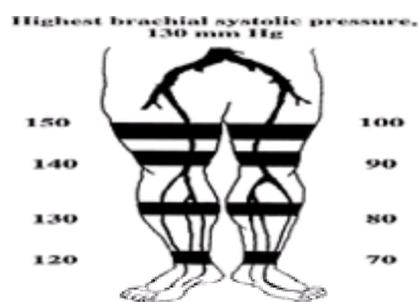

FIGURE 81.2. Segmental systolic blood pressure measurements. Cuffs are placed on the proximal and distal thigh and on the proximal and distal calf. Systolic pressure at each level is given next to the cuff in mm Hg. The systolic pressure of 100 mm Hg in the left proximal thigh indicates more proximal iliofemoral stenosis.

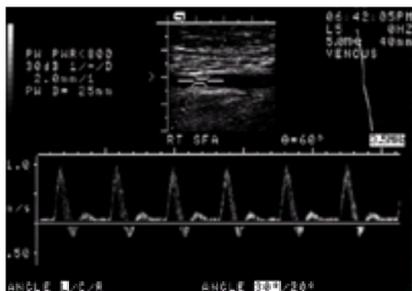

FIGURE 81.3. Pulse-wave Doppler examination. The superficial femoral artery is located with duplex imaging. The Doppler waveform is sampled in the center of the superficial femoral artery. This is a normal triphasic waveform.

Three-dimensional arterial reconstruction using magnetic resonance imaging (MRI) arteriography and spiral computed tomography (CT) arteriography can provide noninvasive assessment of the distal aorta and iliac vessels, but presently with less clarity than is available with invasive arteriography. Contrast arteriography is necessary to completely evaluate the anatomical extent of disease in the distal aorta and lower extremity arteries. It is generally performed only to determine the optimal revascularization procedure. The functional significance of the arterial occlusive disease can be quantified by invasive pressure measurements proximal and distal to the stenosis and can be determined before and after administration of a vasodilator.

MANAGEMENT OF PERIPHERAL ARTERIAL DISEASE

The two goals of treatment in patients with peripheral atherosclerosis are to decrease their considerable cardiovascular risk and to improve symptoms. The identification of peripheral atherosclerosis should prompt evaluation of modifiable risk factors for atherosclerosis such as cigarette smoking, dyslipidemias, hypertension, diabetes, and high homocysteine. Patients should also be evaluated for coexisting cerebrovascular and coronary atherosclerosis. Smoking cessation results in decreased cardiovascular mortality and reduced risk of progression to critical limb ischemia and amputation. Few studies have evaluated the benefits of lipid-lowering therapy on symptom relief in patients with peripheral atherosclerosis. However, in the Scandinavian Simvastatin Survival Study the risk of new or worsening intermittent claudication was reduced by 38% compared with that in the placebo group. Control of diabetes may decrease nephropathy and retinopathy, but it is not known whether this will improve symptoms of claudication or decrease the risk of amputation. Antiplatelet therapy with aspirin and clopidogrel reduces cardiovascular events in patients, including those with peripheral arterial disease. A supervised exercise program can increase pain-free walking time by 50% to 300%. Patients with arterial occlusive disease should be instructed in foot hygiene and told to examine their feet daily to seek urgent treatment for foot ulcers.

Most vasodilators have been ineffective in patients with peripheral atherosclerosis as the resistance vessels of the lower extremity are already vasodilated during exercise to meet the metabolic demands of the tissues. Current pharmacotherapy for peripheral arterial disease includes pentoxifylline and cilostazol. Pentoxifylline is an adenosine diphosphate receptor antagonist that is purported to decrease blood viscosity and improve red cell deformity. Clinical trials with pentoxifylline have reported both favorable and insignificant results compared with placebo. The more severely affected population may be the most responsive.

Cilostazol is a phosphodiesterase inhibitor with vasodilator and platelet-inhibitory properties. Treatment with cilostazol in randomized, controlled trials resulted in

improved physical performance, walking ability, and functional status. Cilostazol should not be administered to patients with heart failure because of the potential for increased mortality risk in these patients, which has been described with other phosphodiesterase inhibitors. Carnitine has been evaluated as a therapy for intermittent claudication as patients with peripheral atherosclerosis develop metabolic abnormalities in the skeletal muscle of the lower extremity. Both L-carnitine and propionyl-L-carnitine improved exercise performance in clinical trials. However, carnitine has not been approved for use in the United States. There is ongoing research evaluating the administration of angiogenic growth factors to improve symptoms in patients with claudication and critical limb ischemia.

Percutaneous or surgical intervention is typically reserved for the patient with disabling claudication or limb-threatening ischemia. Percutaneous transluminal angioplasty and stent placement have both high success and high patency rates when used to treat stenoses less than 2 cm in the iliac arteries (Fig. 81.4), but limited success and lower patency rates in the femoral and tibioperoneal arteries. For example, 5-year patency rates after iliac angioplasty are 85% compared with 65% for femoropopliteal angioplasty. The standard operative procedures used for the patient with arterial occlusive disease are bypass procedure around the stenosis or endarterectomy of the diseased segment. More durable results are obtained with bypass grafting procedures. In aortoiliac disease, a bifurcated graft is attached from the distal aorta to the femoral vessels. When one iliac artery is severely diseased and the other is normal, a bypass graft can be placed from one femoral artery to the other femoral artery to improve arterial inflow to the leg beyond the iliac stenosis. The patency rate for both limbs of an aortobifemoral bypass is 85% over 5 years. The patency rates are lower for infrainguinal bypass grafts, varying from 70% over 5 years with femoropopliteal bypass above the knee to 40% over 5 years for femoropopliteal bypass grafts extending below the knee. For prosthetic grafts placed below the knee the patency rate is as low as 20%. When narrowing occurs at the distal anastomosis of a graft, it may be corrected by patching open the anastomosis before it occludes. Patients undergo duplex ultrasound surveillance of their grafts to detect and correct such narrowings before the graft occludes.

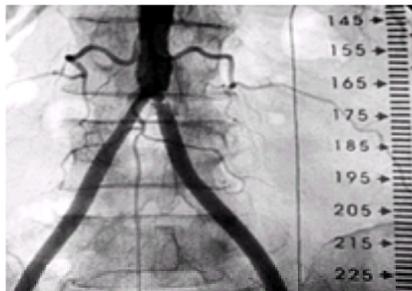

FIGURE 81.4. Contrast arteriography of the distal aorta and iliac bifurcation. A short stenosis is evident at the origin of the left iliac artery.

Potential complications after peripheral bypass surgery are myocardial infarction, renal failure, bypass graft thrombosis, pseudoaneurysm formation, wound infection, impotence, and death. Preoperative evaluation is recommended to accurately assess the perioperative risk for a cardiovascular event.

SPECIFIC ARTERIAL DISEASES

TAKAYASU'S ARTERITIS

Takayasu's arteritis is a chronic inflammatory disease predominantly in the aorta and its branches. This periarteritis is initially characterized by inflammation of the media and adventitia, with a prominent cellular infiltrate and occasional giant cells at sites of disintegration of the elastic lamina. The inflammation is accompanied by intimal hyperplasia (Fig. 81.5). In the chronic phase, there is fibrosis of the vessel. The pattern of vessels affected varies according to the geographic location of the patient. The aortic arch and its branches are often involved in North American and Japanese patients, whereas the abdominal aorta and its branches are involved in Indian patients. It occurs predominantly in young women. Takayasu's arteritis often begins with fevers, malaise, and myalgias. Occasionally, there is pain over the affected vessels, as in carotodynia. Over time, symptoms of arterial insufficiency such as claudication, cerebrovascular ischemia, or visceral pain occur. These patients may also develop aortic aneurysm or aortic dissection. Bruits are often encountered over the subclavian and carotid vessels. Takayasu's arteritis should be suspected in persons with unequal pulses or blood pressures in their extremities. Takayasu's arteritis is a common cause of renovascular hypertension in India.

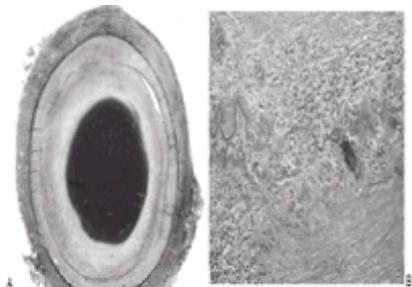

FIGURE 81.5. Arterial histology in Takayasu's arteritis. **A:** Marked intimal hyperplasia is seen in a cross-section of superficial femoral artery. **B:** High-power magnification demonstrates inflammation in the vessel wall.

There is no diagnostic laboratory test for Takayasu's arteritis. The American College of Rheumatology has listed criteria for reporting this diagnosis, with three of the six criteria resulting in high specificity and sensitivity for the diagnosis (Table 81.2). Angiography can identify the long segmental narrowings that are typical of Takayasu's arteritis. CT and magnetic resonance angiography may demonstrate inflammation in the artery wall. The erythrocyte sedimentation rate has been used to estimate disease activity and may be more reliable when used in combination with systemic complaints or new symptoms of arterial insufficiency.

Onset before age 40
Extremity claudication
Decreased brachial pulse
> 10 mm difference in brachial systolic blood pressures
Bruit over subclavian artery or aorta
Angiographic evidence of narrowing or occlusion in the aorta or its proximal branches

* Three of six necessary for diagnosis. (Data from Arend WR. The American College of Rheumatology 1990 Criteria for the Classification of Takayasu arteritis. *Arthritis Rheum* 1990;33:1129-1134, with permission.)

TABLE 81.2. DIAGNOSTIC CRITERIA FOR TAKAYASU ARTERITIS^a

Medical treatment begins with corticosteroids, which are effective in 60% of the patients. Methotrexate and cyclophosphamide may be added if prednisone alone is ineffective or poorly tolerated. These cytotoxic drugs may decrease clinical and angiographic evidence of Takayasu's arteritis. Percutaneous transluminal angioplasty and stenting have been used successfully in short, concentric stenoses. Surgical arterial bypass can be used for patients with symptomatic ischemia; however interventions performed during periods of active disease have dramatically higher restenosis and complication rates.

GIANT CELL ARTERITIS

Giant cell arteritis, also known as *temporal arteritis*, occurs in those over age 50 years. The mean age of onset is 70 years, with the highest prevalence in whites of northern European ancestry. The entity was first described as "thrombotic arteritis of the aged." Giant cell arteritis has been found in the arteries of nearly every organ. The inflammation begins with lymphocyte infiltration, destruction of the elastic lamina, and intimal thickening. The classic findings are focal necrosis and granuloma with multinucleated giant cells in the region of the fragmented elastic lamina. The pattern is one of "skip" lesions, and many sections of the affected artery must be examined before this diagnosis is excluded. The predominant vessels involved include temporal, vertebral, carotid, subclavian, coronary, and brachial arteries, as well as the aorta.

Symptoms at presentation include headache, visual changes, scalp tenderness, weight loss, fever, and malaise. Claudication of the masticatory muscles, tongue, arm, neck, and legs may occur. The presentation can be dramatic with aortic dissection or myocardial infarction. Nearly 50% of the patients have the clinical syndrome of polymyalgia rheumatica. Laboratory findings such as elevated erythrocyte sedimentation rate are common but are not required for the diagnosis. The diagnosis is made from the clinical presentation and confirmed by pathologic examination.

Corticosteroids are the mainstay of treatment for giant cell arteritis, and their use has dramatically decreased the incidence of blindness with temporal arteritis. Death is rare and results from stroke, myocardial infarction, ruptured aortic aneurysms, and aortic dissection. Treatment begins with prednisone, 60 mg per day. The prednisone dose can typically be tapered in 2 to 4 weeks. Remission can occur on occasion after 1 to 2 years of therapy. Surgical intervention may be necessary to achieve limb salvage and to decrease mortality from aortic aneurysm or dissection.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans, also known as Buerger's disease, involves the small and medium arteries in the extremities. The histologic pattern includes extensive intimal inflammation and thickening, thrombosis, and preservation of the media. Migratory superficial thrombophlebitis occurs. The disease mainly affects young male cigarette smokers, but is now reported with increasing frequency in young female cigarette smokers. Patients may present with Raynaud's phenomenon, calf and foot claudication, and gangrene of the digits. Peripheral neuropathy may be present because of severe ischemia. Arteriography reveals segmental occlusions of small and medium arteries, usually those at the distal part of the upper and lower extremities, accompanied by corkscrew collaterals ([Fig. 81.6](#)). Treatment must include abstinence from tobacco. New lesions are less likely to develop if the patient stops smoking. Digital ulcers often require debridement. Pharmacologic therapy includes calcium channel blockers and α -adrenergic blockers and possibly vasodilator prostaglandin infusion to decrease vasospasm. The use of pentoxifylline and aspirin has also been advocated, but randomized trials proving benefit of these therapies are lacking.

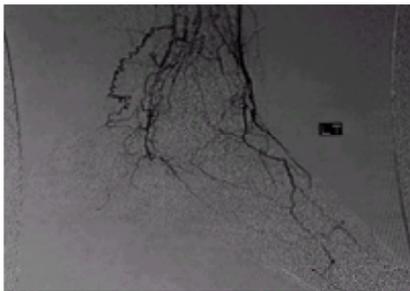

FIGURE 81.6. Distal runoff in lower extremity arteriography. Cork screw collaterals typical of thromboangiitis obliterans are evident on the left. Segmental arterial occlusions are also noted.

ACUTE ARTERIAL OCCLUSION

Sudden arterial occlusion may result from embolism or thrombosis. Embolism is the major cause, and the primary source is the heart. Once emboli lodge in an artery, there may be further extension by thrombosis. Sudden arterial occlusion can develop in patients with peripheral arterial disease when thrombosis occurs at the site of atherosclerotic plaque. Arterial thrombosis can also occur in normal arteries in patients with hypercoagulable states and after traumatic injury. The severity and extent of ischemia with sudden arterial occlusion depend on the size of the occluded vessel and the presence or absence of collateral circulation. Pain is present in 80% of patients. Numbness, paresthesias, and weakness may accompany severe ischemia. Pallor and absent pulses distal to the occlusion characterize the physical examination. The presentation is often described as that of the six "p"s: **p**allor, **p**olar (cold), **p**ulselessness, **p**ain, **p**aresthesias, and **p**aralysis. A saddle embolus to the aortoiliac bifurcation can cause such a profound state of leg ischemia that a state of shock ensues ([Fig. 81.7](#)).

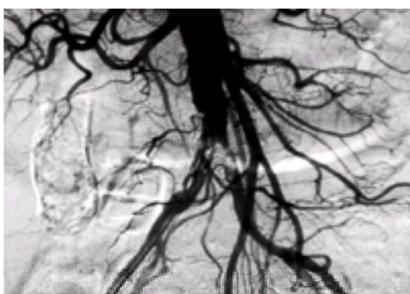

FIGURE 81.7. Angiogram of the distal aorta and iliac bifurcation. A large filling defect consistent with a saddle embolus is seen at the bifurcation.

Assessment of the capillary refill, muscle weakness, sensory loss, and Doppler signals from the vessels can establish the clinical grade of acute limb ischemia ([Table 81.3](#)). For limbs that are viable or threatened but not irreversibly ischemic, reestablishing patency of the occluded vessel is achieved through removal or dissolution of the thrombus with thrombolytic therapy, embolectomy, or bypass surgery. Urgent embolectomy is the optimal therapy when a large artery is occluded, and the limb's viability depends on achieving adequate perfusion within hours. The success of thrombolytic therapy depends partly on how soon the agent is administered after the arterial occlusion. This therapy is followed by conventional anticoagulation to prevent recurrent thrombus formation. The hospital course after revascularization may be complicated by the release of potassium, metabolites, and myoglobin from the ischemic tissue into the circulation. If the patient with a viable or threatened limb cannot undergo surgery or thrombolysis, heparin should be administered and the extremity should be kept warm and in a dependent position. The patient must be followed up closely for signs of deterioration at which time the surgical therapy should be reconsidered.

Category of Ischemia	Muscle Weakness	Sensory Loss	Capillary Refill	Arterial Doppler	Venous Doppler
Viable	None	None	Intact	Audible	Audible
Threatened (salvageable with prompt action)	Mild	Mild	Intact	Not audible	Audible
Irreversible (will require major amputation)	Profound	Anesthetic	Absent; mottling pattern present	Not audible	Not audible

(From Ad Hoc Committee on Reporting Standards. Suggested standards for reports dealing with lower extremity ischemia. *J Vasc Surg* 1986;8:80-84, with permission.)

TABLE 81.3. CLINICAL CATEGORIES OF LIMB ISCHEMIA

ATHEROEMBOLISM

Microemboli of lipid and thrombotic atherosclerotic debris commonly originating in the aorta may travel distally resulting in occlusion of small arteries. The clinical presentation is often referred to as *blue toe syndrome*. Affected patients present with pain and cyanosis in their toes and with livedo reticularis and petechiae on their feet and legs. Embolic occlusion of small intramuscular arteries result in calf tenderness. These patients often have fever and eosinophilia. A skin or muscle biopsy demonstrating needle-shaped cholesterol clefts in small arteries is diagnostic of atheroembolism. These lesions can also have significant inflammatory cells and lipid-laden giant cells. Atheroemboli are most often seen after cardiac catheterization but may occur spontaneously from sites of friable atherosclerotic plaque. Antiplatelet therapy may reduce the risk of recurrent atheroembolism. Surgical treatment may be necessary to remove the source of the friable atherosclerotic plaque.

VASOSPASM AND TEMPERATURE-RELATED DISORDERS

Raynaud's Phenomenon

Raynaud's phenomenon is episodic vasospasm resulting in digital ischemia. Episodes of well-demarcated digital pallor or cyanosis follow exposure to cold and emotional distress. The diagnosis is based primarily on the patient's history because simple office maneuvers such as cold water immersion do not reliably induce an episode of digital ischemia in these patients. Raynaud's phenomenon occurs in up to 8% of men and up to 18% of women. The higher prevalence is reported in populations living in colder climates. Unique features of digital arterial circulation contribute to the occurrence of Raynaud's phenomenon. The cutaneous vessels of the fingers and toes are supplied only by sympathetic adrenergic vasoconstrictor fibers. Increased sympathetic efferent activity normally causes vasoconstriction, and may cause profound vasospasm in persons predisposed to Raynaud's phenomenon. Digital arterial narrowing, decreased perfusion, and increased blood viscosity have been postulated as some of the mechanisms that may contribute to Raynaud's phenomenon. Digital blood flow is altered by these changes, and digital ischemia then develops more readily in the presence of vasoconstrictor stimuli.

The classification of Raynaud's phenomenon is separated into primary, not associated with another disease process, or secondary, occurring as a consequence of another disease or treatment. Criteria for the diagnosis of primary Raynaud's phenomenon include history of episodes of bilateral acral pallor or cyanosis, symptoms for more than 2 years, and physical examination with strong, symmetric pulses and no evidence of digital pitting, ulcerations, or gangrene ([Table 81.4](#)). In primary Raynaud's phenomenon, nail-fold capillaroscopy, antinuclear antibody, and erythrocyte sedimentation rate are normal. Patients with primary Raynaud's phenomenon have a favorable prognosis.

Bilateral episodes of acral cyanosis or pallor
 No digital ulceration, pitting, or gangrene
 Strong, symmetric peripheral pulses
 Symptoms > 2 years
 No signs or symptoms of disease associated with secondary Raynaud's phenomenon
 Normal erythrocyte sedimentation rate
 Normal antinuclear antibody test
 Normal nailfold capillaries

(Modified from LeRoy EC, Medsger TA Jr. Raynaud's phenomenon: a proposal for classification. *Clin Exp Rheumatol* 1992;10:485-488.)

TABLE 81.4. DIAGNOSTIC CRITERIA FOR PRIMARY RAYNAUD'S PHENOMENON

The presence of asymmetric pulses, or evidence of prolonged digital ischemia such as digital ulcers, suggests a secondary cause of Raynaud's phenomenon. Secondary causes of Raynaud's phenomenon include connective tissue disease, arterial occlusive disease, thermal or vibration injury, blood dyscrasias, neurologic disorders, drugs, and toxins. Most secondary causes of Raynaud's phenomenon are evident before the onset of episodes of digital ischemia. An exception is scleroderma, in which the onset of Raynaud's phenomenon may precede evidence of scleroderma by many years. In cases of secondary Raynaud's phenomenon, the arterial supply to the digits can be assessed by a number of techniques. These include systolic pressure measurements, and blood flow assessment by digital plethysmography or Doppler flow. If abnormal arterial flow is seen, the study can be repeated with warming. If the arterial flow appears normal after warming, vasospasm rather than fixed arterial occlusion is present ([Fig. 81.8](#)). Arteriography is not required in most cases and would be indicated only if an obstructive lesion requiring revascularization is sought.

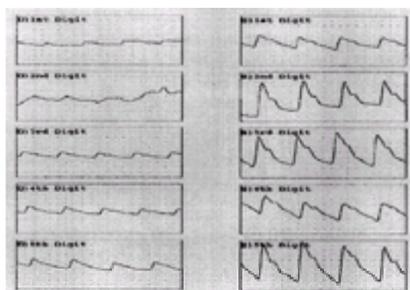

FIGURE 81.8. Photoplethysmography of the digits in the presence and absence of warming. Blunt waveforms consistent with moderate arterial occlusion are evident on the left. The waveforms in the same digits return to normal after warming (*right*).

The mainstay of treatment is patient education regarding avoidance of stimuli that precipitate digital ischemic attacks. Patients should be instructed to dress warmly, wearing not only gloves, but sweaters, coats, and hats because reflex sympathetic vasoconstriction occurs in the digits in response to cold exposure elsewhere (e.g., head or trunk). Calcium channel blockers with the exception of verapamil and α -adrenergic blockers have proved to be useful in improving digital blood flow and

ameliorating symptoms. Iloprost given intravenously improves healing of ulcers in patients with scleroderma. Selective digital sympathectomy and microarteriolysis may facilitate ulcer healing and symptom improvement in severe cases of secondary Raynaud's phenomenon. Cervical and lumbar sympathectomy have also been performed in cases of severe Raynaud's phenomenon, but with limited long-term success.

Acrocyanosis

Acrocyanosis is a rare disorder of the peripheral circulation in the general population but is seen in 20% of patients with anorexia nervosa. Acrocyanosis is seen in adolescents and young women, and patients present with episodes of cyanosis and coldness in the hands and feet. Unlike in Raynaud's phenomenon, the cyanosis extends proximal to the digits. These manifestations are attributed to arteriolar spasm. Cyanosis increases with cold exposure and is relieved by warming. On physical examination, mild edema and excess sweating of the hands and feet may be found. There are no trophic changes or ulceration of the digits. If the patient is examined during an episode, pallor is seen when the extremity is raised above the heart level, ruling against venous obstruction. There should not be physical evidence of central cyanosis. The laboratory evaluation in these patients is normal. The prognosis is excellent, and the disorder is self-limited. In patients with anorexia nervosa, the acrocyanosis generally resolves with weight gain.

Erythromelalgia

Erythromelalgia is an uncommon disorder characterized by erythema, warmth, and burning pain in the extremities. Although there is evidence of arteriolar spasm, this disorder is often thought of as the antithesis of Raynaud's phenomenon. Episodes are precipitated by warmth and relieved by cold. It can be primary, familial, or secondary. There is a striking association between secondary erythromelalgia and myeloproliferative disorders, and the onset of erythromelalgia may precede that of the myeloproliferative disorder by several years. Patients over age 30 should be evaluated with periodic blood counts. Other secondary causes of erythromelalgia include systemic lupus erythematosus, rheumatoid arthritis, spinal cord disease, multiple sclerosis, and drugs such as nifedipine, pergolide, and bromocriptine.

The diagnosis of erythromelalgia is based on clinical history, including erythema, severe burning pain, precipitation by warmth, relief with cooling, and exclusion of disorder such as reflex sympathetic dystrophy and thromboangiitis obliterans. Primary erythromelalgia is not life threatening, but the symptoms can be continuously debilitating. Aspirin is recommended for all patients with erythromelalgia. Sympathectomy has not been effective in treating this disorder. Secondary erythromelalgia requires treatment of the underlying disorders and discontinuation of inciting drugs such as nifedipine and bromocriptine. The prognosis of secondary erythromelalgia is tied to the underlying disease.

ANEURYSMAL DISEASE

An aneurysm is a widening or dilation of a segment of blood vessel and may be defined as an increase in the lumen more than one and a half times that of the nearest normal proximal segment. Aneurysms tend to enlarge over time, since radius relates to wall tension as described by Laplace's law. True aneurysms involve all three layers of the vessel wall; intima, media, and adventitia. They may be fusiform or saccular. Aneurysmal disease is most commonly identified in the thoracic and abdominal aorta, but it may occur in the peripheral and visceral arteries. The incidence, cause, natural history and management vary according on the location. Abdominal aortic aneurysms are described in the following section, since many of these are seen by vascular medicine specialists.

ABDOMINAL AORTIC ANEURYSM

Abdominal aortic aneurysms account for most aortic aneurysmal disease, and most of these occur below the level of the renal arteries. This segment of aorta has decreased elastin lamellae compared with the thoracic aorta. The infrarenal abdominal aorta also lacks vasa vasorum and derives its nutrient supply from the lumen. Abdominal aortic aneurysms occur more often in men than in women. Most abdominal aortic aneurysms are associated with atherosclerosis, whereas cystic medial necrosis accounts for most ascending aortic aneurysms. Important risk factors for the development of abdominal aortic aneurysm in addition to male gender include cigarette smoking, chronic hypertension, and family history of abdominal aortic aneurysm. Other causes include trauma, infection, and arteritis.

Most abdominal aortic aneurysms are asymptomatic. In fact, the diagnosis arises incidentally during radiologic examination in up to 70% of cases. Some patients experience abdominal, back, or flank pain. Expansion of the aneurysm can also cause symptoms by compressing neighboring structures such as the ureter or iliac vein. Embolism of thrombus or atheromatous plaque from within the aneurysm may occlude distal arteries and cause limb ischemia. Physical examination can reveal a pulsatile midabdominal mass, particularly in lean patients or those with large aneurysms. However, 25% are not palpable on physical examination even when the diagnosis is known. Rupture is characterized by severe back or abdominal pain with hemodynamic collapse. Tachycardia, pallor, hypotension, and shock are related to the extent of the hemodynamic insult.

Ultrasonography is the simplest method to detect, measure, and monitor abdominal aneurysms. The sensitivity of this test approaches 100%. However, it may not identify features such as branch vessel involvement or length of the aneurysm. Contrast-enhanced CT is particularly useful in patients with large abdominal girth and is as sensitive as ultrasonography. Techniques such as spiral or helical imaging, faster acquisition times, and three-dimensional reconstruction may further improve CT image resolution. MRI can provide anatomical information of comparable accuracy without the ionizing radiation or contrast. Contrast aortography provides clear anatomical delineation of length and branch vessel involvement, but it is of limited use in assessing the diameter of the aneurysm because thrombus within the lumen may obscure definition of the aortic wall. Abdominal aneurysms larger than 4 cm occur in 1% to 2% of men. Targeted screening in persons with marked increase in risk may be effective. These include first-degree relatives of aneurysm patients who are over 50, patients with atherosclerosis, and those with popliteal artery aneurysms because up to 50% have aneurysms elsewhere.

Mortality rates are up to 60% for patients who present to the hospital with rupture of their aneurysms. Therefore, optimal management is focused on elective repair of the aneurysm before rupture ([Table 81.5](#)). The timing of surgery depends on symptoms, size of the aneurysm, rate of aneurysm growth, and its potential for rupture. Rupture occurs in 1% to 2% of those with aneurysms less than 5 cm and in 10% to 40% of those with aneurysms greater than 5 cm. However, in a recent study, early elective surgery on abdominal aortic aneurysms of 4 to 5.5 cm did not result in improved mortality at 2, 4, or 6 years compared with a control group with similar aneurysms. The timing of surgery is dependent on the presence of symptoms, aneurysm size, rate of aneurysm growth, and the potential for rupture. Most asymptomatic aneurysms greater than 5 cm should be repaired because of the high likelihood of rupture.

Size ≥ 5 cm
Growth of ≥ 0.5 cm/y
Abdominal aortic aneurysm with symptom of rupture

TABLE 81.5. CLEAR INDICATIONS FOR SURGICAL REPAIR OF ABDOMINAL AORTIC ANEURYSM

The mortality with elective operative repair is typically less than 5%, and in some reports as low as 1.6%. Risk factors for poor outcome include age, female gender, renal artery involvement, significant blood loss, angina, and renal insufficiency. If surgery is not performed because of size or comorbid conditions, the ultrasonographic assessment should be repeated every 6 to 12 months. Increase in size of aneurysm of more than 1 cm per year or occurrence of any symptoms should prompt reevaluation for surgery, given the threat of rupture. Endovascular repair of abdominal aortic aneurysms is currently under evaluation and holds promise for a less invasive repair for those who are poor operative candidates. However, the first large trials reported with this technique found complication rates up to 20%.

POPLITEAL ARTERY ANEURYSMS

People with a family history of abdominal aortic aneurysm also have an increased likelihood of peripheral aneurysms, including popliteal artery aneurysms. Popliteal artery aneurysms are bilateral in more than 50% of cases. These aneurysms may cause claudication or limb ischemia in cases in which thrombosis of the aneurysm has significantly narrowed the arterial lumen or when there is distal embolization of the thrombus lining the aneurysm. Rupture is an unusual occurrence. Popliteal artery aneurysms also may cause popliteal vein thrombosis because of compression of the companion vein in the confined space of the popliteal fossa. These aneurysms can be diagnosed by duplex ultrasound. Elective resection and bypass grafting constitute the treatment of choice when the distal circulation is adequate. The risk of limb loss increases after thromboembolic complications have occurred.

ARTERIOVENOUS FISTULA

Arteriovenous fistulas are either congenital or acquired defects in which there is continuity between arteries and veins without intervening capillaries. Small hemangiomas, a spongy texture to the subcutaneous tissue, and dilated superficial veins can be seen on physical examination. A common finding is a palpable thrill or a continuous bruit from turbulence, which results from high-pressure flow entering a low-pressure system. A “machinery” murmur is indicative of a fistula. Venous insufficiency with consequent venous varicosities and edema may be present. Hemodynamically significant shunts can cause high-output heart failure. Evidence of hemodynamic significance includes the development of bradycardia when the fistula is compressed. Comparison between venous oxygen saturation in the involved and noninvolved limbs may be useful in making the diagnosis.

Several syndromes have been described that include arteriovenous fistulas, such as Osler–Weber–Rendu, Parkes–Weber, and Klippel–Trenaunay syndromes. These arteriovenous fistulas may present as late as the second or third decade of life with symptoms of discomfort, heaviness, and increased warmth in the affected region. Hereditary hemorrhagic telangiectasia (HHT) is known as *Osler–Weber–Rendu disease*. This disease affects mucocutaneous and visceral vascular tissue. Patients have family history, telangiectasias, arteriovenous malformations, and epistaxis or gastrointestinal bleeding. Pulmonary arteriovenous malformations are present in up to 20% of affected persons and may be multiple. Hemangiomas and arteriovenous fistulas are noted in Klippel–Trenaunay syndrome, and Parkes–Weber syndrome is associated with arteriovenous malformations. Venous varicosities and limb hypertrophy are present in both.

Most acquired arteriovenous fistulas occur after trauma to the blood vessels. However, infection and malignancy may disrupt vascular walls, and aneurysms can penetrate veins and lead to an arteriovenous fistula. Many acquired arteriovenous fistulas result from percutaneous interventions such as intra-arterial cannulas, cardiac catheterization, intra-aortic balloon pumps, and occasionally percutaneous biopsies. Other causes include penetrating trauma with a knife or bullet.

Diagnosis of arteriovenous fistula is made by noninvasive imaging with duplex ultrasonography or by arteriography. Conservative treatment measures include wearing compressive bandages and pain relief. Cardiac decompensation from high-output state is an indication for repair of the arteriovenous fistula, which amounts to the surgical closure of the fistula and reestablishment of the continuity of the involved artery and vein. This may not be practical in patients with multiple fistulas.

VENOUS DISEASE

Veins are thin-walled tubes with endothelium-lined intima, loosely arranged media, and adventitia. Veins larger than 2 mm in diameter have bicuspid valves located at varying intervals along their length. Valves are common in the extremity veins and absent in the visceral and central nervous system veins. When a person stands, the venous pressure in the feet rises typically from 7 mm Hg up to 90 mm Hg, and as much as 20% of the blood volume is sequestered in the legs within 15 minutes. The calf muscles contract with walking, they squeeze blood into the veins, propelling it toward the heart. The venous valves open when blood is moving centrally and close at other times to prevent blood from flowing back toward the feet. Together, the pumping action of calf muscles and unidirectional action of valves decrease venous pressure in the feet.

The venous system in the lower extremity is composed of superficial, communicating, and deep veins. The superficial veins are those in the skin and subcutaneous tissues down to the level of the muscles. These veins are often visible, in contrast to the deep veins. Veins that supply organs, muscles, and bones constitute the deep venous system. The superficial and deep veins are connected by perforating or communicating veins. Communicating veins are well-developed in the distal lower extremities. One-way valves in the communicating veins allow blood to flow only away from the superficial veins and toward the deep veins.

VENOUS THROMBOSIS

An estimated 500,000 cases of deep venous thrombosis occur in the United States every year. This condition is a major cause of mortality because of pulmonary embolism and morbidity in the form of chronic venous insufficiency. Venous thrombi are composed of fibrin, red cells, platelets, and leukocytes. Venous thrombosis originates in the in valve cusp pockets, in venous sinuses of the calf, and in segments of vein exposed to direct trauma. Deep venous thrombosis occurs in the deep and superficial vessels of the arms and legs as well as in visceral veins. Venous thrombosis can result from any combination of venous stasis, venous endothelial damage, and hypercoagulable state.

Postoperative acute deep venous thrombosis affects up to 70% of orthopedic patients and up to 40% of general surgical patients. Deep venous thrombosis also may complicate other conditions requiring inactivity or prolonged bed rest, such as stroke and congestive heart failure. Deep venous thrombosis may occur during pregnancy and the postpartum period because pregnancy can cause extrinsic venous compression and hypercoagulability. It may result from a hypercoagulable state, including abnormalities of clotting factors, exogenous estrogen administration, and malignancy. Patients at increased risk for deep venous thrombosis should receive prophylaxis with at least one of the measures shown to be effective, such as leg elevation, elastic stockings, low-dose heparin, low-molecular-weight heparin, dextran, and external pneumatic calf compression ([Table 81.6](#)).

TABLE 81.6. CONDITIONS INCREASING RISK OF VENOUS THROMBOSIS

Clinical Manifestations

Symptoms and signs of venous thrombosis are caused by obstruction to venous outflow, inflammation of venous tissue, or thrombus embolization into the pulmonary circulation. The leg veins are the most common sites of deep venous thrombosis. It occurs in the proximal veins (iliac, common femoral, profunda femoral, superficial femoral, and popliteal veins), the calf veins (tibial, peroneal, soleal, and sural), and the superficial leg veins. Proximal deep venous thrombosis in the lower extremity can manifest as swelling and pain, but may occur without local symptoms. The edema is usually unilateral, occurring only in the affected leg, and may involve the ankle, calf, and thigh. In patients with iliofemoral venous thrombosis, tenderness may be elicited over the femoral veins, and venous collaterals may be evident at the groin. The presentation of lower extremity venous thrombosis is most dramatic in patients with extensive iliofemoral venous thrombosis. Swelling of the entire limb, with pallor and pain is referred to as *phlegmasia alba dolens*. *Phlegmasia cerulea dolens* is the term applied when the swollen limbs are markedly cyanotic.

Swelling can compromise arterial flow and peripheral pulses may be diminished. There is often thrombosis of nearly all significant deep and superficial leg veins, and there are petechiae and elevated calf compartment pressures. Patients can be in shock given the sequestration of blood and interstitial fluid in the leg. In the most severe cases, there is formation of hemorrhagic bullae, ischemia, and wet gangrene. Calf deep venous thrombosis may present with focal calf discomfort and tenderness. Edema may not occur if only one vein is occluded, since venous return can be accommodated by the other calf veins. Calf vein thrombosis may propagate to the proximal veins in approximately 30% of untreated patients.

Pelvic vein thrombosis can involve the internal iliac veins and the ovarian veins. There are few distinct symptoms when the internal iliac veins alone are involved without extension of thrombus into the common iliac veins. In this case, edema is less likely, since venous return from the leg will not be significantly compromised. The first manifestation in pelvic vein thrombosis is likely to be pulmonary embolism. Patients with prostate cancer and tumor throughout the pelvis may present with pelvic vein thrombosis. One of the most common presentations of pelvic vein thrombosis is ovarian vein thrombosis. Women present with ovarian vein thrombosis most often in the postpartum period and have symptoms of lower quadrant abdominal pain. Ovarian vein thrombosis can extend to the vena cava, particularly in the presence of malignancy, and can be associated with septic pulmonary emboli. Venous thrombosis of the internal jugular, subclavian, axillary, and brachial veins is becoming more common given the frequent use of central venous catheters.

Neck and arm vein thrombosis may be associated with edema, fever, and local tenderness. These sites are potential sources of pulmonary emboli, with a reported incidence of up to 30%. Very low doses of warfarin may prevent thrombosis with central venous catheters. Paget-Schroetter syndrome or effort thrombosis refers to primary, spontaneous axillary vein thrombosis. It often follows vigorous activity that is unusual for that person or vigorous activity that is unusual for most individuals. Affected patients present with a feeling of tightness and swelling in the dominant arm. Superior vena cava syndrome occurs secondary to obstruction and thrombosis of the superior vena cava as a result of mediastinal spread from a neoplasm, usually carcinoma of the lung. This causes dramatic and painless swelling of the neck and distention of the superficial veins of the upper chest and neck.

Pulmonary embolism and venous thrombosis occur together. In one study, 50% of the patients with proximal vein thrombosis and no suspected pulmonary embolism did indeed have evidence of pulmonary embolism by perfusion lung scanning. Conversely, asymptomatic deep venous thrombosis is found in up to 80% of patients presenting with clinically symptomatic pulmonary embolism. Pulmonary emboli occur more frequently and are larger in patients with proximal vein thrombosis than in patients with calf vein thrombosis. Internal jugular, subclavian, and axillary vein thromboses are potential sources of pulmonary emboli, with a reported incidence of up to 30%. Most clinically significant and fatal emboli arise from thrombi in the proximal veins of the legs.

Diagnosis of Venous Thrombosis

A venous duplex ultrasound scan, combining B-mode imaging and pulse Doppler analysis of venous flow, is the procedure of choice for the initial evaluation of venous disease. Venous ultrasonography is an accurate noninvasive test for confirming the presence of deep venous thrombosis. The sensitivity and specificity exceed 90% in proximal deep venous thrombosis. Two-dimensional real-time images are obtained as the transducer is placed over the common femoral vein and moved distally. Gentle pressure is applied with the probe to determine whether the vein under examination is compressible ([Fig. 81.9A](#)). Many thrombi are not visible by ultrasonographic examination; therefore, noncompressibility is the ultrasound criterion for diagnosing deep venous thrombosis ([Fig. 81.9B](#)).

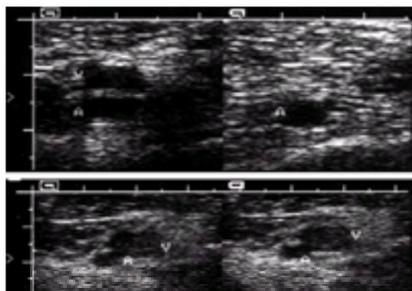

FIGURE 81.9. Duplex ultrasonography of the popliteal vein. **A:** The artery and vein are seen on the left, but with gentle compression on the right the vein is completely compressed. **B:** The popliteal vein remains evident with gentle compression, consistent with the presence of venous thrombosis.

Venous flow is evaluated by pulse wave and color Doppler imaging. A lack of respirophasic variation provides additional evidence of venous obstruction. Venous thrombus can be completely lysed with no residual thrombus remaining; however, more often it organizes with narrowing and at times complete occlusion of the lumen. Ultrasonographic findings of thickened walls and valve disorganization indicate previous venous thrombosis. Calf veins are smaller than proximal veins, which makes their evaluation by duplex ultrasonography more difficult. Venous ultrasonography is used also to diagnosis thrombosis of the internal jugular and arm veins.

Venography is indicated when venous duplex ultrasonography is unavailable or cannot answer the clinical questions. Venography is used to diagnose inferior vena cava and ovarian and iliac vein thrombosis and is used to guide catheter based thrombolytic therapy. Magnetic resonance venography can be used to evaluate the presence of thrombus in veins that are difficult to access by ultrasonography.

Treatment

The objectives of treatment in proximal deep venous thrombosis are to prevent pulmonary embolism and recurrent deep venous thrombosis and to reduce the likelihood of postphlebotic syndrome. Bed rest with leg elevation above the level of the right atrium is indicated for those with edema. Bed rest is usually discontinued after the patient is symptom-free and anticoagulation is therapeutic. Anticoagulation with unfractionated or low-molecular-weight heparin and conversion of the heparin anticoagulant to warfarin for at least 3 to 6 months are prescribed for patients with proximal deep venous thrombosis as described in the following text.

Calf vein thromboses can be treated with standard anticoagulation, or patients can be followed up with sequential ultrasound examination and treatment deferred unless the thrombus extends into the proximal venous system. Extension is estimated to occur in 30% of cases. Compression stockings with a gradient of at least 20 to 30 mm should be prescribed to prevent recurrent edema when patients become ambulatory. Treatment of pelvic vein thrombosis is similar to that for proximal deep venous thrombosis. When pelvic vein thrombosis is associated with pelvic sepsis, any resulting pulmonary emboli can form lung abscesses. Intensive antibiotic therapy is needed, and surgical interruption of the appropriate veins may be required. Treatment of upper extremity venous thrombosis includes anticoagulation with heparin, followed by conversion to warfarin. Elevation with the arm on pillows and the upper body upright is recommended.

Heparin, Low-Molecular-Weight Heparin, and Warfarin Therapy

Heparin therapy, with continuous intravenous infusion of unfractionated heparin or subcutaneous injections of low-molecular-weight heparin, is the initial treatment of choice for deep venous thrombosis. Both can be used in pregnant patients, since heparin does not cross the placenta. Unfractionated heparin is given as an intravenous bolus of 100 U per kilogram (typically 7,500 to 10,000 U) followed by a continuous infusion of 15 U per kilogram per hour (typically 1,000 to 1,500 U per hour). The partial thromboplastin time (PTT) should be checked at 6 hours to confirm that the level is increased to 1.5 to 3.0 times the baseline values. If the PTT is subtherapeutic, the heparin infusion is adjusted and the PTT is determined every 6 hours until therapeutic levels are achieved, then every 24 hours subsequently.

Platelet counts should be checked daily during heparin administration. If potentially life-threatening bleeding (e.g., intracerebral) occurs, the heparin is discontinued and anticoagulation is reversed with protamine sulfate. Hirudin, a direct thrombin inhibitor, may be necessary in patients with heparin-induced thrombocytopenia.

Enoxaparin is the only low-molecular-weight heparin approved for treatment of deep venous thrombosis in the United States. Appropriate patients to consider for therapy are those who do not require prolonged hospitalization, such as those without increased risk of bleeding and without extensive iliofemoral venous thrombosis. The length of hospitalization necessary for patients treated with low-molecular-weight heparin is under evaluation. Patients may require admission to begin therapy

with enoxaparin at the dose of 1 mg per kg subcutaneously every 12 hours and to receive education and arrange home services. Dosing with low-molecular-weight heparin is difficult in patients with morbid obesity and those with end-stage renal disease; therefore, heparin levels are determined in these patients 6 hours after the second dose. A level between 0.5 and 1 U per milliliter is therapeutic. Platelet counts should be checked during treatment, since heparin-induced thrombocytopenia can develop. Low-molecular-weight heparin treatment should overlap with warfarin for at least 5 days. Low-molecular-weight heparin should be continued until the international normalization ratio (INR) is therapeutic for 2 consecutive days. Criteria have been proposed for outpatient deep venous thrombosis management ([Table 81.7](#)).

Inclusion	Exclusion
Adult age	Phlegmasia
Hemodynamically stable	Documented pulmonary embolism
Proximal deep venous thrombosis of the leg	Heparin-induced thrombocytopenia
Calf vein thrombosis	Surgery or trauma within 2 weeks
Willing to be treated as an outpatient	Stroke within 2 weeks
	Significant renal dysfunction
	Pregnancy
	Guaiac-positive stool, gastrointestinal bleeding
	Morbid obesity
	Significant comorbid disease
	Potential for poor compliance with regimen

TABLE 81.7. CRITERIA TO CONSIDER FOR OUTPATIENT TREATMENT OF DEEP VENOUS THROMBOSIS

Oral anticoagulation with warfarin should begin with a dose of 5 mg daily and may be started on the first or second day of heparin treatment. Lower doses should be considered in the very thin and the elderly, and higher doses in patients who weigh more than 80 kg. Warfarin is contraindicated in pregnant patients because it crosses the placenta and may result in embryopathy. Warfarin achieves its anticoagulant effect by interfering with hepatic production of the vitamin K–dependent clotting factors II, VII, IX, and X. It also interferes with the production of proteins C and S. Warfarin is highly protein-bound in the plasma, and this contributes to a number of drug interactions with other protein-bound drugs. The anticoagulant effect of warfarin is delayed until the preexisting clotting factors are cleared from the circulation.

In the early stages of warfarin administration, a hypercoagulable state can occur owing to the different half-lives of the vitamin K–dependent clotting factors and the vitamin K–dependent coagulation inhibitor, protein C. Therefore, heparin treatment should be continued for 3 to 5 days of warfarin therapy after the prothrombin time indicates adequate oral anticoagulation. The test used to monitor warfarin anticoagulation is the prothrombin time. This test is sensitive to the decrease of factors II, VII, and X. The maintenance dose of warfarin is adjusted to achieve the recommended therapeutic range, which is an INR of 2.0 to 3.0.

Thrombolysis and Vena Caval Interruption

Catheter-directed thrombolysis with urokinase, streptokinase, and tissue plasminogen activator produces successful clot lysis, but it is also associated with more frequent bleeding complications than heparin therapy is. A potential benefit of thrombolysis is rapid clot lysis, in addition to preservation of venous valves, although this therapy has not been proved to reduce the risk of postphlebotic syndrome. Catheter-directed thrombolysis may be useful in selected patients with deep venous thrombosis in the iliofemoral and axillosubclavian vein, particularly those whose limbs are threatened. Heparin is administered concomitantly at therapeutic doses to decrease the incidence of pericatheter thrombosis. Vena caval interruption should be considered in patients who cannot receive anticoagulation. More controversial indications for vena caval filter are as adjunctive therapy with pulmonary embolectomy and as therapy for patients with deep venous thrombosis and severe underlying lung disease. The initial beneficial effect of vena caval filters for the prevention of pulmonary embolism is subsequently counterbalanced by extension and recurrence of deep venous thrombosis, leading to postphlebotic syndrome.

SUPERFICIAL THROMBOPHLEBITIS

Thrombosis of the greater or lesser saphenous vein or their tributaries is the most common presentation of superficial thrombophlebitis. It is also frequently seen in the cephalic and basilic veins and their tributaries in the upper arm. It may present as tenderness, erythema, and a firm cord along the course of the affected vein. Superficial thrombophlebitis is treated with warm compresses and mild anti-inflammatory analgesic agents. Anticoagulation is not necessary unless superficial thrombosis extends to the saphenofemoral junction, risking propagation into the deep system. Migratory thrombophlebitis is thrombosis that develops in superficial veins at various sites and times. It occurs in the legs, arms, and torso. It is associated with pancreatic cancer and other visceral cancers and is seen in thromboangiitis obliterans or Buerger's disease.

Thrombophlebitis limited to the superficial veins of the anterior chest wall and breast occurs in both men and women and is often referred to as *Mondor's disease*. Patients present with pain, followed by erythema along the course of the thoracoepigastric veins. A firm cord is often palpable by the second day of symptoms. Suppurative thrombophlebitis refers to infection with purulent drainage along the course of a thrombosed vein. It usually results from associated intravenous catheter infection, and is therefore typically in superficial veins. Purulent thrombophlebitis may require drainage in addition to systemic antibiotics. Intravenous drug users are likely to have thrombophlebitis in association with localized abscesses at injection sites. Superficial thrombophlebitis is treated with warm compresses and mild anti-inflammatory analgesic agents. Anticoagulation is not necessary unless superficial thrombosis extends to the saphenofemoral junction, risking propagation into the deep system.

CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency affects many persons under age 60 and is present in up to 3% of the population. The pathophysiology of chronic venous insufficiency includes valve incompetence with associated reflux and venous obstruction. Primary deformities of venous valves and congenital valve rings are rarely the cause of valve incompetence. Incompetency of the venous valves more often follows damage when the cusps are permanently scarred and retracted. Valve incompetence leads to venous hypertension owing to the hydrostatic pressure and the pressure imposed by calf muscle contraction that is not counterbalanced by effective valve closure. Incompetent communicating veins develop as a result of valve damage from prior thrombosis or because increased venous pressure in the deep system overcomes the valve. Flow then refluxes back into the superficial veins and results in the development of varicosities. Lower extremity edema occurs secondary to fluid extravasation into the soft tissues. The elevated venous pressure is transmitted to the subcutaneous tissue and skin, particularly in the distal part of the leg, and forces the extravasation of red cells from the capillaries. This eventually results in brawny hyperpigmentation, induration, skin ulceration, and recurrent bouts of cellulitis. *Lipodermatosclerosis* refers to the hard, tender, thickened subcutaneous tissue that develops in severe cases.

The clinical manifestations of chronic venous insufficiency can be divided into stages according to severity ([Table 81.8](#)).

Grade of Venous Insufficiency	Physical Examination	Symptoms
1	Dilated superficial veins Normal subcutaneous tissues and skin Ankle edema less than 1 cm	Mild swelling Leg heaviness
2	Many dilated veins Incompetent communicating veins Skin pigmentation changes Skin fissures Lower extremity edema >1 cm	Moderate to severe swelling Itching Varicosis Brawny skin changes
3	Many dilated veins Incompetent communicating veins Many venous varicosities Marked skin pigmentation Severe lipodermatosclerosis Venous ulcers Edema >2 cm	Severe swelling Calf pain

TABLE 81.8. CLINICAL GRADE OF VENOUS INSUFFICIENCY

General Management

The goals of management in chronic venous insufficiency are to ameliorate symptoms and reduce the possibility of skin ulceration. This is accomplished by reducing venous hypertension as much as possible. Conservative management includes daily use of graded elastic compression stockings (30 to 50 mm Hg at the ankle), avoidance of prolonged standing, periodic leg elevation during the day, leg elevation throughout the night, and ulcer treatment with medicated compressive dressings. The prototypical antiembolism stockings have a uniform pressure throughout and are used for prophylaxis of deep venous thrombosis in patients at bed rest. They are not effective in reducing edema in ambulatory patients either immediately after diagnosis of deep venous thrombosis or when there is chronic venous insufficiency.

Gradient elastic compression stockings must be prescribed. These have the highest pressure at the ankle and the lowest pressure in the proximal segment of the stocking. Surgical treatment should be considered if these measures fail. Surgical therapy may consist of compression sclerotherapy and ablative surgery for superficial and communicating vein insufficiency. Ablative surgery refers to procedures such as stripping of the greater saphenous vein and division of incompetent communicating veins. Surgical options for valvular incompetence include valvuloplasty for patients with a primary deep vein valve abnormality. Surgical repair of valve incompetence also includes transposing a vein segment with valve incompetence to an adjacent vein segment with a competent valve. Competent valves in a segment of upper extremity vein can be transplanted into a lower extremity vein with incompetent valves. There are venous bypass procedures for patients with chronic venous insufficiency due to obstruction.

LYMPHATIC DISEASE

Lymphedema results from excessive accumulation of tissue fluid in the extremities as a result of impaired lymphatic drainage. It can be primary, but is more often secondary or acquired. Lymphedema should be distinguished from the edema of venous insufficiency; however, they do on occasion occur together. Venous edema rarely affects the toes and is characteristically soft and pitting. Lymphedema, in contrast, almost always involves the toes and is usually firm with thickened skin ([Fig. 81.10](#)). Primary lymphedema is classified by the age at presentation. Congenital lymphedema results from failure of lymphatic development and appears at birth or within the first 2 years of life. There is a familial form of congenital lymphedema with autosomal dominant inheritance called *Nonne–Milroy's disease*. Lymphedema praecox is the most common form of primary lymphedema and occurs between the ages of 2 and 35 years. It is most commonly observed in women and often at the onset of menses or with the first pregnancy. *Meige's disease* refers to a specific form of familial lymphedema with a recessive pattern of inheritance, which manifests at puberty. *Lymphedema tarda* is idiopathic lymphedema occurring after age 35 years. Lymphedema can also occur secondary to malignancy, trauma, infection, burns, surgery, or radiation therapy. Neoplasms are the most common cause of secondary lymphedema and should always be considered when one extremity is lymphedematous. Lymphatic obstruction caused by infections such as filariasis may cause lymphedema in endemic areas.

FIGURE 81.10. Lymphedema praecox. Edema is seen throughout the lower extremity and includes the toes.

The characteristic clinical presentation is sufficient to make the diagnosis in many cases of established lymphatic disease. Tests are sometimes necessary to confirm the presence and location of impaired lymphatic flow. MRI and CT can demonstrate thickened skin and a characteristic distribution of edema above the fascial compartment. Lymphoscintigraphy may provide a functional assessment of the lymphatic system. Radiolabeled tracer is injected subdermally between the toes, and transport of the tracer is tracked using the gamma camera. Abnormalities seen include absent or delayed transport, crossover filling with backward flow, and delayed imaging of the lymph nodes. Contrast lymphography is not usually necessary but may be performed before lymphatic reconstructive surgery.

The goal of treatment is to reduce edema and prevent fluid accumulation. Effective therapy includes gradient compression stockings. Local heat application can be useful in decreasing edema. Intermittent external compression pressure machines require daily use of a minimum of 3 hours. Complex physiotherapy or massage therapy has also been used successfully in lymphedema. Antibiotics are indicated for cellulitis and may be used prophylactically in patients with recurrent episodes of cellulitis. Surgical treatment may be considered in selected cases of severe refractory lymphedema associated with severe extremity disfigurement. Surgical therapy includes excisional procedures and creation of artificial limb channels.

CHAPTER 82: GENETICS OF THE CARDIOVASCULAR SYSTEM

CRAIG T. BASSON AND CARL J. VAUGHAN

[General Approach](#)
[Genetics of Dyslipidemias](#)
[Genetics of Cardiomyopathies](#)
[Genetics of Congenital Structural Heart Disease](#)
[Genetics of Cardiac Arrhythmias](#)
[Genetics of Inherited Vascular Disease](#)
[Inherited Cardiac Tumors](#)

Recent developments in molecular analysis of cardiovascular disease form the foundation for design of novel diagnostic and therapeutic approaches to patients. Over the last decade, the application of genetic mapping techniques has identified a number of gene defects that cause inherited cardiovascular disorders. Advances have been propelled by the development of a genetic map of highly informative polymorphisms in conjunction with efficient statistical methods for linkage analysis and molecular biologic techniques such as positional cloning. Microsatellite polymorphisms are the most common choice for genetic mapping studies, and the comprehensive genetic maps developed with the support of the Human Genome Project include more than 5,000 microsatellite markers that span the entire genome with an average resolution of 1 centimorgan. These studies have demonstrated a wide variety of defects in structural and contractile proteins, ion channels, transcription factors, signaling molecules, and receptors, which underlie many prominent diseases of the heart and vasculature. Lessons learned in the study of rare monogenic cardiovascular diseases have also provided additional insight into the pathogenesis of more common polygenic disorders such as hypertension and atherosclerosis. While the relative contribution of particular genetic factors to some cardiovascular diseases remains unknown, single- and multiple-gene defects clearly participate in pathogenesis of most cardiovascular disorders. Molecular genetic studies have thus not only defined the mutated disease-causing genes, but have also provided important insights into the cellular and organ physiologic processes whose secrets had remained locked within the genetic code. In this chapter, we describe recent advances in inherited cardiovascular diseases. Although a definitive discussion of all chromosomal loci and genes associated with cardiovascular disease is beyond the scope of this chapter, we will discuss archetypal examples of several categories of cardiovascular disease: (a) dyslipidemias, (b) cardiomyopathies, (c) congenital structural heart disease, (d) arrhythmias, and (e) vascular anomalies.

GENERAL APPROACH

As attention increasingly focuses on novel developments in the molecular genetics of cardiovascular disease, a vital, and often overlooked, part of any patient's clinical evaluation is the ascertainment of a family history. A detailed analysis of the family history forms the basis for any subsequent clinical or molecular genetic study. The family pedigree may indicate patterns of heritability (e.g., autosomal versus X-linked or mitochondrial, and dominant versus recessive), provide information on penetrance and expressivity, and focus attention on family members who have not yet been clinically evaluated but who are at risk for a heritable disorder. In the future, genetic testing will become increasingly available in the diagnosis of monogenic cardiovascular disorders, but it currently remains a research tool. As clinicians begin to use DNA-based testing, guidelines need to be developed to indicate when and in whom to conduct such tests. In some cases, DNA-based diagnoses will provide important information to guide diagnosis, surveillance, and therapy. However, genetic testing is not without problems. Used inappropriately, such preclinical testing of asymptomatic individuals may fail to aid management and may be psychologically distressing to patients and their families. Furthermore, establishment of family disease patterns by history, clinical examination, and adjunctive imaging studies is often more than adequate to secure a diagnosis and guide surveillance. Therefore, genetic testing for cardiovascular disease should be applied in a selective manner. Careful consideration should be given in advance to the likely social, psychological, and economic impact of such testing on a given individual. Patients must be carefully counseled before and after testing by a physician and geneticist with substantial experience in heritable cardiovascular diseases.

GENETICS OF DYSLIPIDEMIAS

Coronary artery disease (CAD) remains the leading cause of morbidity and mortality in the United States. Dyslipidemias, which affect over 140 million adults in the United States, are major risk factors in the development of atherosclerosis and CAD. The term dyslipidemia refers to the abnormal metabolism of plasma lipids and may result from accelerated synthesis or decreased degradation of lipoproteins that transport cholesterol and triglycerides through the plasma. Such abnormal metabolism can be caused by genetic, dietary, or secondary disease factors. Dyslipidemias have been clinically characterized using the Fredrickson classification, which categorizes disorders based on the lipoprotein profile. In this classification, familial hypercholesterolemia (Fredrickson type IIa) and familial combined hyperlipidemia (Fredrickson type IIb or IV) are the most prominent disorders. Other Fredrickson class dyslipidemias are rare; they include type I dyslipidemia, characterized by markedly elevated triglycerides and due to lipoprotein lipase deficiency, and type III hyperlipidemia, in which plasma accumulation of chylomicron remnants and intermediate density lipoprotein occurs.

FAMILIAL HYPERCHOLESTEROLEMIA

Familial hypercholesterolemia (FH) is an autosomal dominant disorder caused by mutation of the low-density lipoprotein receptor (*LDLR*) gene. Familial hypercholesterolemia is common; 1 in 500 individuals is heterozygous for the disorder. Homozygous FH is rare, with a frequency of approximately 1 per million. In addition to elevated serum LDL, affected individuals may exhibit deposition of cholesterol in the cornea (corneal arcus) and in tendons (xanthoma) (Fig. 82.1). In homozygous FH, symptoms of CAD begin in childhood or early adult life. In the heterozygous form, the onset of symptomatic CAD occurs in later life, between ages 40 and 60. Homozygous FH is particularly difficult to treat since the drugs that lower cholesterol depend on a normally functioning LDLR and act primarily by increasing hepatic synthesis of the receptor. Liver-directed *LDLR* gene transfer has been performed in patients with homozygous FH. This approach entails resection of a portion of the liver with harvest of hepatocytes and their infection with a viral vector containing the *LDLR* gene. This technique is not widely available and has only been applied to small numbers of patients. Efforts are ongoing to develop strategies to target the *LDLR* gene to the liver in vivo. This approach has considerable potential and may be a very effective method of lowering LDL in FH. Other strategies that have been employed to lower LDL in patients with homozygous FH include LDL apheresis and hepatic transplantation. Heterozygous FH is treated with a low-cholesterol diet and hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), which lower LDL cholesterol by up to 50%.

FIGURE 82.1. Tendon xanthoma. Prominent tendon xanthomas (arrows) on the hand of a patient affected by homozygous familial hypercholesterolemia. (Courtesy of Dr. Bruce Gordon, Weill Medical College of Cornell University.)

The *LDLR* locus maps to chromosome 19p13.2-p13.1, and several different mutations in this receptor have been described in FH. Nonsense and frameshift mutations that abrogate translation of the LDLR protein may result in undetectable LDLR levels in the case of homozygous FH or a reduced number of receptors in heterozygous FH. Missense mutations may either hinder intracellular transport and internalization of the receptors (transport-defective alleles) or inhibit receptor binding and endocytosis of LDL. The DNA analysis of FH families is not routinely clinically useful, since diagnosis of specific mutations rarely affects management. A careful family history, with particular attention to the age of onset of myocardial infarction, stroke, and/or peripheral vascular disease, will establish clinical suspicion of

FH. The diagnosis can be confirmed by analysis of the lipoprotein profile among family members.

Despite a detailed understanding of the role of the LDLR in FH, our knowledge of the molecular genetic basis for other inherited dyslipidemias remains rudimentary. Familial combined hyperlipidemia (FCH) is the most common dyslipidemia. It occurs with a frequency of 1% in the general population and with a frequency of 10% in patients who have suffered a myocardial infarction. Familial combined hyperlipidemia is characterized by elevated LDL and triglycerides. Although an FCH locus has been described on chromosome 1q21-q23, the specific gene defect responsible for this disorder has not been elucidated.

GENETICS OF CARDIOMYOPATHIES

FAMILIAL HYPERTROPHIC CARDIOMYOPATHY

Familial hypertrophic cardiomyopathy exhibits considerable diversity in terms of its clinical presentation, cardiac morphology, natural history, and molecular genetics. The incidence of the disorder is about 1 in 500. Molecular genetic studies have demonstrated that FHC is genetically heterogeneous and that the defects causing it involve mutations in genes encoding cardiac sarcomere proteins.

The clinical presentation of FHC is highly variable; symptoms may occur at any age and include dyspnea, chest pain, and syncope. Patients may also present with symptoms of overt heart failure. Sudden death may be the initial presentation, most commonly in children and young adults, and often occurs during periods of vigorous physical exertion. Physical findings include a characteristic carotid pulse (pulsus bisferiens), a thrill at the lower sternal border, and a coarse systolic murmur, best heard at the lower left sternal border, that decreases with the patient squatting and is accentuated by the strain phase or phase 2 of the Valsalva maneuver. The electrocardiogram (ECG) is abnormal in most cases of FHC. The most common abnormalities are ST-segment and T-wave abnormalities, followed by increased QRS voltage and evidence of left ventricular hypertrophy. The diagnosis is confirmed with echocardiography ([Fig. 82.2](#)), which classically demonstrates asymmetric septal hypertrophy with systolic anterior motion of the anterior mitral valve leaflet and a variable degree of left ventricular outflow tract obstruction. Severity of FHC symptoms may not correlate with the presence or severity of outflow tract obstruction and intracavitary pressure gradient. However, impaired ventricular diastolic filling is generally considered a uniform finding. Because the clinical presentation and spectrum of disease in FHC is so diverse, universally applicable guidelines for management have not been defined. Initial management usually involves therapy with β -blocking drugs or verapamil. Patients with symptoms secondary to outflow tract obstruction that are refractory to pharmacologic therapy may be considered for septal myotomy and myomectomy with or without mitral valve replacement. Septal ablation has also been successfully achieved on an experimental basis through a catheter-based approach by infusion of alcohol into the septal perforator branches of the left anterior descending artery. This causes infarction and thinning of the proximal interventricular septum, thus reducing outflow obstruction. Dual-chamber pacemaker therapy has also been used in patients with outflow tract obstruction, but this approach remains controversial. Finally, implantable cardiac defibrillator therapy should be considered in patients at high risk for sudden cardiac death, such as survivors of a cardiac arrest.

FIGURE 82.2. Hypertrophic cardiomyopathy. Two-dimensional transthoracic echocardiography of a patient with familial hypertrophic cardiomyopathy reveals marked thickening of the left ventricle including the posterior wall (arrowhead) and the interventricular septum (arrow). (Courtesy of Dr. Mary Roman, Weill Medical College of Cornell University.)

Familial hypertrophic cardiomyopathy is inherited as an autosomal dominant trait, although it may also occur in a sporadic manner. Penetrance in familial disease is age-related, with clinical manifestations typically developing by adolescence. Familial hypertrophic cardiomyopathy is a disease of the sarcomere, and mutations in at least eight genes encoding sarcomeric proteins have been described in this disorder. Initial linkage analysis and molecular genetic studies in large families affected by the disorder demonstrated mutations in the cardiac β -myosin heavy chain (β -MHC) gene. To date, molecular genetic studies have revealed mutations in genes encoding the β -MHC (chromosome 14q1), cardiac troponin T (chromosome 1q31), cardiac troponin I (chromosome 19p13.2-q13.2), α -tropomyosin (chromosome 15q2), myosin-binding protein C (chromosome 11p13-q13), ventricular myosin regulatory light chain (chromosome 12q2), ventricular myosin essential light chain (chromosome 3p), and α -cardiac actin (chromosome 15q14). Interestingly, mutation in any of these genes may give rise to a clinically identical phenotype. The numerous β -MHC mutations account for 35% to 40% of cases of FHC. Mutations in cardiac troponin T account for disease in approximately 15% of cases, α -tropomyosin 5%, and myosin-binding protein C 10%. The β -MHC gene mutations correlate with survival in patients affected by FHC. Several “malignant” mutations have been described that correlate with a poorer prognosis and are associated with a significant risk of sudden death. Conversely, a number of “benign” β -MHC mutations are associated with long-term survival. Mutations associated with a worse prognosis are often those that alter the charge in the encoded amino acid residue. Although mutations in cardiac troponin T are often associated with subtle myocardial hypertrophy, survival in these individuals is poor and similar to that of patients with malignant mutation in the β -MHC gene. Of note, mutations in myosin-binding protein C are correlated with a benign phenotype and good long-term survival. In addition, cardiac myosin-binding protein C mutations exhibit reduced penetrance until the fifth decade of life, whereas FHC caused by mutations in other genes is almost completely penetrant by the second or third decade. Since left ventricular hypertrophy is relatively common in the elderly and is usually attributed to hypertension, it is possible that mutations in cardiac myosin-binding protein C are more common than expected in the elderly. While rare mutations in α -cardiac actin have been described in patients with dilated cardiomyopathies, recent molecular genetic studies in one family with FHC also have revealed mutations in the α -cardiac actin gene. The cellular mechanisms through which mutated sarcomeric proteins give rise to cardiac hypertrophy in this disorder are unclear. It has been speculated that sarcomeric mutations give rise to abnormal sarcomeric calcium handling, leading to enhanced transcription of cardiac protein genes.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is a heterogeneous group of diseases of the myocardium characterized by dilatation and impaired contraction of the left or both ventricles ([Fig. 82.3](#)). Dilated cardiomyopathy occurs in approximately 37 per 100,000 individuals, is a frequent cause of heart failure, and is the most common indication for cardiac transplantation in the United States. This disorder usually presents with typical symptoms and signs of congestive heart failure, but it may also present with unexplained fatigue, syncope, and/or sudden death. Metabolic abnormalities (such as vitamin B₁ deficiency), toxins (such as alcohol), and viral infections can cause dilated cardiomyopathy, but there is a growing appreciation that more than 25% of cases are inherited. Familial dilated cardiomyopathy (FDC) has also been described in association with a variety of other cardiac disorders including atrioventricular (AV) block, ventricular tachyarrhythmias, and atrial cardiomyopathy. The application of molecular genetic analysis to this familial disorder has led to the identification of chromosomal locations of several etiologic gene defects.

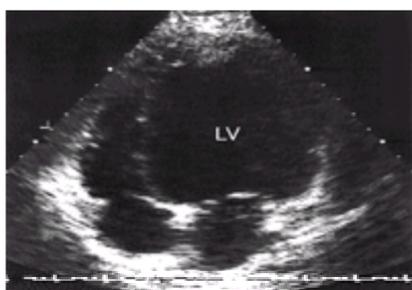

FIGURE 82.3. Dilated cardiomyopathy. Two-dimensional transthoracic echocardiography of a patient with dilated cardiomyopathy reveals marked dilatation of the left ventricular (LV) chamber. (Courtesy of Dr. Mary Roman, Weill Medical College of Cornell University.)

Autosomal Dominant Cardiomyopathies

Family studies indicate that FDC is transmitted most commonly as an autosomal dominant trait. Less frequently, X-linked and recessive forms are observed. A number of chromosomal loci have been described in autosomal dominant FDC (e.g., chromosome 1p-1q, 1q32, 2q31, 3p25-22, 10q21-23, and 9q13-22). However, the only specific gene implicated thus far is the cardiac actin located on chromosome 15q14. As with FHC, genetic studies of FDC indicate that considerable genetic and clinical heterogeneity exist in this disorder. For example, prominent conduction system disease has been described in association with one form of FDC linked to the chromosome 1p-1q locus. Individuals often present in early life with conduction disease and atrial arrhythmias, progressing to congestive heart failure in later life. Missense mutations in the lamin A/C gene have been shown to cause this form of autosomal dominant cardiomyopathy associated with conduction defects. In addition, mutations in desmin, a muscle-specific intermediate filament, as well as cardiac actin have been described in rare families with FDC without conduction defects. Based on observations that mutations in the anchoring portion of cardiac actin cause dilated cardiomyopathy and mutations in cardiac actin that affect actin–myosin binding cause hypertrophic cardiomyopathy, it has been proposed that dilated cardiomyopathy is a consequence of defective transmission of force in cardiomyocytes. The observation that mutations in the nuclear protein lamin A/C cause FDC may suggest that these proteins contribute to force transmission via interaction with cytoskeletal elements. However, the possibility remains that dilated cardiomyopathy may result from nuclear transport dysfunction and cell death.

X-Linked Cardiomyopathy

Two genes related to X-linked cardiomyopathies have been identified: defects in the dystrophin gene are responsible for Duchenne's and Becker's muscular dystrophy, and defects in the tafazzin (G4.5) gene for Barth syndrome. Dystrophin is a member of a large multiprotein complex (the dystrophin-associated glycoprotein complex, or DAG) that links the muscle cytoskeleton to the extracellular matrix, thereby anchoring the cardiomyocytes to the extracellular matrix. In this disorder, characteristic proximal muscle weakness is present, and most patients exhibit a variable degree of cardiac involvement. Heart failure in X-linked Duchenne's muscular dystrophy occurs rapidly after the onset of symptoms in the teens or early 20s. The precise cellular function of tafazzin remains unknown but Barth syndrome secondary to tafazzin mutations is a highly lethal neonatal form of cardiomyopathy associated with other abnormalities including fibroelastosis and neutropenia.

Mitochondrial cardiomyopathies

Mitochondria are maternally inherited, and thus maternal transmission is the hallmark of human mitochondrial disease. Mitochondrial diseases exhibit considerable clinical variability. The development of cardiomyopathy is a common feature of several mitochondrial syndromes such as MELAS syndrome (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes); MERFF syndrome (myoclonic epilepsy and ragged red fibers); NADH-coenzyme Q reductase deficiency; Kearns–Sayre syndrome (which also includes a characteristic ocular myopathy and cardiac conduction defects); MIMyCA (maternally inherited myopathy and cardiomyopathy). Mutations in mitochondrial DNA may also occur as secondary genetic abnormalities in other familial and sporadic cardiomyopathies.

Further advances in the genetics of familial cardiomyopathies will not only unravel the molecular pathways that lead to cardiac failure but may also direct attention to novel therapeutic targets to prevent or treat these disorders.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a recently recognized familial cardiomyopathy characterized by fibrofatty replacement of the right ventricular myocardium. Individuals with ARVC have a propensity to die suddenly from ventricular arrhythmias that originate in the right ventricle and may in fact exhibit left ventricular pathology also. Diagnosis is difficult and may depend on the combined use of electrocardiography, echocardiography, and magnetic resonance imaging (Fig. 82.4). Both autosomal dominant and recessive variants of this disorder have been described and several loci have been reported in the autosomal dominant variant. No specific gene defect has yet been identified. Ultimately, genetic testing in this syndrome will provide an important ancillary diagnostic tool that will assist sudden death risk stratification.

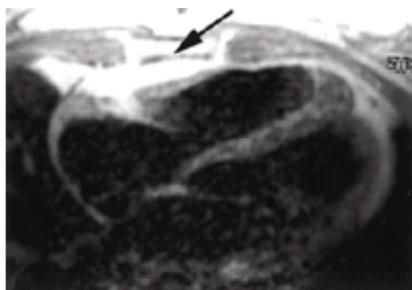

FIGURE 82.4. Arrhythmogenic right ventricular cardiomyopathy. Magnetic resonance imaging of an individual affected by arrhythmogenic right ventricular cardiomyopathy demonstrates extensive fatty infiltration (*bright signal indicated by arrow*) of the anterior wall of the right ventricle. (Courtesy of Dr. Steven Markowitz, Weill Medical College of Cornell University.)

GENETICS OF CONGENITAL STRUCTURAL HEART DISEASE

Congenital structural heart disease is estimated to occur in approximately 0.5% of the general population. Early studies of the general population have estimated the risk of recurrent congenital heart disease in a patient with one affected sibling to be 2.3% and in the offspring of an affected mother to be greater than 6.7%. However, the advent and widespread use of diagnostic tools such as color Doppler and transesophageal echocardiography has improved detection of subtle congenital defects, and some studies report an overall neonatal incidence of ventricular septal defects as high as 5%. Bicuspid aortic valve disease and mitral valve prolapse occur in 0.9% and 4% of individuals, respectively. Thus the true incidence of congenital heart defects has likely been underestimated. Moreover, given that many such defects may be transmitted as autosomal dominant traits, the recurrence risk to an individual with an affected first-degree relative can reach 50%.

SEPTATION DEFECTS

Defects in cardiac septation including atrial septal defect (ASD), ventricular septal defect (VSD), and AV canal septal defects form a major proportion of congenital heart disease. Considerable advances have been made in our understanding of the genetic orchestration of cardiac septation. Mutant genes encoding two transcription factors have been described in families with inherited atrial or ventricular septal defects. Holt–Oram syndrome, also called heart–hand syndrome, is an autosomal dominant condition characterized by upper extremity abnormalities in association with ASDs and VSDs. Mutation of the T-box transcription factor *TBX5* gene causes Holt–Oram syndrome. *TBX5* is expressed in the developing upper limb and heart, and its precise role in cardiogenesis is actively being investigated. Most *TBX5* mutations are truncation mutations (nonsense or frameshift) that result in *TBX5* haploinsufficiency, but missense mutations have been identified. Although *TBX5* haploinsufficiency produces severe malformation of both heart and limbs, the missense mutations thus far identified modify specific DNA binding sites and produce either severe heart or severe limb abnormalities, but not both. Mutations in the homeobox transcription factor gene *NKX2.5* have also been described in families with inherited structural heart disease, in particular ASDs and progressive AV node dysfunction. *NKX* gene family members are homologous to the *Drosophila* tinman gene, which participates in specification of heart muscle progenitors. At least some human *NKX2.5* mutations disrupt the homeobox encoding region of the

gene and are predicted to cause disease through *NKx2.5* haploinsufficiency. Mutations in human *NKx2.5* have been described in diverse congenital heart defects, including atrial and ventricular septal defects associated with atrioventricular block, conotruncal defects, and Ebstein's anomaly. The array of anomalies attributable to mutation in *NKx2.5* has led to the suggestion that these anomalies may reflect indirect effects of *NKx2.5* on multiple cardiac structures due to a critical role for *NKx2.5* in early cardiac development and cardiac looping.

CONOTRUNCAL ANOMALIES

Conotruncal defects are cardiac anomalies thought to result from a disturbance of ventricular outflow tract morphogenesis or impairment of branchial arch development. Conotruncal anomalies include truncus arteriosus, tetralogy of Fallot (TOF), interrupted aortic arch, transposition of the great vessels, double-outlet right ventricle, and posterior malalignment VSD (Fig. 82.5). Conotruncal abnormalities account for approximately 15% of congenital heart disease. Conotruncal anomalies have been associated with two overlapping human syndromes: the velocardiofacial syndrome and DiGeorge syndrome. Velocardiofacial syndrome is a syndrome including cleft palate, cardiac anomalies, and a characteristic facial phenotype. DiGeorge syndrome includes absent thymus and parathyroid glands, as well as cardiac outflow tract anomalies with abnormal facies. These syndromes are often aggregated under the acronym CATCH 22 (cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia).

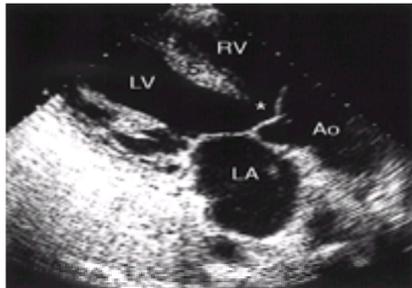

FIGURE 82.5. Double-outlet right ventricle conotruncal defect. Two-dimensional transthoracic echocardiography of a patient with a double-outlet right ventricle demonstrates typical anatomical features of this and other conotruncal defects such as tetralogy of Fallot. Note the subaortic ventricular septal defect (*) created by the malalignment of the aortic (Ao) outflow tract overriding the interventricular septum dividing the anatomical left ventricle (LV) from the right ventricle. The left atrium (LA) is denoted as well.

Initial studies described a deletion of chromosome 22q in DiGeorge syndrome, and subsequent analyses showed that deletions in chromosome 22q were present in both isolated conotruncal abnormalities and the velocardiofacial syndrome. Accordingly, karyotyping and fluorescent in situ hybridization analysis (FISH) with probes specific to the chromosome 22q11 is now a recommended part of the standard evaluation of individuals with conotruncal anomalies. The minimally deleted region of chromosome 22 is currently estimated to be approximately 250 kb of DNA. The CATCH 22 syndrome is thought to result from deletion of contiguous genes and the 22q locus contains a number of genes (e.g., *clathrin heavy chain protein*, *CDC45L*, *HIRA*, and *UFDIL*) that are currently under investigation. Further work will define the gene(s) involved and the nature of the aberrant gene product underlying this variable constellation of anomalies.

Tetralogy of Fallot was initially thought to be a multicomponent disorder comprising ventricular septal defect with pulmonic stenosis, overriding aorta, and right ventricular hypertrophy. It is now recognized that TOF is primarily a failure of right ventricular infundibulum development with the accompanying anatomical abnormalities a manifestation of this embryonic field defect. Experimental studies in chick embryos support this concept and indicate that TOF is one form of anomalous conotruncal development. It accounts for approximately 10% of congenital heart disease and can occur in isolation or in association with ASDs, or AV septal defects, as well as more complex syndromes such as Holt–Oram syndrome and Down's syndrome. Tetralogy of Fallot frequently occurs in patients with extracardiac manifestations that comprise the characteristic CHARGE syndrome (colobomata, heart defects, choanal atresia, retardation, genital hypoplasia, and ear abnormalities). Investigations have revealed that chromosome 22q11 microdeletions are present in 15% of TOF patients as well as in 50% of interrupted aortic arch patients, 35% of truncus arteriosus patients, and 33% of posterior malalignment VSD patients. Microdeletions in chromosome 22q11 have also been described in cases of double-outlet right ventricle. All conotruncal anomalies may reflect de novo genetic events, but they can also be transmitted in an autosomal dominant fashion. Offspring of individuals with conotruncal abnormalities such as CATCH 22 or TOF may have a 50% risk of congenital heart disease. Prenatal diagnosis in families with chromosome 22q11 deletions is clinically available.

GENETICS OF CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are common and lead to considerable morbidity and mortality. It is increasingly recognized that many arrhythmias have a heritable basis including atrial fibrillation, Wolff–Parkinson–White syndrome, and, most notably, the hereditary long QT syndrome (LQTS).

HEREDITARY LONG QT SYNDROME

Long QT syndrome is usually an autosomal dominant genetic disorder characterized (Fig. 82.6) by prolonged ventricular repolarization on the ECG and a predilection for syncope, polymorphic ventricular tachycardia (torsades de pointes), and sudden cardiac death. This syndrome has been clinically characterized in two forms: (a) the Romano–Ward variant and (b) the more rare autosomal recessive Jervell and Lange–Nielsen variant, which is associated with congenital deafness. A number of specific mutations in cardiac sodium and potassium ion channels have been identified in this disorder.

FIGURE 82.6. Hereditary long QT syndrome. **A:** This 12-lead electrocardiogram of a patient who presented with syncope demonstrates marked QTc interval prolongation (632 milliseconds) and bifid T waves consistent with long QT syndrome. **B:** Telemetry recording of the same patient during the onset of polymorphic ventricular tachycardia (torsades de pointes).

Long QT syndrome is characterized by prolongation of the QT interval and T-wave abnormalities on the ECG (Fig. 82.6). It has been estimated that LQTS is responsible for 3,000 to 4,000 sudden deaths in the United States each year. Symptoms typically begin in teenage years, but they may begin in early childhood or as late as middle age. Syncope occurs in over 50% of gene carriers, and sudden death occurs in 10% to 30% of symptomatic patients, more commonly in those with a history of syncope or resuscitated cardiac arrest. Syncope and sudden death most commonly occur during exercise or emotional stress but may also occur during sleep. Events may be precipitated by drugs that prolong the QT interval or by electrolyte abnormality. Long QT syndrome should be suspected in any case of unexplained syncope, especially when syncope occurs in association with exercise or emotional upset. A corrected QT (QTc) interval of 480 milliseconds in females

or 470 milliseconds in males, in the absence of drugs or electrolyte abnormality, corroborates the diagnosis. In about 10% of patients the QTc will be normal. In addition, T-wave abnormalities are common, especially bifid T waves. There is considerable variability in clinical presentation, at times making diagnosis difficult. To assist diagnosis, diagnostic criteria incorporating electrocardiographic, clinical, and family history have been developed. Therapy is recommended for all symptomatic subjects. Because 30% of LQTS sudden deaths occur as the primary event, some investigators also recommend therapy for all asymptomatic subjects under age 40. Initial therapy for most patients is β -blockade. Other therapies include permanent pacemaker insertion and implantation of cardiac defibrillators, which are increasingly used to prevent sudden death in this disorder.

Molecular genetic studies have revealed that LQTS is genetically and clinically heterogeneous. It results from mutations in genes that encode cardiomyocyte ion channels. Heterozygous mutations in the potassium channel genes *KVLQT1*, *KCNE1* (*minK*), *KCNE2*, and *HERG*, and the cardiac sodium channel gene *SCN5A*, cause autosomal dominant LQTS. Autosomal recessive LQTS, which is associated with deafness and comprises the Jervell and Lange-Nielsen syndrome, occurs with homozygous mutations in *KVLQT1* and *KCNE1*. Mutation of the *KVLQT1* gene at the *LQT1* locus on chromosome 11 gives rise to an abnormal potassium channel protein (a subunit). Similarly, mutation of the *HERG* gene at the *LQT2* locus on chromosome 7 also gives rise to an abnormal potassium channel. Mutations in the *minK* gene have been identified at the *LQT5* locus on chromosome 21. Very recently, a novel potassium channel subunit gene, *KCNE2*, has been cloned and localized to chromosome 21q22.1. *KCNE2* encodes *MiRP1* (Mink-related peptide 1), a small membrane protein that coassembles with *HERG*, and *MiRP1* mutations have been identified in LQTS patients. Mutation of the *SCN5A* gene at the *LQT3* locus on chromosome 3 results in an abnormal sodium channel that fails to inactivate sodium inflow with consequent abnormal myocardial repolarization.

Cardiac potassium channels contribute to the termination of the action potential, and LQTS mutations in these channels have been thought to prolong the cardiac action potential through a "loss-of-function mutation." Sodium channels initiate the myocellular action potential, and then close and remain inactivated. It is generally believed that LQTS mutations in the sodium channel cause it to remain open, thus prolonging the action potential. This concept has been termed a "gain-of-function" mutation. In the case of the *HERG* channel, it appears that intracellular trafficking of the mutant channel is defective whereby the mutant channel is not translocated from the Golgi apparatus to the cell membrane. Thus, there are a reduced number of normally functioning potassium channels in the cell membrane and consequent abnormal myocellular repolarization.

The precise frequency of the different LQTS genotypes is unknown, but it is estimated that most disease is due to mutation of *KVLQT1* (*LQT1*) or *HERG* (*LQT2*). The LQTS genotypes correlate with clinical course. The risk of cardiac events is significantly higher in individuals with *KVLQT1* or *HERG* mutations than in those with *SCN5A* mutations. Presymptomatic molecular genetic diagnosis of LQTS would be particularly helpful in preventing sudden cardiac death. Genetic testing may also aid diagnosis when clinical diagnosis is unclear, e.g., borderline QTc prolongation. Such DNA-based testing is particularly effective and efficient for members of families in which a disease-causing mutation has already been defined. However, because of the labor and costs involved in sequencing the multiple LQTS genes when no prior familial mutation is known, LQTS genetic testing is not widely clinically available. With molecular characterization of all LQTS genes and their disease-causing mutations, and the development of more efficient DNA analysis technologies such as DNA microchip arrays, genetic testing will become increasingly feasible in diagnosing and risk-stratifying patients suspected of harboring this disorder. Finally, gene-specific therapy may be useful in some forms of the LQTS. This may relate not only to advice given to patients regarding the dangers of vigorous exercise but also to specific pharmacologic therapy. For example, it has been suggested that LQTS secondary to excessive sodium channel activation may respond to sodium channel-blocking drugs such as mexilitine. In addition, as with FHC, characterization of LQTS genotypes with a high risk of sudden death may prompt consideration of prophylactic implantable defibrillator implantation.

GENETICS OF INHERITED VASCULAR DISEASE

There is a wide spectrum of inherited vascular disease. Some disorders reflect disease of large vessels and extracellular matrix assembly, e.g., Marfan's syndrome (fibrillin mutation) and type IV Ehlers–Danlos syndrome (type III procollagen gene mutation). Other inherited disorders reflect disease of the microvasculature, e.g., hereditary hemorrhagic telangiectasia (HHT), also known as Rendu–Osler–Weber syndrome (endoglin or activin receptor–like kinase 1 mutation).

THE MARFAN SYNDROME

Although the Marfan syndrome was recognized as a heritable disorder of connective tissue more than 40 years ago, the precise molecular defect was discovered in 1991. The Marfan syndrome is named after the Parisian pediatrician who in 1896 described severe skeletal abnormalities in a child with the syndrome that now bears his name. The Marfan syndrome is estimated to affect 1 in 20,000 people and exhibits an autosomal dominant pattern of inheritance. In the classic Marfan syndrome, skeletal, ocular, and cardiovascular abnormalities are present. However, there is wide phenotypic variation in the syndrome's expressivity, ranging from mild skeletal involvement and ocular anomalies, to severe neonatal disease with lethal cardiovascular malformations. Skeletal abnormalities comprise a tall thin stature with long thin limbs (dolichostenomelia) and "spider fingers" (arachnodactyly) as well as pectus excavatum ("hollow chest"), pectus carinatum ("pigeon chest"), and kyphoscoliosis. Ocular disease includes lens abnormalities with myopia and ectopia lentis as well as a predisposition to retinal detachment. Cardiovascular disease is the most lethal manifestation of the Marfan syndrome and includes dilatation of the ascending aorta (Fig. 82.7), aortic valvular insufficiency, and aortic dissection. The mitral valve is also commonly affected and exhibits thickened nodular leaflets, leaflet fenestration, and disrupted chordal attachments. Mitral valve prolapse with regurgitation and congestive heart failure is a common indication for mitral valve replacement in young children affected by the disorder. Composite aortic valve replacement with ascending aortic conduit surgery (Bentall procedure) is usually recommended when moderate aortic insufficiency is present or when the maximal aortic root diameter exceeds 5.5 cm. Clinical studies have shown that pharmacologic therapy with β -blocking drugs may influence both absolute aortic growth rate and aortic growth rate adjusted for age and body size in Marfan patients. Consequently, β -blockade is recommended in most Marfan patients to attenuate aortic dilatation.

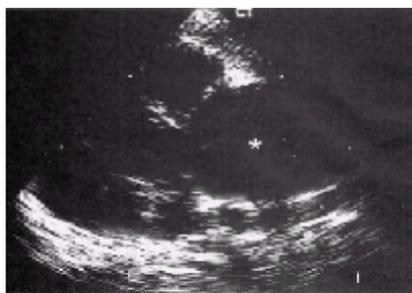

FIGURE 82.7. The Marfan syndrome. Two-dimensional transthoracic echocardiography of a patient affected by the Marfan syndrome demonstrates marked dilatation (6.3 cm) of the aortic root (*) at the level of the sinuses of Valsalva. (Courtesy of Dr. Richard Devereux, Weill Medical College of Cornell University.)

The Marfan syndrome is transmitted as an autosomal dominant trait due to mutations in the chromosome 15q fibrillin-1 (*FBN-1*) gene, and approximately 25% of cases represent de novo mutations. Immunohistochemical studies show that the extracellular matrix protein fibrillin, abundant in the aorta and the suspensory ligament of the lens, may be defective or deficient in Marfan patients. Mutations in the related chromosome 5q fibrillin-2 gene cause congenital contractural arachnodactyly, a condition that shares some of the features of the Marfan syndrome but does not include cardiovascular disease. Since the identification of the first mutation in *FBN-1* more than 80 mutations of the gene have been described. Mutations are evenly spaced along the *FBN-1* gene and cause a wide phenotypic spectrum even within families with the same *FBN-1* mutation. Over 60% of the mutations are missense mutations. Cysteine substitutions are particularly common and give rise to instability within the fibrillin molecule. Approximately 30% of mutations result in *FBN-1* haploinsufficiency with resultant defective microfibrillar structure. Most families have unique *FBN-1* mutations, and thus the widespread clinical application of molecular probes to diagnose the Marfan syndrome is limited. Mutational analysis is restricted to families in which a mutation in *FBN-1* has already been described since complete sequence analysis of the large 100-kb *FBN-1* gene is labor-intensive and remains a research tool. In large families, presymptomatic or prenatal screening is possible using haplotype segregation analysis with highly polymorphic markers of *FBN-1*. Recently, *FBN-1* mutations have been described in patients with ascending thoracic aortic aneurysms but without a classic Marfan body habitus. Therefore, *FBN-1* mutations may also contribute to isolated thoracic aortic aneurysmal disease. Genotype/phenotype correlation studies have shown that the clinical criteria used to diagnose the Marfan syndrome are accurate. Therefore, the diagnosis of the Marfan syndrome can be made in most suspected cases through the careful application of these criteria.

SUPRAVALVULAR AORTIC STENOSIS

Supravalvular aortic stenosis (SVAS) is also a disorder of connective tissue matrix assembly that may present as an isolated familial autosomal dominant disorder or as a feature of the autosomal dominant Williams syndrome, which is characterized by SVAS in association with an abnormal “elfin” facies, mental retardation, and hypercalcemia. Rearrangements and deletions in the chromosome 7q11.2 elastin gene are responsible for isolated SVAS, and more complex rearrangements of this chromosomal region are found in Williams syndrome. Studies in mice heterozygous for the elastin gene show an increased number of elastic lamellae and smooth muscle in the arterial wall.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia (HHT), or Osler–Rendu–Weber syndrome, is an autosomal dominant systemic vascular dysplasia with an incidence of 1 in 40,000. The disorder is characterized by mucosal, cutaneous, and visceral telangiectasias that have a predilection for recurrent hemorrhage, especially from mucosal surfaces and within the gastrointestinal tract. In addition, arteriovenous malformations (sometimes with clinically significant shunts) may develop in the pulmonary, cerebral, or hepatic circulations. Pathologic analysis reveals that telangiectasias are lined by a single layer of endothelium attached to a continuous basement membrane. Linkage analysis led to the identification of two loci for HHT, one at chromosome 9q33–q34 (*HHT1*) and the other on chromosome 12q (*HHT2*). Mutations in the gene encoding endoglin at *HHT1* cause HHT. Endoglin is the most abundant transforming growth factor b (TGF-b) binding protein on the surface of endothelial cells. Mutations in the activin receptor–like kinase (*ALK1*) gene have been described at *HHT2*. It has been suggested that endoglin binds TGF-b and presents it to the *ALK1* signaling complex, which in turn modulates signal transduction in endothelial cells. This endoglin/ *ALK1* cellular pathway is critical for angiogenesis, and although mouse models deficient in endoglin exhibit normal vasculogenesis, they exhibit lethal arrested angiogenesis.

Telangiectasias are components of several other familial syndromes. For example, families with autosomal dominant mucocutaneous venous malformations, such as the “blue rubber-bleb nevus” syndrome, have been shown to have a missense mutation in the endothelial cell specific tyrosine kinase (*TIE2*) gene, which maps to chromosome 9p21.

INHERITED CARDIAC TUMORS

Although rare, cardiac tumors may present as components of complex heritable disorders. Cardiac rhabdomyomata and myxomas are the most common tumors of infancy and adulthood, respectively, and both can be heritable traits. Cardiac rhabdomyoma is an important feature of neonatal autosomal dominant tuberous sclerosis. This disorder is characterized by skin lesions and by neurologic and ophthalmologic anomalies. Tuberous sclerosis is most often due to mutations in the *TSC1* gene (chromosome 9q34) or the *TSC2* gene (chromosome 16p13.3). In tuberous sclerosis, rhabdomyomata may be multiple and may occur in more than one cardiac chamber. More than half of all infants with cardiac rhabdomyomata have tuberous sclerosis, and all infants with rhabdomyomata should be evaluated for clinical features of tuberous sclerosis. Importantly, cardiac rhabdomyomata in infants with tuberous sclerosis might not require surgical resection because most spontaneously regress during childhood and patients remain asymptomatic.

Cardiac myxomas are the most common primary cardiac tumor in the general population and occur with a frequency of 7 per 10,000 individuals. Although myxomas are usually sporadic, several autosomal dominant familial syndromes that combine lentiginosis and cardiac myxomas have been described. Previously termed syndromes such as LAMB (lentiginosis, atrial myxomas, mucocutaneous myxomas, and blue nevi) syndrome and NAME (nevi, atrial myxoma, myxoid neurofibroma, and ephelides) are now grouped under the broader category of Carney complex, which accounts for 7% of all cardiac myxomas. Myxomas in the Carney complex ([Fig. 82.8](#)) are often multiple, can occur in any cardiac chamber, and have a predilection to recur after surgical resection. Although usually benign, cardiac myxomas are associated with significant cardiac morbidity due to stroke from tumor embolization and due to heart failure from intracardiac obstruction. Individuals with Carney complex also exhibit spotty pigmentation of the skin, particularly on the face, trunk, lips, and sclera. Extracardiac myxomas may also occur in the breast, testis, thyroid, or adrenal gland. Patients can exhibit a variety of endocrine disorders, including Cushing's syndrome secondary to primary pigmented nodular adrenocortical hyperplasia. The gene defect that produces the cardiovascular and cutaneous disease in Carney complex is unknown. Initial genetic analyses suggested that a gene defect maps to chromosome 2p. More recent linkage analysis in several families affected by the Carney complex has also mapped a disease locus to chromosome 17q2. Identification of the Carney complex disease gene(s) will enhance our diagnosis and management of patients with cardiac myxomas, and will also provide insights into basic mechanisms that regulate cardiac growth and differentiation.

FIGURE 82.8. Right atrial myxoma in the Carney complex. Transesophageal echocardiogram of a woman with autosomal dominant Carney complex. Patient has spotty hyperpigmentation of the skin and had previously undergone cardiac surgery to resect a left atrial myxoma. Echocardiography done after patient presented with constitutional symptoms demonstrated a large pedunculated right atrial myxoma (*arrow*) abutting the eustachian valve (*arrowhead*).

CHAPTER 83: CARDIOVASCULAR RADIOLOGY

ROBERT D. TARVER, DEWEY J. CONCES, JR. AND LYNN S. BRODERICK

[Cardiovascular Measurements](#)
[Assessment of Chamber Size](#)
[Cardiac Calcifications](#)
[Pulmonary Vasculature](#)

Despite the development of many sophisticated imaging modalities, the plain chest roentgenogram remains the most commonly used method for the study of the cardiovascular system. Chest roentgenograms make up more than half of all radiographic studies performed. In a significant percentage, the reason for the examination is to help evaluate the cardiovascular status of the patient. Because of the low density of the air-containing lungs, it is possible, without the injection of contrast material, to discern the size and configuration of the heart, the pulmonary arteries and veins, and the aorta. In no other area of the body is detailed anatomy so well shown on plain roentgenograms.

Most chest roentgenograms are performed in the posteroanterior (PA) projection, with the X-ray tube 6 feet from the plane of the film. Because of the long tube-to-film distance and the fact that the heart is in the anterior portion of the chest, magnification of the heart is minimized to about 10%. Chest roentgenograms are routinely obtained in the upright position in full inspiration. In infants, the anteroposterior (AP) projection, with the patient in the supine position, is used. Portable roentgenograms are almost always performed in the AP position. If possible, the patient is positioned in a sitting position. On occasion, these examinations must be performed with the patient supine, although this is less desirable. Because portable roentgenography is done in the AP projection, there is greater magnification of the heart as compared with PA films performed in the radiology department. The tube-to-film distance is also frequently less on portable roentgenograms than the 6-foot-distance standard for PA films. For these reasons, the apparent cardiac size may be 10% to 20% larger on portable roentgenograms as compared with chest films performed in the radiology department.

The borders of the mediastinum are clearly outlined against the dark, air-containing lung. On the PA view ([Fig. 83.1](#)), the upper right margin is usually formed by the superior vena cava. In older or hypertensive patients in whom the aorta is larger, the ascending aorta may become border forming in this segment. The remainder of the right cardiac border is formed by the right atrium. On occasion, if the patient has taken a deep breath, the inferior vena cava may be discerned as a straight line along the inferolateral aspect of the right cardiac margin. On the left side, the superior margin is made up of the aortic arch. The right margin of the aorta indents the trachea at this level, so that the diameter of the aortic arch may be discerned. Below the aortic arch is a convex bulge comprising the pulmonary trunk and left pulmonary artery. It may vary in size in normal persons and is inclined to be more prominent in young women. Below the pulmonary trunk is the left atrial appendage. This usually cannot be discerned in a normal person; however, with left atrial enlargement, a convex bulge of the left atrial appendage may be apparent below the pulmonary trunk ([Fig. 83.2](#)). The remainder of the left cardiac margin and apex is formed by the left ventricle. The right ventricle is not border forming either to the right or to the left. On the lateral view ([Fig. 83.3](#)), the superoanterior margin is made up of the ascending aorta. The right ventricle and right atrium make up the inferior aspect of the anterior margin. The posterior margin of the heart superiorly is the left atrium, and more inferiorly it is the left ventricle. The inferior vena cava usually can be seen also as a straight line on the inferior aspect of the posterior cardiac margin. The relationship of cardiac chambers is shown in [Figure 83.2](#) and [Figure 83.3](#).

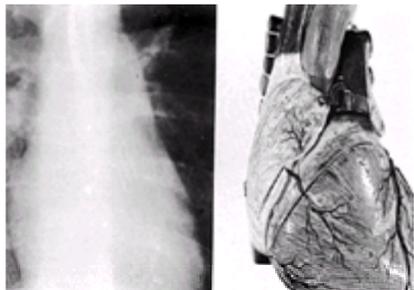

FIGURE 83.1. Comparison of a posteroanterior roentgenogram and anatomical model of the heart, anterior view. The superior right margin is formed by the superior vena cava. The remainder of the right cardiac border is formed by the right atrium. The inferior vena cava joins the right atrium just superiorly to the diaphragm. The left cardiac border comprises the aortic arch, pulmonary artery, left atrial appendage, and left ventricle.

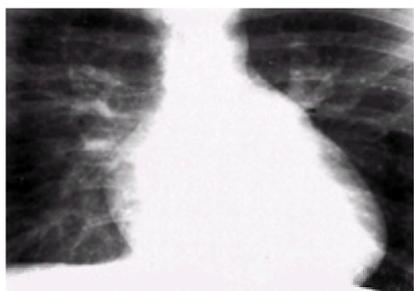

FIGURE 83.2. A 33-year-old woman with atrial septal defect had enlargement of the right atrium and right ventricle. The right cardiac margin is normal in spite of the enlargement of the right atrium. With dilatation of the right ventricle, the heart rotates in a clockwise fashion so that the right ventricular margin may extend to the left cardiac border. This gives the heart a globular shape with some elevation of the apex. Note the enlargement of the pulmonary artery (*arrowhead*).

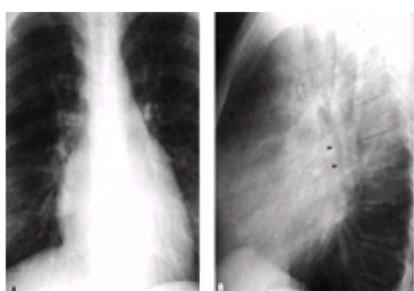

FIGURE 83.3. Mitral stenosis with enlargement of the left atrium and right ventricle. **A:** Posteroanterior view shows the enlarged left atrial appendage forming a convex bulge below the pulmonary artery (*arrowhead*). **B:** Lateral view shows a dilated right ventricle filling in the retrosternal space. The large left atrium can be seen

as a convex bulge posteriorly. Note the posterior displacement of the left lower lobe bronchus by the large left atrium (arrowheads).

CARDIOVASCULAR MEASUREMENTS

The size of the heart is related to the size of the patient. Charts are available that compare normal cardiac size with height, weight, and surface areas of patients. From a practical viewpoint, they are rarely used. The most common measurement is the cardiothoracic ratio. The greatest distance of the heart to the right of the midline plus the greatest distance of the heart to the left of the midline is divided by the transverse thoracic diameter at the level of the right diaphragm. This ratio is usually between 0.45 and 0.5. The ratio is larger in children and persons of hypersthenic habitus. If serial films are available, the changing cardiac status may best be measured by comparing the transverse cardiac diameter. It must be reemphasized that portable roentgenograms are obtained in the AP projection, which may result in an apparent 10% to 20% increase in the transverse cardiac diameter as a result of differences of magnification. Cardiac size may vary as the result of differences in blood volume as well as cardiac decompensation. Patients who are severely dehydrated may have small cardiac silhouettes that return to normal after hydration. Patients who are overhydrated may have a significant increase in cardiac size despite normal cardiac function. This is commonly seen in a patient receiving intravenous fluids or patients with chronic renal failure on dialysis. A change of transverse cardiac diameter greater than 2 cm on serial roentgenograms performed in the same projection are usually indicative of a change in the physiologic status of the heart.

Aortic size is important in the evaluation of the systemic circuit. Because of changes in the elastic tissue of the aortic media, the aorta gradually dilates throughout life. There is thus a change in aortic configuration with aging. The ascending aorta usually is not discerned in young persons but is readily seen in older persons as well as in those with hypertension or aortic stenosis. A useful measurement is that of the aortic arch, which is made up of the junction of the transverse and descending aorta. The lateral margin is visible on almost all PA roentgenograms. The aorta also has an indentation on the trachea at the same point. In a man in his 40s, the aortic arch diameter is about 3 cm. This can be corrected for age by adding or subtracting 2 mm for each decade of life. A measurement of the aorta in female patients is 2 mm less than that of male patients. Patients with hypertension have significantly larger aortas, usually 4 to 5 mm greater than those of their normotensive counterparts.

ASSESSMENT OF CHAMBER SIZE

The right atrium forms the entire right cardiac border on the PA projection. One might assume, if the right atrium were to enlarge, that the right cardiac margin would extend farther to the right. Although this can occasionally be noted in patients with massive enlargement of the right atrium, the right cardiac margin is rarely changed in patients with right atrial enlargement (Fig. 83.4). When the right atrium enlarges, it frequently does so anteriorly and may be border forming anteriorly, as noted on the lateral projection. This may encroach on the retrosternal space.

FIGURE 83.4. Lateral view of the chest roentgenogram and cardiac model as viewed from the left side. The anterior margin of the heart is formed by the right ventricle. The right atrium may, on occasion, also form the upper anterior portion of the heart. The posterior margin of the heart is the left atrium superiorly and the left ventricle inferiorly. The inferior vena cava usually can be discerned as a straight line just above the diaphragm.

With increasing volume, the right ventricle enlarges anteriorly. The heart also rotates in a clockwise fashion (as viewed from below). Normally, the left atrium and left ventricle form the left cardiac border; however, when the right ventricle enlarges as the result of the clockwise rotation, the upper left cardiac border may be formed by the right ventricle. This changes the configuration of the left cardiac border as seen on a PA chest roentgenogram, so that there is straightening or, at times, bulging of the upper left cardiac border, giving the heart a globular shape (Fig. 83.4). There also may be some elevation of the cardiac apex. On the lateral view, the enlarged right ventricle encroaches on the retrosternal space (Fig. 83.2B). Because the retrosternal space may vary depending on the habitus of the patient, this sign has limited value.

The left atrium is a posterior structure. As it enlarges, it forms a convex bulge on the posterosuperior portion of the heart as viewed in the lateral projections. If there is barium in the esophagus, an enlarged left atrium will displace the esophagus posteriorly. The enlarged left atrium also may displace the left lower lobe bronchus posteriorly as viewed on the lateral view (Fig. 83.2B). On the PA projection, an enlarged left atrial appendage may form a convex bulge below the pulmonary artery (Fig. 83.2A). Also, as there is an increase in left atrial size, the enlarged left atrium may be surrounded by air-containing lung, so that its margins are visualized, giving it a double density on the PA roentgenograms.

The left ventricle forms the left lower lateral aspect of the cardiac silhouette on the PA roentgenogram and the posteroinferior portion on the lateral roentgenogram. As the left ventricle enlarges, it enlarges inferiorly to the left and posteriorly so that the apex moves downward, outward, and posteriorly. This is readily appreciated on both the PA and lateral projections (Fig. 83.5). It must be emphasized that the roentgenogram accurately depicts chamber dilatation; however, there may be thickening of the walls of either the left or the right ventricle without significant cardiac dilatation. When this occurs, there may be little change in the outer configuration of the heart. It is not unusual to have a patient with aortic stenosis and a thickened left ventricle in whom the roentgenographic appearance of the left ventricle appears normal. At times, with left ventricular hypertrophy, there may be an exaggerated rounding of the apex of the heart.

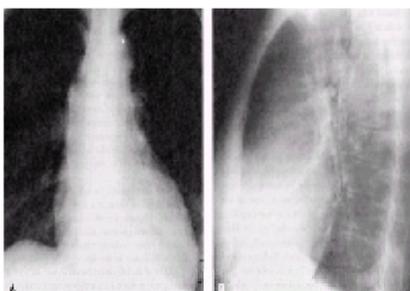

FIGURE 83.5. Aortic insufficiency and dilatation of the left ventricle. **A:** Posteroanterior view shows that the apex of the heart is displaced inferiorly and to the left (arrowheads). **B:** Lateral view shows that the dilated left ventricle also extends as a convex bulge along the posteroinferior portion of the heart (arrowheads).

CARDIAC CALCIFICATIONS

The presence of cardiac calcifications may be important clues to the diagnosis of cardiac disease. Calcified coronary arteries usually are associated with significant coronary disease. Calcification of the aortic valve is present in almost 90% of adults with aortic stenosis. On the PA roentgenogram, the aortic valve is superimposed on the spine and a calcified aortic valve frequently may be missed. The mitral valve is located to the left of the spine and slightly more inferiorly, and is more easily seen. Valvular calcification may be better noted on the lateral views. In most radiology departments, chest films are performed with high-kilovoltage settings of 120 to 140 kV. With this high-kilovoltage technique, valvular and coronary artery calcifications are less well seen. Cardiac fluoroscopy may be helpful in discerning valvular or coronary artery calcifications.

PULMONARY VASCULATURE

ANATOMY

The pulmonary arteries and veins are accurately depicted on a PA roentgenogram. The right lung is better suited for evaluation of the pulmonary vessels than the left. On the left, the heart overlaps a significant portion of the lung. Also on the left, the arteries and veins are parallel and differentiation of these vessels is difficult. On the contrary, the vessels of the right lung are well seen. The right pulmonary artery divides into its upper and lower branches within the mediastinum. The right descending pulmonary artery may be noted on a PA roentgenogram as an inverted comma-shaped structure extending from the hilum into the right lower lung field (Fig. 83.6). The vessels taper smoothly, and usually four or five divisions can be discerned before the vessel disappears in the outer third of the lung. The pulmonary veins in the right lower lung field are horizontal structures as contrasted with the more vertical arteries. They usually can be seen coursing back to the left atrium. On the upright PA roentgenogram, 70% of the blood pumped by the right ventricle goes to the lower lobes. Because of gravitational effects, the upper lobes are relatively underperfused. This difference in blood flow causes the arteries and veins in the lower lobes to be about three times the diameter of the vessels in the upper lobes. If the patient is in the supine position, blood flow to the upper lobe equals that of the lower lobe, and as a result there is a significant change in the roentgenographic appearance. This change of perfusion may mimic the changes noted in congestive heart failure. This is one reason that it is always preferable to obtain chest roentgenograms with the patient in an upright position if at all possible. The distal right upper lobe pulmonary arteries and vein are parallel; however, more proximally the artery goes to the higher placed hilum while the veins form one or two vessels that pass laterally, making up the lateral aspect of the hilum, and then descend to enter the left atrium (Fig. 83.6). Because of their differences in course, differentiation of right upper lobe pulmonary arteries and veins is easy.

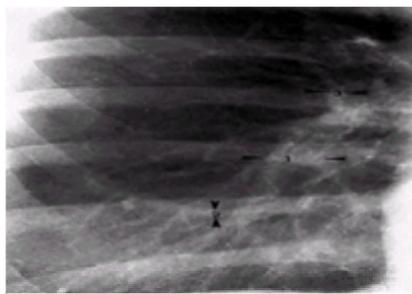

FIGURE 83.6. Right lung of a normal patient. Note the descending branch of the right pulmonary artery (1), which tapers evenly and is shaped like a reversed comma. The pulmonary veins of the right lower lobe are horizontal structures (2) that run almost at right angles to the pulmonary arteries. The vessels in the lower lobes are approximately three times the diameter of the vessels in the upper lobes. The upper lobe pulmonary vein (3) can be seen crossing the right hilum and extending down to the left atrium. The upper lobe pulmonary vein forms the lateral aspect of the right hilum.

PULMONARY BLOOD FLOW

Pulmonary vascular size accurately reflects blood flow. If blood flow increases for any reason, the vessels enlarge. If blood flow decreases as a result of pulmonary stenosis or a failing right ventricle, the size of the pulmonary arteries and veins decreases. These lower lobe vessels are larger in a normal person in the upright position because of the increased blood flow to the lower lobes as compared with that to the upper lobes. When there is an increase in pulmonary blood flow, not only does dilatation of the lower lobe vessels occur, but the upper lobe vessels also dilate and there is greater equalization of the size of the upper lobe and lower lobe vessels. It usually takes a doubling of pulmonary blood flow to cause discernible changes on a roentgenogram.

PULMONARY ARTERIAL HYPERTENSION

In patients with significant pulmonary arterial hypertension there is dilatation of the pulmonary arteries in the inner third of the lung. The pulmonary vessels in the middle and outer thirds are normal to decreased in size, and thus there is a marked disproportion in the size of the proximal as compared with the distal vessels. In these patients, pulmonary blood flow is usually decreased; as a result of this, the pulmonary veins are normal to small. This is in contradistinction to the pulmonary vascular changes of increased blood flow in which there is enlargement of both proximal and distal pulmonary arteries and enlargement of pulmonary veins. This disproportionate enlargement of the proximal pulmonary arteries in individuals with pulmonary hypertension is the result of Laplace's law, which states that the tension on the wall is proportional to the radius of the vessel. Larger vessels thus have increased wall tension as compared with medium-sized and smaller vessels, even though the pressure is equal. This causes greater fragmentation of elastic tissue of the arterial wall, and dilatation results. The medium-sized and smaller vessels may actually appear small. This may be secondary to the decreased pulmonary blood flow noted in many of these patients.

PULMONARY VENOUS HYPERTENSION

Pulmonary venous hypertension may be seen in patients with venous stenosis or stenosis of the mitral valve, but most are secondary to left ventricular failure. In a normal person, most blood pumped by the right ventricle goes to the lower lobes. In a patient with pulmonary venous hypertension, there is a reversal of pulmonary perfusion so that most blood flow is to the upper lobes. The relative pulmonary capillary pressure of the lung depends on the position as it relates to the level of the left atrium. It is equal to left atrial pressure at the level of the left atrium. It is less than left atrial pressure above the left atrium, and it is increased above left atrial pressure below the level of the left atrium. In patients with elevated left atrial pressure, pulmonary capillary pressure of the lower lobes may exceed the oncotic pressure of the blood; this is not present in the upper lobes. Thus, there may be interstitial edema limited to the lower lobes that may be roentgenographically manifested by blurring of the margin of the pulmonary vessels and, at times, by increase in linear markings of the lower lobes (Fig. 83.7). This interstitial edema may encircle the bronchi and cause increased density surrounding the bronchi when viewed on end. As a result of the lower lobe interstitial fluid, there may be increased vascular resistance as compared with the upper lobes, which may result in increased upper lobe blood flow and enlarged pulmonary vessels in the upper lobe. This is seen usually as enlargement of the upper lobe veins. These veins course downward, forming the lateral aspect of the hilum, and this may cause enlargement of the hilum of the lung. As interstitial pressure increases, fluid may enter the alveoli. This is typically most marked in the perihilar area, giving a so-called bat-wing appearance (Fig. 83.8). No evidence of an air bronchogram exists. The roentgenographic appearance of pulmonary edema secondary to a failing heart should be contrasted to the roentgenographic appearance of pulmonary edema seen with a change in capillary permeability. In the later case, the increased density is more diffuse, involving all segments of both lungs, and air bronchograms may be prominent.

FIGURE 83.7. Severe interstitial pulmonary edema. Note the increased linear markings throughout the right lung. The vessels in both the upper and lower lobes are indistinct because of the interstitial fluid surrounding the vessels. The right upper lobe pulmonary veins are enlarged.

FIGURE 83.8. Pulmonary alveolar edema. The homogeneous perihilar hazy density has been compared to a bat's wing.

CHAPTER 84: ELECTROCARDIOGRAPHY, EXERCISE STRESS TESTING, AND AMBULATORY MONITORING

CHARLES FISCH

[Electrocardiogram](#)
[Conditions Producing Abnormal Electrocardiograms](#)
[Exercise Testing](#)
[Ambulatory Monitoring](#)

ELECTROCARDIOGRAM

As a noninvasive laboratory procedure for evaluating the heart, electrocardiography is without equal. There is no risk to the patient, the relative cost is minimal, the technique is simple and reproducible, and the record lends itself to serial studies. The procedure may serve as an independent marker of myocardial disease. It often reflects anatomical, metabolic, and hemodynamic alterations. An electrocardiogram (ECG) often is essential for proper diagnosis and therapy. It is without equal for diagnosis of arrhythmias, and it is the procedure of choice in patients presenting with chest pain and syncope, which are the most common presenting symptoms of potential cardiovascular catastrophes.

For proper use of the ECG, its sensitivity and specificity must be understood and considered. The ECG is composed of waveforms, each of which may be influenced differently by a variety of factors and by the sequencing of those factors. The sensitivity and specificity of the test depend to a large extent on the clinical questions asked.

The sensitivity of the ECG for myocardial disorders varies considerably, depending on the cause and on the size and location of the myocardium or specialized tissue involved in a pathologic process. The sensitivity and specificity for arrhythmias are consistently high, and the ECG is the only practical approach to analysis of abnormalities of cardiac rhythm. Because of its major contribution to the care of the patient with cardiac disorders, the ECG has been used continuously and with increasing frequency since it was first introduced in 1903 by Einthoven.

GENERAL CONCEPTS

Depolarization and Repolarization

In the resting state, the outside of the cell or tissue is electrically uniformly positive. Electrodes in contact with the cell membrane record no difference of potential. When the cell is stimulated, sodium enters the cell rapidly and that part of the cell or tissue is said to be depolarized. It is electrically negative with respect to the resting, polarized part of the cell or tissue. Local current is generated, and a potential difference between polarized and depolarized areas can be recorded ([Fig. 84.1](#)). The process of depolarization travels rapidly along the length of the cell or tissue, preceded by a positive and followed by a negative field or charge.

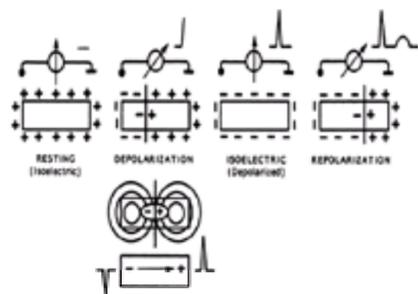

FIGURE 84.1. Diagrammatic representation of depolarization and repolarization of the heart. The moving boundary can be represented as a dipole or a vector (see text).

Repolarization can be viewed as restitution of the electrical state to that which existed before depolarization. Because repolarization proceeds in the direction of the depolarized or electrically negative part of the cell, repolarization is preceded by a negative and followed by a positive field or charge. When placed in a volume conductor such as the human body, the cell or tissues of the heart impart an electrical field, the voltage difference of which can be recorded from the body surface.

Dipole and Vector

The process of depolarization and repolarization—more specifically, the moving boundary separating the positive and negative fields—can be represented by a single dipole consisting of a positive and a negative charge, representing the respective electrical fields ([Fig. 84.1](#)). Such a dipole can also be viewed as a vector that has direction, sense (plus or minus), and magnitude. The arrow of the vector identifies the positive field.

When interpreting an ECG, it is essential to recognize vectors and fields. When depolarization moves toward the recording electrode, also called the exploring electrode, the latter is in the positive field, and the ECG registers an upright positive deflection. Conversely, when depolarization proceeds away from the recording electrode, the electrode is in the negative field, and the ECG registers a downward or negative deflection. The opposite is true for repolarization because repolarization is preceded by a negative field and followed by the positive, repolarized field. The electrode facing the oncoming wave of repolarization is still in the negative field and records a negative deflection. The electrode facing the repolarized area records an upright deflection.

Instantaneous and Mean Vector

At any given moment, the electrical potential can be represented by an instantaneous vector that reflects the net of all electrical forces existing at that particular moment. The sum of all forces generated during total depolarization can be represented by a mean vector. In the case of ventricular depolarization or activation, the resultant vector is referred to as the mean QRS vector.

Activation of the Heart and the Electrocardiographic Waves

The cardiac impulse originates in the sinoatrial node, located in the right atrium at the opening of the great veins ([Fig. 84.2](#)), and activates first the right atrium and then the left atrium. The general direction of atrial activation is inferiorly, to the left, and posteriorly, and it is recorded as the P wave. The atrial impulse is delayed in the atrioventricular (AV) node, and the ECG registers an isoelectric PR segment. After the impulse emerges from the AV node, it conducts rapidly along the bundle of His, the right and left bundles, the anterior and posterior divisions (fascicles) of the left bundle, and the Purkinje system. The activation (i.e., depolarization) of the ventricles is represented by the QRS complex.

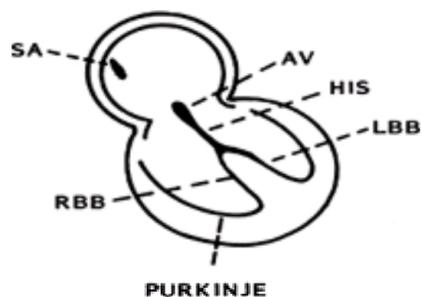

FIGURE 84.2. Specialized tissue. SA, sinoatrial node; AV, atrioventricular node; HIS, bundle of His; RBB and LBB, right and left bundle branches, respectively; PURKINJE, Purkinje fibers.

Repolarization follows, with atrial and ventricular repolarization inscribing the Ta and T waves, respectively. The T wave is followed by a U wave, the genesis of which is unclear. There are two prevailing concepts of the generation of the U wave. One suggests that the U wave represents delayed repolarization of Purkinje fibers, and the other states that the U wave is secondary to a diastolic myocardial event.

A more detailed understanding of the order of ventricular activation is essential for proper interpretation of the ECG (Fig. 84.3). The earliest activation of the ventricles occurs in the septum, directed from left to right, anteriorly, inferiorly, and, occasionally, superiorly. This is followed by depolarization of the free ventricular wall, proceeding from the endocardium to the epicardium. The left ventricle, which is considerably thicker than the right, continues to depolarize after depolarization of the right ventricle is completed and generates a strong, unopposed force directed to the left, inferiorly, and posteriorly. In essence, ventricular activation can be represented by two vectors: the early vector reflecting depolarization of the septum directed from left to right and the second reflecting depolarization of the much larger left ventricle directed to the left, inferiorly, and posteriorly.

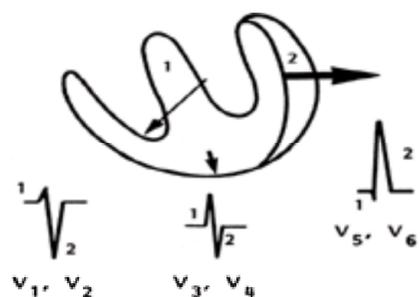

FIGURE 84.3. Sequence of ventricular activation and derivation of the precordial QRS complex. Leads V_1 and V_2 , right ventricular; V_3 and V_4 , transitional; V_5 and V_6 , left ventricular.

NORMAL ELECTROCARDIOGRAM

Normal Values

The magnitude of the electrical potential generated by the heart (Fig. 84.4 and Fig. 84.5) is recorded on the ordinate (1 mm = 0.1 mV) of the ECG, and the duration of the event is reflected on the abscissa (1 mm = 0.04 second). The bolder lines on the recording paper identify 0.2-second intervals. Proper standardization of the voltage is indicated by a 10-mm deflection for each 1 mV. To avoid distortion of the ECG pattern due to stylus inertia, it is important that the upstroke be prompt and perpendicular to the baseline.

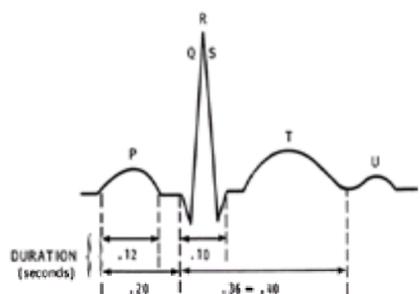

FIGURE 84.4. Electrocardiographic waveforms and normal values.

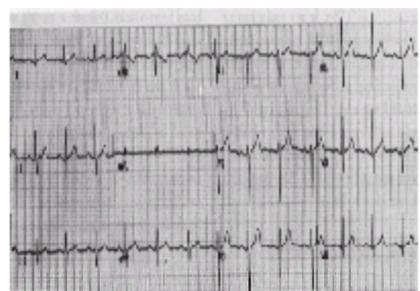

FIGURE 84.5. Normal electrocardiogram.

The maximum duration of a normal P wave is 0.12 second, and its amplitude is 2 mm (0.2 mV). The PR interval varies inversely with the heart rate, but the maximal duration is 0.20 second (perhaps 0.22 second in the presence of sinus bradycardia). The upper limit of the QRS duration is 0.10 second. The QT interval varies from 0.36 to 0.40 second, depending on the patient's heart rate, sex, and age. Because of the influence of a variety of physiologic factors on the duration of the QT interval,

mild to moderate deviation from the accepted norm is probably of no clinical significance.

Estimation of Heart Rate

Because there are 300 0.2-second intervals in 1 minute, the heart rate can be determined by dividing 300 by the number of 0.2-second intervals and fractions thereof within one RR cycle. For example, if there are two 0.2-second intervals in an RR cycle, the heart rate equals 300 divided by 2, or 150 beats per minute. Similarly, if there are 2.5 0.2-second intervals in an RR cycle, the heart rate equals 300 divided by 2.5, or 120 beats per minute.

For a more accurate estimate of the heart rate, the number of RR cycles and fractions thereof present in a 3-second period (15 0.2-second intervals equals 3 seconds) is multiplied by 20.

LEADS

The electrical potential generated by the heart can be recorded with a unipolar or a bipolar lead (Fig. 84.6). With bipolar leads, both electrodes register an electrical potential, and the ECG reflects the difference of potential between the two points. Conversely, the potential of the indifferent electrodes of a unipolar lead is for all practical purposes zero. This zero potential is achieved by connecting the leads from the three extremities into a single common electrode, called the central terminal of Wilson. As a result, unipolar leads record only the potential subtending the exploring electrode rather than a difference between two points, as is the case with a bipolar lead. The exploring electrode determines the polarity of the ECG wave. When the exploring electrode is in the positive field, the ECG records an upright or positive deflection, and when the exploring electrode is in the negative field, the ECG registers a downward or negative deflection.

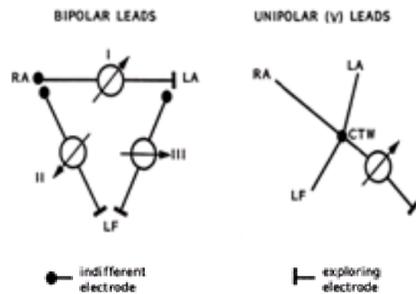

FIGURE 84.6. Bipolar and unipolar leads. RA, right arm; LA, left arm; LF, left foot; CTW, central terminal of Wilson.

Bipolar Leads

Lead I is formed by connecting the left and right arms, with the electrode on the left arm designated as the exploring electrode. Lead II is formed by connecting the right arm and the left foot, with the electrode on the left foot designated as the exploring electrode. Lead III is formed by connecting the left arm and the left foot, with the electrode on the left foot designated as the exploring electrode.

Unipolar Leads

The unipolar leads are identified by the letter V. Three unipolar limb leads and six unipolar precordial leads are used.

In leads VR, VL, and VF, the exploring electrode is connected to the right arm, left arm, and left foot, respectively. By disconnecting from the central terminal the limb from which the voltage is being recorded, the amplitude of the wave is augmented by two-thirds, and such leads are identified as augmented leads: aVR, aVL, and aVF, respectively.

The six precordial V leads are recorded from the following points on the thorax: V₁, fourth interspace to the right of the sternum; V₂, fourth interspace to the left of the sternum; V₄, midclavicular line in the fifth interspace; V₃, halfway between V₂ and V₄; V₅, fifth interspace in the anterior axillary line; and V₆, fifth interspace in the midaxillary line. Occasionally, leads V_{3r} and V_{4r} may prove helpful, and these are recorded from the same points as leads V₃ and V₄ but from the right anterior chest wall.

Lead Axis

A line drawn between the two connections of a lead is referred to as the lead axis. The magnitude of deflection of an ECG wave in any lead is greatest if the direction of activation parallels the lead axis and is isoelectric or equiphasic when the direction of activation is perpendicular to the lead axis.

Derivation of the QRS Complex in the Limb Leads

The three bipolar limb leads constitute the Einthoven triangle. The assumptions are that the triangle is equilateral, that the heart is a point source located at the center of this triangle, and that the thorax is a uniform boundary and a uniform volume conductor. Although none of the assumptions are absolutely correct, they are nevertheless useful in analysis of the clinical ECG.

The initial activation of the septum from left to right, inferiorly and anteriorly, and occasionally superiorly projects a negative potential recorded as a Q wave in leads I and aVL. When the initial activation proceeds superiorly, a Q wave is recorded in leads III and aVF (Fig. 84.5). When the initial septal activation is directed inferiorly (a positive potential), an R wave is recorded in leads aVF, II, and III. This usually is followed by activation in a direction from the right shoulder toward the left hip, inscribing a dominant R wave in leads I, II, III, aVL, and aVF. The QRS complex in aVR is negative because of the initial inferior, left-to-right activation of the septum, followed by endocardium-to-epicardium activation of the ventricles. These vectors project a negative potential to the right arm.

PRECORDIAL ELECTROCARDIOGRAM

As the septum depolarizes from left to right, the right ventricular (RV) leads V₁ and V₂ face the positive field and register a small R wave (Fig. 84.3 and Fig. 84.5). At the same time, the left ventricular (LV) leads V₅ and V₆ face the negative field and register a small septal Q wave. This is followed by the dominant LV activation from endocardium to epicardium, with the RV leads V₁ and V₂ facing the negative field and registering a deep S wave. Simultaneously, the LV leads V₅ and V₆ face the positive field and register a tall R wave. Leads V₁ and V₂ are considered right and V₅ and V₆ are considered LV leads, leads V₃ and V₄ are septal or transitional and register an equiphasic QRS. The equiphasic configuration is explained by an initial depolarization of the septum from left to right inferiorly and anteriorly inscribing the R wave, followed by depolarization of the LV wall away from leads V₃ and V₄ and inscribing the S wave.

As the electrode is moved from the V₁ to V₆ position, it subtends an increasing myocardial mass, and because the R wave expresses the magnitude of the electrical potential generated by the subtending muscle mass, the amplitude of the R wave increases progressively. The amplitude of the R wave may remain unchanged in leads V₁ and V₂ and occasionally in lead V₃, with a sudden transition of the QRS complex to an LV configuration. With rare exception, after an R wave is recorded in lead V₁, it should neither diminish in amplitude nor disappear in leads located farther to the left. Ordinarily, an abnormal progression of the R-wave amplitude from V₁ through V₆ suggests a decrease or loss of muscle mass.

In the adult, the precordial T waves are upright, with the exception of those recorded by lead V_1 and rarely by lead V_2 , in which the T waves may be inverted (Fig. 84.5). As a rule, a negative T wave from leads other than V_1 should be considered abnormal in adults. Occasionally, the inverted RV T waves present at birth may persist into the teens and rarely into the early 20s and are a normal variant, called the juvenile T waves.

ELECTRICAL POSITION

The frontal axis of the QRS and rotation on the anteroposterior and on the longitudinal (apex to base) axes define the electrical position of the heart.

Axis Deviation

Axis deviation is estimated by plotting the peak values of the R or S wave on two of the three bipolar leads of a hexaxial reference system (Fig. 84.7). From that point, lines perpendicular to the lead axis are drawn. The QRS axis is obtained by connecting the center of the hexaxial lead system and the point where the two perpendicular lines cross (Fig. 84.7).

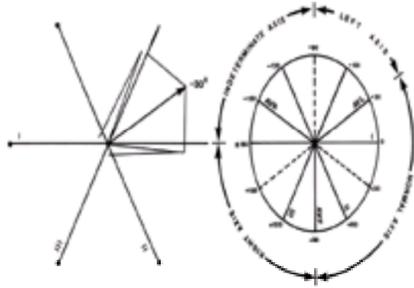

FIGURE 84.7. Plot of QRS axis on hexaxial system (*left*) and range of axis (*right*).

An axis in the range of -30 degrees to $+90$ degrees is normal. An axis in the range of -30 degrees to -90 degrees is a left axis. A left axis greater than -30 degrees is abnormal, not because of cardiac anatomic position but most likely because of a conduction defect. Left axis deviation of -30 degrees is easily identified by an equiphasic QRS complex in lead II. An axis in the range of $+90$ degrees to $+180$ degrees is right axis deviation. Right axis deviation of $+90$ degrees is recognized by an equiphasic QRS complex in lead I. An axis in the range of -90 degrees to $+180$ degrees is an indeterminate axis.

Rotation on the Anteroposterior Axis

Rotation in the frontal plane on an anteroposterior axis allows the apex of the heart to face the left arm or left foot and points in between. When the apex points in the direction of the left foot, the QRS complex in aVF has the same configuration as the QRS complex in leads V_5 and V_6 , and the position is vertical. When the apex points in the direction of the left arm, the QRS complex in lead aVL has the same configuration as the QRS complex in leads V_5 and V_6 , and the position is horizontal. When the apex is halfway between the left arm and left foot, the QRS complex is similar in leads aVL and aVF, both resemble the QRS complex in leads V_5 and V_6 , and the position is intermediate.

Rotation on the Longitudinal Axis

Rotation on the longitudinal axis (apex to base) is best visualized by viewing the patient in the supine position with the observer facing the diaphragmatic aspect of the heart. Clockwise rotation projects the right ventricle farther to the patient's left, and as a result, the RV QRS complexes (rS) are recorded in leads V_3 and V_4 and occasionally as far to the left as leads V_5 or V_6 . Counterclockwise rotation projects the left ventricle to the patient's right, and LV QRS complexes (qR) are recorded in leads V_3 and V_4 and rarely in leads V_1 and V_2 .

CONDITIONS PRODUCING ABNORMAL ELECTROCARDIOGRAMS

CHAMBER ENLARGEMENT AND HYPERTROPHY

Atrial Hypertrophy

Right atrial enlargement shifts the P-wave axis to the right. As a result, the P wave in lead I is low or isoelectric; in leads II, III, and aVF, it is increased in amplitude and its configuration is *pointea*. In leads V_1 and V_2 , the P wave may be upright and increased in amplitude.

Left atrial enlargement manifests by notching and prolongation of the P wave, encroachment of the P wave on the PR segment, and, not infrequently, left axis deviation of the terminal component of the P wave. In lead V_1 , the P wave is negative and prolonged, with an amplitude of 1 mm (0.10 mV) or greater, and its duration is 0.04 second or longer.

P-wave enlargement does not necessarily indicate atrial hypertrophy. Patterns similar to hypertrophy may be caused by chamber dilation, intra-atrial conduction delays, or ectopy.

Ventricular Hypertrophy

Ventricular hypertrophy implies an increase in muscle mass that is manifested by an increased amplitude of the QRS complex. The increased QRS voltage ultimately is associated with changes in the ST segment and T waves.

Left Ventricular Hypertrophy

The QRS voltage criteria for LV hypertrophy include the following:

- R wave in lead I plus an S wave in lead III greater than or equal to 2.5 mV
- R wave in aVL greater than 1.2 mV
- R wave in aVF greater than 2.0 mV
- S wave in V_1 greater than or equal to 2.4 mV
- R wave in V_5 or V_6 greater than 2.6 mV
- R wave in V_5 or V_6 + S wave in V_1 greater than 3.5 mV

The following point system for diagnosing LV hypertrophy has been suggested:

Amplitude of R or S wave in limb leads greater than or equal to 2.0 mV or S wave in lead I or in V_1 or V_2 greater than or equal to 3.0 mV or R wave in V_5 or V_6 greater than 3.0 mV = 3 points

ST-segment changes with or without digitalis = 1 or 2 points, respectively

Left atrial enlargement = 3 points

Left axis deviation of -30 degrees or more = 2 points

QRS complex duration greater than 0.09 second and intrinsicoid deflection in V_5 and V_6 greater than 0.05 second = 1 point each

Based on this point system, the diagnosis of LV hypertrophy is probable with 4 points and definite with 5 points. The diagnosis of LV hypertrophy is never secure without associated ST-segment and T-wave changes. Shifts in the ST segment and T wave are directed opposite to the QRS complex; the ST segment is depressed in leads I, aVL, V_5 , and V_6 , and the T wave is negative and asymmetric, and its ascending limb is steeper, with occasional terminal positive inscription. When the position is vertical, the ST-segment and T-wave changes are recorded in leads II, III, and aVF. The pattern of left atrial preponderance is commonly seen in LV hypertrophy.

Right Ventricular Hypertrophy

Because the right ventricle is about one-third of the thickness of the left ventricle, considerable hypertrophy must take place before the RV mass can generate a voltage that equals or exceeds the voltage generated by the left ventricle. Consequently, the sensitivity of the ECG for RV hypertrophy is low, varying from 40% to 50%.

In general, four patterns indicating RV hypertrophy may be recorded in lead V_1 : an rSR', or incomplete right bundle-branch block (RBBB) pattern; a tall R wave with a slurred early upstroke; a qR pattern; and an R/S ratio greater than 1, with an R wave amplitude of 5 mm (0.5 mV) or greater.

If RV hypertrophy exists, correlation of the ECG pattern in lead V_1 with intraventricular pressures suggests the following:

An rSR' pattern indicates an elevated RV pressure, although one that is lower than that of the left ventricle (e.g., atrial septal defect).

A tall R wave with a slur on the upstroke suggests that right and LV pressures are equal (e.g., tetralogy of Fallot).

A qR pattern indicates that the RV pressure exceeds that of the left ventricle (e.g., pulmonary stenosis with an intact septum, primary pulmonary hypertension).

INTRAVENTRICULAR CONDUCTION DEFECTS

Right Bundle-Branch Block

The duration of RBBB is 0.12 second or longer, with a characteristically delayed and slow terminal activation of the right ventricle in a right and anterior direction. In RBBB, the initial septal activation is normal, directed from left to right, and inscribed as an initial small upright R wave in leads V_1 and V_2 . Activation of the left ventricle follows, and a notch or an S wave is inscribed in leads V_1 and V_2 . Final activation is that of the right ventricle directed to the right and anteriorly, and is inscribed as a prolonged terminal R, the R' wave.

The R wave in LV leads V_5 and V_6 is tall and narrow, reflecting the normal activation of the left ventricle. A shallow, prolonged S wave reflects the terminal activation of the right ventricle and is recorded simultaneously with the R' inscribed in leads V_1 and V_2 .

Repolarization and the T wave are abnormal in the presence of intraventricular conduction delays. The abnormality is secondary to and obligatory to the abnormal order of depolarization. Such T-wave changes are referred to as secondary T-wave changes. The T-wave change is frequently accompanied by displacement of the ST segment in a direction concordant with the direction of the T wave. A secondary ST-T-wave change does not contribute information other than that inherent in the intraventricular conduction delay. In contrast to the secondary T-wave change, a T-wave change that is independent of QRS alteration and often seen with normal QRS complexes reflects local abnormalities, often prolongation of the excited state (e.g., ischemia). Such T-wave changes are referred to as primary T-wave changes. In RBBB, the T wave is directed opposite to the terminal portion of the QRS, that portion inscribed during the last 0.4 second of the QRS.

Left Bundle-Branch Block

Left bundle-branch block (LBBB) results in late activation of the left ventricle. The initial order of septal activation is reversed, with activation proceeding from right to left, resulting in an initial upright deflection in leads I, aVL, V_5 , and V_6 . This is followed by activation of the right ventricle, which may be recognized by a notch or a plateau of the R wave in leads I, aVL, V_5 , and V_6 . Terminal activation is that of the left ventricle from right to left, inscribing an R' in leads I, aVL, V_5 , and V_6 . The pattern in RV leads is that of a QS or rS.

In LBBB, the left intracavitary potential is initially positive, the result of the right-to-left depolarization of the septum. Consequently, the hallmark of myocardial infarction (MI), the Q wave, is not recorded. Only rarely, usually only during the acute phase of infarction, can a diagnosis of MI be made in LBBB.

Divisional or Fascicular Blocks

The left bundle branch is functionally divided into two fascicles, the anterior and posterior (Fig. 84.8). Block of conduction through either fascicle results in a characteristic ECG pattern.

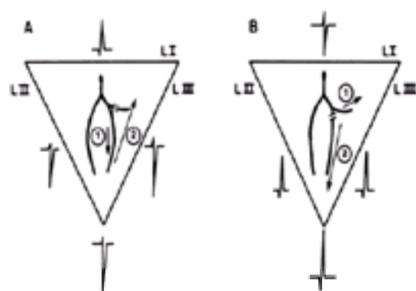

FIGURE 84.8. Left anterior (A) and posterior (B) divisional (fascicular) block.

Left anterior divisional block (LADB) results in initial activation inferiorly, followed by a superiorly directed activation. In leads II, III, and aVF, the initial activation inscribes a small R wave, followed by a dominant, deep S wave. Lead aVL inscribes an initial q wave, and lead I inscribes an initial q or R wave. The QRS duration rarely exceeds 0.10 second and never exceeds 0.12 second. Because of the superiorly oriented mean QRS axis, away from the precordial lead positions, the configuration of the precordial QRS complexes is often that of an RS.

Left posterior divisional block (LPDB) results in initial activation superiorly, followed by an inferiorly directed activation. Leads II, III, and aVF inscribe an initial q wave, followed by a tall R wave. Because this QRS pattern can be recorded in the absence of LPDB, as, for example, in tall, asthenic persons or in patients with chronic obstructive pulmonary disease, a diagnosis of LPDB requires evidence of prior normal intraventricular conduction. The duration of the QRS rarely exceeds 0.10 second and never exceeds 0.12 second.

Although LADB is common, especially in the older persons, LPDB is rare. And while LADB is frequently recorded in patients without evidence of clinical heart disease, LPDB usually is accompanied by clinical evidence of heart disease. As a rule, both are acquired abnormalities.

Incomplete Bundle-Branch Block

Incomplete bundle-branch block is recognized when the QRS complex has the morphology of RBBB or LBBB but the duration is less than 0.12 second.

Nonspecific Intraventricular Conduction Delay

When the QRS duration is 0.12 second or longer but without the configuration of RBBB or LBBB, the intraventricular conduction defect is nonspecific. Such conduction defects are usually due to intramyocardial delays.

WOLFF-PARKINSON-WHITE SYNDROME

The ECG pattern of Wolff-Parkinson-White (WPW) syndrome is characterized by a short PR interval, slur on the upstroke of the R wave or on the downstroke of an S wave (i.e., delta wave), prolonged QRS complex, and often secondary ST-T changes (Fig. 84.9). The WPW pattern results from conduction through an alternative pathway (bundle of Kent), which bypasses the normal AV junction. Conduction through the bypass results in pre-excitation of the ventricle. The abnormal sequence of ventricular activation is responsible for the delta wave and the widening of the QRS complex.

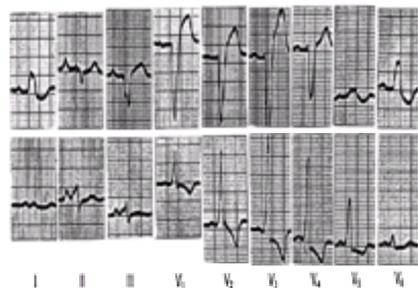

FIGURE 84.9. Left bundle-branch block (upper) and Wolff-Parkinson-White syndrome (lower).

Traditionally, the WPW syndrome has been divided into type A, characterized by a positive delta wave recorded in leads V_1 and V_2 , and type B, characterized by a negative delta wave recorded in leads V_1 and V_2 . With the introduction of intracardiac electrophysiologic studies, multiple sites of bypass conduction have been identified. The WPW syndrome pattern can be mistaken for intraventricular conduction defects, MI, and RV hypertrophy. Because the ventricular activation through the bypass may result in an initially positive intraventricular potential, WPW syndrome may mask the pattern of MI in a manner similar to that observed with LBBB. About one half of patients with WPW syndrome manifest supraventricular arrhythmias, often with rapid ventricular rates. For additional discussion of WPW syndrome, see Chapter 84.

ABERRATION

Aberration is defined as abnormal intraventricular conduction initiated by a supraventricular impulse originating from the atria or AV junction (Fig. 84.10). Aberration usually is initiated by acceleration of the heart rate, and only rarely is it caused by slowing of the heart rate. In normal and most abnormal hearts, aberration is of the RBBB configuration because the refractory period of the right bundle is normally longer than that of the left bundle. Recognition and differentiation of aberration from ventricular arrhythmias is clinically important because the prognosis and therapy for the two differ significantly.

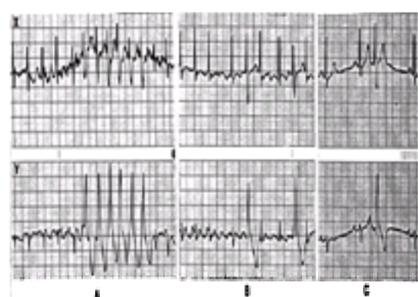

FIGURE 84.10. Ventricular aberration in the presence of atrial fibrillation (A), flutter (B), and sinus rhythm with atrial premature systole (C). The aberration is recognized by the fact that the bizarre QRS complexes follow a relatively prolonged RR cycle, the configuration is that of right bundle-branch block, there is no compensatory pause in panels A and B, and the coupling of the bizarre QRS complex to preceding normal QRS varies. Once initiated, aberration can persist for a number of cycles.

MYOCARDIAL INFARCTION

The evolution of a classic ECG pattern of MI includes ischemia, injury, and necrosis.

Ischemia

During ischemia, depolarization (i.e., QRS) proceeds normally from endocardium to the epicardium. Conversely, the direction of repolarization (i.e., T wave), which normally proceeds from epicardium to endocardium, is reversed, moving from endocardium to epicardium. The surface leads face the negative field, and a negative T wave is inscribed. The reversal of the order of repolarization is most likely caused by delayed recovery of the epicardial layer.

Injury

Normally, during the inscription of the ST segment there is no recordable difference of potential, and the ECG inscribes an isoelectric segment. Injury alters this status, and a difference of potential appears, with the injured area relatively positive with respect to the resting myocardium and the normally isoelectric ST segment displaced. When the exploring electrode faces the current of injury, the ST segment is elevated. Conversely, when the exploring electrode faces the normal muscle, which is relatively negative with respect to the injured myocardium, the ST segment is depressed.

In the intact heart, when the current of injury is subepicardial, the overlying leads record an elevated ST segment, and when the current of injury is subendocardial,

the same leads record a depressed ST segment.

Necrosis

Conventionally, the Q wave denotes myocardial necrosis. Normally, the septum depolarizes from left to right, and the left intracavitary potential is negative. Because ventricular depolarization continues from the endocardium to the epicardium, the negativity of the cavity persists. Throughout the inscription of the QRS complex, the potential of the LV cavity is negative, and an intracavitary electrode records a QS pattern. According to the window concept, necrosis of the myocardium results in a window through which the surface electrode records the intracavitary negativity in the form of a Q wave.

Localization of Myocardial Infarction

The general location of MI may be anterior, right ventricular, inferior, or posterior. As a rule, anterior MI results from occlusion of the left anterior descending coronary artery, and occlusion of the right or circumflex coronary arteries results in inferior infarctions. Right ventricular and posterior MIs result from obstruction of the right or circumflex coronary artery, respectively.

A Q wave is frequently recorded in the presence of a nontransmural infarction, and a Q wave may be absent in the presence of a transmural infarction. Accordingly, it appears preferable to refer to MI as Q wave or non-Q wave rather than transmural or nontransmural.

Anterior Infarction

Anterior infarction (Fig. 84.11) is registered in leads I, aVL, and V₁ to V₆. Anterior infarction is further subdivided into septal (V₁, V₂), anterior (V₃, V₄), anteroseptal (V₁ to V₄), lateral (V₅, V₆), extensive anterior (V₁ to V₆), and isolated high lateral (I, aVL). Reciprocal ST-segment changes, namely ST-segment depression, may be recorded in leads II, III, and aVF. This pattern occurs because the distal, reciprocal leads face the normal myocardium, which is relatively negative with respect to the opposite positive field generated by the current of injury.

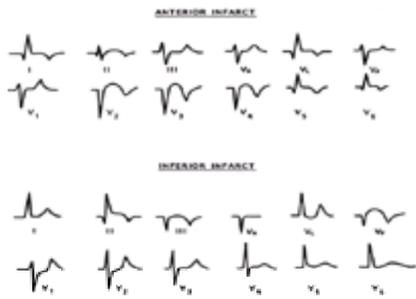

FIGURE 84.11. Diagrammatic presentation of anterior and inferior myocardial infarction.

Right Ventricular Infarction

Right ventricular infarction usually is associated with a diaphragmatic infarct that also involves the inferior part of the septum. It may be recognized by elevation of the ST segment in lead V₁ and occasionally in V₂. Elevation of the ST segment in leads V_{3r} and V_{4r}, however, has the highest sensitivity and specificity for RV infarction.

Inferior or Diaphragmatic Infarction

Inferior or diaphragmatic infarction (Fig. 84.11) is recognized by a Q wave, displacement of the ST segment, and T-wave changes in leads II, III, and aVF. When a positive current of injury is recorded in the inferior leads, the reciprocal leads face the normal myocardium, which at that moment is completely depolarized (isoelectric) and therefore relatively negative with respect to the injured area. As a result, leads I, aVL, V₁ to V₄, and occasionally V₅ may register a depressed, reciprocal ST segment. Reciprocal changes are characteristic of MI.

Posterior Infarction

Posterior infarction is indicated by a tall, somewhat delayed R in V₁ when associated with an inferior or lateral infarction.

High Lateral Infarction

High lateral infarction is manifested by an inverted T wave confined to leads I and aVL and rarely by a Q wave.

Electrocardiographic Diagnosis of Myocardial Infarction

About half of the first ECGs recorded in the course of the evolution of MI are diagnostic of infarction. The remainder may show minimal ST-segment abnormality and often show only T-wave changes. In 10% of patients, the first tracing is normal. The sensitivity of the ECG for MI increases to about 90% with serial tracings and especially when correlated with the clinical and other laboratory findings. In many patients, the infarct is ultimately manifested by T-wave changes only, and because T-wave abnormalities lack specificity, the change must be evaluated in light of all other available data (Fig. 84.12 and Fig. 84.13). Comparison with an old ECG, when available, may prove most helpful in the diagnosis of infarctions.

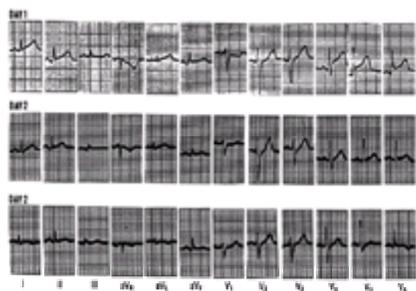

FIGURE 84.12. Acute anterolateral current of injury on day 1 with normalization on day 2. The infarction is manifested by T-wave inversion only (bottom). The latter, if interpreted without serial cardiograms or without correlation with available clinical information, is not diagnostic of infarction.

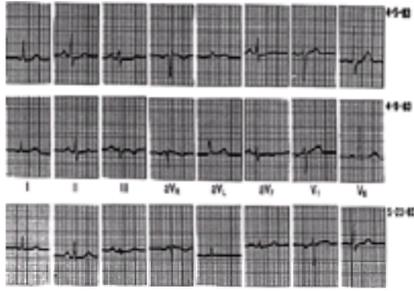

FIGURE 84.13. Acute inferior myocardial infarction manifested by inversion of the T wave in leads III and aVF on April 9, 1983. The electrocardiogram was normal on May 23, 1983.

It is frequently difficult or impossible to estimate the age of infarction from a single tracing. With time, the diagnostic feature of infarction, the Q wave, may disappear, leaving only a T-wave abnormality as the residual finding. The ECG may normalize with time, particularly after inferior infarction (Fig. 84.13). Occasionally, the ECG fails to display any evidence of infarction. This is particularly true when the *silent area*, such as the posterior wall, the high lateral segment, or right ventricle, is involved. Similarly, a new infarction may be masked by an old infarction, intraventricular conduction defects, especially LBBB, and occasionally by WPW syndrome or LADB.

Not all pathologic Q waves indicate infarction. Some are caused by directional changes (e.g., chronic obstructive lung disease, LADB), hypertrophy of the septum (e.g., idiopathic hypertrophic subaortic stenosis, diastolic overload of left ventricle), or myopathies (e.g., congestive cardiomyopathy, progressive muscular dystrophy, amyloidosis). Because most abnormal Q waves are caused by MI, an abnormal Q wave should be considered secondary to infarction until proven otherwise (see Chapter 73).

PERICARDITIS

The current of injury recorded with pericarditis is generated by the involved subjacent myocardium. Characteristically, pericarditis involves the entire heart, and therefore all of the leads, with the exception of aVR, show a current of injury and register an elevated ST segment. Reciprocal ST-segment depression characteristic of MI usually is absent. For more detail of ECG changes with pericarditis (see Chapter 79).

CONDITIONS CAUSING A PROLONGED QT INTERVAL

The QT interval reflects, with some exceptions, the duration of the ventricular recovery time. Prolongation of the QT interval, largely caused by prolongation of phase 2 of the action potential, can be recorded in the presence of hypocalcemia, hypertension, antiarrhythmic drugs, alkalosis, myocardial ischemia, cerebrovascular accident, and bradycardia, after resuscitation, and with other less common conditions. The common causes of QT-interval shortening include hypercalcemia, hyperkalemia, acidosis, and digitalis therapy.

CONDITIONS CAUSING ST-SEGMENT DEPRESSION AND T-WAVE INVERSION

Depression of the ST segment and inversion of the T wave are common findings, which alone rarely indicate a specific cardiac abnormality. As a rule, it is difficult to differentiate between the ST-T changes induced by organic disease, such as coronary heart disease or hypertrophy resulting from hypertension, and other noncardiac causes, such as electrolyte and pH disturbances, endocrine abnormalities, or drug effects. Although the genesis of the ST segment and the T wave differ, these changes, because of their frequent coexistence, are referred to in clinical electrocardiography as ST-T changes.

Determination of the significance of T-wave abnormality is probably the best example of the importance of specificity in interpretation of the ECG. Although the T wave is the most sensitive of all the ECG waveforms because it is altered by a variety of disorders, it lacks the specificity or predictive value that would permit recognition of the cause of the T-wave change. The search for a specific cause of an ST-T change must take into account all available clinical and laboratory information. The information must be evaluated with great care to avoid causing ECG iatrogenic heart disease, with all of its undesirable and often serious sequelae.

ELECTROLYTE ABNORMALITIES

Hyperkalemia

The earliest change of hyperkalemia is peaking or *tenting* of the T wave, usually at a plasma potassium concentration of 5.5 to 7.0 mEq per L (Fig. 84.14). Prolongation of the PR interval and the QRS complex follows. With further rise of plasma potassium concentration, the P-wave amplitude is lowered, and the wave may disappear, the ST segment becomes depressed, and the QRS complex continues to widen. Characteristically, the QRS prolongation is diffuse, involving the initial and terminal components. It may simulate all forms of intraventricular conduction. The terminal event is cardiac standstill or ventricular fibrillation.

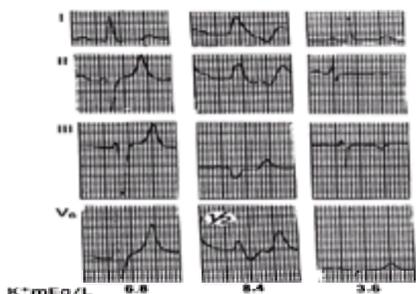

FIGURE 84.14. Electrocardiographic changes of hyperkalemia. After treatment and at a level of 3.6 mEq per L, the PR interval, QRS complex, and T waves are normal. At 6.8 mEq per L, the PR interval and QRS complex are prolonged, with a shift of the QRS axis to the left, and the T waves are symmetric, narrow-based, and tall (so-called tented T waves). At a potassium concentration of 8.4 mEq per L, there is further prolongation of the PR interval, with the P wave becoming difficult to identify, the QRS axis shifted to the right, and the QRS complex prolonged to 0.2 second. The characteristic prolongation of both initial and terminal portions of the QRS is best illustrated in lead V₆. (From Fisch C. Electrolytes and the heart. In: Hurst JW, ed. *The heart*. New York: McGraw-Hill, 1986:1473, with permission.)

Hypokalemia

Hypokalemia is manifested by depression of the ST segment, decrease in amplitude, and inversion of the T wave, which merges with a prominent U wave (Fig. 84.15). The changes are best seen in leads V₂ to V₄. The duration of the QT interval is normal; the QU interval is prolonged.

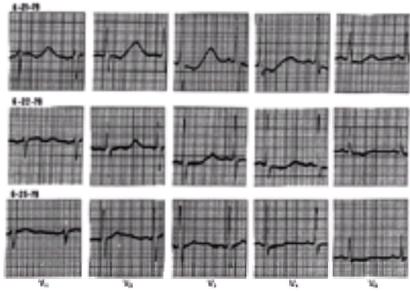

FIGURE 84.15. Electrocardiographic changes of hypokalemia. A striking U wave with a marked prolongation of QU interval was recorded on June 21, 1979. The potassium concentration at that time was 1.3 mEq per L. With correction of potassium loss, there was a gradual improvement with a normal QT interval and U wave recorded on June 25, 1979, at a plasma potassium concentration of 3.9 mEq per L. (From Fisch C. Electrolytes and the heart. In: Hurst JW, ed. *The heart*. New York: McGraw-Hill, 1986:1474, with permission.)

Hypercalcemia

Hypercalcemia is expressed by shortening of the QT interval, largely due to shortening of the ST segment. The ST segment may be absent, with the QRS complex followed by a T wave ([Fig. 84.16A](#)). Occasionally, the PR interval is prolonged and the T wave inverted.

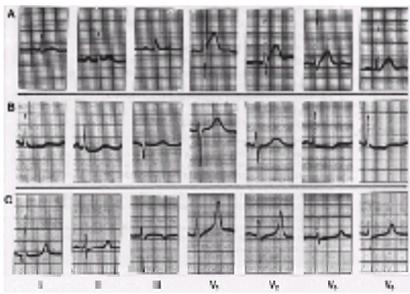

FIGURE 84.16. A: Electrocardiogram (ECG) recorded at a calcium level of 17 mg per dL illustrates the short ST segment characteristic of hypercalcemia. **B:** ECG recorded at a calcium level of 5.9 mg per dL shows prolongation of the ST segment of hypocalcemia. **C:** ECG recorded at a potassium concentration of 6.2 mEq per L, calcium level of 5.3 mg per dL, and phosphorus level of 12.2 mg per dL. The prolongation of the QT interval is due to hypocalcemia, terminated by the tented T of hyperkalemia, and is characteristic of both hypocalcemia and hyperkalemia found in chronic renal disease. (From Fisch C. Electrolytes and the heart. In: Hurst JW, ed. *The heart*. New York: McGraw-Hill, 1986:1475.)

Hypocalcemia

The ECG in hypocalcemia is characterized by a prolonged QT interval, primarily resulting from prolongation of the ST segment ([Fig. 84.16B](#)). Hypocalcemia with hyperkalemia is a common finding in chronic renal disease ([Fig. 84.16C](#)).

EXERCISE TESTING

The primary objective of exercise testing is to determine whether the patient exhibits myocardial ischemia at a given workload. The accepted standard of a positive response is a horizontal or downsloping depression of 0.1 mV or greater or, rarely, an elevation of the ST segment, with either of these indications occurring 0.08 second after the QRS, using the TP or PQ segments as the point of reference ([Fig. 84.17](#)). The test should be terminated for the following reasons: attainment of the target heart rate, onset of angina or dyspnea, decline in systolic blood pressure, decrease in heart rate, and appearance of three consecutive premature ventricular contractions.

FIGURE 84.17. Simultaneously recorded X, Y, and Z leads illustrate downsloping depression of the ST segment that appears during a stress test: **(A)** resting; **(B)** 7 minutes, stage III; **(C)** 10 minutes, stage III; **(D)** 6 minutes after exercise.

As in any laboratory procedure, the importance of sensitivity and specificity of the test must be recognized. In asymptomatic patients for whom the test is used to detect occult disease, the procedure has a sensitivity of about 50% and a specificity of about 90%. The same values for patients with known three-vessel disease are about 96% and 100%, respectively. The predictive accuracy of the stress test, particularly when applied to coronary artery disease, is in keeping with Bayes' theorem, which indicates that the likelihood that a test is truly positive increases as the prevalence of the disease for which it is being used increases. The test yields maximum benefit when correlated with the history, physical examination, and other laboratory findings.

INDICATIONS FOR EXERCISE TESTING

The primary indication for exercise testing is for symptomatic patients with known or suspected coronary artery disease. Occasionally, the test is used for asymptomatic patients in whom coronary artery disease is likely. For patients with coronary artery disease, the procedure is used as a diagnostic test; to identify patients at high risk for MI or sudden death ([Table 84.1](#)); to evaluate responses to surgical therapy, angioplasty, or medical management; and, occasionally, to follow the course of the disease. In the group without symptoms, patients older than 40 years with two or more of the conventional risk factors or a family history of premature cardiovascular disease may benefit from exercise testing. In an effort to identify the patient who is at low or high risk for new events, the test is used increasingly after acute MI, as a pre-discharge test 10 to 14 days after the acute episode or 3 to 8 weeks after infarction. The data suggest that a negative test result

after MI predicts a less than 2% mortality risk during the first year of follow-up.

Duration of symptom-limiting exercise
 Failure to complete stage II of Bruce protocol or equivalent workload (≈ 6.5 MET) with other protocols
 Exercise HR at onset of limiting symptoms
 Failure to attain HR ≥ 120 beats/min (if β -blockers)
 Time of onset, magnitude, morphology, and postexercise duration of abnormal Q-waves or downslowing ST-segment depression
 Onset at HR ≥ 120 beats/min or ≈ 6.5 MET
 Magnitude ≥ 2.0 mm
 Postexercise duration ≥ 6 min
 Depression in multiple leads
 Systemic blood pressure response during or after progressive exercise
 Sustained decrease of ≥ 10 mm Hg or flat blood pressure response (≤ 120 mm Hg) during progressive exercise
 Other potentially important abnormalities
 Exercise-induced ST-segment elevation in leads other than aVR
 Angina pectoris during exercise
 Exercise-induced LV wall motion abnormalities
 Exercise-induced ventricular tachycardia

Energy expenditure at rest, equivalent to an oxygen uptake of approximately 3.5 ml/kg/min
 HR, heart rate; MET, metabolic equivalent
 (From American College of Cardiology and American Heart Association Guidelines for exercise testing. *J Am Coll Cardiol* 1997; 30:1725, with permission.)

TABLE 84.1. EXERCISE TEST PARAMETERS ASSOCIATED WITH POOR PROGNOSIS AND INCREASED SEVERITY OF CORONARY ARTERY DISEASE

CONTRAINDICATIONS TO STRESS TESTING

The contraindications to stress testing are listed in [Table 84.2](#).

Absolutes

- Acute myocardial infarction (within 2 d)
- Unstable angina not successfully stabilized by medical therapy
- Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
- Symptomatic severe aortic stenosis
- Uncontrolled symptomatic heart failure
- Aortic dissection or aortic aneurysm
- Aortic regurgitation or pericarditis
- Aortic aneurysm

Relative

- Left main coronary stenosis
- Moderate aortic valvular heart disease
- Electrolyte abnormalities
- Severe arterial hypertension
- Tachyarrhythmias or bradyarrhythmias
- Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
- Atrial or gynecal impairment leading to inability to exercise adequately
- High-degree atrioventricular block

*Appropriate timing of testing depends on level of risk of unstable angina, as defined by ACC/AHA Unstable Angina Guidelines.
 †Relative contraindications can be considered if the benefits of exercise outweigh the risks.
 ‡In the absence of definitive evidence, the committee suggests a heart rate target of ≥ 120 beats/min.
 (From American College of Cardiology and American Heart Association Guidelines for exercise testing. *J Am Coll Cardiol* 1997; 30:1725, with permission.)

TABLE 84.2. CONTRAINDICATIONS TO EXERCISE TESTING

ECG abnormalities present at rest make it difficult or impossible to interpret the results of an exercise test. Such abnormalities include LBBB or other intraventricular conduction defects, a WPW pattern, and ST-T changes due to drugs, electrolyte abnormalities, or myocardial disease. β -Adrenergic blocking agents and calcium antagonists interfere with the test by preventing an increase in heart rate and delaying the onset of angina. If possible, these drugs should be discontinued before the test.

AMBULATORY MONITORING

A technique for recording the ECG while the patient continues his or her usual daily activities was introduced in 1957 and quickly became a widely used diagnostic tool for the detection of cardiac arrhythmias as correlated with patient symptoms, for the presence of arrhythmias thought to be prognostic and/or of therapeutic importance, and for the evaluation of the efficacy of antiarrhythmic therapy. Ambulatory ECGs (also called Holter or dynamic ECGs) are obtained with a portable tape recorder; later they are scanned and the pertinent data extracted.

Since the early 1960s there have been advances in both recording and playback methodologies. Currently there are two generic forms of ambulatory electrocardiographic recorders: (a) continuous recorders are typically used for 24 to 48 hours to capture arrhythmic events that are common and likely to occur in that time period; and (b) intermittent recorders (loop and event recorders) to detect events that occur less frequently and therefore require longer periods of monitoring (sometimes for weeks or months). Both types have a patient-activated event marker and a time recorder. The most common recording technology to date is the magnetic cassette tape recorder. It allows for playback and interrogation of the entire recording period (full disclosure). Most recorders record two or three leads of the ECG simultaneously. The leads generally used are modified leads V_5 and V_3 and a modified inferior lead. The technique is quite adequate for arrhythmic detection but has limitations for the detection of low-frequency signals such as the ST segment and T waves. Direct recording of the ECG signal in digital format using solid-state recording devices ameliorates these problems. Digital tracings can be analyzed on-line and allow direct transfer to a central analysis facility. The primary limitations in the minds of many clinicians and investigators is, in the case of on-line analysis, the need to “believe” the computer analysis and the inability to verify the computer interpretation because the electrocardiographic data are not recorded and full disclosure is not available. Newer devices are under development to provide for full disclosure by attaching storage devices that can then be interrogated on a separate device. Newer loop recorders may be implanted for longer term monitoring if required.

The characteristics of the patient's symptoms often determine the choice of recording techniques. As the reliability of fully automated systems has not yet been established for clinical use, the technician who scans the results from any of the recording devices plays a vital role in obtaining accurate results. The technician must select pertinent parts of the recordings for printouts that the physician can interpret and must be conscientious and dedicated to the task. Significant portions must not be overlooked. In the case of loss of signal or noise, samples must be printed out for physician decision making. Overreading is essential.

CLINICAL CONSIDERATIONS

There is general agreement that ambulatory electrocardiographic techniques are useful and effective to assess symptoms possibly related to rhythm disturbances such as in patients with otherwise unexplained syncope, episodes of dizziness, or unexplained recurrent palpitations. While other potential uses are numerous and include the evaluation of ischemia in many clinical states, heart rate variability, QT dispersion, T-wave alternans, and signal-averaged analyses, in most instances these analyses are not yet recommended for routine use as the possible sources of inaccuracy are ubiquitous. For research purposes, however, the application of ambulatory electrocardiography may be highly rewarding when performed in laboratories with sophisticated and well-trained physicians and technical professionals.

CHAPTER 85: ECHOCARDIOGRAPHY

WILLIAM F. ARMSTRONG

[Methods](#)
[Clinical Indications](#)
[Congenital Heart Disease](#)
[Coronary Artery Disease](#)
[Cardiomyopathies](#)
[Other Lesions](#)
[Common Clinical Indications](#)
[Future Directions](#)

Echocardiography refers to the use of ultrasound to evaluate cardiac structures and to render clinical diagnoses of heart disease. Initially demonstrated to be feasible in the early 1970s, it has become the single most widely utilized cardiac diagnostic test outside of electrocardiography. This chapter will review the basic principles and clinical utility of echocardiography.

METHODS

ULTRASOUND PRINCIPLES

Clinical echocardiography uses sound waves in the ultrasound frequency range, defined as 1.0 to 10 MHz. For practical imaging purposes in adult patients, frequencies range from 2.0 to 5.0 MHz. Ultrasound is emitted from a transducer that consists of a series of ultrasound crystals, which also act as receivers. Modern ultrasound equipment sends out a 90-degree array of ultrasound beams, along which there are multiple reflected targets. As the speed of sound in tissue is known (1,450 m per second) the distance of a reflective target can be determined from the round trip transit time of the ultrasound packet from the face of the transducer and back. This series of reflected targets is then converted to an ultrasound image of the heart. Several different ultrasound modes can be utilized for complete cardiovascular evaluation ([Fig. 85.1](#)). Repeating this process at frequent intervals creates a series of sequential images that are displayed as a tomographic moving two-dimensional image of the heart ([Fig. 85.2](#)). The number of images or frames that can be imaged is limited by the size of the area being interrogated and the speed of sound in tissue. For imaging large sectors of the adult heart, images are acquired at a rate of 30 to 50 frames per second. Newer generation equipment can provide faster imaging frame rates, but only in fairly limited areas.

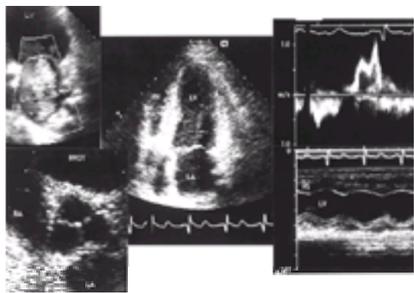

FIGURE 85.1. Composite figure showing the different echocardiographic modalities. The center frame is a four-chamber view from the apex of the left ventricle on which a Doppler cursor line can be seen running through the left ventricle and left atrium. The other four panels illustrate the derived views and modalities that can be obtained from the echocardiogram. The panel in the upper right shows a typical pulsed wave transmittal Doppler recording. Note the biphasic flow above the line, which represents flow from the left atrium to the left ventricle. The bottom right panel is a typical M-mode echocardiogram through the left ventricle. The lower left panel is an expanded, highly detailed view of a normal three-leaflet aortic valve. The upper left panel shows a mitral regurgitation jet recorded in color Doppler flow imaging (here produced in black and white). All four of the smaller images can be derived from the main echocardiographic image. LA, left atrium; LV, left ventricle; VS, ventricular septum; RA, right atrium; RV, right ventricle; RVOT, right ventricular outflow tract; MR, mitral regurgitation.

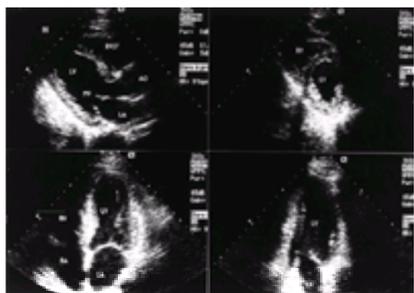

FIGURE 85.2. Four panels illustrating different two-dimensional echocardiographic views. The upper panels were recorded from the parasternal transducer position and the lower two panels were recorded from the apical position. In each case, the orientation of the transducer is rotated 90 degrees to obtain the views on the right after obtaining the view on the left. MV, mitral valve; AO, aorta; other abbreviations per previous figure.

DOPPLER ULTRASOUND

The Doppler principle states that the frequency of an ultrasound beam reflected from a moving object differs from the transmitted frequency. If an object is moving toward the transducer, the reflected frequency is higher than the transmitted frequency. Conversely, if the object is moving away from the transducer, the reflected frequency is less than the transmitted frequency. The difference between the transmitted and reflected frequency is the “Doppler shift.” The Doppler equation translates this Doppler shift into direction and velocity of motion of the interrogated target.

Doppler ultrasound is used in three basic forms. The first is pulsed Doppler, which effectively is a “steerable stethoscope.” It provides an analysis of the direction and velocity of flow at any interrogated site within the imaged frame. A limitation of pulsed Doppler is that the maximum velocity that can be detected is determined by the Nyquist limit and is limited to approximately 2.5 m per second.

Continuous wave Doppler interrogates velocities along a single beam in a continuous fashion and is not limited by any maximum detectable velocity. However, it is limited by “range ambiguity,” which implies that it is not possible to determine where along a line of interrogation a velocity originates.

Color flow imaging is a technique in which multiple pulsed Doppler sample volumes are simultaneously interrogated in a region of interest. The Doppler shift is color-encoded to represent both direction and velocity of motion. This effectively “paints” an image of the velocity of moving blood on top of the two-dimensional image of the heart.

M-MODE ECHOCARDIOGRAPHY

M-Mode echocardiography was the earliest echocardiographic modality utilized clinically. It allowed interrogation of cardiac structures along a single line of interrogation and has been largely supplanted by two-dimensional echocardiography. M-Mode echocardiography has high temporal resolution and still has some value in determining the motion characteristics of rapidly moving structures.

STRESS ECHOCARDIOGRAPHY

Stress echocardiography refers to the utilization of echocardiographic imaging before, during, and/or after cardiovascular stress. By comparing left ventricular wall motion and function at rest and after exercise, the effects of induced ischemia can be detected and hence the diagnosis of coronary artery disease made.

CONTRAST ECHOCARDIOGRAPHY

Gas-filled structures such as microbubbles are intense reflectors of ultrasound. Contrast echocardiography refers to the injection of one of these ultrasound contrast agents into the blood pool. The agent is assumed to parallel the distribution of blood flow and hence can be used to track flow through the cardiovascular system. Commonly employed ultrasound agents include agitated saline and commercially available perfluorocarbon agents. Saline contrast injections are a valuable means of detecting right-to-left intracardiac shunts, as the bubbles are filtered by the lungs and do not appear in the left heart except in the presence of a shunt such as an atrial septal defect (ASD), patent foramen ovale, etc. Newer commercially available agents are of sufficiently small size to pass through the lungs and fully opacify the left ventricular cavity. In this setting they can be used to enhance endocardial definition and improve wall motion analysis. In addition, they have shown substantial promise for detecting and quantifying myocardial perfusion.

ADVANTAGES AND DISADVANTAGES OF ECHOCARDIOGRAPHY

As with all imaging techniques, echocardiography has a distinct set of advantages and disadvantages. These are outlined in [Table 85.1](#). Perhaps the greatest advantage of echocardiography is that it is an entirely risk-free procedure and confers no known biologic risk to the patients, operators, pregnant women, or fetuses. Standard transthoracic echocardiography is a painless examination that can be accomplished in 15 to 60 minutes, depending on the detail with which the examination must be accomplished.

Advantages	Disadvantages
Noninvasive	Limited visualization in 5–10% of patients
Risk-free	Potential for overuse
Highly versatile	
Approaches all forms of heart disease	
Rapid	
Portable	
Highly accurate in skilled hands	
High patient acceptance	
High resolution	
Tomographic imaging	

TABLE 85.1. ECHOCARDIOGRAPHY: ADVANTAGES AND DISADVANTAGES

The major disadvantage of echocardiography is the potential for limited applicability in some patient subsets. Ultrasonography transmits without distortion through fluid and body tissues, but it is not transmitted through bone and it reflects intensively off air-containing structures. As such, obese patients may have poor acoustic windows that limit the ability to visualize the cardiac structures adequately. Additionally, patients with obstructive lung disease represent problematic imaging.

CLINICAL INDICATIONS

The balance of this chapter will deal with individual cardiovascular disease states and the role in which echocardiography can play. It is meant not as an all-encompassing review of echocardiography but only as a brief introduction to basic principles of echocardiography as it relates to specific diseases. Similarly, lines of logical evaluation can be drawn for patients presenting with chest pain, fatigue, arrhythmia, syncope, neurologic diseases, and other complaints for which there are possible cardiovascular etiologies. [Table 85.2](#) outlines many presenting complaints for which echocardiography may be indicated and the preferred echocardiographic methodology for each.

FIGURE 85.3. Short-axis two-dimensional echocardiograms recorded in patients with a small (*upper*) and large (*lower*) pericardial effusion. In the upper panel there is a 1- to 1.5-cm echo-free space posterior to the heart representing pericardial fluid (*arrows*). In the upper panel there is a larger circumferential effusion (*arrows*) visible both posterior and anterior to the heart in this short-axis view.

Constrictive pericarditis remains an elusive diagnosis. Using a combination of M-mode, two-dimensional, and Doppler interrogation, both direct and indirect evidence of constrictive pericarditis can be found with echocardiography. In classic constriction there is an exaggerated interaction between the right and left ventricles during respiration. This is seen as an exaggerated motion of the ventricular septum with the respiratory cycle. This can also be seen on Doppler interrogation of valvular inflows and outflows. Attempts at determining actual pericardial thickness with echocardiography have not met with success. Computed tomography and magnetic resonance imaging remain superior for the determination of pericardial thickness.

VALVULAR HEART DISEASE

Using transthoracic two-dimensional echocardiography, valve morphology can be identified as normal or abnormal, and varying degrees of valve thickening, rigidity, fibrosis, and calcification can be quantified. Doppler ultrasound provides an excellent means for determining the velocity of jets through a stenotic valve, from which both peak instantaneous and mean valvular pressure gradients can be determined. Color flow imaging, supplemented by spectral flow profiles, is an excellent means for determining the severity of regurgitant valvular lesions. In routine clinical practice, regurgitant valvular lesions are characterized qualitatively as absent, minimal, mild, moderate, and severe. Quantitative techniques for determining the severity of valvular insufficiency exist, but they are highly operator-dependent and frequently are not employed in routine clinical practice.

MITRAL STENOSIS

The normal mitral valve consists of two leaflets, the larger of which is the anterior leaflet. When fully opened the leaflets are relatively parallel and the tip of the anterior mitral valve leaflet opens to within 1.0 cm of the anterior ventricular septum. In mitral stenosis there is thickening and fibrosis, predominantly of the tips of the mitral valve leaflets and chordal apparatus ([Fig. 85.4](#)). In early mitral stenosis the belly of the leaflet is relatively preserved, resulting in a funnel-shaped or domelike opening of the mitral valve. In many instances the actual restrictive orifice can be imaged in its short axis and measured to provide an accurate assessment of the area of the stenotic mitral orifice. Secondary features of rigidity, calcification, and chordal involvement can also be characterized. These features have specific relevance with respect to the feasibility of performing mitral balloon valvuloplasty. Patients with substantial degrees of calcification and rigidity are less likely to have a good result from mitral balloon valvuloplasty.

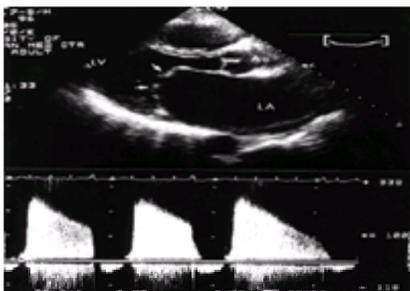

FIGURE 85.4. Mitral stenosis. The upper panel is a parasternal long-axis view recorded in diastole. Note that the left atrium is dilated and that the mitral valve, rather than opening in a straight line, “domes” as the leaflet tips (*arrows*) have restricted mobility. The lower panel is a transmitral continuous wave Doppler recording from which a trans mitral pressure gradient can be calculated.

Quantitation of mitral stenosis relies heavily on Doppler techniques to determine the mean great transmitral gradient. In borderline cases this can be done both at rest and with exercise. Other features of mitral stenosis that can be evaluated using echocardiography include the degree of secondary dilatation of the left atrium, the presence or absence of left atrial thrombus (transesophageal echo required), and the presence of concurrent mitral regurgitation and secondary pulmonary hypertension.

MITRAL REGURGITATION

Both the mechanism and severity of mitral regurgitation can be determined with echocardiography. Mitral valve prolapse with or without leaflet thickening, flail leaflets, concurrent mitral stenosis, and vegetations or other masses can all be reliably identified as the etiologic cause of mitral regurgitation. Transesophageal echocardiography plays an incremental role in determining the mechanism of regurgitation as it relates to potential surgical repair. Mitral regurgitation is quantified as minimal, mild, moderate, and severe. Quantitative techniques for determining its severity exist, including calculation of a regurgitant orifice area and calculation of regurgitant volumes. Most clinical laboratories rely on a qualitative assessment of severity rather than detailed quantitative techniques. The severity of mitral regurgitation is directly proportional to the size of the regurgitant jet within the left atrium ([Fig. 85.5](#)). Jets that are eccentric and impinge on a wall will understate the total regurgitant volume, and this must be factored into the clinical assessment. Additionally, highly eccentric jets are more likely to represent the effects of a flail mitral valve leaflet.

FIGURE 85.5. Four-panel view of patients with mitral regurgitation. The two panels on the left are transthoracic echocardiograms. The upper panel was recorded in a

parasternal long-axis view and reveals moderate mitral regurgitation filling approximately 50% of the left atrium. The lower panel reveals a more eccentric mitral regurgitation jet along the lateral wall of the left atrium. The upper right panel is a transesophageal echocardiogram revealing severe mitral regurgitation and the lower panel the same view with the color signal suppressed. In this view, a flail anterior and posterior mitral valve leaflets (*arrows*) can be visualized as the mechanism for severe mitral regurgitation. LAA, left atrial appendage. See [color figure 85.5](#)

AORTIC STENOSIS

As for mitral valve disease, both the anatomical substrate and the severity of stenosis can be determined. In approximately 80% of cases the individual leaflets can be visualized with certainty, and a bicuspid valve be either excluded or diagnosed. The degree of leaflet thickening and restriction of motion is easily determined in most patients from the transthoracic echocardiogram ([Fig. 85.6](#)). Direct measurement of the stenotic orifice is feasible in only a minority of patients, even with the transesophageal approach. Secondary features of aortic stenosis, including poststenotic dilatation of the aorta and left ventricular hypertrophy, can also be evaluated. Attention should be paid to overall left ventricular function as reduced left ventricular function may result in a reduced gradient in the presence of a severely stenotic valve.

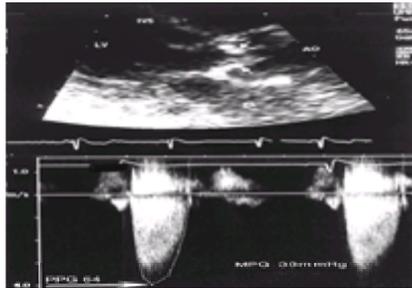

FIGURE 85.6. Two-dimensional echocardiogram and Doppler of a patient with aortic stenosis. The upper panel was recorded in the parasternal long-axis view in systole. Note the thickened aortic valve leaflets with restricted mobility (*arrows*). The lower panel is a continuous wave Doppler recorded from the apex from which a peak pressure gradient (PPG) of 64 mm Hg and a mean pressure gradient (MPG) of 38 mm Hg can be calculated.

Continuous wave Doppler is essential for determining the peak and mean gradient through a stenotic aortic valve ([Fig. 85.6](#)). The gradient determined with transthoracic Doppler ultrasound correlates favorably with simultaneously determined gradients in the catheterization laboratory. The aortic valve gradient may be underestimated in suboptimal quality exams in which the interrogation beam is improperly aligned with the aortic outflow and when compared to nonsimultaneous cardiac catheterization. Doppler ultrasound only rarely overestimates an aortic stenosis gradient. By combining Doppler parameters of flow and a measurement of the left ventricular outflow tract area, aortic valve area can be calculated using the continuity equation.

AORTIC INSUFFICIENCY

Aortic insufficiency is quantified both by color Doppler flow imaging and spectral Doppler. Unlike mitral regurgitation, in which the size of the insufficiency jet correlates well with the severity of regurgitation, the size of an aortic insufficiency jet in general correlates poorly with severity. The actual height or width of a jet, indexed to the left ventricular outflow tract, probably represents the best index of aortic insufficiency severity with color Doppler flow imaging ([Fig. 85.7](#)). Additionally, by evaluating the pressure half-time from a spectral display, additional indexes of the severity of aortic insufficiency can be determined.

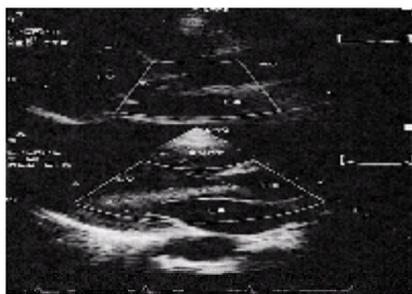

FIGURE 85.7. Parasternal long-axis views of two patients with aortic insufficiency. In each case the images were recorded in diastole. In the upper panel mild aortic insufficiency with a relatively small, narrow jet is seen (*arrow*). The lower panel demonstrates a greater degree of aortic insufficiency with a wide jet that penetrates down past the tips of the mitral valve leaflets. See [color figure 85.7](#).

TRICUSPID VALVE DISEASE

The majority of tricuspid valve disease encountered is secondary to right heart dilatation and commonly seen in association with pulmonary hypertension. Tricuspid regurgitation is quantified in a manner similar to that for mitral regurgitation. Additionally, right ventricular systolic pressure can be determined from the velocity of a tricuspid regurgitation jet. Primary intrinsic disease of the tricuspid valve is rare. The tricuspid valve may be involved in rheumatic heart disease, in which case mitral involvement virtually always occurs. Isolated tricuspid valve disease can also occur in endocarditis and in the carcinoid syndrome.

PULMONIC VALVE DISEASE

Pulmonic stenosis is largely a disease of childhood. Its quantitation is based on the appearance of the valve as well as on determination of transpulmonic gradients. Mild degrees of pulmonic insufficiency are very common in the normal adult population and do not necessarily represent a pathologic state, unless seen in association with valvular thickening or subsequent chamber enlargement.

CONGENITAL HEART DISEASE

Modern echocardiographic techniques are sufficient for nearly complete characterization of virtually all forms of congenital heart disease in both children and adults. In adults the most common congenital lesion to be detected de novo is the ASD. Its location can be reliably determined as either primum, secundum, or sinus venosus. An ASD results in dilatation of the right atrium and ventricle and a relative volume overload of the right ventricle ([Fig. 85.8](#)). Additionally, using specialized scanning planes the ASD frequently can be directly visualized with transthoracic echocardiography. Contrast echocardiography with agitated saline is a reliable mechanism for detecting a right-to-left shunt. Transesophageal echocardiography in experienced hands has nearly a 100% accuracy rate for detecting or excluding the presence of an ASD. Transesophageal echocardiography is an excellent method for determining the feasibility of percutaneous ASD closure, based on the ASD size and integrity

of the peridefective tissue.

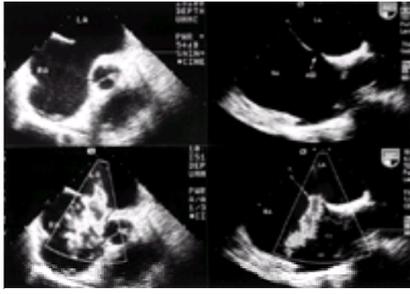

FIGURE 85.8. Transesophageal echocardiograms recorded in two patients with ASDs. On the left is a large ASD seen as echo dropout in the atrial septum on the two-dimensional image. The lower left panel shows the color flow image representing flow from the left atrium to the right atrium. The two right panels represent standard two-dimensional imaging and color flow imaging of a patient with a smaller ASD and predominant left-to-right shunting. ASD, atrial septal defect. See [color figure 85.8](#).

Other congenital lesions that are common in childhood, such as ventricular septal defect (VSD), are infrequently encountered in adult populations as a de novo diagnosis. The combination of two-dimensional imaging and Doppler ultrasound is a reliable mechanism for determining the presence and location of VSDs when suspected. Other than the simpler lesions such as ASDs, the majority of adult congenital heart disease is in a repaired or palliated state. Echocardiography provides virtually all of the information needed to follow patients with repaired tetralogy of Fallot, closed VSD, and previously closed ASD.

CORONARY ARTERY DISEASE

Myocardial ischemia, occurring either during a spontaneous or induced episode of angina or as part of myocardial infarction, results in abnormalities of ventricular wall motion ([Fig. 85.9](#)). These abnormalities are detected as a lack of myocardial thickening as well as decreased motion of the endocardium. There is a minimum threshold of involved myocardium required before a wall motion abnormality occurs. However, the majority of Q-wave myocardial infarctions and most non-Q-wave infarcts of substantial size are associated with detectable wall motion abnormalities. Numerous studies have demonstrated that more than 90% of individuals with impending myocardial infarction will have a detectable wall motion abnormality and that the size of this abnormality correlates well with the degree of myocardial necrosis and, similarly, with prognosis. Recovery of myocardial function following successful intervention with lytic therapy or primary angioplasty can also be documented and tracked using echocardiography.

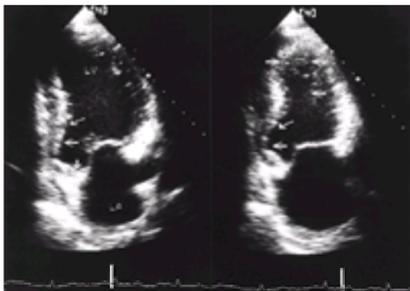

FIGURE 85.9. Apical two-chamber view of a patient with an inferior myocardial infarction. Compare the shape of the left ventricle in diastole and systole to the normal example represented in [Figure 85.2](#). In this example, the left panel is in diastole and the right panel in systole. The proximal inferior wall is dyskinetic and aneurysmal (arrows). The remaining walls move normally.

Virtually all mechanical complications of myocardial infarction can be detected with echocardiography. An aneurysm is detected as a distinct bulge in the shape of the left ventricle present both in systole and in diastole. Echocardiography is the standard examination for excluding or diagnosing ventricular thrombus following myocardial infarction. Mechanical complications such as VSD, free-wall rupture, and papillary muscle rupture can be detected. Doppler interrogation is essential for finding abnormal flow associated with a postinfarct VSD and in quantifying the degree of mitral regurgitation. Transesophageal echocardiography plays an incremental role in determining the mechanism and severity of mitral regurgitation. Chronic complications of myocardial infarction such as infarct expansion, chronic left ventricular thrombus ([Fig. 85.10](#)), and left ventricular dilatation with reduced left ventricular systolic function can likewise be detected with echocardiography.

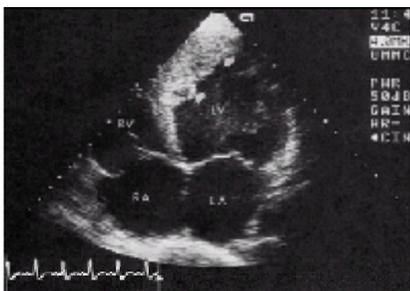

FIGURE 85.10. Apical four-chamber view in a patient with a large anterior apical myocardial infarction and a large mural thrombus. Note the echo-dense mass that fills the apex of the left ventricle. The border of the mass with the blood pool is denoted by white arrows.

Occult coronary artery disease can be detected using stress echocardiography. This technique relies on detection of exercise or pharmacologically induced myocardial ischemia, which is associated with a transient wall motion abnormality. By comparing left ventricular wall motion at rest and with stress, a reliable indicator of the presence of occult coronary artery disease is obtained. In experienced laboratories the accuracy of stress echocardiography for detecting coronary disease is equivalent to radionuclide imaging. Both imaging techniques are superior to routine treadmill ECG alone.

CARDIOMYOPATHIES

Echocardiography is a superb technique for demonstrating the presence of both dilated and hypertrophic cardiomyopathy. Dilated cardiomyopathy of any cause is manifest as dilatation of the left ventricle and is usually secondary to dilatation of the left atrium. Variable degrees of mitral regurgitation are frequently present ([Fig. 85.7](#)). Either primary involvement of the right ventricle or secondary involvement due to pulmonary hypertension is not uncommonly seen and is often associated with

tricuspid regurgitation. Ejection fraction can be reliably measured by calculation of diastolic and systolic volumes. Complications of ventricular thrombus, secondary mitral and tricuspid regurgitation, and pulmonary hypertension can all be reliably documented. Evaluation of mitral valve inflow may provide valuable prognostic information. Patients with end-stage dilated cardiomyopathy reach a “restrictive physiology” phase manifest as a high E-to-A ratio of mitral valve inflow. This finding has been demonstrated to confer an adverse prognosis. Finally, infiltrative cardiomyopathy, such as amyloid, can be reliably diagnosed with echocardiography ([Fig. 85.11](#)).

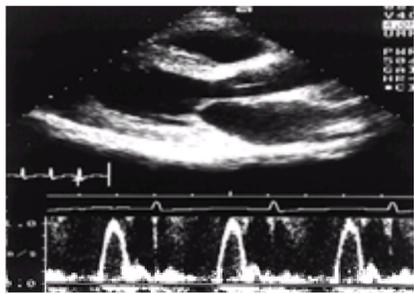

FIGURE 85.11. Parasternal long-axis view of a patient with cardiac amyloidosis. Note the left ventricular hypertrophy and the abnormal texture of the ventricular myocardium, which appears echo-dense and white compared to the normal myocardial texture represented in earlier figures. The lower panel is a transmittal Doppler showing the high E to A ratio, suggestive of a restrictive physiology in this setting.

Hypertrophic cardiomyopathy (also called idiopathic hypertrophic subaortic stenosis, or IHSS) is readily diagnosed with two-dimensional echocardiography. In the classic form there is disproportionate and inappropriate hypertrophy of the ventricular septum in association with systolic anterior motion of the mitral valve and dynamic left ventricular outflow tract obstruction. Hypertrophic cardiomyopathy is a very heterogeneous entity, and numerous variations of hypertrophy including diffuse, symmetric left ventricular hypertrophy, isolated apical hypertrophy, and isolated lateral or inferior wall hypertrophy have all been described. The degree of left ventricular outflow tract obstruction can be quantified using continuous wave Doppler, and the degree of associated mitral regurgitation can be quantified with color flow imaging. Two-dimensional echocardiography plays a critical role in the initial diagnosis of hypertrophic cardiomyopathy and in screening of family members once the disease is detected.

OTHER LESIONS

CARDIAC VEGETATIONS AND MASSES

Infectious endocarditis both in acute and chronic forms is associated with valvular abnormalities in well over 95% of patients. A vegetation represents a combination of infected thrombus, inflammatory and infectious material, and platelet fibrin deposition on the valve. Depending on the virulence of the organism, it is variably destructive leading to perforation of the valve leaflets and disruption of the supporting apparatus. Vegetations are detected on two-dimensional echocardiography as mobile, oscillating masses attached to a valvular structure ([Fig. 85.12](#)). Varying degrees of valvular insufficiency are present in the vast majority of instances. It is exceptionally uncommon for valvular stenosis to be caused by a vegetation. Typically fresh, active vegetations have a high degree of mobility and oscillatory motion. Their tissue character is rather “soft” and frequently has the same reflective properties as myocardial tissue. Old, healed vegetations take on a far more fibrotic, scarred, and dense appearance. There are several characteristics of vegetations that confer an increased risk of complications, such as progressive valvular destruction, failure to sterilize with antibiotics, and embolic phenomena.

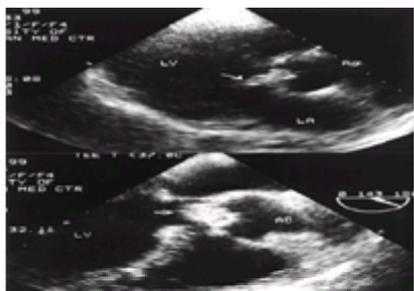

FIGURE 85.12. Parasternal long-axis transthoracic (*upper*) echocardiogram and transesophageal echocardiogram recorded in a longitudinal view (*lower*) in a patient with an aortic valve vegetation (*arrow*). In each case, a large bulky mass is seen nearly replacing the normal aortic valve and prolapsing into the left ventricular outflow tract in diastole.

Intracardiac tumors represent a very rare form of organic heart disease. The most common primary benign tumor of the heart is the left atrial myxoma. This typically appears on a stalk arising from the atrial septum. The classic atrial myxoma has a homogeneous texture and is highly mobile. It often results in mitral valve obstruction. The echo appearance of a myxoma is typical enough that confirmatory studies are rarely necessary prior to the recommendation for surgical resection. Other intracardiac tumors including primary malignancies can be easily be detected with echocardiography as can metastatic disease. In the majority of instances metastatic disease of the heart is associated with myocardial effusion.

PULMONARY HYPERTENSION

Evidence of both primary and secondary pulmonary hypertension can be demonstrated with echocardiography and Doppler ultrasound techniques. Many causes of secondary pulmonary hypertension, such as congenital heart disease, primary valvular heart disease, and cardiomyopathy, can be easily diagnosed. It is important that the pulmonary artery systolic pressure can be estimated from the tricuspid regurgitation jet ([Fig. 85.13](#)). Some degree of tricuspid regurgitation is ubiquitous in patients with pulmonary hypertension. By calculating the transvalvular gradient between the right ventricle and right atrium, and then adding an assumed right atrial pressure, an estimate of right ventricular and hence pulmonary artery systolic pressure can be determined. This correlates favorably over the full physiologic range of pulmonary artery pressures when compared to cardiac catheterization.

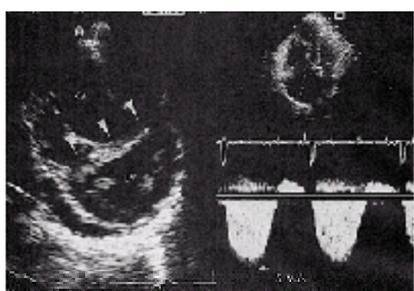

FIGURE 85.13. Two-dimensional echocardiogram and Doppler recorded in a patient with severe pulmonary hypertension. The left panel is a short-axis view at the level of the papillary muscles. Compare the relative size and shape of the right and left ventricles in this patient to the normal example in [Figure 85.2](#). In this case, the left ventricle has assumed a “D”-shaped geometry because of the flattening of the ventricular septum (*arrowheads*). The right ventricle is dilated and hypertrophied. The right panel is a continuous wave Doppler of a tricuspid regurgitation jet. The peak velocity is 5 m per second, from which a right ventricle to right atrial gradient of 100 m Hg can be calculated. Assuming a right atrial pressure of 14 m Hg, the right ventricular systolic pressure can be estimated to be 114 m Hg.

DISEASE OF THE AORTA

Disease of the thoracic aorta can be reliably evaluated with transesophageal echocardiography. Transesophageal echocardiography is a highly accurate technique for diagnosing aortic dissection and aortic aneurysm and for documenting the presence of atherosclerotic disease ([Fig. 85.14](#)). The accuracy of transesophageal echocardiography for detecting aortic dissection is equal to that of magnetic resonance imaging and computed tomography.

FIGURE 85.14. Four transesophageal echocardiographic images are presented. The upper left panel is a longitudinal view of a normal aorta. Points 1, 2, 3, and 4 represent the anatomical annulus, sinus of Valsalva, sinotubular junction, and ascending aorta, respectively. The upper right panel is a similar long-axis view recorded in a patient with an ascending aortic dissection. A portion of the intimal flap is easily visualized. The lower right panel was recorded in the same patient and shows a larger area of the ascending aorta in which the complex nature of the intimal flap (*arrows*) can be clearly seen. The lower left panel is a transverse view of the descending thoracic aorta in the same patient, demonstrating propagation of the dissection into the descending thoracic aorta.

COMMON CLINICAL INDICATIONS

CONGESTIVE HEART FAILURE

Congestive heart failure frequently presents as a combination of dyspnea and fatigue. In many instances the differential diagnosis is between organic heart disease, pulmonary disease, and other major medical illnesses. Two-dimensional echocardiography is a superb tool to quickly screen for the presence of underlying organic heart disease. When present, its nature (valvular heart disease, cardiomyopathy, occult coronary artery disease, pericardial disease, etc.) can be readily ascertained and in the presence of cardiomyopathy the degree of ventricular dysfunction quantified. The American College of Cardiology/American Heart Association position paper on evaluation of patients with congestive heart failure recommends echocardiography as a primary screening tool in virtually all patients with known or suspected congestive heart failure.

CHEST PAIN

In patients with chest pain that could possibly be attributed to organic heart disease, an echocardiogram is an excellent diagnostic tool. A resting wall motion abnormality is frequently detected in patients with acute ischemic syndromes. When ischemic heart disease is suspected, stress echocardiography can reliably identify the presence of underlying coronary artery disease. Other forms of organic heart disease likely to result in chest discomfort include aortic stenosis, chronic and acute disease of the aorta such as dissection (for which transesophageal echocardiography is required), pulmonary hypertension, and valvular and pericardial heart disease. The major consideration in a patient with chest pain is the diagnosis or exclusion of coronary artery disease for which stress echocardiography is frequently necessary. On occasion, the routine resting study demonstrates evidence of occult coronary disease manifested by a previously unrecognized myocardial infarction.

MURMURS

A common indication for performance of an echocardiogram is the elucidation of a cardiac murmur. With careful auscultation a skilled clinician should be able to identify the majority of patients who have a benign flow murmur and likewise identify the origin of a pathologic murmur. Echocardiography is clearly more accurate for determining the severity of valvular stenosis and regurgitation when compared even to skilled auscultation. Both stenosis and regurgitation of all four cardiac valves as well as determination of intracardiac shunts due to congenital heart disease are reliably determined with echocardiography.

CARDIAC SOURCE OF EMBOLUS

It has been increasingly recognized that many patients with acute neurologic events have underlying cardiac disease that may be a contributing factor. The classic example is a patient with a stroke, subsequently found to have a left atrial thrombus ([Fig. 85.15](#)). Other entities that can result in embolization include intracardiac tumors, vegetations, aortic debris, and anatomical defects leading to an intracardiac shunt. The most common entity in the latter category is patent foramen ovale, which can be diagnosed using an intravenous contrast injection, occasionally augmented by either cough or Valsalva. This serves as a reliable mechanism for demonstrating the presence of an occult intracardiac shunt, which can be the source of the cardioembolic phenomena.

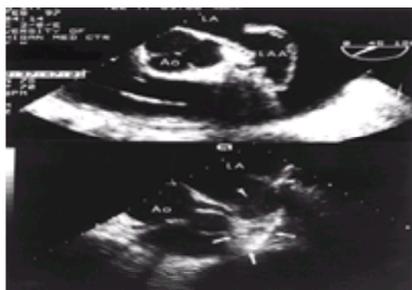

FIGURE 85.15. Transesophageal echocardiograms with specific attention paid to the left atrial appendage. The upper panel shows a normal left atrial appendage without evidence of spontaneous contrast or thrombosis. The lower panel is recorded in a similar view in a different patient. The anatomic boundary of the atrial appendage is noted by the arrows. Note the dense filling defect in the apex of the left atrial appendage and the vaguer, smokelike echoes just superior to the denser thrombosis (*arrows*).

The role of echocardiography in determining the source of embolus is similar to its role in patients with atrial fibrillation. Patients in atrial fibrillation who undergo conversion have an increased prevalence of embolic events shortly after cardioversion. These embolic events arise from dislodgement of thrombi preexisting in the left atrium, most commonly in the left atrial appendage, or that form due to atrial appendage stunning shortly after cardioversion. Many laboratories have adopted a strategy of transesophageal echocardiography to exclude atrial thrombi prior to cardioversion in patients with atrial fibrillation.

CARDIAC DISEASE IN MAJOR MEDICAL ILLNESSES

Echocardiography serves as a highly accurate screening tool for evaluating the presence of cardiac disease in medical illnesses known to be associated with cardiac abnormalities. This includes evaluation of left ventricular hypertrophy and diastolic dysfunction in patients with recently diagnosed hypertension, evaluation of valvular anatomy in patients with connective tissue diseases such as systemic lupus erythematosus, and screening of patients previously exposed to weight loss drugs. Other roles that echocardiography plays in medical illnesses include documentation of left ventricular function in patients undergoing cancer chemotherapy and detection of secondary right heart involvement in patients with significant lung disease.

FUTURE DIRECTIONS

The modern echocardiography laboratory is capable of answering virtually any question regarding the anatomical status of the cardiovascular system. Future developments in echocardiography include new ultrasound platforms that provide higher resolution and higher frame rate images with a greater ability to identify chamber borders. New ultrasound contrast agents, many of which are perfluorocarbon-based, have shown tremendous promise for enhancing the ability of echocardiographic wall motion detection and for determining the status of myocardial perfusion. Equipment advances will provide an intrinsically digital imaging platform, which will obviate the need for videotape and allow instantaneous retrieval of images at remote sites.

CHAPTER 86: RADIONUCLIDE AND MAGNETIC RESONANCE TECHNIQUES

MARK A. LAWSON AND GERALD M. POHOST

[Radionuclide Techniques](#)
[Magnetic Resonance Methods](#)

Both radionuclide and magnetic resonance techniques can be used to evaluate cardiac morphology, function, perfusion, and metabolism. This chapter describes the instrumentation, materials, and methods used with each technique and discusses current and future applications for the diagnosis and management of diseases affecting the cardiovascular system.

RADIONUCLIDE TECHNIQUES

Radionuclide techniques use radionuclides (radioactive isotopes) or agents labeled with radionuclides. Radionuclides used for diagnostic purposes emit photons (g rays) or positrons (positively charged b particles). Image data are obtained from the interaction of g photons with the imaging instrument.

INSTRUMENTATION

Single-Photon Planar Imaging

Single-photon planar imaging requires three basic components: (a) a radioactive tracer selected to evaluate specific cardiac pathology or function; (b) a detection device, called a gamma or scintillation camera; and (c) a computer to collect, display, store, and retrieve image data.

In its simplest form, a gamma camera consists of a sodium iodide crystal positioned in front of a tight grouping of photomultiplier tubes. Photons emitted by the radiotracer from within the heart are detected by the gamma camera through a process of scintillation. As photons strike the crystal, a flash of light, or scintillation, occurs that is detected by the photomultiplier tubes and converted to electrical signals. The position of the scintillation on the crystal is mapped by logic circuits within the camera. The density and distribution of scintillations is recorded by the imaging computer.

Photons emitted by the radiotracer from within the heart can be deflected by surrounding bone and soft tissues before interacting with the gamma camera. This scattering of photons degrades image contrast and spatial resolution. A lead collimator, fastened onto the front of the gamma camera, can improve image quality. A collimator is a lead disk through which a homogeneous distribution of parallel holes is drilled. The lead septa between holes absorb the scattered photons, whereas photons traveling parallel to the holes (mainly nonscattered photons emanating from the field of view) are allowed to pass and interact with the crystal.

Another type of gamma camera contains multiple small crystals, usually arranged in a rectangular array. Each crystal is associated with a photomultiplier tube. These cameras, called multicrystal cameras, detect photons at a faster rate than do single-crystal cameras. Multicrystal cameras are used primarily for first-pass imaging, during which a concentrated bolus of radiotracer is imaged rapidly as it travels through the heart and great vessels. Although multicrystal cameras possess higher count rates, they have lower spatial resolution than do single-crystal cameras.

With the camera positioned over the chest, planar images are acquired in several (usually three) projections ([Figure 86.1](#)). The radioactivity of all structures within the field of view is counted and displayed in the image; photons originating from the heart overlap the activity of structures behind or in front of the heart relative to the orientation of the gamma camera.

FIGURE 86.1. Planar thallium 201 myocardial imaging study with anterior, 45-degree left anterior oblique (LAO), and 70-degree LAO views obtained immediately after exercise (**left**) and 3 hours later (**right**). Defects are seen (*arrows*) in the anterolateral and apical walls in the anterior view and in the anterior wall in the 70-degree LAO view. The defects have resolved in the delayed views, demonstrating redistribution with myocardial ischemia.

Single-Photon Emission Computed Tomography

Single-photon emission computed tomography (SPECT) acquires image data to generate cross-sectional images of the heart in any given orientation. Tomography has the potential to distinguish between structures that overlap one another, and SPECT has been reported to increase the diagnostic accuracy of myocardial perfusion imaging by improving image quality and anatomical localization of defects. Although SPECT may improve accuracy, certain limitations may reduce specificity because of a higher incidence of false-positive results. These limitations include artifacts resulting from attenuation or patient motion, or from reconstruction errors (e.g., center of rotation, orbit, reorientation, and misalignment errors).

Single-photon emission computed tomography acquires image data using a single-crystal camera that rotates about the patient's chest in an arc, stopping momentarily to acquire image data at each stop before rotating to the next stop. From this acquired array of data, a computer reconstructs (using a filtered back-projection algorithm) and displays the desired tomographic images. Cardiac tomographic planes conventionally are displayed in the short, vertical, and horizontal long axes (Color [Figure 86.1](#)). To decrease the image acquisition time, two or three cameras can be mounted on the revolving gantry.

Positron Emission Tomography

Positrons are positively charged b particles generated by certain radionuclides. When a positron encounters an electron, the two annihilate one another and produce two photons with an energy of 511 keV traveling 180 degrees apart. A positron emission tomography (PET) camera consists of a series of detectors arranged in a ring surrounding the body. A computer counts only the photons arriving simultaneously (coincidence detection) on oppositely positioned detectors, and excludes all other photons (i.e., scattered photons) from the image data. These characteristics of PET (less artifact from attenuation and enhanced exclusion of scattered photons) provide images with higher resolution and contrast when compared with single-photon methods.

However, the camera and on-site cyclotron needed to generate the short-lived radionuclides are costly, and their operation requires substantial space and technical expertise. These disadvantages have restricted the widespread application of PET imaging.

RADIONUCLIDES

Technetium 99m

Technetium 99m (^{99m}Tc) is the most commonly used radionuclide in nuclear cardiology laboratories ([Table 86.1](#)). It has a single photon peak of 140 keV, which is ideal for detection by imaging equipment. Because of its relatively short half-life of 6 hours, higher activity can be administered. These two characteristics provide images with higher resolution.

Characteristic	Thallium 201	Technetium 99m
Photo peak	69–83 keV	140 keV
Half-life	73 hr	6 hr
Activity	2.5–4.0 mCi	25–30 mCi
Excretion	Renal	Hepatobiliary
Myocyte extraction fraction	85%	40%
Viability assessment	Yes	Probably
Attenuation artifact	More	Less
Lung activity uptake	Yes	No
Redistribution	Yes	Minimal
Gated acquisition/contrast	No	Yes
Image resolution/contrast	Lower	Higher
Calculation of left ventricular ejection fraction	No	Yes

TABLE 86.1. CHARACTERISTICS OF THALLIUM 201 AND TECHNETIUM 99m

Technetium 99m-labeled radiopharmaceuticals are used to evaluate ventricular function as well as myocardial perfusion and infarct size. Agents labeled with ^{99m}Tc can be obtained from a commercial radiopharmacy already prepared for administration. Another source of ^{99m}Tc is a generator kept in the nuclear cardiology department. A ^{99m}Tc generator, about the size of a thermos bottle, contains molybdenum 99 (^{99}Mo), which decays to ^{99m}Tc . By injecting the generator with saline solution, ^{99m}Tc is washed or eluted from the generator and ready to use. The generator can supply ^{99m}Tc -pertechnetate for about a week. However, because ^{99}Mo is a nuclear reactor by-product, it is strictly regulated by the Nuclear Regulatory Commission. It often is more convenient to obtain ^{99m}Tc agents from a commercial radiopharmacy.

Thallium 201

Thallium 201 (^{201}Tl) is a single-photon radionuclide that is the most widely used and best understood agent for assessing myocardial perfusion and viability. Thallium 201 is somewhat less desirable than ^{99m}Tc for gamma camera imaging because ^{201}Tl has a lower photon energy peak (70 to 80 keV) and a longer half-life (73.5 hours). The longer half-life limits the total activity administered to the patient. As a consequence, image quality is somewhat less when compared with that of ^{99m}Tc ; however, the difference in image quality does not affect the accuracy of study interpretations. Thallium 201 is produced by a cyclotron and is ordered weekly from a radiopharmacy. It is not regulated by the Nuclear Regulatory Commission.

Positron-Emitting Radionuclides

Positron-emitting radionuclides used in cardiac studies include carbon 11 (^{11}C), nitrogen 13 (^{13}N), oxygen 15 (^{15}O), fluorine 18 (^{18}F), and rubidium 82 (^{82}Rb). Most of these agents are cyclotron-produced, except ^{82}Rb , which is eluted from a generator. These radionuclides have many applications in nuclear cardiology. Carbon 11 is used to label fatty acids (e.g., ^{11}C -palmitate) for evaluation of lipid metabolism and to label carbon monoxide (^{11}C -CO) for assessment of ventricular function. Labeled ammonia (^{13}N - NH_3) is used as a myocardial perfusion tracer. Other metabolic processes, such as oxygen consumption (^{15}O) and glycolysis (^{18}F -fluorodeoxyglucose), can be evaluated with PET. An important property of PET agents is their short half-lives: 20.4 minutes for ^{11}C , 9.8 minutes for ^{13}N , 2 minutes for ^{15}O , 75 seconds for ^{82}Rb , and 110 minutes for ^{18}F . Because the half-lives are short, repeated injections are possible that can reflect changes in perfusion or metabolism in response to a number of interventions. However, a cyclotron to generate PET agents must be located on site to supply the agents before they decay.

APPLICATIONS

Radionuclide techniques have a number of applications, including assessment of cardiac function, perfusion, viability, and necrosis.

ASSESSMENT OF VENTRICULAR FUNCTION

Radionuclide Ventriculography

Radionuclide ventriculography is used predominantly to assess regional and global ventricular performance ([Table 86.2](#)). Three approaches can be used: the gated blood pool method, the first-pass method, and the gated SPECT method. Global ventricular performance can be expressed using the ejection fraction (EF), which is the percentage of blood volume ejected from the ventricle during contraction:

Rest
<ul style="list-style-type: none"> Assessment of global left ventricular function and calculation of left ventricular ejection fraction Assessment of regional wall motion Identification of ventricular aneurysms and pseudoaneurysms Detection of doxorubicin cardiotoxicity Evaluation of the status of a cardiac allograft Assessment of valvular regurgitation and shunt ratios
Exercise
<ul style="list-style-type: none"> Detection of ischemic dysfunction caused by coronary artery disease Risk assessment of patients with coronary artery disease Determination of optimal timing for valve replacement

TABLE 86.2. INDICATIONS FOR RADIONUCLIDE VENTRICULOGRAPHY

$$EF = (EDV - ESV)/EDV = \text{stroke volume}/EDV$$

where EDV = end-diastolic volume and ESV = end-systolic volume.

Gated Blood Pool Method

By labeling red cells with ^{99m}Tc , radioactivity within the blood pool will be proportional to volume. The counts obtained during end-systole and end-diastole can be substituted in the above equation to calculate the ejection fraction. Technetium 99 pertechnetate binds to red blood cells in the presence of stannous phosphate, allowing ^{99m}Tc to remain in the blood pool; because the heart is the largest blood pool within the chest, it can be imaged with the gamma camera. Gated blood pool ventriculography is performed using a multigated acquisition. It is because of this approach that the study frequently is called MUGA, for “multigated acquisition.” That is to say, a series of 16 to 32 equally spaced “snapshots” (or frames) of the cardiac blood pool are acquired during each cardiac cycle, with the first frame being triggered (gated) to the R wave of the patient’s electrocardiogram (ECG).

During successive cardiac cycles, the computer assigns incoming image data to frames in sequence. The first MUGA frame is generated by adding together all of the counts acquired during the first temporal segment that follows the R wave. The second frame follows the first, and so on. After a 2- to 10-minute acquisition, sufficient counts accumulate within each frame. The sequence of frames can be viewed repeatedly in a movie (cinematic) mode that depicts the events of ventricular contraction and relaxation after the initiating R wave. Global ventricular function is assessed using the ejection fraction calculation and abnormal regional wall motion can be assessed by observing asymmetric contraction of the chamber silhouette in the movie mode (Figure 86.2). Customarily, studies at rest are acquired in two or three projections, including an anterior and at least one left anterior oblique view. The left ventricular ejection fraction (LVEF) is computed using the projection that best separates the left from the right ventricular cavity, about a 45-degree left anterior oblique view.

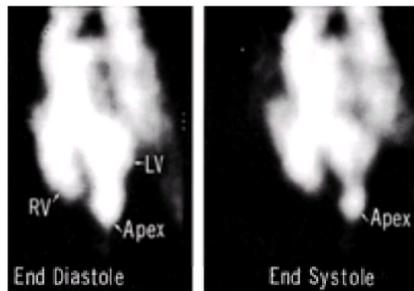

FIGURE 86.2. Equilibrium-gated radionuclide ventriculogram in the left anterior oblique view performed at rest in a patient with an apical aneurysm. The left panel shows end-diastole with the right ventricle (RV) and left ventricle (LV) and its apex. The right panel shows end-systole. In both the end-systolic and end-diastolic frames, a prominent bulge is noted at the apex of the LV, representing an aneurysm of moderate size.

Interpretation of the study begins with a qualitative impression of the movie display by an experienced reviewer to define morphologic abnormalities and evaluate regional and global ventricular function. Computer-aided quantitative analysis of the ventricle determines the ejection fraction. Other indexes of ventricular performance also can be derived, including end-diastolic and end-systolic volumes, and ejection and filling rates.

Gated blood pool studies are performed at rest, or serial studies are combined with exercise to evaluate the response of ventricular performance to stress. The most widely used exercise is performed with the patient semisupine and pedaling a bicycle, which increases the level of stress in a fashion similar to exercise treadmill testing. A 2-minute radionuclide ventriculogram acquisition is obtained at the end of each stage. In general, LVEF should increase with each progressive stage of exercise in patients free of cardiac pathology, reaching a value at least 10% higher than at rest. The development of segmental wall motion abnormalities suggests regional myocardial ischemia caused by coronary artery disease with an overall sensitivity of 86% to 90% and a specificity of 79% to 84%. An abnormal fall or blunting of LVEF is sensitive but not specific for coronary artery disease because untrained normal patients can show an abnormal LVEF response as they achieve their anaerobic threshold.

Gated blood pool studies have been used primarily to evaluate regional and global ventricular function at rest or with stress to diagnose and assess prognosis in patients with ischemic heart disease, valvular heart disease, hypertensive heart disease, congenital heart disease, and cardiomyopathy. In addition, serial studies can be performed over time to monitor left ventricular function in patients who have undergone cardiac transplantation and in those who are receiving cardiotoxic chemotherapeutic drugs (e.g., doxorubicin).

First-Pass Method

The first-pass method acquires images during the initial passage of an intravenously administered bolus of radiotracer through the central circulation and heart. A high-speed or multicrystal gamma camera that acquires images at a rate of 20 frames per second is positioned in the anterior or right anterior oblique projection to optimize separation of the atria from the ventricles. Because there is no background activity at the time of injection, the bolus can be viewed as it passes through the superior vena cava into the right atrium and ventricle, through the pulmonary vasculature, and, finally, into the left atrium and ventricle.

Qualitative analysis consists of visual inspection of sequential frames for abnormalities of morphology and for regional and global ventricular function. Quantitative analysis is performed by outlining the right or left ventricular regions of interest. Time-activity curves reflect radioactivity within the given chamber every 20 to 40 milliseconds, which corresponds to changes in chamber volume.

Gated Single-Proton Emission Computed Tomography Method

Due to the increased count density from 99m , it is clinically feasible to acquire tomographic radionuclide ventriculograms. Unlike the MUGA and first-pass techniques discussed above, which produce an image of the blood pool, the gated SPECT technique calculates ejection fraction from tomographic perfusion images by comparing the change in ventricular geometry between end-systole and end-diastole.

Tomographic perfusion images are acquired using the procedures discussed later in this chapter. The cardiac cycle is divided into approximately 8 to 16 frames. A computerized automated edge detection algorithm outlines the endomyocardial surface in the end-systolic and end-diastolic frames, and the LVEF is calculated using a modified Simpson's equation (Fig. 86.3).

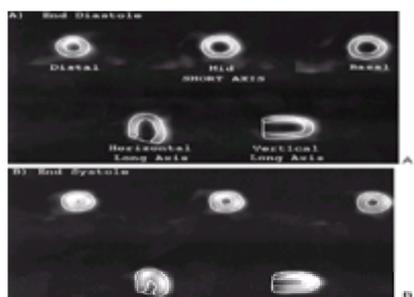

FIGURE 86.3. Gated single-proton emission computed tomography image frames at (A) end-diastole and (B) end-systole. The endocardial and epicardial surfaces have been outlined by a computerized automated edge detection program.

The added advantages to this technique include the assessment of regional wall thickening and calculation of myocardial mass. Because regional wall motion can be visualized, it is possible to determine myocardial viability (presence of thickening) and evaluate the significance of questionable perfusion defects—most commonly attenuation artifacts whereby seemingly fixed perfusion defects demonstrate normal wall motion. Thus, with gated SPECT techniques, it is possible to simultaneously determine perfusion and function with a single diagnostic study. However, the assessment of ventricular function obtained from this approach is determined during image acquisition, when the patient is under the camera in a resting state. If LVEF during exercise is desired, the first-pass technique should be employed.

Positron Emission Tomography

Ventricular function can be evaluated using an equilibrium approach after inhalation of a tracer dose of ^{11}CO . Carbon monoxide labels the red blood cells, allowing blood pool imaging.

ASSESSMENT OF MYOCARDIAL PERFUSION AND VIABILITY

Radionuclide methods to assess myocardial perfusion and viability rely on imaging the distribution of a tracer throughout the myocardium. Myocardium supplied by a stenosed vessel may appear normally perfused under resting conditions. Jeopardized myocardium usually is identified after some cardiovascular provocation accomplished by exercise or pharmacologic manipulation. Perfusion images obtained during stress or coronary vasodilatation are compared with images obtained under resting conditions to identify abnormalities in myocardial perfusion.

Thallium Imaging

Thallium 201 (^{201}Tl), a monovalent cation, behaves like ionic potassium and is actively transported across cell membranes by the Na^+/K^+ -ATPase pump. Because it is extracted by myocardial cells with high efficiency (80% to 90%), it is an ideal agent for studying perfusion patterns. Initial extraction of thallium by the myocardium depends on cellular viability and blood flow to myocytes. Thallium 201 is administered at peak exercise or during the peak coronary vasodilative effect of dipyridamole or adenosine (see discussion later in this chapter). Peak myocardial activity distal to a physiologically significant coronary artery stenosis is delayed relative to normally perfused tissue. Regional deficits in myocardial distribution of ^{201}Tl on initial images are related to reduced myocardial blood flow in ischemic viable tissue or nonviable tissue (e.g., acutely infarcted or scarred myocardium). Of all the perfusion agents, thallium uniquely demonstrates the phenomenon of redistribution. Redistribution involves the observation of a defect on initial images resulting from reduced perfusion during stress, following the administration of dipyridamole or adenosine, or even at rest. If the defect is related to underperfused yet viable myocardium, it “fills in” on delayed imaging (Color Fig. 86.1;). Redistribution may be better understood by considering myocardial and blood pool activity. Thallium accumulates within viable myocytes over time to a peak and then begins to decrease. Normally perfused myocardium peaks before ischemic myocardium. Clearance or washout of thallium from normal myocardium also is more rapid and parallels blood pool activity. Myocardium that is underperfused during stress achieves equilibrium with blood thallium by extracting thallium as a result of continued bathing by blood containing thallium, albeit at relatively low levels. Over time, the activity levels of normal and underperfused myocardium approach one another. If a sufficient delay (typically 3 to 4 hours) transpires to achieve equilibrium, ischemic but viable myocardium gradually accumulates thallium on serial imaging studies. The phenomenon of redistribution is the basis for ^{201}Tl imaging in differentiating myocardial ischemia (transient or “reversible” defect) from myocardial infarct or scar (persistent or “fixed” defect).

Exercise

Thallium 201 is administered most commonly during a graded exercise treadmill test. Dynamic changes during exercise include elevation of heart rate, blood pressure, and cardiac output, all of which affect myocardial oxygen consumption ($V\text{O}_2$). In addition, coronary blood flow increases because of elevation in $V\text{O}_2$. A mismatch in supply and demand occurs as increases in myocardial metabolic requirements during exercise exceed the ability of the vasculature to supply adequate oxygen and substrate. Myocardial ischemia results in diastolic and systolic left ventricular dysfunction, ischemic ECG changes, and, ultimately, the syndrome of angina pectoris. ^{201}Tl is administered intravenously as a bolus injection during peak exercise, or when the patient develops angina, worrisome ECG changes, or fatigue. Exercise is encouraged for an additional 30 to 60 seconds following injection, and initial imaging (planar or SPECT) should begin within 15 minutes of the termination of exercise. Regional differences in ^{201}Tl distribution are accentuated by exercise-induced regional differences in blood flow, which are proportional to the extent and severity of coronary artery disease. Delayed scans are performed 3 to 4 hours later. The images are evaluated qualitatively and quantitatively for changes in regions with decreased ^{201}Tl uptake between the initial and delayed images.

Additional information regarding ischemic myocardium can be gleaned from thallium imaging. Increased lung uptake of ^{201}Tl during exercise presumably reflects ischemia-induced left ventricular dysfunction. Stress-induced increases in pulmonary capillary wedge pressure and decreases in cardiac output correlate with increases in ^{201}Tl lung accumulation. However, patients with chronic obstructive lung disease also may demonstrate increased ^{201}Tl lung activity, which usually is observed on both the stress and delayed scans. Transient ischemic dilatation of the left ventricular cavity seen on early post-exercise imaging also is a marker of severe, often multivessel, disease. Left ventricular dilatation on early stress images is caused by diffuse subendocardial hypoperfusion, leading to an increase in cavity dimension.

The primary application of exercise–thallium studies is for detection, evaluation, and prognostication of patients with known or suspected coronary artery disease (Table 86.3). When qualitatively interpreted by experienced observers, planar exercise–thallium studies have a sensitivity and specificity of 82% and 88%, respectively, for detecting coronary artery disease. Quantitative planar analysis improves sensitivity to 89%, whereas SPECT acquisitions improve sensitivity to 94% to 95%. In some studies, however, an improved sensitivity with SPECT is offset by a reduction in specificity. Because exercise studies always are performed with ECG monitoring, ECG and radionuclide studies together substantially improve the reliability of either study alone. One of the major roles of exercise–thallium testing is risk stratification of patients for future cardiac events (e.g., myocardial infarction, ischemia-related death). The future cardiac event rate is best predicted by the extent and reversibility of perfusion defects. Patients with normal stress thallium perfusion studies are at low risk (0.1% to 0.9% per year) for subsequent events, whereas patients with abnormal thallium scans (with reversible or fixed defects, or both) are at higher risk. A poor prognosis has been reported in patients with a greater number of abnormal segments (especially reversible defects). Finally, exercise–thallium testing is used increasingly as an adjunct to coronary angiography to determine the significance of an angiographically demonstrated coronary stenosis. Whereas coronary angiography only demonstrates coronary arterial morphologic abnormalities, ^{201}Tl distribution relates to the physiologic significance of a stenosis. A radionuclide myocardial perfusion study often is used in concert with coronary angiography to help indicate whether revascularization may be beneficial.

- Diagnosis of coronary artery disease
 - As an adjunct to exercise-ECG testing in patients with prior positive stress ECGs having nonanginal or no pain, or in patients with stress-induced angina without ECG changes
- Assessment of prognosis in patients with coronary artery disease
- Assessment of the functional significance of angiographically documented stenoses
- Risk stratification after infarction before hospital discharge
- Assessment of adequacy of therapy or revascularization
- Situations in which the stress ECG alone is unreliable
 - Patients with abnormal ST segments and T waves on baseline ECG
 - Patients taking digitalis
 - Patients with left ventricular hypertrophy
 - Patients with ventricular pacemakers
- Evaluation of viability and planning for revascularization

ECG, electrocardiogram.

TABLE 86.3. INDICATIONS FOR RADIONUCLIDE-EXERCISE PERFUSION IMAGING

Dipyridamole and Adenosine

Evaluation of coronary artery disease by exercise testing relies on the patient's ability to achieve an adequate level of exercise to produce a technically acceptable study. However, many patients with suspected coronary artery disease cannot achieve a diagnostic level of exercise because of poor physical conditioning, advanced pulmonary disease, peripheral vascular disease, or physical debilitation resulting from arthritic, orthopedic, or neurologic conditions. Pharmacologic agents, such as dipyridamole or adenosine, can be used as an alternative to exercise. Dipyridamole is a coronary artery vasodilator that acts to inhibit adenosine uptake or to stimulate the adenosine receptor located on the coronary endothelium. In normal coronary vessels, dipyridamole and adenosine can cause up to a fivefold increase in myocardial blood flow, whereas in diseased vasculature, blood flow rises to a lesser extent or sometimes even decreases. These vasodilators usually cause only a mild increase in myocardial oxygen demand resulting from a mild increase in heart rate and a decrease in blood pressure. On occasion, the resulting distribution in blood flow between normal and jeopardized myocardium leads to a decrease in blood flow to the jeopardized myocardium. This situation occurs when the resistance

to blood flow becomes substantially lower in the normal vessels, “stealing” blood from the jeopardized myocardium and leading to ischemia. The heterogeneity in ^{201}Tl distribution induced by dipyridamole between normally perfused and jeopardized myocardium is the basis for the detection of stenoses. Adenosine also is a potent coronary vasodilator and has been used in place of dipyridamole in conjunction with myocardial perfusion imaging.

Dipyridamole is administered intravenously over a 4-minute interval (0.14 mg per kg per minute). Blood pressure and heart rate should be measured frequently to ascertain the hemodynamic response to dipyridamole. Two to three minutes after the infusion of dipyridamole is complete, ^{201}Tl is injected intravenously as a bolus. Initial and delayed imaging is performed, and images are interpreted qualitatively and quantitatively in the same manner as exercise studies. A pharmacologic study using adenosine instead of dipyridamole is performed in a similar fashion except that adenosine is administered as a continuous intravenous infusion over 6 minutes (140 μg per kg per minute) and the radionuclide is administered 3 to 4 minutes into the infusion.

The body of literature is greater with dipyridamole than adenosine. The sensitivity and specificity for the detection of coronary artery disease using the dipyridamole-thallium approach is similar to that of exercise thallium studies. Although the ECG results obtained during dipyridamole-thallium studies are not of much clinical importance, the presence of diagnostic ST-segment and T-wave abnormalities in the presence of angina is specific for important coronary artery disease. On the other hand, exercise-ECG testing in conjunction with radionuclide perfusion imaging has the advantage of providing both image and ECG data, enhancing the diagnostic power of the test.

Indications and applications for dipyridamole-thallium testing are similar to those for exercise-thallium testing. However, there are additional situations in which this study appears to be indicated ([Table 86.4](#)). Several studies have indicated that patients scheduled to undergo peripheral vascular surgery may benefit substantially from preoperative dipyridamole-thallium testing because these patients have (1) a high prevalence of coexistent coronary artery disease, which often is asymptomatic, and (2) limited exercise capacity because of claudication. Patients with abnormal perfusion scans (especially those demonstrating redistribution) are at increased risk for perioperative cardiac ischemic events and should be considered for perioperative invasive cardiac monitoring or preoperative cardiac catheterization. Exercise-thallium studies performed in patients with left bundle-branch block have been reported to demonstrate perfusion defects (especially in the septal regions) in the absence of coronary artery disease (false-positive results), resulting in lower specificity. These defects are less likely to occur with dipyridamole, and dipyridamole-thallium studies are preferred in patients with left bundle-branch block. Dipyridamole also may be administered safely to patients in the early postinfarction period, who may be unable to perform submaximal exercise-ECG testing before hospital discharge. Although normal perfusion images obtained during dipyridamole-thallium testing identify a low-risk group after infarction, redistribution in the infarct zone is reported to be a significant predictor of in-hospital ischemic cardiac events.

- As a substitute for exercise for patients who are unable to exercise (e.g., those with advanced pulmonary disease, peripheral vascular disease, physical debilitation from arthritic, orthopedic, or neurologic conditions)
- As a substitute for exercise for patients who can exercise but are unlikely to achieve a diagnostic level of exercise (e.g., those who are obese or sedentary, are receiving β -blocker therapy, or are elderly)
- In the presence of left bundle-branch block
- As preoperative risk stratification for patients scheduled to undergo surgery for peripheral vascular disease or aneurysm repair
- In the presence of a fixed-rate ventricular pacemaker

TABLE 86.4. INDICATIONS FOR RADIONUCLIDE-DIPYRIDAMOLE PERFUSION IMAGING

Dobutamine

Dobutamine is a positive inotropic agent that stimulates both α - and β -adrenergic receptors. It produces a marked increase in contractility, a modest increase in heart rate, and, consequently, a significant increase in myocardial oxygen consumption leading to ischemia in jeopardized myocardium. Dobutamine-thallium imaging may be an alternative strategy to induce stress in patients with obstructive lung disease in whom dipyridamole is contraindicated. The overall sensitivity (91%) and specificity (79%) of this approach is similar to that reported for the other stress tests.

Study at Rest

Thallium 201 administered at rest is reported to be of value in patients with unstable angina or myocardial infarction for the detection of severe coronary stenoses and evaluation of myocardial viability. The myocardial images often are of lower quality and consequently may be more difficult to evaluate compared with exercise or dipyridamole studies. Segmental contraction abnormalities and ejection fractions have been reported to improve after revascularization in patients who demonstrated resting ^{201}Tl defects that redistributed.

Viability

When a perfusion image defect demonstrates redistribution, it can be said to be viable with a high degree of confidence. On the other hand, up to 50% of defects that persist over a 3- to 4-hour interval have been reported to be viable (confirmed using PET techniques), even though the “fixed” defect should represent nonviable tissue. One reason this occurs is because of a low concentration of blood thallium leading to slower redistribution, which could be incomplete within the 3- to 4-hour period between early and delayed images. Imaging substantially later (e.g., 24 hours) allows adequate time for redistribution to occur to assess viability in defects that appear to be irreversible or fixed on the 4-hour delayed images. Because redistribution of thallium depends on thallium blood levels, a second strategy to promote “fill-in” of fixed defects in viable myocardium is to use a second injection to boost thallium blood pool concentration. A second injection or “reinjection” method has been reported during which a second dose of thallium (usually 1 mCi) is given to augment thallium blood levels after the 3- to 4-hour delayed images have been acquired. Reinjection images are obtained 15 minutes later. If the 3- to 4-hour fixed defect fills in on late or reinjection images, viability has been documented. When the reinjection method is used, the entire study can be completed in a day.

Technetium-Based Agents

Because of the lower photon energy and longer half-life of ^{201}Tl , imaging agents labeled with $^{99\text{m}}\text{Tc}$ have been developed and produce images with higher resolution and contrast compared with ^{201}Tl . Two reasons account for this improved image quality. The emitted photon energy of $^{99\text{m}}\text{Tc}$ (140 keV) is higher than that of ^{201}Tl , and the half-life (6 hours) is shorter, making the administration of doses with more activity (25 to 35 mCi) feasible.

Technetium $^{99\text{m}}\text{Tc}$ Sestamibi

Sestamibi (MIBI) belongs to a family of chemicals known as the isonitriles, which have varying abilities to enter and remain within the myocyte. It is believed that MIBI passively enters myocardial cells (unlike ^{201}Tl) and is sequestered within mitochondria as a result of a large negative transmembrane potential. In contrast to ^{201}Tl , MIBI exhibits minimal redistribution and is believed to be less useful for evaluating viability. However, recent studies have shown that MIBI may play an increasing role in determining viability. Image data obtained from MIBI are similar to those obtained from thallium, and the sensitivity (94%) and specificity (77%) of MIBI for the detection of coronary artery disease or identification of individual coronary artery stenoses are comparable.

Several applications of MIBI are recognized ([Table 86.5](#)). Patients in whom soft-tissue attenuation may be problematic, such as obese patients or female patients with large breasts, should be considered for MIBI protocols. MIBI also may be more sensitive for the detection of coronary artery disease in women who have small hearts because of the increased resolution it achieves. Although several of its characteristics make MIBI attractive, it has some potential limitations. MIBI is believed to be less useful than ^{201}Tl for the demonstration of myocardial viability. The fractional extraction of MIBI is lower than that of ^{201}Tl . Because MIBI is excreted through the enterohepatic route, it localizes in splanchnic viscera and can confound the interpretation of inferior and apical myocardial segments when visceral activity is adjacent

to the heart.

- Female patients, especially those with large breasts or small hearts
- Patients with a low likelihood of disease (such patients receive high-dose sestamibi during exercise on the first day of a 2-day protocol)
- Obese patients in whom attenuation might be problematic
- Patients who require a combined perfusion-left ventricular function study
- Patients who require assessment of myocardial perfusion at the time of an acute ischemic episode

TABLE 86.5. SITUATIONS IN WHICH TECHNETIUM^{99m} TC SESTAMIBI MIGHT BE THE RADIOTRACER OF CHOICE

Because MIBI demonstrates clinically insignificant redistribution, images must be obtained using two separate injections. Two protocols for performing a MIBI perfusion study have been reported: a same-day protocol and a 2-day protocol. For the same-day protocol, a resting study is performed first, after the administration of a low dose of MIBI (8 to 12 mCi). After a delay of 2 to 3 hours, a second, higher dose of MIBI (20 to 30 mCi) is administered during peak exercise or after an infusion of dipyridamole or adenosine. With the 2-day approach, the patient receives a high dose of MIBI at peak stress and undergoes imaging about 30 to 60 minutes later. If the scan is abnormal, the patient returns on another day for resting imaging. However, if the perfusion pattern is normal, the patient need not return on the second day for a resting imaging study.

A so-called hybrid or dual-isotope technique uses ²⁰¹Tl and MIBI in a convenient, efficient, and practical manner whereby the entire study can be completed within 2 hours. Initially, the patient receives thallium in the resting state and imaging begins about 5 to 10 minutes later. Then, the patient exercises, is injected with MIBI, and undergoes imaging. There is no contamination by ²⁰¹Tl in MIBI stress images because the gamma camera can discriminate photons of differing energies. Exercise (MIBI) and resting (thallium) images are compared to determine the fate of exercise-induced defects with an overall sensitivity of more than 90% and a specificity of 75% for the diagnosis of coronary artery disease (Color [Fig. 86.2](#)).

As a result of high count rates from MIBI, it is possible to assess myocardial perfusion and left ventricular performance using a single radionuclide. The LVEF can be determined using two approaches: gated SPECT and first-pass. Using principles discussed earlier, gated SPECT acquires about eight separate tomograms during a cardiac cycle. Tomograms can be displayed in a continuous loop of ventricular contraction and relaxation.

Other Technetium-Based Agents

Technetium-99m-teboroxime is not a widely used radiotracer, largely because of its elimination and washout characteristics. Like MIBI, it is slowly cleared through the hepatobiliary system, which can interfere with evaluation of the inferior left ventricular wall. Sensitivity decreases if a conventional single-detector gamma camera is used to acquire images. Optimal imaging is accomplished using a multiple-detector gamma camera so that sufficient counts can be obtained before washout (within about 6 minutes). As instrumentation moves toward multiple-detector systems, teboroxime may gain further popularity. However, teboroxime has unique application using a single-detector camera in determining the patency of an infarct-related artery after thrombolysis because its kinetics mimic a pure flow tracer.

Technetium-99m-tetrafosmin is a myocardial perfusion agent with kinetics similar to that of MIBI; however, it offers the advantage of less concentration in splanchnic viscera, thus potentially less interference with left ventricular inferior wall activity. It allows imaging shortly after administration.

Technetium-99m-N-NOET [bis-(N-ethoxy, N-ethyl dithiocarbamate) nitrido] is a new, neutral, lipophilic, myocardial perfusion agent that combines the radiophysical properties of ^{99m}Tc and the redistribution kinetics of ²⁰¹Tl. These properties are optimal for perfusion assessment by providing high-quality images using a single injection of radionuclide.

Positron Emission Tomography

Regional myocardial blood flow can be evaluated using positron-emitting radiotracers, including ¹³N-labeled ammonia, ¹⁵O-labeled water, and ⁸²Rb. These agents have very short half-lives, on the order of minutes. Multiple injections are used to assess perfusion under various physiologic states (at rest, during exercise, or after the administration of dipyridamole or adenosine). Aside from high-resolution images and the ability to perform multiple studies over a short period, one advantage of PET is the ability to measure myocardial blood flow in milliliters per second per gram of tissue. The PET and SPECT imaging modalities have similar sensitivities and specificities for detecting coronary artery disease. Unfortunately, the equipment and operating costs of PET are substantially more expensive, and it appears that single-photon methods will prevail.

Assessment of Myocardial Metabolism

Myocardial metabolic changes can be visualized using radionuclide methods. During ischemia, myocardial metabolism changes from the oxidation of fatty acids to glycolysis. Labeled fatty acids and glucose analogs have been used to assess changes in myocardial metabolism. The only single-photon method available for the evaluation of fatty acid metabolism uses fatty acids labeled with ¹²³I. PET radiotracers are used more widely to assess the myocardial metabolism. Palmitic acid labeled with ¹¹C can assess transient ischemia and the extent of infarction. An elegant approach to assess myocyte glucose utilization, and therefore viability, uses ¹⁸F-fluorodeoxyglucose. ¹⁸F-fluoro-deoxyglucose accumulates in viable myocardium, which metabolizes glucose. This approach is particularly helpful in assessing viability in regions of asynergic myocardium for which revascularization may be beneficial. If ¹⁸F-fluorodeoxyglucose accumulates in a region with a perfusion defect (determined by ¹³N-ammonia or ⁸²Rb), the region is ischemic but viable. These applications continue to be important primarily for research purposes and are not used widely because of the limited availability and cost of PET instrumentation.

Assessment of Myocardial Necrosis

Technetium-99m-pyrophosphate binds to calcium salts released in regions of acute myocardial necrosis. Usually, adequate deposition of ^{99m}Tc-pyrophosphate for clinical detection occurs between 24 and 72 hours after the onset of infarction. This study is interpreted qualitatively by comparing the degree of uptake of the agent by infarcted myocardium with that of adjacent bony structures. Pyrophosphate imaging is indicated for the detection of myocardial infarction when ECG and cardiac enzyme analyses are nondiagnostic.

Radiolabeled cardiac myosin-specific antibody has been developed and is more specific than pyrophosphate for identification of areas of myocardial necrosis. Uptake occurs within 6 hours of the onset of infarction.

MAGNETIC RESONANCE METHODS

Magnetic resonance (MR) is the newest imaging technology. Magnetic resonance imaging (MRI) has excellent temporal and spatial resolution and is ideally suited for visualizing the heart and blood vessels ([Table 86.6](#)). Advantages of MRI are its ability to acquire images noninvasively in the absence of ionizing radiation, in any tomographic plane, without interference from surrounding bone or soft tissues. MR spectroscopy (MRS) provides a means of biochemically characterizing tissues by obtaining spectra of metabolites containing MR-sensitive nuclei.

Assessment of:

- Right and left ventricular function (global and segmental)
- Right and left ventricular volumes
- Aortic disease (e.g., aneurysm, dissection, coarctation)

Central pulmonary arteries

- Complex congenital heart disease
- Cardiac and paracardiac masses
- Pericardial disease
- Valvular regurgitation
- Peripheral and cerebral vasculature

TABLE 86.6. INDICATIONS FOR A CARDIOVASCULAR MAGNETIC RESONANCE IMAGING STUDY

INSTRUMENTATION

The MR instrument (scanner) consists of a large, cylindrical supercooled magnet. The patient is placed in the supine or prone position within the bore of the magnet. This magnet creates a strong magnetic field. Gradient coils are positioned along the length of the magnet and vary the strength of the magnetic field from one point to another. The body coil, acting as an antenna, surrounds the inside of the bore and transmits and receives radiofrequency waves. An operator's console and computer are located in an adjacent room. The computer executes the operator's imaging instructions, sorts out the complex signal received from the patient, and generates the final images.

MRI is based on observing the behavior of certain atoms within a magnetic field. Three steps are necessary for imaging. First, with the patient placed in the magnetic field, MR-sensitive nuclei become aligned with the field. Second, radiofrequency energy is applied to perturb the aligned nuclei. Finally, a radiowave signal is received from the perturbed nuclei as they return to their original lower-energy state (i.e., resting orientation).

Atoms and the External Magnetic Field

Atomic nuclei containing odd numbers of protons, neutrons, or the sum of these two possess nuclear spin, that is, they spin about their axis in the same way that the earth spins. The electrical charge associated with each atom also spins, creating a tiny magnetic field. These atoms may be thought of as tiny "bar magnets" that can interact with the magnetic field and radiowaves of the MR scanner. Hydrogen nuclei (or protons) possess this characteristic and are the predominant atomic species in the human body. Hydrogen is the nucleus that is used to generate MR images. Normally, these hydrogen "bar magnets" are oriented randomly within the body. When exposed to an external magnetic field, they align with the magnetic field. As hydrogen nuclei spin, they wobble, or precess, just as a toy top wobbles as it spins. The unique frequency of the wobble (precession) is governed by the Larmor frequency equation: $\omega = \gamma M$, where ω = frequency, γ = gyromagnetic ratio, and M = field strength. Each nuclear species has a unique gyromagnetic ratio, and at a field strength of 1.5 T, ^1H hydrogen nuclei precess at 64 MHz. By using the gradient coils to produce a graded magnetic field, atoms in different locations precess at slightly different frequencies. For example, if the field strength is less at the head compared with the feet, the precession frequency at the head is slower than at the feet. Hydrogen atoms are localized within the body based in part on this frequency, providing the basis for tomographic MRI.

Radiofrequency Pulse and Relaxation

Image data are obtained by recording the magnitude and rate of relaxation of precessing hydrogen nuclei after the application of radiofrequency energy (radiowaves). Stimulation with radiofrequency energy causes the hydrogen nuclei to "tip over" and become misaligned with the external magnetic field, and to synchronize their precession. The radiofrequency energy is applied as a pulse, and once it is terminated, the perturbed nuclei return or relax back to their original alignment in the magnetic field and their incoherent, random precession. As they relax, energy is released or emitted that is detected by the body coil (antenna). Relaxation is dependent on the interaction of adjacent nuclei, the local chemical and electrical environment, and the external magnetic field. Different tissues relax at different rates, providing contrast between tissues on MR images.

Gating and Pulse Sequences

Cardiovascular MRI applications require gating, or synchronization with the cardiac cycle, because data from repeated cardiac cycles are needed to generate images. Gating enhances image quality and prevents blurring by sampling data during comparable parts of the cardiac cycle. A pulse sequence is a series of gradient and radio-frequency pulses that are generated by the scanner to excite appropriate nuclei to acquire the image data. The two primary sequences used in cardiac imaging are the spin-echo and the gradient-echo pulse sequences. The spin-echo, or "dark blood," sequence provides images with excellent spatial resolution and is used primarily to assess anatomy and morphology. The gradient-echo, or "bright blood," sequence samples multiple data points over a cardiac cycle to improve temporal resolution. Sequential images obtained throughout the cardiac cycle are displayed in movie mode as a continuous loop of ventricular contraction and relaxation, so-called cine MRI. Regional and global ventricular function can be evaluated using this approach. These sequences produce high-quality images with excellent intrinsic contrast between intracavitary blood and the myocardium.

APPLICATIONS

Assessment of Cardiac Anatomy and Morphology

Magnetic resonance imaging (MRI) is unique in its ability to capture an image of the heart in any tomographic plane selected by the operator. Common plane orientations used in cardiac imaging include vertical long axis, horizontal long axis, and short axis ([Fig. 86.4](#)). Chamber sizes and wall thickness can be measured and used to determine myocardial mass. The location, extent, and attachment of intracardiac and paracardiac masses and thrombi can be demonstrated by MRI.

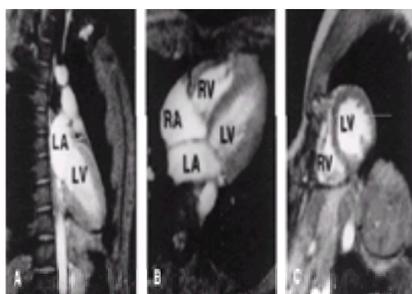

FIGURE 86.4. Mid-systolic, gradient-echo magnetic resonance images of the heart in the (A) vertical long axis, (B) horizontal long axis, and (C) midventricular short axis orientations. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Magnetic resonance imaging is invaluable in assessing congenital heart disease. Venoatrial, atrioventricular, and ventriculoarterial connections are readily identified, as are chamber morphology, position, and their relation to the great vessels and other visceral organs. Because MRI is flow-sensitive, atrial and ventricular septal defects can be detected by the presence of turbulent flow using the cine MRI technique (see discussion of turbulent flow later in this chapter). Computer-assisted

three-dimensional reconstruction of multi-slice images produces a visual model of complex cardiac anatomy that can be rotated and viewed from any perspective.

Assessment of Ventricular Function

Global and regional right and left ventricular systolic function can be measured from cine MRI. The ejection fraction is calculated from tomographically determined end-systolic and end-diastolic volumes using the area-length method with long-axis images ([Fig. 86.5](#)) or Simpson's rule with serial short-axis images. Unlike other imaging modalities, MRI can provide an accurate evaluation of right ventricular function without making geometrical assumptions regarding the shape of the right ventricle. Regional wall motion can be analyzed with cine MRI. Ventricular remodeling and myocardial thinning after myocardial infarction can be readily appreciated.

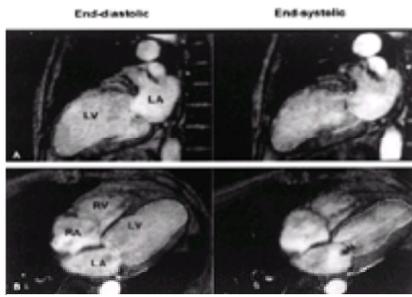

FIGURE 86.5. End-diastolic and end-systolic gradient echo images of the heart in the **(A)** vertical and **(B)** horizontal long-axis orientations. The left ventricular ejection fraction (LVEF) is determined using the area-length method. Note that the endocardial-blood pool border is outlined to determine changes in cavity size. This patient has had an anterior myocardial infarction with akinesis of the antero lateral wall and dyskinesis of the apex.

Valvular Assessment

The received signal from the body (after excitation from the radiofrequency pulse sequence) has both amplitude and phase. Turbulent flow appears as loss of signal (black) in gradient-echo images resulting from randomization of the phases of the blood in the turbulent jet. Accordingly, a regurgitant valve is identified by a jet of signal loss in the respective receiving chamber ([Fig. 86.6](#)). The degree of regurgitation can be measured by the size of the jet, the size of the chamber receiving the regurgitant flow, the persistence of the jet during the cardiac cycle, and the size and persistence of the proximal convergence zone. ²

Turbulent flow also results from stenotic valves. Information similar to that derived from Doppler echocardiography can be obtained by a magnetic resonance technique known as phase velocity mapping. Whereas amplitude data are used to construct anatomical images, phase images (or maps) determine the flow velocity of precessing hydrogen atoms passing through a given plane. Depending on the scanner's specifications, velocities up to 6 to 8 m per second can be measured, making it possible to diagnose severe valvular stenoses.

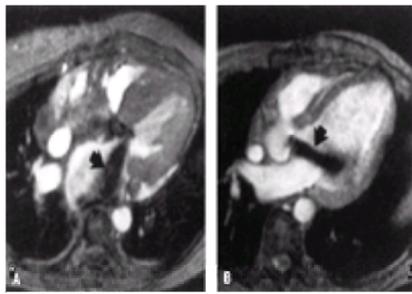

FIGURE 86.6. **A:** Mid-systolic, gradient-echo horizontal long axis image of the heart in a patient with severe mitral regurgitation (*arrow*). **B:** Mid-diastolic, gradient-echo left ventricular outflow tract view of the heart in a patient with severe aortic regurgitation (*arrow*).

Assessment of the Pericardium

Because magnetic resonance images can be acquired in any plane, the full extent of pericardial effusions can be defined. Some generalities about fluid composition can be made based on signal intensity. Magnetic resonance imaging can aid in the diagnosis of constrictive pericarditis by measuring the thickness of the pericardium, which normally should be less than 4 mm.

Vascular Imaging and Angiography

Many believe that MRI has become the gold standard for evaluating stable thoracic aortic disease. Intimal flaps, thrombus formation, origin of the tear, involvement of the brachiocephalic vessels, and the presence of aortic regurgitation or pericardial effusion all can be demonstrated during an MRI examination for aortic dissection ([Fig. 86.7A](#)). Furthermore, cine MRI can identify flow within the true and false lumina. Three-dimensional reconstruction of the aorta from multislice transaxial images is helpful in planning surgical repair of aortic dissection and aneurysms ([Fig. 86.7B](#)). In coarctation of the aorta, the dimensions of the narrowing and the pressure gradient can be measured. In addition to producing images of the aorta, magnetic resonance angiography of the carotids ([Fig. 86.8A](#)) and peripheral vasculature ([Fig. 86.8B](#)) can be performed to evaluate the severity of vascular stenoses and the nature of the distal vessel.

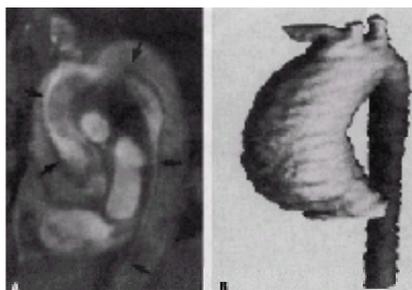

FIGURE 86.7. **A:** Magnetic resonance angiogram of the aorta in a left anterior oblique projection in a patient with a type I dissection (*arrows*). **B:** Computer-assisted three-dimensional reconstruction from multiple transaxial magnetic resonance images of an aorta with an aneurysm in the ascending portion.

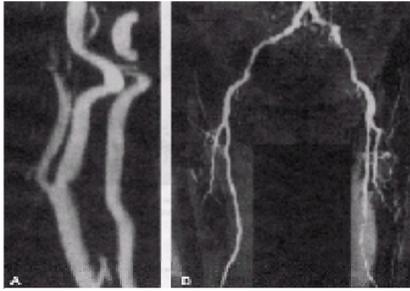

FIGURE 86.8. A: Magnetic resonance angiogram of the carotid and vertebral arteries. There is about a 30% narrowing of the proximal internal carotid artery. **B:** Magnetic resonance angiogram of the lower extremities in a patient with diffuse atherosclerotic disease. Severe disease is noted in the left iliofemoral arteries and bilaterally in the distal anterior tibial arteries. It is important to note that these angiograms are obtained without the administration of contrast agents since intrinsic contrast is provided by flowing blood.

FUTURE APPLICATIONS OF CARDIOVASCULAR MAGNETIC RESONANCE IMAGING

Given the rapid development of cardiovascular MRI, continual reference to the literature is necessary to remain current on this powerful diagnostic modality. With these developments, magnetic resonance methods should provide an approach to the assessment of many additional aspects of cardiac and vascular pathology.

Coronary Angiography

One of the most important potential MRI applications is magnetic resonance coronary angiography. The coronary arteries can be imaged in-plane or viewed using computer-aided projection techniques or three-dimensional reconstruction (Fig. 86.9). Coronary magnetic resonance angiography is limited by artifacts and alignment errors resulting from cardiac and respiratory motion, and by interference of high-signal epicardial fat, which reduces artery contrast. As this technique improves, it should be useful in screening for proximal or mid-vessel coronary artery disease in patients who otherwise might be referred for conventional X-ray coronary angiography.

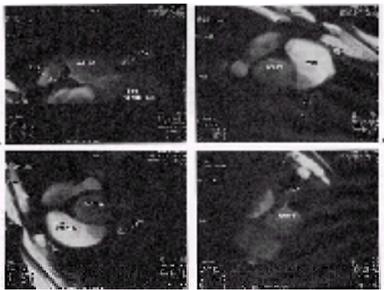

FIGURE 86.9. Coronary magnetic resonance angiograms of the **(A)** right (RCA) and left (LCA) coronary arteries arising from the aortic root, **(B)** left anterior descending (LAD) artery, **(C)** left circumflex (LCx) artery, and **(D)** right coronary artery (RCA).

Myocardial Function Assessment with Dobutamine

In a manner similar to stress echocardiography, ischemic wall motion changes can be assessed by cine MRI during an infusion of dobutamine. The relatively longer time required to obtain magnetic resonance images is the disadvantage of this technique. As faster MRI methods become available, this disadvantage probably will disappear.

Myocardial Perfusion Imaging

Contrast-enhanced MRI to evaluate myocardial perfusion uses a first-pass technique during which a bolus of a magnetic resonance contrast agent is injected intravenously and serial magnetic resonance images track the bolus through the cardiac chambers and finally into the myocardium. Paramagnetic resonance contrast agents are chelates of gadolinium. Gadolinium atoms have electrons with unpaired spins. These generate a local magnetic moment that shortens relaxation times in tissues perfused by blood containing gadolinium. In the presence of obstructive coronary stenosis, inhomogeneity in myocardial perfusion is induced after an infusion of dipyridamole. Ischemic myocardium supplied by a stenotic coronary artery has a lower peak signal intensity (which is proportional to the delivery of contrast medium) and a delay in the appearance of contrast.

Spectroscopy

Spectroscopy increasingly is being used to assess myocardial metabolism. Other nuclei besides hydrogen also possess nuclear spin, including ^{31}P , ^{13}C , ^{19}F , and ^{23}Na . Magnetic resonance spectroscopy acquires the spectrum of a particular nucleus in a selected region of tissue. For example, the bioenergetic profile of the myocardium can be investigated by acquiring a phosphorus spectrum that demonstrates phosphocreatine, inorganic phosphate, and adenosine triphosphate levels. Spectroscopy has been used to detect ischemia during isometric hand-grip exercise by demonstrating reductions in the phosphocreatine-to-adenosine triphosphate ratio in jeopardized myocardium in patients with coronary artery disease.

The Comprehensive Magnetic Resonance Cardiovascular Examination

Ultimately, it should be possible for magnetic resonance methods to provide a comprehensive imaging study that includes assessment of cardiac morphology and ventricular function, coronary angiography, and myocardial perfusion imaging. Such an examination would obviate the need for multiple other imaging studies and would make magnetic resonance evaluation for coronary artery disease highly cost-effective.

CHAPTER 87: DIAGNOSTIC AND THERAPEUTIC CATHETERIZATION

RICHARD A. LANGE AND L. DAVID HILLIS

[Application](#)
[Hemodynamic Measurements](#)
[Angiography](#)
[Assessment of Valvular Heart Disease](#)
[Intracardiac Shunting](#)
[Interventional Catheterization](#)

Over the past 40 years, cardiac catheterization has greatly improved our understanding of cardiovascular anatomy, physiology, and pathophysiology. In its early years it was performed sparingly and with substantial risk; however, with increased operator experience and technical improvements, its associated morbidity and mortality have fallen substantially. Today diagnostic catheterization is performed with minimal risk, and therapeutic catheterization (percutaneous coronary revascularization and balloon valvuloplasty) is performed without incident in most patients. Thus, cardiac catheterization plays a pivotal role in the evaluation of patients with suspected or known cardiac disease; in addition, it has become an important therapeutic alternative to cardiac surgery in many patients who require nonmedical therapy.

APPLICATION

INDICATIONS

Diagnostic cardiac catheterization is appropriate under several conditions. First, it is often performed to confirm or to exclude the presence of a cardiac condition that is suspected from the patient's history, physical examination, or noninvasive evaluation. In such a circumstance, it allows assessment of the presence and severity of cardiac disease. For example, in a person with progressive angina pectoris or a positive exercise test, coronary angiography allows the physician to visualize the coronary arteries sufficiently to assess the presence and extent of coronary artery disease. Second, catheterization is often helpful in the patient with a confusing or difficult clinical presentation in whom the noninvasive evaluation is inconclusive. For instance, a hemodynamic evaluation or coronary angiography may be useful in the patient with unexplained dyspnea. Third, in a patient being considered for corrective cardiac surgery, catheterization often is performed to assess the suspected abnormality and to exclude associated conditions. For example, catheterization may be performed in the patient with valvular heart disease to evaluate the severity of the valvular abnormality, its influence on overall cardiac function, and the presence of concomitant coronary artery disease that may require revascularization at the time of valvular surgery. Fourth, data obtained at catheterization may provide prognostic information that is helpful in guiding therapy. Such is the case, for example, in the patient with cardiomyopathy, in whom the hemodynamic data obtained at catheterization are used to guide medical therapy and to assess the need for and timing of cardiac transplantation.

Therapeutic catheterization is appropriate in several circumstances. Percutaneous coronary revascularization (angioplasty, atherectomy, or endovascular stenting) may be indicated in the patient with symptomatic atherosclerotic coronary artery disease and suitable coronary anatomy. Because both percutaneous coronary revascularization and coronary artery bypass grafting often are effective in such patients, the factors that influence which procedure is selected include coronary anatomy, the presence of concomitant comorbid medical conditions (which may increase the risk of either procedure), and patient preference. In the patient with symptomatic valvular stenosis, percutaneous balloon valvuloplasty may be performed. With symptomatic, isolated pulmonic stenosis, it is the treatment of choice. With mitral stenosis and favorable valvular anatomy, it is a viable alternative to surgery. In the subject with symptomatic aortic stenosis in whom valve replacement has an unfavorable risk/benefit ratio because of comorbid disease (i.e., chronic obstructive pulmonary disease, hepatic or renal disease, or malignancy), percutaneous aortic balloon valvuloplasty may be considered.

CONTRAINDICATIONS

The only absolute contraindication to catheterization is the refusal of a mentally competent patient to provide informed consent. Relative contraindications ([Table 87.1](#)) mostly involve conditions in which the risks of the procedure are increased or the information obtained from it is potentially unreliable. In these circumstances, the benefits of the data obtained at catheterization must be weighed against the procedure's increased risks. Catheterization usually is not performed in the patient who refuses therapy for the condition for which diagnostic catheterization is recommended.

- Decompensated heart failure (e.g., pulmonary edema)
- Uncontrolled ventricular irritability
- Uncontrolled systemic arterial hypertension
- Acute or severe renal insufficiency
- Difficulty with vascular access
- Electrolyte imbalance (hypo- or hyperkalemia)
- Digitalis intoxication
- Active infection or febrile illness
- Uncorrected bleeding diathesis
- Severe anemia
- Active bleeding from internal organ
- Severe allergy to radiographic contrast material
- Mental incompetence

TABLE 87.1. RELATIVE CONTRAINDICATIONS TO CARDIAC CATHETERIZATION

COMPLICATIONS

Because catheterization is an invasive procedure, its use is associated with certain major and minor risks ([Table 87.2](#)). The incidence of complications is higher with therapeutic procedures than with diagnostic ones, but in general either can be performed safely with little morbidity or mortality. Complications are more likely to occur in certain patient groups, including those of advanced (more than 70 years) or very young (less than 1 year) age, marked functional impairment (class IV angina or heart failure), severe left ventricular dysfunction or coronary artery disease (particularly left main disease), severe valvular disease, severe comorbid medical conditions (renal, hepatic, or pulmonary disease), and a history of an allergic reaction to radiographic contrast material. Of those with a known allergy to contrast material, only about 15% have an adverse reaction with its repeat administration, and most of these reactions are minor (e.g., urticaria, nausea, vomiting). In most patients with a previous allergic reaction to radiographic contrast material, angiography can be performed safely, but premedication with glucocorticosteroids and antihistamines and the use of nonionic contrast material are usually recommended.

Complication	Incidence (%)
Major Complications	
Death	0.1
Cerebrovascular accident	0.07
Myocardial infarction	0.07
Arrhythmias (life-threatening)	0.5
Vascular compromise	0.5–1.5
Anaphylaxis (contrast allergy)	0.007
Minor Complications	
Hives	2–3
Nausea/vomiting	5
Vertigo reactions	3

calculate pulmonary blood flow using the formula:

$$\text{Cardiac output (L/minute)} = \frac{\text{oxygen consumption (mL/minute)}}{\text{arteriovenous oxygen difference (mL/L)}}$$

In the absence of intracardiac shunting, pulmonary and systemic blood flows are similar, so that the Fick method provides a measurement of systemic blood flow. The results of the Fick method are most reliable when the arteriovenous oxygen difference is wide (e.g., a low cardiac output) and least reliable when it is narrow (e.g., a high cardiac output; [Table 87.4](#)).

Method	Most Reliable	Least Reliable
Fick	Low cardiac output	High cardiac output
Thermodilution	High cardiac output	Pulmonic regurgitation Tricuspid regurgitation Intracardiac shunting
Indocyanine green	High cardiac output	Aortic regurgitation Mitral regurgitation Low cardiac output Intracardiac shunting
Angiographic	Normal-shaped ventricle	Extreme segmental wall motion abnormalities Dilated ventricle Aortic regurgitation* Mitral regurgitation*

* In these circumstances, angiographic output is greater than forward cardiac output (see text).

TABLE 87.4. METHODS FOR DETERMINING CARDIAC OUTPUT AND CONDITIONS IN WHICH THEY ARE MOST (OR LEAST) RELIABLE

The oxygen consumption is determined by collecting a timed sample (usually for 3 to 4 minutes) of expired air in a receptacle called a Douglas bag. From the volume of air collected and the difference in oxygen content between inspired and expired air, the amount of oxygen consumed per minute can be determined. Alternatively, oxygen consumption can be estimated with a metabolic rate meter. With this device, a plastic hood is placed over the patient's head and the oxygen content of expired air is monitored continuously as it is withdrawn from the hood with a blower motor.

In some catheterization laboratories, an assumed value for oxygen consumption is derived from a formula or nomogram. The average oxygen consumption for adults is 125 (range 65 to 250) mL per minute per square meter of body surface area. Because oxygen consumption varies greatly from one patient to another, the use of an assumed value is potentially unreliable. In general, oxygen consumption is higher in men than in women and decreases gradually with age. It increases with hyperthyroidism, hyperthermia, and exercise, and it decreases with hypothyroidism and hypothermia.

The determination of the arteriovenous oxygen difference across the lungs requires that blood be obtained from the vessels entering the lungs (pulmonary artery) and draining the lungs (pulmonary vein). In the absence of right-to-left shunting, the oxygen content of pulmonary venous blood is similar to that of systemic arterial blood. Therefore, in practice, a systemic arterial (rather than a pulmonary venous) blood sample is procured. The oxygen contents of systemic arterial and pulmonary arterial blood are measured directly or calculated from the oxygen saturation using the formula:

$$O_2 \text{ content (mL/dL)} = \text{saturation} \times \text{Hgb (g/dL)} \times 1.34 \text{ (mL } O_2/\text{g Hgb)}$$

where 1.34 is the oxygen-carrying capacity of 1 g of hemoglobin (Hgb). The normal arteriovenous oxygen difference is 3.0 to 4.5 mL/dL.

The following is an example of the calculation of cardiac output using the Fick principle:

Oxygen consumption = 250 mL per minute
Hemoglobin = 15 g per dL
Oxygen saturation of systemic arterial blood = 95%
Oxygen saturation of pulmonary arterial blood = 70%
Conversion factor = 10 (number of deciliters per liter)

$$\text{Cardiac output (L per minute)} = \frac{250 \text{ mL per minute}}{(0.95 - 0.70)(15 \text{ g per dL})(1.34 \text{ mL } O_2/\text{g})(10 \text{ dL/L})} = 5.0 \text{ L/minute}$$

Indicator Dilution Method

With indicator dilution, a known amount of indicator is injected as a bolus into the circulation and allowed to mix completely in the blood, after which its concentration is measured. A time–concentration curve is generated ([Figure 87.1](#)), and a minicomputer calculates the cardiac output from the area of the inscribed curve.

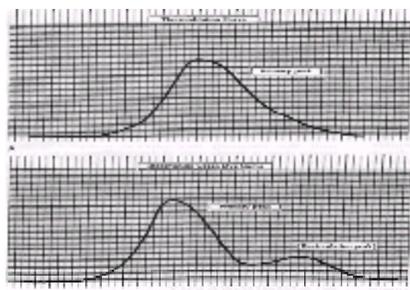

FIGURE 87.1. Time–activity curves for the indicator dilution technique of determining cardiac output: thermiodilution **(A)** and indocyanine green **(B)**. With indocyanine green, there is a primary peak and a recirculation peak; with thermiodilution, only a primary peak is observed.

Thermiodilution

The most widely used indicator to measure cardiac output is cold solution. A balloon-tipped, flow-directed, polyvinyl chloride catheter with a thermistor at its tip and an opening 25 to 30 cm proximal to the tip is inserted into a vein and advanced to the pulmonary artery, so that the proximal opening is located in the vena cavae or right atrium and the thermistor is in the pulmonary artery. A known amount of cold fluid is injected through the proximal port; it mixes completely in the right ventricle and causes a change in blood temperature, which is detected by the thermistor. The thermiodilution method is relatively inexpensive and easy to perform, and does not require arterial sampling or blood withdrawal. In most patients, it accurately determines pulmonary blood flow, which (in the absence of intracardiac shunting) is similar to systemic blood flow. However, certain conditions may render the results of the thermiodilution technique unreliable, including tricuspid or pulmonic

regurgitation and intracardiac shunting ([Table 87.4](#)).

Indocyanine Green

The second most widely used indicator to measure cardiac output is indocyanine green. This water-soluble, nontoxic substance is usually introduced through a catheter positioned in a right heart chamber, and its concentration is sampled in arterial blood withdrawn at a constant rate through an optical densitometer. The lungs and left heart serve as sites of complete mixing, and there is no degradation of indocyanine green between the site of injection and sampling. As with thermodilution, a time–activity curve is inscribed, and the cardiac output is determined from the area of the curve, excluding the recirculation peak ([Figure 87.1](#)). The results obtained with this method compare favorably with those of other techniques for measuring cardiac output, but it may provide inaccurate results if the recirculation peak cannot be easily separated from the primary peak (e.g., low cardiac output) or if one of the valves between the site of injection and sampling (mitral or aortic) is regurgitant ([Table 87.4](#)).

Angiographic Method

From the left ventriculogram, the volume of blood ejected with each heartbeat (stroke volume) can be determined. It is then multiplied by the heart rate, yielding the angiographic cardiac output. In patients with mitral or aortic regurgitation, a portion of the blood ejected from the left ventricle regurgitates into the left atrium or ventricle and does not enter the systemic circulation. In these patients, the angiographic cardiac output is higher than the forward output. The measurement of cardiac output by the angiographic method is potentially erroneous in patients with extensive segmental wall motion abnormalities or misshapen ventricles, in whom the determination of stroke volume may be inaccurate ([Table 87.4](#)).

PRESSURES

One of the most important functions of cardiac catheterization is to measure and record intracardiac pressures. Once a catheter is positioned in a cardiac chamber, it is connected through fluid-filled, stiff, plastic tubing to a pressure transducer, which transforms the pressure signal into an electrical signal that is recorded. The accurate measurement of pressure requires close attention to the details of the catheter system, including proper transducer balancing, removal of air bubbles and blood from the catheters and connections, and avoidance of an excessive length of plastic tubing. All transducers should be referenced to the same zero level and their position adjusted if the patient's position changes. Pressure transducers should be calibrated frequently against a mercury manometer to ensure proper function.

During catheterization, pressures are usually measured directly from each of the cardiac chambers—right atrium, right ventricle, pulmonary artery, ascending aorta, and left ventricle. In contrast, a left atrial pressure is seldom measured directly unless a trans-septal catheterization is performed. Because the left atrial pressure is transmitted to the pulmonary capillaries, it is recorded “indirectly” as the pulmonary capillary “wedge” pressure. To measure the wedge pressure, an endhole catheter is placed in the main pulmonary artery and advanced until it is wedged in a small pulmonary artery. If the catheter is adequately wedged, the tracing observed is that of a transmitted left atrial pressure, and the blood aspirated through the catheter is fully saturated (oxygen saturation ⁹⁵%). Normal values for intracardiac pressures are shown in [Table 87.3](#).

In addition to measuring pressures from each cardiac chamber, pressures from certain chambers are examined simultaneously to identify or exclude a gradient between them that is indicative of valvular stenosis. Thus, left ventricular and left atrial (or pulmonary capillary wedge) pressures are recorded simultaneously to identify the diastolic gradient of mitral stenosis ([Figure 87.2A](#)). Likewise, left ventricular and aortic (or systemic arterial) pressures are recorded simultaneously to determine if there is a systolic gradient indicative of left ventricular outflow tract obstruction ([Figure 87.2B](#)).

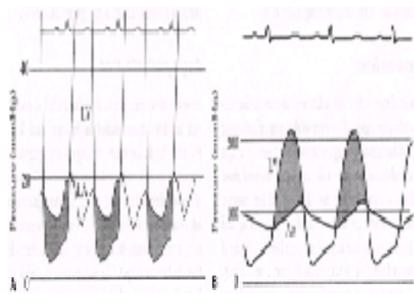

FIGURE 87.2. A: Simultaneous pressure recordings from the left atrium and left ventricle, demonstrating a diastolic gradient in a patient with mitral stenosis. **B:** Simultaneous pressure recordings from the left ventricle and aorta, demonstrating a systolic gradient in a patient with aortic stenosis. Gradients are indicated with shading.

RESISTANCES

The resistance of a vascular bed is calculated by dividing the pressure gradient across the bed by the blood flow through it. Thus:

$$\text{Systemic vascular resistance} = \frac{\text{mean systemic arterial pressure} - \text{mean right atrial pressure}}{\text{systemic blood flow}}$$

$$\text{Pulmonary vascular resistance} = \frac{\text{mean pulmonary artery pressure} - \text{mean left atrial pressure}}{\text{pulmonary blood flow}}$$

Because a properly obtained pulmonary capillary wedge pressure is similar to left atrial pressure (except in the rare condition of pulmonary vein stenosis), it can replace it in the above equation. These formulas express resistances in arbitrary resistance units. More commonly, these values are multiplied by 80 to express them in metric units of dynes per second per square centimeter. Normal values are displayed in [Table 87.3](#).

An elevated systemic vascular resistance is often present in the patient with systemic arterial hypertension. It may also be observed in patients with a reduced forward cardiac output and compensatory arteriolar vasoconstriction (often seen in patients with congestive heart failure). Conversely, systemic vascular resistance may be reduced in patients with arteriolar vasodilation (due, for example, to sepsis) or those with an increased cardiac output (due, for example, to an arteriovenous fistula, severe anemia, fever, or thyrotoxicosis). Elevated pulmonary vascular resistance often is observed in patients with primary lung disease or Eisenmenger's physiology and those with a greatly elevated pulmonary venous pressure resulting from left-sided myocardial or valvular dysfunction.

ANGIOGRAPHY

During angiography, radiographic contrast material is injected into the cardiovascular structure of interest as cineangiography is performed on 35-mm film at 30 to 60 frames per second. The resultant cineangiogram permits the study of cardiac structures in real time, in slow motion, or by single frame. Alternatively, angiographic images can be projected onto a high-resolution screen and converted with computer processing from an analog to a digital form. Digital angiography allows image enhancement, computer processing, and quantitative analysis, features that are not available with routine cineangiography. With computer digitization, less radiographic contrast material is required, and the angiographic images can be stored on a central computer or computer-accessible medium (optical disk, magnetic tape, or compact disk) and recalled later for processing and analysis.

LEFT VENTRICULOGRAPHY

With cineangiography of the left ventricle, global and segmental left ventricular function, left ventricular volumes and ejection fraction, and the presence and severity of mitral regurgitation can be assessed. Typically, a power injector is used to deliver 30 to 60 mL of contrast material over 3 to 4 seconds through a catheter in the left ventricular cavity, and the silhouette is filmed in one (single-plane) or two (biplane) projections ([Figure 87.3](#)). Using a standard area-length formula, left ventricular volumes and ejection fraction are determined. Specifically, end-diastolic and end-systolic volumes are measured, from which stroke volume is derived (the difference between end-diastolic and end-systolic volumes) and the ejection fraction is calculated (the quotient of stroke volume and end-diastolic volume). The angiographic cardiac output is the product of stroke volume and heart rate.

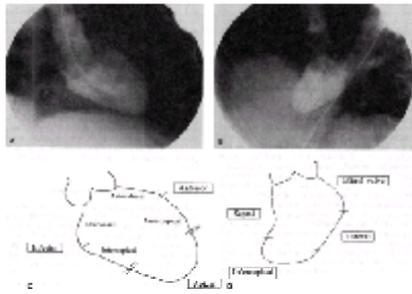

FIGURE 87.3. With biplane ventriculography, two projections 90 degrees apart in obliquity are performed: 30E right anterior oblique (A) and 60 degrees left anterior oblique (B). The segments of the left ventricle that are visualized with each obliquity are labeled (C, D). With typical single-plane ventriculography, only the right anterior oblique view is obtained.

In addition to providing information about volumes and global systolic function, left ventriculography allows assessment of segmental wall motion. A segment of the left ventricular wall with reduced systolic motion is said to be hypokinetic; a segment that does not move is akinetic; and a segment that moves paradoxically during systole is dyskinetic.

CORONARY ANGIOGRAPHY

Selective coronary angiography is usually performed to determine the presence and severity of fixed, atherosclerotic coronary artery disease and to guide subsequent percutaneous (e.g., angioplasty) or surgical (e.g., bypass grafting) therapy. It is sometimes used to evaluate the presence of dynamic alterations in coronary arterial tone (coronary arterial spasm), to define congenital abnormalities of the coronary arteries, and to establish the patency of bypass grafts. Under fluoroscopic guidance, the ostia of the native right and left coronary arteries or bypass grafts are engaged selectively with a catheter, and radiographic contrast material is injected manually as cineangiography is performed. Because atherosclerotic coronary arterial stenoses are often eccentric and the coronary vessels overlap one another, images are obtained in multiple obliquities to procure a complete angiographic assessment of each arterial segment.

The left main coronary artery arises from the left coronary cusp and divides into the left anterior descending and left circumflex arteries. The left anterior descending courses in the anterior interventricular groove and provides a variable number of septal perforators, which perfuse the interventricular septum, and diagonal branches, which perfuse the high lateral left ventricular wall. The left circumflex artery is located in the posterior atrioventricular groove and provides obtuse marginal branches—also called circumflex marginal branches—that perfuse the lateral left ventricular free wall. The right coronary artery arises from the right coronary cusp, courses anteriorly in the atrioventricular groove, and supplies acute marginal branches to the right ventricular free wall. The artery located in the inferior interventricular groove is known as the posterior descending coronary artery. In 90% of patients, it emanates from the right coronary artery (right-dominant system), and in 10% its origin is the left circumflex artery (left-dominant system).

Coronary angiography provides radiographic images of the coronary lumina but does not visualize the actual arterial walls. A stenosis is present when there is a discrete reduction in luminal diameter, and its severity is assessed by comparing it to presumably normal adjacent segments of the same artery ([Figure 87.4](#)). Thus, if atherosclerosis is diffuse and involves the entire artery, angiography may lead to an underestimation of the severity of disease.

FIGURE 87.4. Coronary angiograms from a patient with an 80% stenosis in the right coronary artery (A, arrow) and a 90% stenosis in the left anterior descending coronary artery (B, arrow).

AORTOGRAPHY

Aortography is accomplished with the rapid injection of a large amount (50 to 60 mL over 2 seconds) of radiographic contrast material into the aorta. With proximal aortography, the severity of aortic valve regurgitation, the location of saphenous vein bypass grafts, and the anatomy of the proximal aorta and its branches can be assessed. Examples of anatomical abnormalities of the aorta that can be visualized by aortography include annuloaortic ectasia, dissection, coarctation, patent ductus arteriosus, and ruptured sinus of Valsalva aneurysm. Distal aortography usually is performed to assess the presence of vascular abnormalities, such as aneurysmal dissection, intraluminal thrombus, coarctation, or branch vessel stenosis.

RIGHT VENTRICULOGRAPHY

Cineangiography of the right ventricle allows assessment of global right ventricular function and possible anatomical abnormalities of the right ventricle, including its outflow tract. Because the right ventricle is asymmetric, there are no reliable ventriculographic methods for quantifying right ventricular volumes and ejection fraction. With right ventriculography, the presence of tricuspid regurgitation can be assessed and its magnitude estimated qualitatively in a manner similar to aortic or mitral regurgitation: trivial (1+), mild (2+), moderate (3+), or severe (4+).

PULMONARY ANGIOGRAPHY

Pulmonary angiography is primarily performed to confirm or to exclude the presence of pulmonary emboli. Occasionally, it is performed in patients with congenital heart disease to assess the size of the main pulmonary artery and its branches, to detect abnormalities of the pulmonary vasculature (e.g., pulmonary artery stenosis,

arteriovenous malformation, anomalous pulmonary veins), or to visualize a coronary artery that originates anomalously from the pulmonary artery. Although pulmonary angiography generally is safe, it carries some risk in patients with pulmonary hypertension or right ventricular failure. In such patients it should be performed only when noninvasive techniques fail to assess the suspected condition adequately or when the potential benefits outweigh the risks.

ASSESSMENT OF VALVULAR HEART DISEASE

VALVULAR STENOSIS

In patients with valvular stenosis, the effective valve orifice area can be calculated with data obtained during catheterization using principles of standard fluid dynamics. The pressures on either side of a stenotic valve are recorded simultaneously ([Figure 87.2](#)) and the flow across it is measured, after which the valve area is calculated with the equation of Gorlin and Gorlin:

$$\text{Valve orifice area (cm}^2\text{)} = \text{Flow across the valve/constant} \times \text{mean pressure gradient}$$

The mean pressure gradient is the average gradient during systole (for aortic or pulmonic valves) or diastole (for mitral or tricuspid valves). The cardiac output is the flow across the valve.

Although the normal mitral valve orifice is 4 to 6 cm², substantial stenosis may occur before a pressure gradient ([Figure 87.2A](#)) or clinical symptoms appear. A mitral valve with an effective area of 1 cm² or less is considered severely stenotic; 1.1 to 1.5 cm², moderately stenotic; and 1.6 to 2 cm², mildly stenotic.

The normal aortic valve has a cross-sectional area of 3 to 4 cm², but hemodynamically important aortic stenosis ([Figure 87.2B](#)) does not develop until the valve orifice area falls below 1 cm². An aortic valve area of 0.7 cm² or less is severely stenotic; 0.8 to 1 cm², moderately stenotic; and 1.1 to 1.3 cm², mildly stenotic. The term “critical” aortic stenosis is reserved for an aortic valve area of 0.5 cm² or less.

The normal pulmonic valve has a cross-sectional area similar to that of the aortic valve. By convention, the severity of pulmonic stenosis is estimated solely according to the peak right ventricular pressure rather than the Gorlin-derived valve area. Pulmonic stenosis with a peak right ventricular pressure of 30 to 50 mm Hg is considered mild; 50 to 100 mm Hg, moderate; and above 100 mm Hg, severe.

The tricuspid valve is normally large, with an orifice area of 6 to 10 cm². The patient with a tricuspid valve area of less than 3 cm² and right-sided heart failure is said to have significant tricuspid stenosis and is considered a candidate for valvuloplasty, commissurotomy, or valve replacement.

VALVULAR REGURGITATION

The presence and severity of mitral regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates into the left atrium during left ventricular systole on a standard left ventriculogram. The magnitude of regurgitation is estimated as trivial (1+), mild (2+), moderate (3+), or severe (4+). To obtain a quantitative assessment of the severity of mitral regurgitation, the volume of blood that regurgitates from the left ventricle into the left atrium per minute (regurgitant volume) can be calculated by measuring the difference between the angiographic cardiac output (determined by left ventriculography) and the forward cardiac output (determined by the Fick or thermodilution method). The regurgitant fraction is the percentage of the total angiographic output that regurgitates into the left atrium: it is the quotient of the regurgitant volume and the angiographic output. Typically, valvular regurgitation with a regurgitant fraction of 0.6 or more is severe; 0.40 to 0.59, moderate; 0.20 to 0.39, mild; and below 0.20, trivial.

The presence and severity of aortic regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates into the left ventricle during ventricular diastole by aortography; it is also graded as trivial (1+), mild (2+), moderate (3+), or severe (4+). As with mitral regurgitation, a quantitative assessment of the severity of aortic regurgitation can be obtained by calculating the regurgitant volume and fraction.

INTRACARDIAC SHUNTING

LEFT-TO-RIGHT SHUNT

In patients with known or suspected congenital heart disease or unexplained heart failure, cardiac catheterization may be performed to assess the presence, location, and magnitude of intracardiac shunting. Several techniques may be used ([Table 87.5](#)).

Method	Able to Localize?	Able to Quantify?	Minimal Q _p /Q _s Reliably Detected
Obesity	Yes	Yes	1.5-2.0 at level of aorta 1.5-2.0 at level of ventricle 1.5 at level of great vessels
Indocyanine green	No	Yes	1.5
Angiography	Yes	No	Unknown

Q_p, pulmonary blood flow; Q_s, systemic blood flow.

TABLE 87.5. COMPARISON OF METHODS TO DETECT, LOCALIZE, AND QUANTIFY INTRACARDIAC LEFT-TO-RIGHT SHUNTING

Oximetric Assessment

Oximetric detection and localization of intracardiac left-to-right shunting are based on the principle that oxygenated blood shunted from the left side of the heart to the right side causes an abnormal increase (“step-up”) in the oxygen content or saturation of blood in the chamber into which shunting occurs. To detect the presence and site of the left-to-right shunt, blood samples are obtained from the pulmonary artery, right ventricle, right atrium, and vena cavae, and the oxygen content or saturation of each sample is evaluated for evidence of such a step-up. An abnormal step-up is present when the right atrial oxygen content is more than 1.9 mL per dL higher than that of the vena cavae, the right ventricular oxygen content is more than 0.9 mL per dL higher than that of the right atrium, or the pulmonary arterial oxygen content is more than 0.5 mL per dL higher than that of the right ventricle. The oxygen content of blood can be measured directly or calculated from the saturation [saturation × hemoglobin (g per dL) × 1.34 mL O₂ per g hemoglobin].

The oximetric quantitation of shunting is accomplished by calculating pulmonic (Q_p) and systemic (Q_s) blood flows according to the Fick principle, where

$$\text{Qp (L per minute)} = \frac{\text{oxygen consumption (mL per minute)}}{\text{arteriovenous oxygen content difference across the lungs (mL per L)}}$$

and

$$\text{Qs (L per minute)} = \frac{\text{oxygen consumption (mL per minute)}}{\text{arteriovenous oxygen content difference across the body}}$$

(mL per L)

The arteriovenous oxygen content difference across the lungs is the difference in oxygen contents between pulmonary arterial and venous blood. The arteriovenous oxygen content across the body is the difference in oxygen contents between systemic arterial and mixed venous blood, with the latter obtained from the chamber immediately before (proximal to) the site of the shunt. For example, if a ventricular septal defect is present, the mixed venous chamber is the right atrium; if a patent ductus arteriosus is present, the mixed venous chamber is the right ventricle. An example of the calculations for a patient with an intracardiac left-to-right shunt is presented in [Table 87.6](#).

Chamber	O ₂ Saturation (%)	O ₂ Content (mL/dL)	O ₂ Content Difference (mL/dL)
Vena cava	65	13.1	0.4
Right atrium	67	13.5	2.2
Right ventricle	78	15.7	0.2
Pulmonary artery	79	15.9	0
Systemic artery	97		

Site of O₂ "trap-up" = right ventricle Mixed venous chamber = right atrium
Q₁ = 250 mL/min (10.97 - 0.79)(15 g/dL) (1.34 mL O₂/g hemoglobin)(10 dL/L) = 6.97 L/min
Q₂ = 250 mL/min (10.97 - 0.67)(15 g/dL) (1.34 mL O₂/g hemoglobin)(10 dL/L) = 4.14 L/min
Q₁/Q₂ ratio = 6.97/4.14 = 1.7

*Measured oxygen consumption = 250 mL/min, Hemoglobin = 15 g/dL.

TABLE 87.6. OXIMETRIC ASSESSMENT OF THE PRESENCE, SITE, AND SIZE OF LEFT-TO-RIGHT INTRACARDIAC SHUNTING IN A PATIENT WITH A VENTRICULAR SEPTAL DEFECT^a

The oximetric determination of intracardiac left-to-right shunting is highly specific but relatively insensitive, in that an oximetric assessment reliably demonstrates the presence of a moderate or large shunt but may fail to detect a small shunt ([Table 87.5](#)).

Indocyanine Green Assessment

As described previously, when a bolus of indocyanine green is introduced into a right heart chamber and its concentration is measured in systemic arterial blood, a concentration–time curve is inscribed, which is characterized by a primary peak and a recirculation peak. In the patient with left-to-right intracardiac shunting, the inscribed curve demonstrates prominent early recirculation ([Figure 87.5](#)) due to indocyanine green's rapid recirculation to the systemic arterial system through the intracardiac shunt. Because the area of the inscribed recirculation curve is proportional to shunt flow, the magnitude of shunting can be calculated with this technique. Although this method cannot identify the site of left-to-right shunting, it can detect shunts with a Q_p/Q_s as small as 1.35; thus, it is somewhat more sensitive than oximetry.

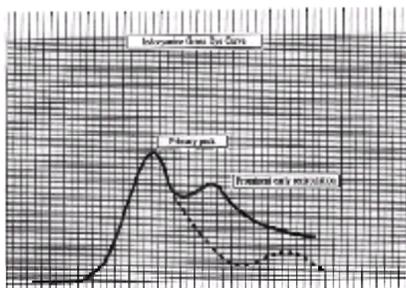

FIGURE 87.5. An indocyanine green curve from one patient with (*solid line*) and one patient without (*dotted line*) left-to-right intracardiac shunting. With the shunt, there is prominent early recirculation.

Angiographic Assessment

When radiographic contrast material is introduced into a left-sided chamber during angiography in a subject with left-to-right intracardiac shunting, its movement into a right-sided chamber may be visualized. The reliability of any angiographic technique for detecting or localizing intracardiac left-to-right shunting depends on the location of the defect and the obliquity in which the angiogram is performed. Left-sided angiography may be used to detect and localize certain kinds of intracardiac left-to-right shunts. For example, the interventricular septum may be visualized by performing left ventriculography in a 40-degree to 50-degree left anterior oblique projection, allowing the diagnosis of a ventricular septal defect. A communication between the thoracic aorta and the pulmonary artery (i.e., patent ductus arteriosus or aortopulmonary window) may be identified by performing aortography in the left anterior oblique or left lateral projection.

Atrial septal defects and anomalous pulmonary venous drainage are difficult to visualize angiographically. Although angiography can detect and localize certain intracardiac left-to-right shunts, it cannot measure the magnitude of shunting.

RIGHT-TO-LEFT SHUNT

In the patient with right-to-left intracardiac shunting, the passage of unoxygenated blood from the venous circulation to the systemic circulation results in arterial desaturation (less than 95%). When desaturation is due to other conditions (i.e., ventilation–perfusion mismatch or hypoventilation), it is corrected when 100% oxygen is administered; this does not happen when the arterial desaturation is due to right-to-left shunting. Thus, demonstration of a systemic arterial oxygen saturation below 95% that does not correct with the administration of 100% oxygen (via face mask) is consistent with right-to-left intracardiac shunting.

INTERVENTIONAL CATHETERIZATION

PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY

For many patients with atherosclerotic coronary artery disease, percutaneous transluminal coronary angioplasty (PTCA) is the treatment of choice. With PTCA, a distensible balloon is inflated under high pressure within the coronary stenosis, with resultant disruption of the plaque and aneurysmal dilatation of the vessel. These alterations provide new pathways for blood flow in the diseased coronary artery, leading to increased luminal size. Angioplasty is performed percutaneously, with local anesthesia; compared with bypass surgery, it usually involves a shorter hospitalization, and its procedure-related mortality (1%) is similar.

Percutaneous transluminal coronary angioplasty is performed with special equipment consisting of a large-lumen guide catheter, a flexible wire, and a balloon catheter. The guide catheter is positioned in the coronary ostium, and angiography of the diseased coronary artery is performed to visualize the stenosis. The flexible wire is advanced through the guide catheter, navigated across the stenosis, and positioned in the distal arterial segment. The deflated balloon catheter is then advanced over the wire and positioned at the stenosis, after which it is inflated for 1 to 5 minutes at 3 to 15 atmospheres of pressure with a mixture of saline and radiographic contrast material. If the stenosis is adequately dilated, the balloon catheter and wire are removed. If the dilatation is considered inadequate, additional inflations at higher pressure or for a longer time may be performed, or the initial balloon may be replaced with a larger one. When a satisfactory result is obtained, a

final angiogram is performed.

Percutaneous transluminal coronary angioplasty has been widely used in several clinical circumstances ([Table 87.7](#)). In experienced hands, it is an effective therapeutic modality in patients with limiting angina who would otherwise require bypass surgery for symptomatic relief. Overall, PTCA's initial success averages about 90%. Acute coronary occlusion—due to coronary arterial dissection, thrombosis, or vasospasm—is reported in 3% to 7% of patients undergoing angioplasty. It is usually corrected with additional dilatations, placement of an endovascular stent, or urgent bypass surgery, so that the overall periprocedural mortality is only 0.5% to 1%. During the 4 to 6 months after successful PTCA, 35% to 50% of stenoses recur, but this restenosis is usually amenable to repeat angioplasty.

- Stable angina pectoris not adequately responsive to medical therapy
- Objective evidence of significant ischemia in a moderate area of myocardium while receiving medical therapy
- Unstable angina pectoris
- Acute myocardial infarction ("primary angioplasty")
- Provocable or spontaneous ischemia after myocardial infarction (with or without antecedent treatment with a thrombolytic agent)
- Significant coronary artery stenosis in a survivor of cardiac arrest or sustained ventricular tachycardia in the absence of myocardial infarction

TABLE 87.7. ACCEPTED INDICATIONS FOR PERCUTANEOUS CORONARY REVASCULARIZATION

DIRECTIONAL CORONARY ATHERECTOMY

The atherectomy device consists of a rigid cylindrical metal housing with a cut-out section ("cutting window") 5 to 9 mm long. Opposite the cutting window is a balloon fixed to the housing unit. The atherectomy device is advanced over a wire positioned across the stenosis and positioned with its cutting window facing the atheromatous plaque. When the balloon is inflated, the cutting window is pushed against the atheromatous plaque. A cup-shaped rotating cutter is slowly advanced through the metal housing, shaving portions of the plaque and depositing the shaved debris in the catheter tip. Enlargement of the coronary artery lumen is achieved by removal of atherosclerotic material and dilatation due to balloon inflation. Accordingly, the increase in luminal diameter achieved with atherectomy is substantially greater than that of balloon angioplasty alone. With atherectomy, the rates of initial success, abrupt closure, and restenosis are similar to those of balloon angioplasty. However, the incidence of local vascular complications and periprocedural myocardial infarction is higher with atherectomy, and its size and relative rigidity make it poorly suited for use in small, tortuous, or angulated coronary arteries.

ROTATIONAL CORONARY ATHERECTOMY

High-speed rotational atherectomy ("rotablation") uses a diamond-coated elliptical metal drill, or "burr," to debulk atherosclerotic plaque. The burr, which rotates at speeds up to 200,000 rpm, is passed over a guidewire that has been advanced through the coronary stenosis. The rotator selectively ablates the most fibrous, calcific plaque, whereas the normally elastic arterial wall deflects away from the rotating burr. This technique is used primarily for coronary stenoses that are long, calcified, or ostial in location.

ENDOVASCULAR STENTS

Intracoronary stents consist of metal coils or metallic mesh cylinders wrapped tightly around a deflated angioplasty balloon. The balloon catheter is advanced over an angioplasty guidewire into the coronary artery and, once properly positioned, is inflated to expand the stent. After balloon deflation, the stent retains its expanded cylindrical configuration, forcing intraluminal irregularities against the vessel wall. Stenting results in a much greater increase in luminal diameter than that achieved with balloon angioplasty alone as well as a lower incidence of restenosis. It is particularly effective in treating acute coronary occlusion from failed angioplasty. In addition, it is preferable to angioplasty for treatment of stenoses located in saphenous vein bypass grafts or coronary ostia.

PERCUTANEOUS BALLOON VALVULOPLASTY

Percutaneous balloon valvuloplasty has been used with success in patients with aortic, mitral, or pulmonic stenosis as an alternative to surgical commissurotomy or valve replacement. One or two large balloon catheters (each 15 to 20 mm in diameter when fully inflated) are positioned across the stenotic valve and inflated with a mixture of saline and contrast material at 3 to 5 atmospheres of pressure for 15 to 30 seconds. Repeated balloon inflations may be necessary to achieve the desired result. Balloon inflation splits the fused valve commissures, thereby increasing the effective valve orifice area and decreasing the transvalvular pressure gradient. Percutaneous balloon valvuloplasty is associated with a mortality of 1% to 2%.

Percutaneous mitral balloon valvuloplasty is usually successful in patients with symptomatic mitral stenosis and suitable valve anatomy. It is ineffective when the mitral leaflets are markedly thickened, immobile, or heavily calcified, or if subvalvular fibrosis is extensive. In the average patient, percutaneous balloon mitral valvuloplasty increases the effective orifice area from 1 to 2 cm². Because it is performed through a transeptal approach, it should not be attempted in the patient with a left atrial thrombus or recent cerebrovascular event.

In the adult patient with aortic stenosis, percutaneous balloon valvuloplasty is only modestly successful in that the transvalvular pressure gradient is reduced by about 50% and the valve area is increased to only 0.7 to 1.0 cm². Stenosis recurs in most patients within 6 to 12 months. Hence, aortic balloon valvuloplasty is a short-term palliative procedure to be used only in severely ill patients who are poor surgical candidates.

Pulmonic balloon valvuloplasty is used primarily in infants and children, but its use in adults with pulmonic stenosis is well described. It is the treatment of choice for isolated, noncalcific pulmonic stenosis.

ENDOMYOCARDIAL BIOPSY

Through a long sheath positioned across the tricuspid valve, a routine biopptome can be advanced to obtain small pieces (1 to 2 mm²) of myocardial tissue from the right ventricular side of the interventricular septum. Endomyocardial biopsy is used most often to detect transplant rejection and to monitor immunosuppressive therapy in survivors of cardiac transplantation. Less commonly, it is undertaken in the patient with suspected infiltrative cardiomyopathy (sarcoidosis, amyloidosis, hemochromatosis, carcinoid). In experienced hands, complications are uncommon; cardiac perforation occurs in only 0.3% to 0.5%, and the procedure-related mortality is roughly 0.05%.

CHAPTER 88: ELECTROPHYSIOLOGIC TESTING

FRED MORADY

[Technical Aspects and Risks](#)
[Evaluation of Sinus Node Function](#)
[Evaluation of Atrioventricular Conduction](#)
[Evaluation of Paroxysmal Supraventricular Tachycardia](#)
[Evaluation of Wolff–Parkinson–White Syndrome](#)
[Evaluation of Sustained Ventricular Tachycardia](#)
[Evaluation of Unexplained Syncope](#)

Electrophysiologic testing plays an important role in the management of patients who have serious arrhythmias. Invasive electrophysiologic studies often are important in guiding the management of patients who have had ventricular tachycardia, the aborted sudden death syndrome, paroxysmal supraventricular tachycardia, Wolff–Parkinson–White (WPW) syndrome, unexplained wide-QRS complex tachycardias, and unexplained syncope. Electrophysiologic testing also may be helpful in the management of patients in whom abnormalities of sinus node function or atrioventricular (AV) conduction are suspected.

This chapter describes the diagnostic information that can be obtained through electrophysiologic testing and reviews the clinical situations in which an electrophysiologic test is appropriate. The field of interventional electrophysiology, consisting of several types of catheter ablation techniques, is described in [Chapter 76](#).

TECHNICAL ASPECTS AND RISKS

Electrophysiologic studies are performed in a catheterization laboratory or procedure room in which fluoroscopy is available. Depending on the clinical indication for the study, two to four electrode catheters are inserted percutaneously, with local anesthesia, into a femoral, brachial, subclavian, or internal jugular vein and positioned in the right atrium, across the tricuspid valve for recording the His bundle electrogram, in the coronary sinus for recording left atrial depolarizations, or within the right ventricle.

The use of multipolar electrode catheters that have four or more electrodes allows use of the distal pair of electrodes for pacing and the proximal electrodes for recording intracardiac electrograms. Pacing is performed with a programmable stimulator capable of introducing premature stimuli, referred to as extrastimuli, in a synchronized fashion. Electrophysiologic testing usually requires both overdrive pacing and the scanning of early diastole with one or more extrastimuli. Pacing generally is performed with stimuli that are 1 to 2 milliseconds in duration and that have a current intensity twice the late diastolic threshold. If necessary, the arterial pressure can be continuously monitored with a short cannula inserted into a femoral, brachial, or radial artery. When left atrial or ventricular mapping is required, either a trans-septal approach is used to enter the left atrium or left ventricle, or an electrode catheter is introduced into a femoral or brachial artery and passed across the aortic valve into the left ventricle.

When performed competently by appropriately trained personnel, the mortality rate of electrophysiologic testing is less than 0.1%, and the risk of nonlethal complications also is low. A potentially lethal complication is perforation of a cardiac chamber by an electrode catheter, which may result in cardiac tamponade requiring needle pericardiocentesis or an emergency thoracotomy. The risk of thromboembolic complications can be minimized by the use of heparin during the electrophysiologic study. The most common complications are thrombophlebitis or hematoma formation at the site of catheter insertion, and the incidence of these complications is about 1% to 2%.

Hemodynamically unstable, sustained ventricular tachycardia or ventricular fibrillation may be induced in the course of electrophysiologic testing. Because this usually is intentional, it is not considered to be a complication. Sustained, monomorphic ventricular tachycardia often can be terminated by rapid pacing. Ventricular fibrillation and sustained ventricular tachycardias that cannot be terminated by pacing and that result in severe hypotension are terminated by direct-current countershock as soon as the patient loses consciousness.

Rarely, ventricular tachycardia or ventricular fibrillation either cannot be terminated by direct-current countershock or recurs repeatedly shortly after conversion to sinus rhythm. Electromechanical dissociation after termination of ventricular tachycardia or ventricular fibrillation is another rare complication of electrophysiologic testing. Immediate cardiopulmonary resuscitation is required if one of these complications occurs. Because these complications are most likely to occur in patients with unstable coronary syndromes or severe congestive heart failure, such patients should not undergo electrophysiologic testing.

EVALUATION OF SINUS NODE FUNCTION

Sinus node function is evaluated primarily by determination of the sinus node recovery time. The right atrium is paced at several rates between 100 and 200 beats per minute for 30 to 60 seconds at each rate. The interval between the last paced atrial depolarization and the first spontaneous sinus depolarization is the sinus node recovery time ([Fig. 88.1](#)). The sinus node recovery time is adjusted for heart rate by subtraction of the baseline sinus cycle length, which yields the corrected sinus node recovery time. The upper limit of normal of the corrected sinus node recovery time is 550 milliseconds.

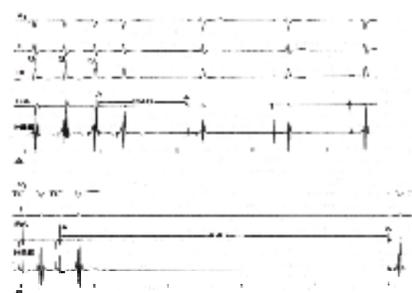

FIGURE 88.1. Examples of normal and abnormal sinus node recovery times. Shown are leads V_1 , I, and III; the intracardiac electrogram recorded in the right atrium (RA); and the His bundle electrogram. The last two or three stimuli (S) of a 45-second pacing train at a rate of 120 to 150 beats per minute are seen. The sinus node recovery time is the interval between the last paced atrial depolarization and the first spontaneous atrial depolarization originating in the sinus node. It is corrected for heart rate by subtracting the baseline sinus cycle length. The time lines in this and all subsequent figures represent 1-second intervals. **A:** The sinus node recovery time is 1,140 milliseconds and the corrected sinus node recovery time is 140 milliseconds (upper limits of normal are 500 to 550 milliseconds). **B:** The sinus node recovery time is 4.4 seconds. The sinus cycle length was 840 milliseconds, and therefore the corrected sinus node recovery time is 3.56 seconds, which is markedly prolonged. A, atrial electrogram.

A prolonged sinus node recovery time indicates an abnormality of sinus node automaticity, although not necessarily a clinically significant degree of sinus node dysfunction. The sensitivity of the sinus node recovery time for the sick sinus syndrome is about 75% to 80%, with a specificity in the range of 90%. Another indicator of sinus node function is the sinoatrial conduction time, which can be measured directly by recording a sinus node depolarization or indirectly by an overdrive pacing or an extrastimulus technique. Although this test provides a measure of conduction of impulses through the sinoatrial junction, it has little or no clinical value.

In patients who have the sick sinus syndrome and a documented bradyarrhythmia associated with symptoms, there is no need for electrophysiologic testing to assess sinus node function; if the symptoms and bradyarrhythmia are severe enough to warrant a permanent pacemaker, a pacemaker should be implanted if a correctable

reason for the sinus node dysfunction cannot be identified. If there is uncertainty about whether a permanent pacemaker is necessary, an electrophysiologic test may be helpful in guiding management of these cases. For example, a patient who complains of dizzy spells or light-headedness may have a resting sinus bradycardia of 40 to 50 beats per minute or sinus pauses of less than 3 seconds in duration; these abnormalities are suggestive of sinus node dysfunction but are not in themselves severe enough to justify pacemaker implantation. If this patient is found to have a markedly abnormal sinus node recovery time (corrected sinus node recovery time more than 1 to 1.5 seconds), this degree of sinus node dysfunction may justify implantation of a permanent pacemaker. However, if the sinus node recovery time is normal or only slightly prolonged, it may be appropriate to follow the patient clinically and to defer pacemaker implantation.

EVALUATION OF ATRIOVENTRICULAR CONDUCTION

The status of the AV conduction system is assessed during an electrophysiologic study by recording the His bundle electrogram and by determining the response to atrial pacing at incremental rates. The His bundle electrogram is recorded by positioning an electrode catheter across the tricuspid valve, which allows division of the PR interval into two components: the atrial His (AH) interval, which reflects AV nodal conduction, and the His ventricular (HV) interval, which reflects conduction in the His–Purkinje system ([Fig. 88.2](#)). The normal ranges of the AH and the HV intervals are 70 to 145 milliseconds and 35 to 55 milliseconds, respectively. When there is AV block during sinus rhythm or atrial pacing, the level of block within the AV conduction system can be localized to the AV node or to the His–Purkinje system by determining if the block occurs proximal or distal to the His bundle depolarization.

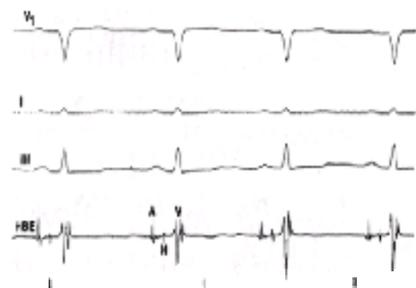

FIGURE 88.2. The His bundle electrogram. Also shown are leads V₁, I, and III. The atrial depolarization (A) corresponds to the P wave on the ECG, and the ventricular depolarization (V) corresponds to the QRS. The His bundle deflection (H) occurs between the A and the V and cannot be seen on the ECG. The AH interval reflects AV nodal conduction, whereas the HV interval reflects infranodal conduction.

Prolongation of the AH interval and mild prolongation of the HV interval are rarely of clinical significance. However, marked prolongation of the HV interval (100 milliseconds) in patients with a bundle-branch block is associated with about a 25% risk of progression to high-degree AV block over 3 years and may be an appropriate indication for a permanent pacemaker in patients who have otherwise unexplained syncope or who require treatment with antiarrhythmic drugs that may further depress infranodal conduction.

During incremental atrial pacing, physiologic block occurs within the AV node when the rate approaches 140 to 170 beats per minute ([Fig. 88.3A](#)). Block distal to the His bundle depolarization may be physiologic under certain circumstances, as during rapid atrial pacing (more than 200 beats per minute) when there is 1:1 conduction through the AV node. Infranodal AV block is pathologic when it occurs during relatively slow rates (less than 150 beats per minute; [Fig. 88.3B](#)). Pathologic block distal to the His bundle depolarization indicates tenuous conduction in the His–Purkinje system, is associated with an increased risk of high-degree AV block, and usually is an indication for implantation of a permanent pacemaker.

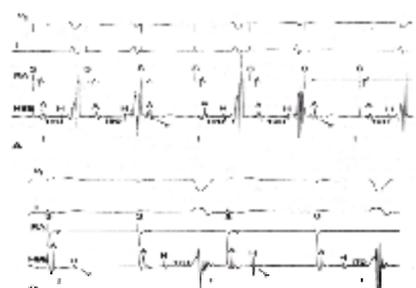

FIGURE 88.3. Atrioventricular (AV) block during atrial pacing. Shown are leads V₁ and I, the right atrial electrogram (RA), and the His bundle electrogram. **A:** Physiologic AV block within the AV node. The AV nodal Wenckebach block occurs during atrial pacing at a rate of 170 beats per minute. There is progressive prolongation of the AH interval, then block between the atrium and His bundle. A His bundle depolarization is not present when the block occurs, indicating that the block was within the AV node. **B:** Pathologic infranodal AV block. This patient had a left bundle-branch block and a prolonged baseline HV interval of 170 milliseconds (upper limits of normal, 55 milliseconds). During atrial pacing at a rate of 100 beats per minute, the AH interval was constant at 150 milliseconds but there was 2:1 infranodal block. This type of block is abnormal. A, atrial depolarization; H, His bundle deflection; S, pacing stimuli.

Spontaneous AV block that occurs within the AV node is rarely an indication for a pacemaker, but AV block that occurs below the AV node usually is. Because the level of AV block can often be determined on a clinical basis, electrophysiologic testing usually is not necessary to evaluate whether a patient with second- or third-degree AV block requires a permanent pacemaker. An electrophysiologic study is indicated to evaluate AV conduction if the results of clinical evaluation are inconclusive. An HV interval of 100 milliseconds or longer, spontaneous block distal to the His bundle electrogram, or pathologic infranodal block during atrial pacing usually indicates the need for a permanent pacemaker.

EVALUATION OF PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

MECHANISMS OF TACHYCARDIA

Paroxysmal supraventricular tachycardia (PSVT) that is caused by reentry usually can be induced by atrial or ventricular pacing during an electrophysiologic test. Because the most common mechanisms of recurrent PSVT are AV nodal reentry, orthodromic tachycardia (in which the AV node is the anterograde limb of a reentry circuit and an accessory pathway is the retrograde limb), and intra-atrial reentry, a patient's PSVT usually can be reproduced in the electrophysiology laboratory. By observing several features of the tachycardia, including the method of initiation, the sequence of atrial activation, and the responses to atrial and ventricular pacing, the precise mechanism of tachycardia can be determined.

In AV nodal reentrant tachycardia, which is the most common type of PSVT, there are two pathways for conduction of impulses through the AV node; these two pathways have different conduction properties and degrees of refractoriness. In the typical AV nodal reentrant tachycardia, a reentry circuit incorporates the more slowly conducting pathway as its anterograde limb and the more rapidly conducting pathway as its retrograde limb.

INDICATIONS FOR TESTING PATIENTS WITH PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

In patients with documented episodes of PSVT, management on purely a clinical basis is often appropriate. However, several clinical situations may indicate electrophysiologic studies, and these are described in the following sections.

Unexplained Wide-QRS Complex Tachycardia

The 12-lead electrocardiogram (ECG) often provides clues to determining whether a wide QRS complex tachycardia represents PSVT with a bundle-branch block or ventricular tachycardia. In some cases, it may not be possible to discern the mechanism of a wide QRS complex tachycardia from the ECG or even from analysis of recordings obtained with an esophageal lead. An electrophysiologic study helps in these cases by establishing the mechanism of the tachycardia, thereby allowing appropriate therapy ([Fig. 88.4](#)).

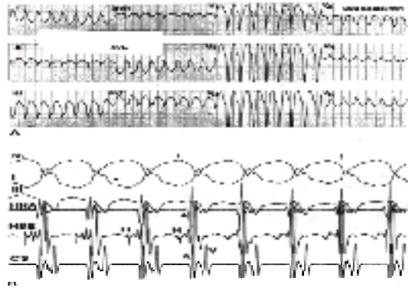

FIGURE 88.4. A wide QRS complex tachycardia. **A:** This ECG was recorded in a 60-year-old man with a history of an anterior wall myocardial infarction who presented to the hospital complaining of rapid palpitations and light-headedness. The tachycardia has a rate of 200 beats per minute and a left bundle-branch block configuration. There are no clues on the ECG that allow differentiation of ventricular tachycardia from supraventricular tachycardia with aberrant conduction. The tachycardia was terminated by intravenous procainamide. The QRS complexes during sinus rhythm were narrow. **B:** An electrophysiologic test in the same patient demonstrated inducible supraventricular tachycardia caused by AV nodal reentry. A His bundle depolarization (H) precedes each ventricular depolarization, and a rate-related left bundleblock is present. Ventricular tachycardia was not inducible. This case illustrates how an electrophysiologic test can clarify the mechanism of a wide QRS complex tachycardia.

Paroxysmal Supraventricular Tachycardia Associated With Severe Symptoms

Some patients with PSVT may have serious symptoms, such as syncope, severe chest pain, or pulmonary edema. Instead of treating these patients purely on a clinical basis, it often is appropriate to perform an electrophysiologic test to establish the mechanism of the PSVT and to guide management. In most cases, it is possible to eliminate the PSVT by catheter ablation using radiofrequency energy. If pharmacologic therapy is chosen for the patient, the efficacy of the therapy can be determined by electropharmacologic testing. The end point of electropharmacologic testing is inability to induce the tachycardia or slowing of the tachycardia to the point where it is no longer associated with severe symptoms.

Recurrent Paroxysmal Supraventricular Tachycardia Not Responding to Pharmacologic Therapy

An electrophysiologic test is performed to determine the mechanism of the PSVT and to eliminate the tachycardia using a radiofrequency catheter ablation technique. For most patients, the diagnosis and cure of PSVT can be accomplished during a single electrophysiology procedure.

Because of the favorable risk/benefit profile of radiofrequency ablation, electrophysiologic testing with a view toward catheter ablation is appropriate for patients with recurrent PSVT who elect to undergo curative therapy instead of pharmacologic therapy.

Recurrent Paroxysmal Palpitations of Uncertain Cause

Using trans-telephonic electrocardiographic monitoring and continuous loop ambulatory electrocardiographic monitoring, it should be possible to document the cardiac rhythm in most patients who have recurrent palpitations. But at times it may be impossible to document the cause of symptoms in a patient who has recurrent episodes of paroxysmal palpitations compatible with PSVT. An electrophysiologic study may be indicated in a patient who has recurrent symptoms of paroxysmal tachycardia in whom documentation of the cause of symptoms cannot be obtained by monitoring (see [Chapter 76](#)).

EVALUATION OF WOLFF–PARKINSON–WHITE SYNDROME

In addition to orthodromic tachycardia, another type of tachycardia that may be associated with WPW syndrome is atrial fibrillation or flutter with a rapid ventricular response. Because accessory pathways may have rapid conduction properties and a short refractory period, atrial fibrillation or flutter may result in extremely rapid ventricular rates in patients with the WPW syndrome. The ventricular rate may exceed 250 to 300 beats per minute, resulting in severe hemodynamic compromise and a risk of degeneration into ventricular fibrillation.

Another type of tachycardia that may occur in patients who have WPW syndrome is antidromic tachycardia. This is a reentrant tachycardia that is much less common than the orthodromic variety. In this type of tachycardia, the accessory pathway is the anterograde limb of the reentry circuit, and the AV node is the retrograde limb. Ventricular activation therefore occurs in an eccentric fashion through the accessory pathway, resulting in a wide QRS complex tachycardia that has the appearance of ventricular tachycardia on the ECG.

The goals of electrophysiologic testing in patients with WPW syndrome are to define the refractoriness and conduction properties of the accessory pathway, to induce and establish the mechanism or mechanisms of tachycardia that the patient has had, to determine the number of accessory pathways and their locations, and to ablate the pathways using radiofrequency energy. Programmed atrial stimulation and ventricular stimulation are used to define the refractory periods and to induce tachycardias. Localization of accessory pathways (mapping) is accomplished by searching either for the earliest site of atrial activation along the tricuspid and mitral annulus during orthodromic tachycardia, or for the earliest site of ventricular activation during pre-excited QRS complexes. The sites of earliest atrial and ventricular activation indicate the atrial and ventricular insertion sites of the accessory pathway, respectively. Sometimes rapid atrial pacing may be used to induce atrial fibrillation, allowing determination of the ventricular rate and the shortest interval between two consecutive, pre-excited QRS complexes. If the shortest interval is less than 250 milliseconds, then the risk of cardiac arrest resulting from atrial fibrillation is increased.

Because electrophysiologic studies are performed in patients who are supine and inactive, the results of testing in the baseline state may not accurately reflect conditions present during states of sympathetic activation, such as exercise or emotional stress. Accessory pathways usually are responsive to sympathetic stimulation, and it often is appropriate to induce sympathetic activation to obtain a more accurate assessment of the tachycardia that a patient may experience spontaneously. This is done by infusing isoproterenol, usually at a rate of 1 to 2 μ g per minute, during the electrophysiologic test.

In the past, an electrophysiologic study was performed in patients with WPW syndrome to identify high-risk patients who were appropriate candidates for surgical ablation of the accessory pathway, either for the purpose of electropharmacologic testing or to identify the number and locations of accessory pathways as a prelude to surgery. After radiofrequency catheter ablation of accessory pathways was demonstrated to be highly effective and relatively safe, almost all electrophysiology procedures in patients with WPW syndrome have been performed for the purpose of ablating the accessory pathways. Appropriate candidates for an electrophysiologic test and catheter ablation include patients with WPW syndrome who have experienced potentially dangerous arrhythmias, who have been refractory or intolerant to pharmacologic therapy, or who prefer definitive therapy over long-term pharmacologic therapy ([Fig. 88.5](#)).

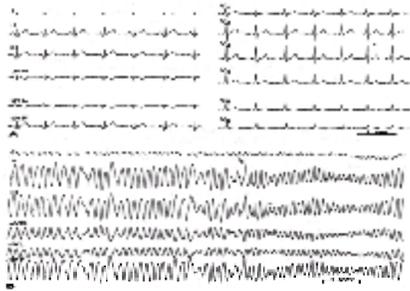

FIGURE 88.5. Life-threatening atrial fibrillation induced during an electrophysiologic test in a patient with Wolff-Parkinson-White syndrome and recurring severe palpitations. **A:** The electroencephalogram during sinus rhythm demonstrated a short PR interval and delta waves characteristic of Wolff-Parkinson-White syndrome. Mapping demonstrated the presence of a right free wall accessory pathway. **B:** Atrial fibrillation was induced by rapid atrial pacing. The frontal plane leads are shown. There was rapid conduction through the accessory pathway and an average ventricular rate of 330 beats per minute. The arrow in lead II marks the point at which the atrial fibrillation degenerated into ventricular fibrillation, which was terminated by a direct-current countershock. The electrophysiologic test demonstrated the life-threatening potential of atrial fibrillation in this patient.

An asymptomatic patient may have delta waves and a short PR interval on an ECG, and there is usually no role for electrophysiologic testing in this situation. The WPW pattern on the ECG does not necessarily imply that symptomatic arrhythmias will occur, and it is usually appropriate to postpone evaluation and treatment until the time at which symptomatic arrhythmias arise. However, thorough evaluation of an asymptomatic patient who has a WPW pattern on the ECG may be appropriate if, for example, there is concern about the possible consequences of the first episode of tachycardia occurring during strenuous athletics or affecting those who have potentially high-risk occupations, such as airline pilots or school bus drivers. Noninvasive evaluation may be helpful in screening these patients. If the electrocardiographic manifestations of ventricular pre-excitation disappear during exercise or after intravenous infusion of 1 g of procainamide, the accessory pathway refractory period is not excessively short, and the patient is not at risk of dangerously rapid tachycardias. If, however, the noninvasive evaluation indicates that the patient is not in the low-risk subgroup, further evaluation with an electrophysiologic test may be indicated to define the risk of dangerous tachycardias. Catheter ablation may be indicated if the electrophysiologic study demonstrates that an asymptomatic patient is potentially at risk of having a tachycardia associated with severe hemodynamic compromise (see [Chapter 76](#)).

EVALUATION OF SUSTAINED VENTRICULAR TACHYCARDIA

Ventricular tachycardia may be classified as monomorphic, in which all of the QRS complexes have the same configuration, or as polymorphic, in which the QRS complexes vary from beat to beat ([Fig. 88.6](#)). This electrocardiographic distinction has important implications regarding the possible mechanisms of ventricular tachycardia and the role of electrophysiologic testing. Polymorphic ventricular tachycardia often occurs in association with acute myocardial injury, acute ischemia, antiarrhythmic drug proarrhythmia, or an electrolyte abnormality such as hypokalemia. The priority in managing these patients is acute treatment of the ventricular tachycardia and correction of the underlying precipitating factor. Although sustained monomorphic ventricular tachycardia also may be a result of an acute metabolic or electrolyte disturbance; it often occurs as a primary arrhythmic event in the absence of any identifiable acute precipitating factor. Electrophysiologic testing plays an important role in the long-term management of patients with this type of ventricular tachycardia.

FIGURE 88.6. Examples of monomorphic and polymorphic ventricular tachycardia (VT). **A:** Sustained monomorphic VT, at a rate of 158 beats per minute, in a patient with coronary artery disease and a history of an anterior myocardial infarction. All of the QRS complexes in each lead have the same configuration. This type of VT often is a primary dysrhythmia, which is not caused by an identifiable precipitant (such as ischemia) or by a metabolic abnormality, and which often can be reproduced during electrophysiologic testing. **B:** An example of polymorphic VT at an average rate of 300 beats per minute. The QRS complexes vary from beat to beat in leads V_1 and V_5 , which were recorded simultaneously. This episode of polymorphic VT occurred in a patient who was hypokalemic and did not recur after the hypokalemia was corrected. If the cause of this type of VT can be identified and corrected, there is usually no role for electrophysiologic testing.

MECHANISMS OF VENTRICULAR TACHYCARDIA

The underlying mechanisms of sustained monomorphic ventricular tachycardia include reentry, abnormal automaticity, and triggered activity. The most common mechanism of ventricular tachycardia is reentry, and this type of ventricular tachycardia usually is inducible by programmed ventricular stimulation. Automatic ventricular tachycardias are not inducible by pacing but may be induced by an infusion of isoproterenol, and ventricular tachycardia caused by triggered activity may be provoked with atrial and ventricular pacing at critical rates.

Many types of therapy directed toward ventricular tachycardia are nonspecific and do not depend on the specific mechanism of ventricular tachycardia. Some forms of therapy, however, are mechanism-specific, and electrophysiologic testing allows identification of patients who are appropriate candidates for these mechanism-specific therapies. These therapies include the use of β -blocking agents for catecholamine-sensitive ventricular tachycardia; the use of calcium channel blockers for ventricular tachycardia caused by triggered activity; catheter ablation of the right bundle for bundle-branch reentry tachycardia; and catheter ablation of a critical zone of slow conduction in the ventricular tachycardia reentry circuit of patients with a prior myocardial infarction.

SENSITIVITY AND SPECIFICITY OF PROGRAMMED VENTRICULAR STIMULATION

The most common mechanism of sustained monomorphic ventricular tachycardia in patients with coronary artery disease (CAD) is reentry, and the sensitivity of electrophysiologic testing in reproducing a spontaneous episode of ventricular tachycardia is high (greater than 90%) for patients with CAD. In patients with other types of heart disease, such as dilated or hypertrophic cardiomyopathy or valvular heart disease, automatic types of ventricular tachycardia may be more common, and the sensitivity of electrophysiologic testing in inducing sustained monomorphic ventricular tachycardia is lower (65% to 75%) than in patients with CAD.

A standard stimulation protocol for inducing ventricular tachycardia has not been as universally accepted. Typical stimulation protocols incorporate the sequential use of one, two, and three extrastimuli introduced during sinus rhythm or after eight-beat pacing trains at rates of 100 to 150 beats per minute. The yield of monomorphic ventricular tachycardia increases as the number of extrastimuli increases, and about 25% of clinically significant monomorphic ventricular tachycardias require three extrastimuli for induction ([Fig. 88.7A](#)).

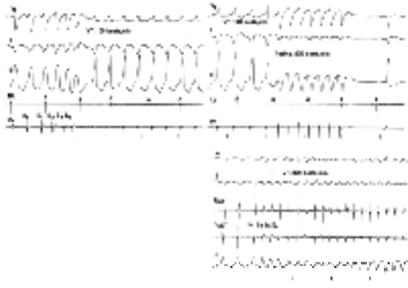

FIGURE 88.7. Induction of monomorphic and polymorphic ventricular tachycardia by programmed stimulation. **A:** Monomorphic ventricular tachycardia (VT), 150 beats per minute, was induced by programmed stimulation with three extrastimuli (S_2 , S_3 , S_4) introduced at the right ventricular outflow tract (RV). The VT had a right bundle branch block configuration that was identical to a previously documented spontaneous episode of VT. Atrioventricular dissociation is seen in the right atrial recording. **B:** Monomorphic VT often can be terminated by rapid ventricular pacing, as shown here. Right ventricular pacing at a rate of 220 beats per minute terminated the VT. **C:** Polymorphic VT, 300 beats per minute, also induced by programmed stimulation with three extrastimuli (S_2 , S_3 , S_4). The QRS morphologies in leads V_1 , I, and III vary from beat to beat. The VT required direct-current countershock to terminate. This type of polymorphic VT induced by programmed stimulation often is a nonspecific finding.

It also is possible to induce polymorphic ventricular tachycardia or ventricular fibrillation, which often are nonspecific arrhythmias and which do not have clinical significance; the yield of these nonspecific dysrhythmias also increases as the number of extrastimuli increases ([Fig. 88.7B](#)). Because nonspecific polymorphic ventricular tachycardia and ventricular fibrillation may require direct-current countershock to terminate, programmed ventricular stimulation protocols should be designed to minimize the induction of these arrhythmias. For example, limitation of coupling intervals to 200 milliseconds improves the specificity of programmed stimulation without compromising the yield of clinically important forms of ventricular tachycardia.

ELECTROPHARMACOLOGIC TESTING

In patients who have frequent episodes of sustained ventricular tachycardia, the efficacy of antiarrhythmic drugs usually can be assessed by noting the clinical response to treatment. Because sustained monomorphic ventricular tachycardia often occurs in a sporadic and unpredictable fashion, it often is not possible to assess antiarrhythmic drug efficacy on a clinical basis.

The ability to induce ventricular tachycardia in the electrophysiology laboratory allows the use of electropharmacologic testing to assess antiarrhythmic drug efficacy. After a baseline study in which ventricular tachycardia is shown to be inducible, antiarrhythmic drug therapy is instituted, and the effects of the drug on inducibility and other characteristics of the ventricular tachycardia are observed. Initial drug testing can be performed at the time of the first electrophysiologic study with drugs that can be administered intravenously, such as procainamide or propranolol. With most antiarrhythmic drugs, however, electropharmacologic testing requires a second electrophysiologic test after a steady-state plasma drug concentration has been achieved with oral therapy. Electropharmacologic testing usually is performed after four or five doses of an antiarrhythmic drug have been administered. In the case of amiodarone, which has unusual pharmacokinetic properties, electropharmacologic testing usually is delayed until 10 to 14 days of an oral loading dose has been administered.

The most desirable end point of electropharmacologic testing is the complete suppression of ventricular tachycardia induction. The inability to induce ventricular tachycardia after initiation of drug therapy generally predicts that the antiarrhythmic drug will have long-term effectiveness in preventing spontaneous episodes of ventricular tachycardia. However, it is often not possible to completely suppress the induction of ventricular tachycardia with antiarrhythmic drugs, and in some instances this may not be necessary. It may be appropriate to implement long-term treatment with a drug that has been demonstrated to be effective in markedly slowing ventricular tachycardia to the point that it is hemodynamically stable and not associated with severe symptoms. This type of response to electropharmacologic testing predicts a low risk of arrhythmia-related death.

MAPPING OF VENTRICULAR TACHYCARDIA

Patients who have recurrent sustained ventricular tachycardia unresponsive to antiarrhythmic drug therapy may be appropriate candidates for definitive therapy aimed at eliminating the site or sites of origin of ventricular tachycardia by various surgical or catheter ablation techniques. In these patients, electrophysiologic testing is performed to identify the sites of origin of ventricular tachycardia using various mapping techniques. The mapping process involves maneuvering electrode catheters to various sites in the right and left ventricles and recording endocardial electrograms at these sites during ventricular tachycardia. Identification of the origin of ventricular tachycardia is based on analysis of the endocardial electrogram patterns and on the response to pacing during ventricular tachycardia and sinus rhythm.

ELECTROPHYSIOLOGIC TESTING IN THE ABORTED SUDDEN DEATH SYNDROME

The most common causes of out-of-hospital cardiac arrest are ventricular tachycardia and ventricular fibrillation. Electrophysiologic testing may be appropriate for patients who are successfully resuscitated from what otherwise would have been lethal cardiac arrest and in whom the cardiac arrest was not precipitated by an acute myocardial infarction. Sustained monomorphic ventricular tachycardia associated with severe hemodynamic compromise is inducible in about one-half of patients with the aborted sudden death syndrome. The ability to induce monomorphic ventricular tachycardia in these patients allows electropharmacologic testing, mapping of the ventricular tachycardia in patients who may be candidates for catheter or surgical ablation, and selection of the appropriate detection criteria in patients who are candidates for devices such as the automatic internal cardioverter–defibrillator. However, because a large-scale multicenter study (Antiarrhythmics Versus Implantable Defibrillators; AVID) demonstrated that the implantable cardioverter–defibrillator is superior to antiarrhythmic drug therapy for increasing survival after ventricular fibrillation or sustained ventricular tachycardia associated with severe symptoms, the role of electropharmacologic testing in survivors of cardiac arrest has rapidly waned. In addition, because the sensitivity of programmed ventricular stimulation is lower in patients with cardiomyopathy and other types of heart disease than in patients with CAD, a negative electrophysiologic test for a patient with the aborted sudden death syndrome who does not have CAD does not rule out the possibility that the cardiac arrest was caused by a primary episode of ventricular tachycardia or ventricular fibrillation. In light of these considerations, and to improve cost-effectiveness, an implantable cardioverter–defibrillator now often is implanted without a prior electrophysiologic test in patients who have survived a cardiac arrest and in whom a correctable cause for the cardiac arrest cannot be identified.

NONSUSTAINED VENTRICULAR TACHYCARDIA

For patients with symptomatic nonsustained ventricular tachycardia, electrophysiologic testing may be used to guide therapy of those who have infrequent arrhythmia episodes and in whom assessment of drug efficacy is not clinically possible. If ventricular tachycardia is inducible by programmed stimulation, drug efficacy can be determined by electropharmacologic testing.

In patients with coronary artery disease and compromised left ventricular function (left ventricular ejection fraction less than 0.35) who have asymptomatic, nonsustained ventricular tachycardia, electrophysiologic testing may be performed for the purpose of risk stratification. If sustained ventricular tachycardia cannot be provoked in the electrophysiology laboratory, treatment of the nonsustained ventricular tachycardia may not be necessary. On the other hand, if sustained ventricular tachycardia can be induced, this may indicate a need for prophylactic treatment to prevent cardiac arrest. Electropharmacologic testing may be performed to assess the efficacy of antiarrhythmic drug therapy in suppressing the inducibility of ventricular tachycardia. A multicenter study (Multicenter Automatic Defibrillator Implantation Trial; MADIT) demonstrated that an implantable cardioverter–defibrillator improves survival compared to conventional medical therapy in patients in whom the inducible ventricular tachycardia is not suppressed by an antiarrhythmic drug. Therefore, electrophysiologic testing is useful in identifying patients with coronary artery disease and nonsustained ventricular tachycardia who are appropriate candidates for antiarrhythmic drug therapy or an implantable cardioverter–defibrillator.

In patients with nonsustained ventricular tachycardia who do not have coronary artery disease, electrophysiologic testing generally is not useful for the purpose of risk

stratification. In such patients, the decision to institute prophylactic antiarrhythmic therapy to prevent cardiac arrest must be made on a clinical basis.

LIMITATIONS OF TESTING PATIENTS WITH VENTRICULAR TACHYCARDIA

Electrophysiologic testing has several limitations when performed in patients with ventricular tachycardia. First, because the ventricular tachycardia is not caused by reentry or because of an unknown reason, some patients with documented sustained ventricular tachycardia may not have inducible ventricular tachycardia, especially patients without CAD. Second, patients who have had a spontaneous episode of sustained monomorphic ventricular tachycardia often have more than one type of monomorphic ventricular tachycardia inducible during electrophysiologic testing, and the clinical importance of these additional configurations may be unclear. Third, although polymorphic ventricular tachycardia or fibrillation is usually a laboratory artifact in patients who have never had a cardiac arrest, the clinical significance of this type of induced arrhythmia is often unclear in patients who have been resuscitated from a cardiac arrest and for whom there is no documentation of the precipitating arrhythmia.

EVALUATION OF UNEXPLAINED SYNCOPE

Electrophysiologic testing may be helpful in uncovering an arrhythmic cause of syncope in patients whose syncope remains unexplained after a complete clinical, neurologic, and noninvasive cardiac evaluation. Electrophysiologic findings indicating abnormalities likely to be related to syncope consist of inducible monomorphic ventricular tachycardia; inducible paroxysmal supraventricular tachycardia associated with significant hypotension; a markedly prolonged sinus node recovery time (corrected sinus node recovery time more than 1 to 1.5 seconds); a markedly prolonged HV interval of 100 milliseconds or more; and pathologic infranodal block during atrial pacing. Some abnormalities may be nonspecific or not severe enough to be considered a likely cause of syncope, including inducible polymorphic ventricular tachycardia or ventricular fibrillation; inducible paroxysmal supraventricular tachycardia not associated with hypotension; mild prolongation of the sinus node recovery time; mild prolongation of the HV interval; and slow conduction or prolonged refractoriness in the AV node.

The diagnostic yield of electrophysiologic testing because of unexplained syncope is in the range of 30% to 60% for patients who have underlying heart disease and 5% or less for those who do not have structural heart disease. The threshold for performing an electrophysiologic test should be high for patients with syncope who are free of heart disease. For these patients, electrophysiologic testing often is reserved for cases of syncope associated with serious injury or that has proven to be recurrent and problematic.

The arrhythmia that most commonly causes syncope in patients who have heart disease is ventricular tachycardia, and it is always important to thoroughly investigate an episode of syncope in this type of patient. Even one episode of unexplained syncope is an appropriate indication for electrophysiologic testing of patients who have significant structural heart disease to rule out a serious or potentially lethal arrhythmia as the cause of syncope.

An electrophysiologic test that does not demonstrate any diagnostic abnormalities in patients with unexplained syncope generally predicts a benign prognosis and a low risk of sudden death. This suggests that electrophysiologic testing is effective in ruling out potentially lethal arrhythmias as the cause of syncope. Although the reasons are unclear, 70% to 80% of patients may have no further recurrences of syncope after undergoing an electrophysiologic test that does not reveal any diagnostic abnormalities. However, about 20% of patients with unexplained syncope and a negative electrophysiologic test result may have had a falsely negative electrophysiologic test result during follow-up, and the most commonly missed abnormalities are symptomatic bradycardias related to sinus node dysfunction or AV block. The absence of abnormalities during electrophysiologic testing in these patients suggests that these symptomatic bradycardias may be related to transient fluctuations in autonomic tone instead of an intrinsic sinus node or AV conduction system abnormality. For additional discussion of syncope, see [Chapter 69](#).

CHAPTER 89: PRINCIPLES OF CARDIAC CONDITIONING AND REHABILITATION

VICTOR F. FROELICHER AND JONATHAN N. MYERS

[Basic Exercise Physiology](#)
[Response to Acute Exercise](#)
[Adaptations to Chronic Exercise \(Training\)](#)
[Phases of Cardiac Rehabilitation After Myocardial Infarction](#)
[Conclusion](#)

Cardiac rehabilitation was conceived in the 1960s as a treatment for patients who had suffered a myocardial infarction (MI). Before the 1970s, the patient who suffered an MI was almost completely immobilized for 6 weeks or more and was even washed, shaved, and fed to keep the work of the heart to a minimum. This approach was thought to provide the heart with the opportunity to form a firm scar. Also, the patient was told not to expect to be able to return to a normal life. These were incorrect beliefs, particularly in the situation of an uncomplicated MI. Prolonged immobilization not only did not speed healing but exposed the patient to the additional risks of venous thrombosis, pulmonary embolism, muscle atrophy, lung infections, and deconditioning. Equally serious was the psychological result of such an approach, often leading to psychological impairment. Thus, the old approach to rehabilitation was an attempt to correct iatrogenic impairment.

Today, the physician's approach to the acute MI has completely changed. A relatively brief period of time monitored by the high technology in the coronary care unit is followed by early mobilization, sitting at the bedside, graduated exercise, and, in the uncomplicated patient, discharge from the hospital in less than 1 week. This policy has been shown by randomized trials to be safe from the point of view of cardiac complications. Inpatient rehabilitation is brief, but educational videos and pamphlets can begin the patient's education. Iatrogenic deconditioning is not a problem because a walking program can begin very early. Psychological rehabilitation takes place in the doctor's office along with prescribing exercise and education. Certainly, all patients do not need all rehabilitative interventions, but exercise programs, educational sessions, group therapy, and psychological and vocational counseling are available in most communities for those who need them. The approach to exercise has also changed; the current emphasis is on physical activity rather than fitness.

BASIC EXERCISE PHYSIOLOGY

The cardiorespiratory response to exercise depends on the type of exercise, the environmental conditions, and the physiologic status of the patient. Changes that occur with a single bout of acute exercise are called responses and are temporary. Adaptations are long-lasting changes in structure or function that occur with training (regular exercise) and improve the body's response to subsequent exercise.

Dynamic exercise (bicycling, walking, running, swimming) involves the movement of large muscle masses. Because this movement is rhythmic, a drop in total peripheral resistance and a "pumping" action in the skeletal muscle that returns blood to the heart occur. Dynamic exercise evokes a series of cardiovascular adjustments, which supply the active muscles with sufficient blood, dissipate the heat generated, and maintain blood supply to the heart and brain. Local increases in metabolites cause dilation of the arteries and arterioles in active muscles, resulting in a decrease in systemic vascular resistance proportional to the muscle mass involved. To maintain arterial blood pressure, sympathetic activity increases, which causes constriction of the resistance vessels in the splanchnic bed, kidneys, and nonworking muscles. The generalized vasoconstriction in inactive tissues and the increased venous return result in maintenance of the heart's filling volume and pressure. The increase in pulmonary blood flow causes a moderate increase in mean pulmonary artery pressure. The extent to which basic hemodynamic and metabolic variables change from rest to a moderately high level of exercise is illustrated in [Figure 89.1](#).

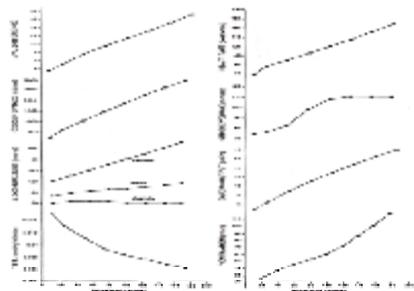

FIGURE 89.1. Basic hemodynamic and metabolic variables and the magnitude of the response from rest to a moderately high level of exercise. Units for $\dot{V}O_2$ difference are milliliters of O_2 per 100 mL of blood. *TPR*, total peripheral resistance. (From Myers JN. The physiology behind exercise testing. *Prim Care* 1994;21:415, with permission.)

Isometric exercise (lifting a weight, forceful squeezing or pressing) involves a constant muscular contraction, which limits blood flow. Instead of an increase in cardiac output and blood flow, blood pressure must be increased to force blood into the active, contracting muscles. Dynamic exercise can be graded to increase myocardial oxygen demand gradually, whereas isometric exercise is more difficult to grade and increases myocardial oxygen demand quickly without as great an increase in cardiac output. Although isometric exercise can enhance peripheral muscle tone and function, it does not result in the same beneficial cardiac and hemodynamic effects as does dynamic exercise.

RESPONSE TO ACUTE EXERCISE

HEART RATE

The body's initial hemodynamic response to dynamic exercise is an increase in heart rate. The elicited heart rate response is proportional to the workload and depends on the person's age and physical condition. Maximal heart rate is an important determinant of maximal cardiac output (because cardiac output = heart rate \times stroke volume) and, therefore, also of exercise capacity.

BLOOD PRESSURE

The systolic and diastolic blood-pressure response to exercise varies with the type and intensity of the exercise and the age of the person. In dynamic exercise of moderate to heavy intensity, there is a gradual linear increase in systolic pressure of about 40 mm Hg at maximum, whereas diastolic pressure stays about the same or decreases. The increase in cardiac output during exercise is balanced by a reduction in peripheral resistance, such that mean arterial pressure increases only modestly.

BLOOD FLOW

At rest, a large portion of the cardiac output is directed to the spleen, liver, kidneys, brain, and heart, with only about 20% going to the skeletal muscles. During exercise, the skeletal muscles can receive more than 85% of the cardiac output ([Fig. 89.2](#)).

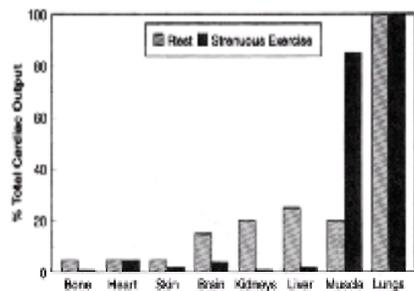

FIGURE 89.2. Changes in the distribution of cardiac output from rest to strenuous work.

The regulation of the circulation during exercise involves the following responses:

Local. The resistance vessels dilate in the active muscle as a result of the release of metabolites. These block constriction in the local vessels caused by the sympathetic nervous system.

Mechanical. The pumping action of skeletal muscle facilitates the return of blood to the central circulation.

Neural. Sympathetic outflow increases while vagal outflow decreases. This causes tachycardia, increased contractility, and constriction of the resistance vessels in the nonactive tissues. As body temperature rises, the sweat glands are activated and skin vessels dilate.

Humoral. Epinephrine is released into the bloodstream in response to sympathetic activation and has a generalized constrictor effect, except in the heart and the skeletal muscle. Sensors within skeletal muscle detect small changes in the local chemical environment, providing the feedback to maintain adequate muscle perfusion.

OXYGEN UPTAKE

The usual measure of total body physiologic work is the oxygen uptake. The upper limits of the cardiopulmonary system are defined by the maximal oxygen uptake (or consumption), which can be expressed by the Fick principle:

$$\dot{V}O_2 \text{ max} = \text{maximal cardiac output} \times \text{maximal arteriovenous oxygen difference}$$

It is important to distinguish between total body oxygen uptake and myocardial oxygen uptake because they are distinct in their determinants and in the way they are measured or estimated. Total body, or ventilatory, oxygen uptake is the amount of oxygen that is extracted from inspired air as the body performs work. The most common method for estimating oxygen uptake involves walking the patient on a treadmill using progressively increasing workloads. If direct measurement is not available, oxygen uptake is best estimated by the peak work rate performed rather than by the total exercise time, because the latter depends on the protocol used and the patient's endurance and muscular strength.

Exercise capacity is estimated in terms of the oxygen requirements, and values commonly are expressed in metabolic equivalents (METs). One MET, which is the metabolic oxygen requirement under basal conditions, is about 3.5 mL of oxygen per kilogram of body weight per minute. Certain factors, such as emotional stress, skill and coordination, and body mechanics, can alter the oxygen cost of an activity. Although exercise capacity is affected by age, gender, exercise status, illness, genetics, and other factors, an exercise capacity of less than 5 METs usually carries a poor prognosis, and values higher than 10 METs are usually associated with a good prognosis.

Myocardial oxygen uptake is the amount of oxygen required by the heart to perform work. Accurate measurement of myocardial oxygen uptake requires the placement of catheters in a coronary artery and in the coronary venous sinus to measure oxygen content. Its determinants include intramyocardial wall tension (left ventricular pressure \times end-diastolic volume), contractility, and heart rate. Myocardial oxygen uptake can be reasonably estimated by the product of heart rate and systolic blood pressure (double product). This is valuable clinically because many patients with coronary artery disease are limited by myocardial oxygen demand (angina) rather than total body oxygen uptake. Angina usually occurs at a reproducible double product. When this is not the case, the influence of other factors should be considered, such as a recent meal, adverse ambient temperature, coronary artery spasm, or changes in coronary artery tone.

The response on electrocardiography (ECG) and angina are closely related to myocardial ischemia (coronary artery disease), whereas exercise capacity, systolic blood pressure, and heart rate responses to exercise can be determined by myocardial ischemia, myocardial dysfunction, or responses in the periphery. Exercise-induced ischemia can cause cardiac dysfunction, which can result in exercise impairment and an abnormal systolic blood pressure response. This complicates the interpretation of exercise test findings and makes it difficult to assess the cause of symptoms. The variables affected by both myocardial ischemia and myocardial dysfunction (exercise capacity, maximal heart rate, and systolic blood pressure) have the greatest prognostic value.

ADAPTATIONS TO CHRONIC EXERCISE (TRAINING)

Physiologic adaptations to training can be divided into morphologic, hemodynamic, and metabolic categories ([Table 89.1](#)). The application of an appropriate stimulus results in adaptation; the greater the stimulus, the greater is the adaptation. The benefits gained from an exercise program depend on a number of factors, including the patient's initial level of fitness, physical endowment, previous training, age, gender, and health.

Morphologic Adaptations
Myocardial hypertrophy
Hemodynamic Adaptations
Increased blood volume
Increased end-diastolic volume
Increased stroke volume
Increased cardiac output
Reduced heart rate for any submaximal work load
Metabolic Adaptations
Increased mitochondrial volume and number
Greater muscle glycogen stores
Enhanced fat utilization
Enhanced lactate removal
Increased enzymes for aerobic metabolism
Increased maximal oxygen uptake

TABLE 89.1. PHYSIOLOGIC ADAPTATIONS TO PHYSICAL TRAINING IN HUMANS

The hemodynamic results of an exercise program include a resting bradycardia, a decrease in heart rate and systolic blood pressure at any matched submaximal workload, an increase in maximal oxygen uptake and maximal cardiac output, an increase in total blood volume, and a more rapid return toward baseline in recovery. These hemodynamic adaptations not only improve exercise capacity but also make the heart more efficient, such that any submaximal workload can be performed

with less demand on the heart muscle.

SCIENTIFIC BASIS FOR EXERCISE PROGRAMS IN PATIENTS WITH CORONARY HEART DISEASE

In terms of prognosis, exercise training has been definitively shown to improve morbidity and mortality. Although few of the randomized trials in cardiac rehabilitation individually have shown significant reductions in mortality, taken together, these trials demonstrate a substantial 20% to 25% reduction in the rate of mortality from cardiovascular causes.

Although some studies of exercise training have demonstrated cardiac changes (enhanced contractility, decrease of exercise-induced ST-segment depression), these studies have used high-intensity training among highly selected patients. Larger, randomized trials using standard training programs in unselected patients have shown modest improvements in thallium perfusion images. Several randomized trials have demonstrated that intensive dietary and lipid-lowering therapy along with exercise may retard or reverse the progression of atherosclerotic lesions in some patients. Certainly, however, the statin drugs are much more effective in this regard.

Advances in the treatment of cardiovascular disease and data supporting the value of secondary prevention have increased greatly the spectrum of patients who may benefit from cardiac rehabilitation. In addition to patients who have sustained MIs, this group now includes patients with chronic heart failure and patients who have undergone coronary artery bypass grafting, cardiac transplantation, catheter interventions, and pacemaker implantation. Of the roughly 1 million persons in the United States who survive acute MIs annually, only 10% to 15% undergo formal outpatient rehabilitation. Not all patients need a formal exercise program, but directing these services to the patients who need them the most remains one of the important challenges for the field.

PHASES OF CARDIAC REHABILITATION AFTER MYOCARDIAL INFARCTION

The typical phases in cardiac rehabilitation are coronary care unit and inpatient care (phase I), convalescence in an outpatient or home program (phase II), and recovery in a long-term community-based or home program (phase III). Phase I has been greatly shortened by thrombolysis and catheter interventions. Most education comes in quick bursts of information, but fortunately the public is much better informed. Reimbursement agencies have greatly decreased funding for Phase III, which usually is supported for only 1 year. Monitored programs usually are reimbursed for only a small proportion of high-risk patients.

SEVERITY OF THE MYOCARDIAL INFARCTION

Electrocardiography

The ECG pattern predicts the clinical course and outcome surprisingly well. The greater the number of areas with Q waves and the greater R-wave loss, the larger is the MI. Non-Q-wave MIs are associated less commonly with congestive heart failure or shock, but they can be complicated. It once was thought that non-Q-wave MIs were unstable and needed intermediate intervention, but this has been shown not to be the case. Also, calcium antagonists are not indicated for non-Q-wave MIs, but they should receive β -blockers just like patients with Q-wave MIs.

Inferior infarctions usually are smaller than anterior infarctions, result in less of a decline in ejection fraction, and are less likely to be associated with shock or congestive heart failure. Anterior infarctions are more likely to cause aneurysms and a greater decrease in ejection fraction.

Size of the Myocardial Infarction

The size of an MI can be judged by the creatine phosphokinase level, mostly by the muscle-brain fraction (CK-MB) released. In general, the higher the amount of MB released and the longer the creatine phosphokinase level remains elevated, the larger is the MI. Troponin now is available as a cardiac enzyme, reflecting damage.

Complicated and Uncomplicated Myocardial Infarction

Morbidity and mortality are much higher in patients with complicated MIs than in those with uncomplicated MIs. The criteria for a complicated MI are presented in [Table 89.2](#). The most important clinical predictors are previous MI and the presence of congestive heart failure or cardiogenic shock. The progressive ambulation program should be delayed until patients with complications reach an uncomplicated status and then should proceed at a slower than normal pace.

Continued cardiac ischemia (pain, late enzyme rise)
Left ventricular failure (congestive heart failure, new murmurs, roentgenographic changes)
Shock (blood pressure drop, pallor, oliguria)
Important cardiac dysrhythmia (more than six premature ventricular contractions per minute, atrial fibrillation, ventricular tachycardia)
Conduction disturbances (bundle-branch block, atrioventricular block, hemiblock)
Severe pleurisy or pericarditis
Complicating illnesses
Marked creatine phosphokinase rise without a noncardiac explanation or after thrombolysis

TABLE 89.2. CRITERIA FOR CLASSIFYING A MYOCARDIAL INFARCTION AS COMPLICATED

EARLY AMBULATION

The program should begin with range-of-motion exercises and sitting with legs dangling and should progress to ambulation and calisthenics. After the patient has been transferred from the intensive care unit, self-care activities can begin and an upright posture should be encouraged as much as can be tolerated. Before exercise is allowed, the patient's condition must be medically stable. There should be no evidence of congestive heart failure, dangerous dysrhythmias, or unstable angina. The blood pressure should remain within 20 mm Hg of the resting level. The heart rate usually should remain within 20 beats per minute of the resting level, and the rating of perceived exertion should not exceed 14. If complications arise, the activity should be discontinued and restarted later at a lower level. The patient should be able to walk up stairs before hospital discharge and should be able to perform activities of daily living independently by the time of hospital discharge (3- to 4-MET level).

EXERCISE TESTING BEFORE HOSPITAL DISCHARGE

Exercise testing after acute MI has been shown to be safe. When performed before hospital discharge, it should be submaximal (5 METs). This test has many benefits, including clarification of the response to exercise, determination of an exercise prescription, and recognition of the need for medications or interventions. It can have a beneficial psychological effect on recovery and begins the outpatient rehabilitation process.

RETURN TO WORK AND RECREATIONAL ACTIVITIES

Historically, decisions regarding the patient's return to work, driving, and sexual and recreational activities have been based on clinical judgments rather than physiologic assessments. These decisions should be based on the consequences of the coronary event (ischemia, symptoms of congestive failure or dysrhythmias), the nature of the patient's occupational or recreational activities, and the patient's response to the pre-discharge exercise test. In general, if the patient does not exhibit any untoward response to submaximal exercise testing and achieves 5 or more METs, it is unlikely that he or she will encounter difficulties during activities of daily living. More strenuous job or recreational requirements should not be undertaken until a symptom-limited exercise test can be performed, and exercise capacity can be determined and related to the desired physical activities. Factors influencing return to work include age, work history, severity of cardiac damage, financial

compensation for illness, employer ignorance, termination of employment, and, most important, the patient's perception of his or her health status.

The transition from an outpatient to a home-based maintenance program occurs more rapidly. Randomized trials have demonstrated that patients can return to work quickly and safely during rehabilitation and that participation in a rehabilitation program facilitates this process. Researchers at Stanford University have advocated home exercise that is unmonitored or monitored by telephone or microprocessor. The safety and efficacy of these home programs have been shown to be similar to those of more conventional programs.

MEDICAL EVALUATION FOR THE EXERCISE COMPONENT

The following is one approach to assessing patients, placing them in a "niche" so the clinician knows how to react to their symptoms and test results. The tools for assessment begin with the history and physical examination. The first step in evaluating patients for outpatient cardiac rehabilitation is to determine whether their coronary heart disease is stable. "Stability" is determined primarily by the presence or absence of myocardial ischemia, congestive heart failure, and dysrhythmias. The hallmark symptom of ischemia is chest pain. Most patients have chest pain of some type and the pain commonly is ignored. After patients are told about heart disease, these routine pains may become frightening. It is important to separate nonischemic from ischemic chest pain. All chest pain should not be called angina pectoris. Angina becomes unstable when it changes its pattern (i.e., occurs more frequently, at rest, or at lower workloads). Increasing symptoms of congestive heart failure include sudden weight gain, edema in the lower extremities, dyspnea on exertion, and paroxysmal nocturnal dyspnea. Although there was early concern that thrombolytic agents could leave patients more likely to experience ischemia, their benefits have been shown to extend over 10 years. In addition, b-blockers are a must drug because they reduce mortality after MI by 25%. Statins appear to reduce cardiovascular events by up to 50%.

In patients who are stable, further assessment can proceed. Initially, the ischemic threshold should be determined by the onset of angina pectoris or ST-segment depression at a particular heart rate, double product, or workload. Once this is clarified, myocardial function should be determined. Clinical clues that suggest the possibility of myocardial dysfunction include a history of congestive heart failure, cardiogenic shock, a previous MI, a large anterior MI, cardiomegaly, a large creatine phosphokinase elevation, multiple Q waves, and underlying problems such as cardiomyopathy or valvular heart disease. These patients must be watched for signs and symptoms of congestive heart failure. They are usually limited by their maximal cardiac output, which leads to early fatigue and pulmonary symptoms, rather than to chest pain. A strong effort should be made to explain the symptoms related to congestive heart failure. In patients who have sustained MIs, the symptoms could be caused by mitral valve insufficiency, resulting from papillary muscle dysfunction or rupture, or from a dilated mitral annulus.

In addition to myocardial ischemia and dysfunction, the other key features of heart disease are arrhythmias, valvular function, and exercise capacity. These five features are important because they usually explain the patient's symptoms and help to establish the prognosis. Evaluation of these features is necessary for optimal management, including individualization of the rehabilitation program. The ECG, chest radiograph, and exercise test are next in importance after a careful history and physical examination. The exercise test is the key to prescribing exercise. Specialized tests such as echocardiography, nuclear imaging, and cardiac catheterization can be used to confirm impressions, clarify incongruous clinical situations, or identify coronary pathologic or anatomical patterns requiring revascularization.

EXERCISE PRESCRIPTION

The major ingredients of the exercise prescription are the frequency, intensity, duration, mode, and rate of progression. Based on numerous studies performed over the last several decades, it usually is accepted that increases in maximal oxygen uptake are achieved if a person exercises dynamically for a period ranging from 15 to 60 minutes, three to five times per week, at an intensity equivalent to 50% to 80% of the person's maximum capacity. Short periods for warm-up and cool-down are strongly encouraged for participants in cardiac rehabilitation programs.

Remember, however, that the prescription is for fitness and increasing aerobic capacity. Increasing physical activity through simple activities such as brisk walking appears to provide the same health benefits with less risk and to be more convenient.

CONTRAINDICATIONS TO EXERCISE TRAINING AND SAFETY

Absolute contraindications to exercise training include unstable angina, dissecting aortic aneurysm, complete heart block, uncontrolled hypertension, uncontrolled congestive heart failure, dysrhythmias, thrombophlebitis, and other complicating illnesses. Relative contraindications include frequent premature ventricular contractions, controlled arrhythmias, intermittent claudication, metabolic disorders, and moderate anemia or pulmonary disease. If these contraindications are observed, the incidence of exertion-related cardiac arrest in cardiac rehabilitation programs is extremely low, and, because of the availability of rapid defibrillation, death rarely occurs. A survey evaluating more than 51,000 participants over a 5-year period demonstrated that only one to three fatalities occurred per million hours of participation in a cardiac rehabilitation program.

MONITORING OF THE EXERCISE COMPONENT

It now is recognized that only a small percentage of patients referred for cardiac rehabilitation require supervised continuous ECG monitoring during exercise. [Table 89.3](#) presents a list of criteria for ECG monitoring outlined by the American College of Cardiology.

Severely depressed left ventricular function (ejection fraction <30%)
Resting complex ventricular arrhythmia (Lown type 4 or 5)
Ventricular arrhythmia appearing or increasing with exercise
Decrease in systolic blood pressure with exercise
Survival of sudden cardiac death
Myocardial infarction complicated by congestive heart failure, cardiogenic shock, or serious ventricular arrhythmia
Severe coronary artery disease and marked exercise-induced ischemia
Inability to self-monitor intensity because of physical or intellectual impairment

Criteria advocated by the American College of Cardiology and the American Heart Association Subcommittee on Cardiac Rehabilitation.

TABLE 89.3. CRITERIA FOR ELECTROCARDIOGRAPHIC MONITORING DURING CARDIAC REHABILITATION

PHASE III (MAINTENANCE PROGRAM)

Progression to an out-of-hospital maintenance program is desirable after patients have participated in a phase II program for a suitable period. The time required before patients move to a maintenance program can vary considerably, but rarely exceeds 12 weeks. The purpose of phase III is to maintain training adaptations, prevent recurrence of events or symptoms, and maintain progress. It is important that patients understand how to monitor their own exercise intensity and recognize symptoms and that they have a basic knowledge of their particular disease and medications. This maintenance program should most often be a self-monitored walking program, although physicians can play an important part in this process by encouraging patients.

Performing an exercise test before the maintenance program is useful to provide an outgoing exercise prescription, confirm the safety of exercise for a given patient, and assess the risk for future cardiac events.

FUTURE DIRECTIONS IN THE UNITED STATES

As suggested by Ribisl and colleagues, a new era requires a new model. The old model of a standard, fixed 36-session program in which every patient receives the same intervention regardless of specific needs or characteristics, is outmoded and a disservice to patients. Part of the reason for adhering to the old model was failure to interact with third-party payers in the design of appropriate programs that met patient needs. The security of a safe and reliable means of obtaining reimbursement was the driving force behind this approach, and programs have been reluctant to make any change because of a fear that revenues would be lost. Some observations

and suggestions follow and then recommendations are provided of several models for consideration. These models are based on impressions of trends and opportunities that exist today. With cardiac rehabilitation care serving approximately 15% to 20% of eligible patients, utilization is low.

The treatment plan for patients with cardiovascular disease is rarely limited to a single diagnosis. It is unusual to find an older patient who is free of other diagnoses of chronic disease. Many patients with cardiac disease are likely to have one or more additional conditions, such as obesity, diabetes, chronic obstructive pulmonary disease (COPD), arthritis, or other complications that must be taken into account in the intervention plan.

There is a clear lack of awareness among those in the medical profession who are responsible for making decisions regarding the treatment options available to their patients in the community. Because training in preventive strategies has never been an integral part of medical education, efforts must be made to convince current practitioners and medical students about the benefits to patients.

Cardiac rehabilitation needs to be restructured by adding newer cost-effective techniques to survive the current reformation of health care. Traditional rehabilitation will be best delivered at centers in the community rather than by following the current fragmented approach in which each hospital has a competitive program. Newer models involve the use of other medical and paramedical professionals, volunteers, and communication with patients by telephone, internet and the postal service.

TREATMENT MODELS

Four specific models are presented, with research documenting their efficacy.

Center-Based Model

Physician referral could be improved as general practitioners become more responsible for triage and have the option of directing patients to a center with multidisciplinary specialists available. Health care managers must be convinced that cardiac rehabilitation is effective. The necessary components of this triaging approach include initial assessment by a team of specialists, risk stratification, exercise prescription (often just a walking program with indirect supervision, when medically appropriate), dietary instruction, lipid abnormality classification and treatment, psychological and vocational counseling, education, and a discharge plan.

The Center-Based Model is the classic model that was the prototype for most programs in recent history. Its major shortcomings are lack of adequate referral. Physician referral could be improved if general practitioners become more responsible for triage and have the option of directing patients to a center with multidisciplinary specialists available.

Home-Based Model

The Home-Based Model has been in place for over a decade, and numerous studies in the literature have documented its effectiveness. This model has been validated at Stanford University in a 1-year randomized clinical trial including 160 women and 197 men 50 to 65 years who were sedentary and free of cardiovascular disease. It included physician referral, assessment, prescription, and multiple interventions. Regular feedback and home visits were carried out to prevent relapses. Home-based exercise was as effective as group exercise in producing these changes. Lower-intensity exercise training was as effective as higher-intensity exercise training in the home setting.

Volunteer Community Model

The Volunteer Community Model is a unique approach that was developed by Lorig and colleagues in patients with arthritis. These investigators trained nonmedical lay volunteers (who themselves had arthritis) to direct educational programs of self-management in the community to help patients with arthritis deal with their disease outside the medical setting. Lorig and colleagues have since expanded this model to include four chronic disorders (coronary heart disease, COPD, stroke, and arthritis).

Health Risk Appraisal Model

A randomized 12-month trial comparing claims data was performed in a large insured population. After assessment with a Health Risk Appraisal (HRA) instrument accomplished by mail, feedback on risk factors and recommendations for change were provided again by mail using an educational packet of self-management materials. This study demonstrated a considerable cost-trend reduction from a simple mail-based health promotion program. The insurance company was so pleased with the reduction in claims that the program has been continued.

CONCLUSION

Much of what began under the label of cardiac rehabilitation now has been assimilated into routine care. Hospital accreditation guidelines specify a multidisciplinary approach that includes progressive ambulation for the cardiac patient. Cardiac rehabilitation has redirected interest to humanistic concerns, providing a balance to the emphasis on high technology. The average patient does not require all components of cardiac rehabilitation, but usually can benefit from some of them. Analyses of controlled trials reveal a decrease in mortality among patients with MIs who have participated in exercise programs. Physiologic studies support the occurrence of beneficial hemodynamic and metabolic changes in a wide range of cardiac patients. Therefore, the physician should consider an exercise program as part of the routine therapeutic regimen.

CHAPTER 90: CLINICAL PHARMACOLOGY OF CARDIOVASCULAR DRUGS

D. CRAIG BRATER

[Drugs Used For Congestive Heart Failure](#)
[Antiarrhythmic Agents](#)
[Antianginal Agents](#)
[Antihypertensive Agents](#)
[Anticoagulant, Thrombolytic, and Antiplatelet Agents](#)
[Lipid-Lowering Drugs](#)

This chapter presents some general concepts of clinical pharmacology as applied to specific cardiovascular drugs. The material in this chapter should be combined with that of other chapters in the text dealing with the same drugs and the diseases for which they are used. A general discussion of clinical pharmacology, with definitions of terms and concepts, is presented in [Chapter 55](#). A discussion of specific aspects of clinical pharmacology in the aged appears in [Chapter 469](#) and [Chapter 167](#) covers the adjustment of drug dosages in patients with renal insufficiency.

DRUGS USED FOR CONGESTIVE HEART FAILURE

For a general discussion of the approach to patients with heart failure, see [Chapter 66](#).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND OTHER PRELOAD- AND AFTERLOAD-REDUCING AGENTS

Vasodilators and, particularly, angiotensin-converting enzyme (ACE) inhibitors have revolutionized the treatment of congestive heart failure (CHF). As a result of disappointing results with inotropic agents and particularly because ACE inhibitors are the only class of pharmacologic agent that has proved to have a salutary impact on survival in patients with heart failure, these drugs are indicated in all patients with left ventricular dysfunction, including those who are asymptomatic. A few patients (perhaps 10%) are not able to tolerate ACE inhibitors, primarily owing to persistent cough or hypotension. For the former, angiotensin antagonists are a logical choice. Despite compelling evidence of efficacy, surveys show that the number of patients receiving ACE inhibitors is disappointingly low, even when patients are cared for by a cardiologist. A goal should be that 90% of patients with left ventricular systolic dysfunction receive an ACE inhibitor.

Disposition and Effect

Initial work demonstrating the feasibility of using vasodilators in CHF was performed with nitroprusside. Because nitroprusside has a short duration of action and must be given intravenously, its use was limited to acute studies in intensive care settings.

Nitrate preparations cause venodilation and thereby decrease preload. They are most effective in patients with elevated cardiac filling pressures. In patients whose filling pressures are not increased, nitrates should be avoided or used with caution because profound hypotension can occur. The numerous nitrate preparations available for clinical use have identical pharmacologic effects but differ in their times of onset and durations of action ([Table 90.1](#)). Transdermal delivery systems provide remarkably stable blood concentrations of nitroglycerin, but tolerance to the patches or sustained intravenous infusions of nitroglycerin develops within about 8 hours. The cyclic variation in nitroglycerin serum concentrations that occurs with all other preparations allows the vascular endothelium to remain responsive to the nitrate. As such, patches should be removed at night to allow responsiveness to be restored by morning.

Preparation	Dose Range (mg)	Frequency of Dosing (hr)	Onset of Effect (min)	Duration of Effect (hr)
Organic nitrates (nitroglycerin)				
Isosorbide	1-2 (oral)	As needed	8	13-45
Sustained-release	0.5-4.8	8 ^b	4-8	13-45
Sublingual	0.5-1.5	4-6	45-120	1-4
Rectal	1-4	3-4	4-15	4-8
Isosorbide DNI	15-40 (2-4 ^c)	4-6	30-120	3-8
Isosorbide	10-20	12-24	30-120	2 ^d
Isosorbide dinitrate				
Sustained-release	25-15	3-4	15-40	1-3
Oral				
Immediate-release	5-40	4-6	45-120	4-8
Oral	5-10	3-4	30-60	3-5
Isosorbide mononitrate (ISMN)				
Oral	20	12	30-60	12
5-allyl nitroglycerin				
Sustained-release	1-15	4-8	2	13-45
Oral	1-20	4-8	30-60	3-4
Permeation-enhanced (nitroglycerin)	20-80	4-6	30-60	3-4

^aFor information about patches, see text.

TABLE 90.1. NITRATE PREPARATIONS USED FOR PRELOAD REDUCTION IN HEART FAILURE AND FOR ANGINA

Hydralazine and some dihydropyridine calcium antagonists (e.g., amlodipine) have been used to reduce afterload in patients with CHF. Such an effect is particularly useful in patients with increased peripheral vascular resistance and with normal or slightly elevated cardiac filling pressures. In hypotensive patients, afterload reducing agents must be used cautiously if at all because they occasionally cause profound hypotension. If the patient also has increased filling pressure, combining afterload reduction with nitrates is helpful; alternatively, agents with mixed effects are useful.

After oral administration, hydralazine reaches peak concentrations within 30 to 120 minutes. Clinically observed effects occur within 20 to 30 minutes of dosing. Hydralazine has an elimination half-life of 2 to 4 hours, but the biologic effect in both CHF and hypertension appears to be longer. As a result, when used for afterload reduction, dosing every 6 hours is sufficient; when used to treat hypertension, hydralazine can be given every 12 hours. As an antihypertensive, daily doses of hydralazine greater than 200 mg seldom are needed. In contrast, it is unusual for patients with CHF to respond to 200 mg per day, and typical doses in this disorder are 300 to 400 mg per day. The reason for the different dose requirements is unknown but may simply represent the higher degree of peripheral vasoconstriction in severe CHF compared with hypertension. Hydralazine commonly induces sympathetically mediated reflex tachycardia in hypertensive patients, whereas in CHF the improved cardiac function decreases sympathetic tone so that tachycardia is infrequent.

Dihydropyridine calcium channel antagonists decrease arteriolar resistance. Although effective in afterload reduction, they are used more frequently as antianginal or antihypertensive agents. Calcium channel antagonists are discussed in the section on antianginal agents.

ACE inhibitors have relegated all other afterload-reducing regimens to secondary alternatives. A number of these drugs are available. The main distinguishing feature is duration of action and degree of dose adjustment needed in patients with renal insufficiency ([Table 90.2](#)). As noted previously, ACE inhibitors extend the life of CHF patients, and they also have documented benefit in patients with asymptomatic left ventricular dysfunction. In the few patients who do not tolerate these drugs, angiotensin antagonists are logical second choices, although they have not yet been proved to decrease mortality. If neither group of drugs is effective, the combination of nitrates and hydralazine should be considered.

Drug	Bioavailability (%)	Half-Life (Hours)		Effect in Patients with Severe Renal Insufficiency (Percent of Normal)
		Normal Renal Function	Severe Renal Insufficiency	
ACE Inhibitors				
Benzylpenicillin	48-57	11-20	30	100
Captopril	25-30	1.5-2	15	100
Enalapril	60-70	11-17	32	100
Furosemide	20-40	1-2	15	100
Lisinopril	20-30	11-15	10-20	100
Perindopril	20	16-24	20	100
Quinapril	20-30	11-15	10-20	100
Trandolapril	20	11-15	10-20	100
Angiotensin Receptor Antagonists				
Candesartan	40	8-11	10	100

Telmisartan	20-30	1.2-1.5	15	No change

TABLE 90.2. PHARMACOKINETIC FEATURES OF ACE INHIBITORS AND ANGIOTENSIN ANTAGONISTS

Effects of Disease

Because the usual strategy for use of nitrates is to start with low doses and titrate upward based on clinical response, minor changes in their disposition that might occur are moot. Hydralazine shows no substantial changes in its disposition in various disease states. Dihydropyridine calcium antagonists are discussed in later sections.

The pharmacokinetics of nitroprusside have not been well studied. It is metabolized to thiocyanate, which is eliminated by the kidney over a half-life of 2 or 3 days. As such, the metabolite accumulates in patients with renal insufficiency. The adverse effects of nitroprusside, other than hypotension, are due to thiocyanate. Its accumulation can cause central nervous system (CNS) side effects, such as restlessness, agitation, and toxic psychoses. Because the compound is excreted so slowly, it is important to monitor all patients clinically and with measurements of circulating thiocyanate. Particular caution is needed in patients with renal impairment. If thiocyanate concentrations reach 10 mg per deciliter, caution is paramount and nitroprusside administration should be discontinued. If severe toxicity develops, thiocyanate can be removed by hemodialysis.

Because all ACE inhibitors depend to some degree on the kidney for excretion, their pharmacokinetics are altered in renal impairment ([Table 90.2](#)). Dosing needs modification, depending on the level of renal function. In patients with severe renal insufficiency, doses of one-fifth to one-sixth of the normal dose of some of these drugs should be used. The half-lives of ACE inhibitors are prolonged in renal insufficiency, so the time to reach steady state is greater (four times the half-life). The frequency of dose increments should be such that steady state is attained at one dose before a change is made. In other clinical conditions such as CHF and in the elderly, no additional changes in disposition appear to occur, except those caused by the patient's renal function. Similar considerations apply to angiotensin antagonists ([Table 90.2](#)).

Drug Interactions

Pharmacokinetic drug interactions have not been described with these preload- and afterload-reducing agents. Various pharmacodynamic interactions can occur with other drugs affecting cardiovascular hemodynamics. These are predictable based on the additive pharmacology of the drugs; a good example is the combined effect of nitrates and hydralazine.

DIURETICS

Disposition and Effect

All diuretics except spironolactone must reach the urine to be effective, because their active sites are on the luminal surface of renal tubular cells. As such, patients with renal insufficiency may have very high serum concentrations of a diuretic but negligible response because no drug can reach the urinary site of action. Hence, therapeutic strategies with diuretics are based on attaining sufficient amounts of drug in the urine.

The carbonic anhydrase inhibitor acetazolamide has a half-life of 13 hours, which extrapolates to a time needed to reach steady state of 2 to 3 days.

Mannitol inhibits sodium reabsorption throughout the nephron, with predominant effects at the proximal tubule and the thick ascending limb of the loop of Henle. In patients with severe renal disease, the half-life of mannitol increases from about 1 to 36 hours. Its administration in such patients can result in retention of mannitol with potentially disastrous consequences as the osmotic effect draws water into the vascular space, resulting in volume expansion, which can be sufficient to precipitate heart failure. Mannitol should be used with caution (if at all) in patients with renal insufficiency.

Unlike mannitol, which is filtered at the glomerulus, loop diuretics enter the tubular lumen by being actively secreted by the organic acid transport pathway of the proximal tubule. Negligible amounts of these drugs are filtered because they are highly bound to serum proteins, as reflected by their small volumes of distribution. The renal elimination of bumetanide and furosemide is fast, accounting for their short half-lives (1 hour). Ethacrynic acid probably has similar pharmacokinetic characteristics. Torsemide is a longer-acting agent, with a half-life of about 4 hours.

The efficacy of the loop diuretics, combined with the short half-life, extrapolates to an intense, short-lived diuresis. In patients with normal renal function, peak diuretic effect occurs within 30 minutes after intravenous dosing and within 1 to 2 hours after oral administration. The diuresis then lasts for 2 to 3 hours (4 to 6 hours for torsemide), after which the kidney's reabsorptive capacities for sodium return. In fact, in this postdiuretic recovery period, the nephron avidly reabsorbs sodium; if dietary intake is too high, the sodium loss caused by the drug can be completely nullified by sodium retention. Therefore, dietary sodium restriction is an important adjunct to therapy with these agents.

Response to all the loop diuretics appears similar. The maximal response in terms of the fractional excretion rate of sodium is about 20%. This compares with a value of about 5% for thiazide diuretics. The loop diuretics differ in terms of potency; that is, different amounts are used to elicit the same response. As such, 1 mg of bumetanide equals 20 mg of torsemide, 40 mg of furosemide, and 50 mg of ethacrynic acid. Because ethacrynic acid has been reported to be more likely to cause ototoxicity, it is less commonly used. Torsemide use has recently been shown to decrease hospitalization rates and improve quality of life compared with furosemide in patients with CHF. This is presumably due to its complete and predictable absorption and longer duration of effect.

Thiazide diuretics also reach the urine by active secretion at the proximal tubule. They have a minor effect to inhibit sodium reabsorption in the proximal nephron and cause most of their effect by blocking sodium reabsorption at the distal tubule. Many different thiazide compounds are marketed, with limited or no data available concerning their pharmacokinetics. The maximal natriuretic response obtainable with each is the same, but they differ in potency (i.e., different milligram amounts are used). The only clinically relevant difference is the duration of action: short (1 to 5 hours; bendroflumethiazide and trichloromethiazide), intermediate (5 to 15 hours; hydrochlorothiazide, hydroflumethiazide, and indapamide), and long-acting (15 to 50 hours; the remainder plus metolazone). The choice of drug should depend on the desired duration of action. Unwanted potassium loss appears to be greatest with the long-acting thiazides, and in most settings short- or intermediate-acting agents are preferable. The choice is probably best determined by which is least expensive.

Although the efficacy of thiazides is modest and as single agents they are not effective in most patients with CHF, thiazides can be particularly effective when combined with loop diuretics. Chronic dosing with loop diuretics can result in diminished efficacy over time owing to hypertrophy of distal nephron segments wherein they avidly retain sodium. These nephron sites are blocked by thiazide diuretics so that their combination with a loop diuretic results in a synergistic response. The combination also results in substantial potassium loss so that patients must be monitored for development of hypokalemia. In addition, the overall diuretic response in some patients can be substantial and actually result in severe volume depletion. Thus, patients should be monitored frequently at the outset of such combination therapy.

Distally acting agents act at portions of the nephron where potassium is secreted. Hence, in addition to inducing sodium excretion, they block potassium excretion and are commonly referred to as potassium-retaining or potassium-sparing diuretics. All other diuretics cause potassium loss concomitant with natriuresis. Amiloride and

triamterene differ from spironolactone in acting independently of aldosterone, in reaching their sites of action from the lumen rather than the peritubular side of the nephron, and in being secreted into the lumen by the organic base transport pathway of the proximal tubule. Amiloride (7 to 11 hours) and triamterene (2 to 5 hours) have relatively short elimination half-lives, so their onset of action is quick and they reach steady state within about 1 day. Triamterene's activity resides in a sulfate ester conjugate. Clinically, the effects of both drugs are similar. The natriuretic effects of all distally acting diuretics are small, so they are used more frequently for their potassium-retaining properties than as natriuretic agents.

Spironolactone is a competitive antagonist of aldosterone and acts by eliminating the effects of this mineralocorticoid. The disposition of spironolactone is complex and poorly understood. The drug is a long-acting agent and requires 3 or 4 days to reach maximum effect, so nothing is gained by changing doses more frequently. Because of these kinetic characteristics and the dependence on aldosterone for efficacy, when used as a diuretic spironolactone is best reserved for settings of primary or secondary (e.g., hepatic cirrhosis) hyperaldosteronism.

Effects of Disease

As renal function declines either because of primary renal disease or as a secondary manifestation of other conditions like CHF, the access of diuretics into the urine decreases in parallel. As such, in patients with creatinine clearance values less than about 40 mL per minute, all diuretics except those affecting the loop of Henle have negligible effects as single agents. In addition, distally acting diuretics carry an unacceptable risk of producing hyperkalemia in patients with renal impairment and are contraindicated. Hence, the mainstay of diuretic therapy in patients with diminished renal function of any cause is loop diuretics. These agents retain their efficacy in patients with renal insufficiency if adequate amounts of the diuretic reach the site of action. The therapeutic strategy in such patients is to administer a large enough dose to allow delivery of adequate amounts of diuretic into the urine. This can be accomplished with the doses suggested in [Table 90.3](#).

Clinical Condition	Dose of Loop Diuretic (mg)					
	Bumetanide		Furosemide		Torsemide	
	IV	Oral	IV	Oral	IV	Oral
Renal insufficiency						
Cr _{cl} <30	2-3	2-3	10-20	10-20	2-3	2-3
Cr _{cl} <20	4-8	4-8	10-20	20-40	5-10	5-10
Nephrotic syndrome	2-4	2-4	10-10	10-20	5-10	5-10
Cirrhosis	1	1	4	8	2	2
Deceptive heart failure	2-3	2-3	4-8	10-10	5-10	5-10

Cr_{cl}, creatinine clearance; IV, intravenous.

TABLE 90.3. MAXIMUM SINGLE DOSES OF LOOP DIURETICS IN VARIOUS CLINICAL CONDITIONS

Diuretics are mainstays of therapy in patients with heart failure, although no formal efficacy trials have been conducted. If renal function is normal in these patients, loop diuretics are delivered to the site of action as efficiently as in normal subjects. It is reasonable to presume that the same is true for other diuretics. Because many patients with heart failure have mild decrements in renal function, they most likely need doses two or three times greater than normal. Such a strategy ensures sufficient access of diuretic into the urine with negligible risks. Even when sufficient drug reaches the nephron in such patients, the tubular response is subnormal and the maximal sodium excretion rate attainable is diminished (e.g., to about 10% of filtered sodium). Clinically, this phenomenon means that the patient will never have the intensity of diuretic response that occurs normally. Yet, larger single doses of diuretic are not useful in overcoming this effect; instead, effective doses should be administered more frequently, such as three or four times a day rather than once or twice.

Patients with hepatic cirrhosis commonly develop secondary hyperaldosteronism; as a result, the drug of choice is spironolactone. The dose must be titrated to a level sufficient to block the effects of endogenous aldosterone, realizing that dosage changes require 3 or 4 days to reach a steady state. Because renal function is relatively normal in patients with cirrhosis, the diuretics that must reach the urine to be active retain their efficacy, but response is subnormal. Because of this change in the pharmacodynamics of response, effective doses often must be administered more frequently to obtain the needed overall response.

Patients with nephrotic syndrome and normal glomerular filtration rates deliver normal amounts of diuretic into the urine. Much of this drug can bind to the albumin in the urine, which is the hallmark of this condition. As such, doses two to four times normal are needed to result in adequate amounts of unbound, pharmacologically active drug at the site of action.

In the edematous disorders, one might speculate that the absorption of drugs would be altered; edema of the gut wall, altered intestinal perfusion, or changed gastrointestinal motility all might affect absorption. Studies in patients with nephrotic syndrome, cirrhosis, and heart failure have shown normal bioavailability of loop diuretics, although the time course of absorption is slowed. Oral doses do not have to be increased in those with the edematous disorders to compensate for malabsorption.

Drug Interactions

Nonsteroidal anti-inflammatory drugs (including aspirin) decrease the effects of probably all diuretics. This most likely occurs by an independent effect of these drugs to stimulate sodium reabsorption at the thick ascending limb, thus diminishing the overall response to the diuretic. Clinically, the effect is often minor or negligible, but it is sometimes sufficient to require discontinuing the nonsteroidal drug, increasing the diuretic dose, or switching to a more effective diuretic.

Diuretic agents lower blood pressure and are often used as antihypertensives. Their effects are predictably additive to other antihypertensives. In addition, with many nondiuretic antihypertensives, reflex fluid retention occurs, expanding intravascular volume and nullifying the blood pressure-lowering effect. This phenomenon is called *pseudotolerance*, because it does not represent true tolerance to the drug. Use of a diuretic in this setting often causes a synergistic antihypertensive effect.

CARDIAC GLYCOSIDES

The positive inotropic effect of digitalis glycosides has been believed to be particularly beneficial for heart failure, and their electrophysiologic effect—slowing conduction through the atrioventricular node—has been useful for controlling the rate of ventricular response in patients with atrial fibrillation. However, until recently, a definitive trial assessing the efficacy of digoxin had not been conducted. The Digitalis Investigation Group (DIG) trial has now shown that digoxin does not affect mortality but that in patients with left ventricular ejection fractions less than 0.45 it improves symptoms and decreases morbidity. Thus, digoxin is a logical choice in such patients who have not responded adequately to ACE inhibitors and diuretics.

Questions have also been raised about the efficacy of digitalis glycosides in patients with atrial fibrillation. In this setting, these drugs have been used both to convert patients to sinus rhythm and to control the rate of ventricular response in patients with persistent atrial fibrillation. One study found that digoxin was no different from placebo in converting to sinus rhythm in patients who had been in atrial fibrillation for 7 days or less. Other drugs may be more efficacious in this setting, although direct comparative trials have not been performed. Digitalis glycosides clearly are effective in maintaining the rate of ventricular response in patients with atrial fibrillation. However, these drugs often do not satisfactorily control the ventricular response during exercise, particularly in younger patients. Other drugs, such as verapamil and diltiazem, are effective both at rest and during exercise and may be preferable in many patients.

Disposition and Effect

Although other preparations of cardiac glycosides are available, digoxin and digitoxin are those used clinically. Digoxin's use is so dominant that it alone is discussed here. Digoxin is eliminated predominantly by the kidney and thus requires dosage adjustment in patients with diminished renal function.

Parameters for digoxin pharmacokinetics are listed in [Table 90.4](#). Both the volume of distribution and the clearance of digoxin depend on renal function. Therapy often is initiated with a loading dose, although this strategy results in a higher incidence of toxicity than if a maintenance dose is used and steady-state serum

concentrations are gradually attained. Hence, a loading dose should not be used unless therapeutic effects are truly needed quickly.

Bioavailability (%)	75
Renal excretion (%)	70
Volume of distribution (L/kg)	$3.12 Cl_c + 3.84$
Clearance (mL/min/kg)	
No heart failure	$1.02 Cl_c + 0.81$
Heart failure	$0.88 Cl_c + 0.33$
Half-life (hr)	40
Therapeutic range (ng/mL)	0.8–2.0

TABLE 90.4. PHARMACOKINETIC PROPERTIES OF DIGOXIN

If a loading dose of digoxin is to be given, it can be calculated (as discussed in [Chapter 56](#)) based on the patient's weight and renal function from the values in [Table 90.4](#). It can be given intravenously, intramuscularly, or orally (preferred, except in the emergency setting). Intravenous administration results in transient arteriolar constriction with increased peripheral vascular resistance, an undesirable effect in patients with heart failure. Intramuscular administration often can result in erratic absorption. Although decreases in splanchnic blood flow or edema of the gut in cardiac disease might be predicted to cause malabsorption of cardiac glycosides, there is no evidence that this occurs. Lastly, if a loading dose is given, spreading the dose over a 24-hour period in four divided doses is sufficient and prevents the high serum concentrations that occur with a large single dose. Because of the long half-life of digoxin, dosing can be limited to once a day, which facilitates compliance. Maintenance doses must be based on renal function.

The therapeutic range for digoxin serum concentrations is listed in [Table 90.4](#). Values must be interpreted relative to each patient because there is considerable overlap between therapeutic and toxic concentrations. For example, patients with atrial fibrillation often require serum concentrations considerably higher than normal to control the rate of ventricular response, and they do not suffer adverse effects. In contrast, numerous conditions increase the sensitivity to the toxic effects of digitalis glycosides, such as potassium and magnesium depletion and hypercalcemia. In these settings, normal glycoside serum concentrations can be associated with toxicity. Hence, serum concentration measurements should be interpreted in the context of clinically evaluated end points of drug efficacy and toxicity.

Digitalis toxicity occurs frequently, with most surveys finding an incidence in hospitalized patients of about 15%. Toxicity can be fatal, particularly if it goes unrecognized, emphasizing the importance of maintaining a high index of suspicion. Although classic symptoms of digitalis intoxication occasionally occur, symptoms are more commonly absent or are nonspecific (e.g., nausea) and could be caused by the primary disease. Similarly, although some cardiac dysrhythmias are classically associated with digitalis toxicity, ventricular premature beats are most common, and toxicity can cause virtually any dysrhythmia. Digitalis toxicity is often difficult to diagnose because many of its manifestations may be attributable to exacerbation of the primary disease. Obtaining glycoside serum concentrations can sometimes be helpful. If these concentrations are high, a clinical diagnosis of toxicity is supported but not confirmed. If the concentrations are normal, however, toxicity still cannot be excluded, because many conditions (e.g., hypokalemia) increase sensitivity to the toxic effects of digitalis. A very low concentration is evidence against a diagnosis of toxicity, but exclusion of digitalis as the culprit occurs only if the concentration is zero. A definitive diagnosis is established only when the signs or symptoms revert with cessation of digitalis administration.

If digitalis toxicity is diagnosed, the drug should be stopped while factors are assessed that may have increased the sensitivity to the effects of the glycoside. If found, such factors should be treated (e.g., with administration of potassium or magnesium supplements). Treatment of life-threatening ventricular dysrhythmias should avoid quinidine-like agents and focus on lidocaine-like drugs or phenytoin. The latter may be particularly effective for digitalis toxic dysrhythmias. If toxicity is severe, antigen-binding fragments (Fab) can be used to bind digitalis glycosides and remove them from sites of activity.

If glycoside serum concentrations are measured, the cautions noted in [Chapter 55](#) must be followed. The largest source of error that renders laboratory values uninterpretable is sampling during the long distribution phase (up to 6 hours) of digitalis glycosides. This pitfall can be avoided by obtaining samples just before the patient is to receive the next dose (a trough concentration)

Effects of Disease

Digoxin has been studied extensively in various disease states. As indicated in [Table 90.4](#), both the volume of distribution and the clearance depend on renal function. Digoxin excretion by the kidney occurs by filtration at the glomerulus and secretion into the urine at the distal nephron. Secretion occurs via the same P-glycoprotein that accounts for multidrug resistance to many chemotherapeutic agents. As discussed in the following section on drug interaction, this secretory component is subject to inhibition by other drugs. It also appears that reabsorption of filtered drug can occur in the renal proximal tubule. This reabsorptive component is enhanced in settings of prerenal azotemia in which overall proximal tubular reabsorption is increased. As a result, in patients with volume depletion or with exacerbated heart failure in which prerenal effects occur, the reabsorption of digoxin increases, thereby decreasing renal elimination over and above the effects of decreased glomerular filtration itself. Clinically, patients with prerenal azotemia may need even greater reductions in digoxin maintenance doses than dictated by their creatinine clearance. Caution should be used in such patients. Otherwise, maintenance doses of digoxin can be calculated from the values in [Table 90.4](#).

Elderly patients need dosage adjustment based on renal function; in other words, there is no change in clearance due to age itself.

Thyroid disease has an independent effect on digoxin clearance. Hyperthyroidism results in increased clearance, with the converse in hypothyroidism. By unclear mechanisms, the same directional relations occur with the volume of distribution. Hence, in patients with thyroid disease, both loading and maintenance doses of digoxin should be adjusted. As thyroid function normalizes, so do the kinetic parameters of digoxin, which will require changes in dosing.

Drug Interactions

Because of the narrow therapeutic range of digitalis glycosides, drug interactions have been assiduously sought. Several drugs can affect the absorption of cardiac glycosides. The bile acid sequestrants cholestyramine and colestipol bind digoxin and digitoxin in the gut and can prevent or diminish their absorption (i.e., decrease bioavailability). If patients are receiving a cardiac glycoside and one of these agents, the interaction probably can be avoided if the glycoside is taken either 1 hour before or at least 4 hours after the sequestrant.

Interactions to decrease the absorption of digoxin have been reported with various other drugs, including antacids, kaolin-pectin, neomycin, and sulfasalazine. Their occurrence is less predictable than with the bile acid sequestrants, but their potential should be kept in mind. To avoid such interactions, doses of glycosides can be separated from those of potential interactants.

About 10% of patients harbor colonic bacteria that can degrade digoxin. This may be the case in a patient who needs large doses of digoxin to attain normal serum concentrations of the drug. If these bacteria are killed by broad-spectrum antibiotics, degradation diminishes, allowing more drug to be absorbed. In such patients, if a broad-spectrum antibiotic is started, digoxin serum concentrations should be observed closely so that appropriate dosage reduction can be instituted before toxicity ensues.

A unique approach to treating digoxin toxicity (particularly overdoses) uses Fab to change the distribution of digoxin, effectively extracting it into the circulation from tissue sites of action (e.g., cardiac muscle). Digoxin serum concentrations increase considerably when Fab fragments are administered, but the pharmacologic effect of the glycoside is diminished because the measured amounts in serum are bound to the Fab fragments and are therefore inactive. These drug–Fab complexes then can be excreted by the kidney.

Several drugs, especially quinidine, decrease the secretory component of the renal excretion of digoxin by blocking P-glycoprotein. An interaction occurs in at least

90% of patients who are administered both quinidine and digoxin, with a doubling of the digoxin serum concentration. Hence, maintenance of a constant serum concentration requires halving the dose. There is some debate as to whether the increased serum concentration during this interaction extrapolates to increased cardiac effects and risk of toxicity. Most authorities recommend adjusting the digoxin dose to attain the same concentration as would be sought when using digoxin alone. Because the interaction with quinidine is so predictable, the digoxin dose should be halved if concomitant quinidine therapy is begun. The similar interaction that occurs with amiodarone, spironolactone, verapamil, flecainide, and diltiazem is less predictable in terms of magnitude of effect, so with these interactants, the dose of digoxin should be adjusted based on measured serum concentrations.

Numerous pharmacodynamic interactions occur with cardiac glycosides, predominantly by increasing sensitivity to their toxic effects. Drugs causing potassium or magnesium depletion or hypercalcemia increase the risk of toxicity. In these settings, the physician must rely on clinical end points of therapeutic response rather than on measured concentrations.

NONGLYCOSIDE INOTROPIC AGENTS

Because of disappointments with the overall efficacy of digitalis glycosides, other inotropic agents have been and are still being explored. These include sympathomimetic agents and drugs that inhibit cardiac phosphodiesterase. The phosphodiesterase inhibitors have generally been disappointing, particularly because of their early promise. The first of these agents, amrinone, showed short-term efficacy but caused thrombocytopenia with long-term use. Milrinone and similar agents appeared to be promising initially, but long-term efficacy trials showed increases in mortality. Milrinone is now available for intravenous infusion for short-term use. There are no promising agents of this type on the horizon.

Disposition and Effect

Dopamine is an endogenous catecholamine. Its clinical usefulness relates to its activation of cardiac β_1 -receptors to increase inotropism, its activation of renal dopaminergic receptors to increase renal blood flow, and its activation at higher doses of peripheral α -adrenergic receptors to cause vasoconstriction. The last effect is often unwanted, and dosing is usually aimed at maintaining infusion rates low enough to avoid increases in peripheral vascular resistance. Because dopamine is eliminated rapidly, it must be administered as a continuous intravenous infusion, with titration of the rate according to monitored end points of its cardiovascular effects. Typical infusion rates are 10 to 30 μg per kilogram per minute; α -mediated vasoconstriction becomes more prevalent at greater doses.

Dobutamine has for the most part supplanted dopamine as an inotropic agent. It does not increase peripheral vascular resistance. Dobutamine has a short half-life (about 2.5 minutes) with a large clearance (60 mL per kilogram per minute) and a small volume of distribution (0.2 L per kilogram). It is administered as a continuous intravenous infusion; the short half-life means that steady state is attained within about 10 minutes. Hence, the dose can readily be titrated according to cardiovascular end points, with usual infusion rates of 2.5 to 10 μg per kilogram per minute.

Milrinone is available for intravenous administration in patients refractory to other agents. It causes peripheral vasodilation and positive inotropic effects. Its salutary effect most likely occurs by both mechanisms. A loading dose of 50 mg per kilogram is administered based on a volume of distribution of about 0.45 L per kilogram. Maintenance doses are usually 0.375 to 0.75 μg per kilogram per minute, with rates titrated according to response. When the dosing rate is changed, however, the physician must remember that about 5 hours is required to reach new steady-state concentrations. Clearance is about 5 mL per kilogram per minute and depends on renal function. The half-life may increase from 1 to about 3 hours in patients with renal insufficiency. Patients with severe renal insufficiency should receive doses that are one-third of those of patients with preserved renal function.

Effects of Disease

No studies have assessed the influence of diseases on the disposition of and response to sympathomimetic agents. Because the infusion rates of these drugs can be so readily titrated against clinical response, there is little need for such data. The pharmacokinetics of milrinone differ in patients with renal insufficiency compared with normal volunteers, mandating dose adjustment as previously indicated.

Drug Interactions

Dopamine is metabolized by monoamine oxidase. Hence, inhibitors of this enzyme can greatly impair the clearance of dopamine, and caution should be used if they are given together. In contrast, dobutamine is metabolized by catechol *O*-methyltransferase, so the same considerations do not apply. Drug interactions have not been described with milrinone.

β -ADRENERGIC ANTAGONISTS

Disposition, effects of disease, and drug interactions with β -adrenergic antagonists will be discussed in the section on antianginal agents. Historically, these drugs were thought to be contraindicated in patients with CHF owing to their negative inotropic effects and potential ability to precipitate CHF itself. More recent studies have shown that the elevated sympathetic tone in patients with CHF has long-term deleterious effects; as such, β -antagonists can be efficacious. Short-term studies with a variety of agents (metoprolol, bisoprolol, practolol, alprenolol, acebutolol, bucindolol, labetalol, and carvedilol) showed that they could be used safely and that they improved cardiac function and alleviated symptoms. More recently, larger long-term trials, particularly with carvedilol and metoprolol have indicated decreases in mortality. β -Adrenergic antagonists clearly are helpful in patients with symptomatic systolic dysfunction. Whether all β -antagonists have the same efficacy is not known, so it is prudent to use those with proven benefit.

ANTIARRHYTHMIC AGENTS

Disposition and Effect

Antiarrhythmic agents can be broadly grouped according to their electrophysiologic effects on the heart, as discussed in [Chapter 76](#), but these classifications are less than optimal because they do not precisely take into account all mechanisms of action. Pharmacokinetic parameters are presented in [Table 90.5](#) for the strictly antiarrhythmic drugs. β -Adrenergic antagonists and calcium channel antagonists are discussed with antianginal agents.

TABLE 90.5. PHARMACOKINETIC PARAMETERS OF SOME ANTIARRHYTHMIC DRUGS

Therapy with all the quinidine-like drugs is complicated because all are converted to active metabolites and because the short half-lives mandate either frequent dosing or use of a sustained-release preparation. The contribution of quinidine's metabolite to overall pharmacologic effect is debated; in contrast, it is clear that *N*-acetylprocainamide (NAPA) and mono-*N*-desisopropylidopyramide (MND) are active. With NAPA, the rate of formation depends on whether a patient is a fast or slow acetylator of procainamide. Its elimination depends on the level of renal function. On average, a patient with normal renal function has higher serum

concentrations of procainamide than of NAPA, and therapy can be based on measurements of procainamide serum concentrations and clinical evaluation. With decreased renal function, however, NAPA preferentially accumulates and may greatly exceed procainamide concentrations. Because the two compounds have different cardiac effects, interpreting serum concentrations becomes impossible. Instead, emphasis should be placed on clinical end points of response. Alternatively, procainamide can be avoided in patients with renal disease.

The metabolite of disopyramide (i.e., MND) has only about one-fourth the efficacy of the parent drug as an antiarrhythmic, but its effects are 20 times greater as an anticholinergic agent. Its accumulation in patients with renal disease increases the risks of adverse effects from disopyramide, so, if possible, this drug should be avoided in such patients.

Use of the quinidine-like drugs sometimes requires a loading dose, which can be given orally or intravenously (except disopyramide). The latter route must be used with caution because profound hypotension can occur if the rate is too rapid (particularly with quinidine). Infusion rates of 10 to 20 mg per minute should be used, with careful monitoring of the patient.

Lidocaine is the agent of choice for ventricular tachyarrhythmias in most patients, particularly those with an acute myocardial infarction. It has poor bioavailability because of a large first-pass effect, so its use has been restricted to parenteral administration. Mexiletine and tocainide were developed as lidocaine-like agents that could be given orally. Lidocaine is converted in the liver to monoethylglycinexylidide (MEGX) and other metabolites. MEGX does not contribute to the beneficial effects of lidocaine but instead is thought by some to contribute to the CNS toxicity associated with lidocaine (agitation, restlessness, and, in its worst form, seizures).

Lidocaine therapy usually is instituted with a loading dose calculated from the volume of distribution ([Table 90.5](#)), which is affected by different disease states. Several methods are used for loading, the most common of which is repeated bolus administration of 50- to 100-mg doses every 10 to 15 minutes. Rapid-bolus administration results in very high serum lidocaine concentrations for a short time, which are sufficient to cause CNS side effects. A better method for attaining desired concentrations is to calculate the total loading dose needed and then to administer half the amount as a bolus injection over 2 to 3 minutes. The rest of the bolus is then given as a continuous infusion over 20 minutes, followed by the maintenance infusion rate calculated from the clearance of lidocaine and the target steady-state serum concentration.

In some patients, the serum concentration of lidocaine increases after maintenance on the same dose for 24 hours or more. With time, the protein binding of lidocaine increases because the concentration of the binding protein, α_1 -acid glycoprotein (an acute-phase reactant), increases. The unbound, pharmacologically active concentration of lidocaine remains unchanged, and hence no dose adjustment is necessary. Because conventional clinical laboratories measure only total serum concentrations of drugs, as opposed to unbound, free concentrations, it is impossible for the clinician to know whether an increased lidocaine concentration in this setting is due to a change in elimination or to the protein-binding phenomenon described. As a result, it is important to correlate clinical assessment with the laboratory measurement and with other indexes of response.

Mexiletine and tocainide are well absorbed and have half-lives that allow dosing two or three times a day. Both drugs are rapidly absorbed, so that sufficiently high peak concentrations occur to cause adverse effects (CNS effects, nausea, vomiting) in many patients. The rate of absorption can be slowed without affecting the extent of absorption (bioavailability) by simply taking the medication with a meal. Because the extent of absorption is not affected, the average steady-state concentration is not altered by this maneuver; instead, the magnitude of difference between peak and trough concentrations is minimized.

Flecainide, encainide (now discontinued), and propafenone modify fast sodium channels. It was thought originally that these drugs would have wide application for the treatment of ventricular dysrhythmias. However, the use of encainide and flecainide was found to increase mortality in patients with ventricular ectopy after a myocardial infarction due to proarrhythmic effects. Propafenone has a complicated pharmacology. It is administered as a racemic mixture; one stereoisomer is a sodium channel blocker; the other, a β -adrenergic antagonist. In addition, propafenone is converted to an active metabolite by CYP2D6. This isoenzyme is polymorphically distributed, such that about 10% of whites are poor metabolizers and cannot form the active metabolite.

Phenytoin is most often used as an anticonvulsant but can be of benefit in some dysrhythmias, particularly those caused by digitalis. Its pharmacokinetics are complex because at clinically used doses it obeys Michaelis–Menten (saturable) kinetics. As such, an increase in dose may result in a disproportionate increase in the serum concentration. For example, if a dosage of phenytoin of 150 mg per day results in a serum concentration of 7.5 mg per liter, a doubling of the dose to 300 mg per day may result in a doubled serum concentration of 15 mg per liter. A further increase in dose to 400 mg per day, however, may not result in a proportional increase in serum concentration to 20 mg per liter, but rather cause the concentration to increase to 30 mg per liter, with a risk of toxicity. When increasing doses of phenytoin, small increments should be used. Because the half-life of phenytoin is at least 1 day, when doses are changed about 1 week must elapse before a new steady state is reached. The half-life is long enough to allow once-a-day dosing.

It is occasionally necessary to administer a loading dose of phenytoin (usually about 1 g in adults). Loading doses can be given intravenously or, preferably, orally. Phenytoin precipitates in many intravenous solutions, and it is best given as a slow bolus dose directly into an accessible port as proximal to the patient as possible. The total loading dose should be divided into 200- to 300-mg doses, which can be administered every 30 to 60 minutes orally or intravenously.

Bretium, amiodarone, *N*-acetylprocainamide, sotalol, ibutilide, and dofetilide are antiarrhythmic agents that prolong repolarization. Bretium and sotalol were developed first as antihypertensives. The efficacy of both was poor compared with that of the other agents, so they have not been used to treat hypertension. Bretium, used for refractory ventricular tachyarrhythmias, is administered almost exclusively in intensive care unit settings as intermittent intravenous doses or as a constant intravenous infusion. Loading doses of bretium can be given as two or three single intravenous boluses of 5 to 10 mg per kilogram every 5 to 10 minutes; alternatively, 5 to 10 mg per kilogram can be infused over 15 minutes and repeated twice if needed. With initial administration, bretium causes catecholamine release from peripheral nerve endings, which increases blood pressure. The catecholamine depletion that follows can cause hypotension.

Amiodarone is effective in many patients with dysrhythmias refractory to other agents. The disposition of amiodarone also makes it difficult to use. Its exceedingly long half-life—usually 25 to 50 days but sometimes 100 days or more—means that a change in dosage does not result in a new steady state for 6 months or more. Similarly, if the patient develops adverse effects, considerable time is required for the drug to dissipate. Because of the length of time needed to reach steady state, a loading dose is usually given. Although numerous dosing schedules have been proposed, a reasonable approach would be 1,200 mg per day for 2 weeks; the usual maintenance dose of 400 mg per day alternating with 600 mg per day then is instituted.

NAPA, the active metabolite of procainamide, has been developed as an antiarrhythmic agent itself. NAPA has different electrophysiologic effects than procainamide, and its use prevents one of the most common adverse effects of procainamide—drug-induced systemic lupus erythematosus. NAPA has good bioavailability and is eliminated predominantly by renal routes; its relatively short half-life requires frequent dosing.

Sotalol, ibutilide, and dofetilide prolong the QT interval and thereby are unequivocally associated with risk of torsades de pointes. Use of these drugs should be by cardiologists who are expert in arrhythmias and their treatment. Adenosine has proved extremely useful in converting supraventricular tachyarrhythmias to sinus rhythm. It is given as a 6-mg bolus dose, repeated in 10 minutes, if necessary. Many patients have a sensation of shortness of breath with its administration.

Effects of Disease

The influence of disease on the disposition of antiarrhythmics can be anticipated by the data in [Table 90.5](#) that specify the routes of excretion of the individual drugs. For agents with predominant excretion by renal routes, renal disease (including the moderate renal decline of the elderly) decreases clearance and requires modification of maintenance doses. In contrast, if hepatic elimination predominates, primary liver disease and congestive hepatopathy affect clearance. Although studies have assessed the influence of various clinical conditions on the disposition of antiarrhythmic agents, many gaps in our knowledge remain and caution should be used if a potential elimination pathway is affected by the patient's disease.

Quinidine is primarily eliminated by hepatic routes, and renal insufficiency does not appreciably affect its pharmacokinetics. Elderly patients and patients with CHF have clearances of quinidine that are about half of normal, so maintenance doses should be about half those normally used. The dose then can be increased if needed, based on measured quinidine serum concentrations and clinical response. By mechanisms that are not understood, patients with CHF also have a diminished volume of distribution for quinidine; in such patients, if a loading dose is given, it should be half that normally used.

The disposition of procainamide is complex because of its conversion to NAPA. In patients with renal impairment, both parent drug and NAPA accumulate, the latter preferentially because it is more dependent on renal routes of elimination than is procainamide. If procainamide must be used in such patients, caution is mandatory.

In patients with CHF, the disposition of procainamide is unchanged.

Disopyramide and its metabolite accumulate in patients with renal disease. Because the metabolite has greater potency in terms of adverse anticholinergic side effects, its accumulation in such patients would be expected to result in considerable toxicity. Hence, disopyramide should be avoided in patients with decreased renal function. Patients with liver disease or CHF also have diminished clearances of disopyramide. If used in such patients, maintenance doses should be 50% to 75% of normal doses.

Lidocaine, for all practical purposes, depends exclusively on hepatic metabolism for its elimination, so its disposition is unaffected by renal disease. In patients with liver disease or CHF, however, the clearance of lidocaine is about 50% of normal. Maintenance infusion rates must be decreased. Changes in the volume of distribution of lidocaine also occur in these settings by mechanisms that are not understood. In patients with cirrhosis, the volume of distribution is increased and a loading dose up to 1.5 times normal may be needed. It is probably best to administer a normal loading dose and then use a supplemental dose that is 50% of normal, if clinically indicated. The converse occurs in patients with CHF: the volume of distribution is half the normal value, and loading doses in such patients should be half of those usually used.

Although mexiletine and tocainide are similar with respect to the relative contribution of the kidney (40%) and the liver (60%) for elimination, they appear to differ with respect to effects of disease. In patients with renal disease, the disposition of mexiletine is unchanged, but for tocainide clearance is 50% to 75% of normal and maintenance doses should be proportionally decreased. Patients with acute myocardial infarction eliminate mexiletine normally, although those with CHF have not been studied. CHF does not affect the disposition of tocainide. Patients with cirrhosis have considerably impaired elimination of mexiletine and should receive maintenance doses one-fourth to one-third of normal. The effects of liver disease on the disposition of tocainide have not been studied.

In both renal and hepatic disease, the protein binding of phenytoin is decreased. This does not, however, result in an increase in the unbound, pharmacologically active concentration. Hence, dosing does not have to be altered. Total phenytoin serum concentrations decrease in this setting, so the target serum concentration is less. For example, in patients with severe renal insufficiency, the desired total drug serum concentration is 7 to 12 mg per liter instead of 10 to 20 mg per liter in patients with normal renal function. In both cases, the unbound drug concentration is about 1 to 2 mg per liter.

Bretylium depends exclusively on the kidney for excretion, so its use should be avoided in patients with renal disease. If it must be given, maintenance doses as low as 20% of normal should be used. Alternatively, a normal loading dose should be given with no further dosing.

Because amiodarone depends entirely on the liver for its elimination, one would predict no influence of renal disease on its disposition. Similarly, hepatic impairment may decrease its elimination, and amiodarone should be used with extreme caution in such patients (although no studies have addressed this question).

N-Acetylprocainamide is excreted by renal routes, and patients with severe renal insufficiency need reductions in maintenance doses to one-fourth those normally used.

Both sotalol and dofetilide are highly dependent upon the kidney for elimination. They should be avoided in patients with severe renal insufficiency. Patients with mild to moderate decreases in renal function should receive lower doses and should be monitored closely clinically.

Adenosine is eliminated from plasma by cellular uptake. There is no appreciable change in patients with renal or hepatic disease.

Drug Interactions

Antiarrhythmic drugs are frequently used in combination, and their effects in concert represent a pharmacodynamic drug interaction. Similar interactions occur with other drugs; for example, the quinidine-like effect of phenothiazines is additive to that of quinidine itself, procainamide, and disopyramide. By understanding the pharmacology of the antiarrhythmics, adverse pharmacodynamic interactions can be avoided.

Numerous pharmacokinetic drug interactions occur with antiarrhythmic agents, both with the antiarrhythmic itself being affected and with the antiarrhythmic affecting the handling of other drugs. Drug interactions should be anticipated, using the general patterns of effect shown in [Table 90.6](#). For example, cimetidine clearly inhibits the metabolism of several drugs, and it should be expected to do so with other drugs for which hepatic elimination is a major pathway of elimination. Amiodarone also has a spectrum of effects like cimetidine. In contrast, rifampin and phenytoin increase the metabolic elimination of numerous drugs, and they would be expected to have a similar effect on other metabolized agents. Adenosine's effects are blocked by xanthines, including theophylline and caffeine. In contrast, dipyridamole blocks adenosine uptake, thereby prolonging and enhancing adenosine's effects.

Drug	Interaction
Adenosine	Thiopurine and caffeine block effect; dipyridamole increases effect
Amiodarone	Increases clearance of digoxin, fentanyl, sedatives, phenolics, and salicylates, and warfarin
Disopyramide	Increases clearance of warfarin
Dofetilide	Clearance increased by phenytoin, phenobarbital, and rifampin; clearance decreased by cimetidine (oral absorption) but not metabolism; clearance decreased by noncompetitive potassium channel blockers and oral sodium
Propafenone	Increases clearance of digoxin and propranolol
Quinidine	Clearance decreased by cimetidine, amiodarone, and phenobarbital
Lidocaine	Clearance decreased by cimetidine, meprobamate, and propofol
Mexiletine	Clearance decreased by phenobarbital, phenytoin, and rifampin
N-Acetylprocainamide	Clearance decreased by intrathecal local anesthetics
Phenytoin	Increases clearance of carbamazepine, diazepam, cefazolin, cefepime, ceftriaxone, digoxin, digoxigenin, digoxin, glycocholate, morphine, nifedipine, nifedipine, theophylline, valproic acid, and zalcitabine
Procainamide	Clearance decreased by amiodarone (metabolic effect) and by cimetidine, valproic acid, and zalcitabine (oral absorption)
Propafenone	Increases clearance of digoxin in a dose-related fashion, leading to increases in digoxin serum concentrations of 32-35%
Quinidine	Increases clearance of digoxin (oral absorption), which causes a 50% drop in digoxin serum concentrations
Tocainide	Clearance increased by rifampin and phenobarbital; clearance decreased by amiodarone, meprobamate, and propofol; clearance decreased by cimetidine

TABLE 90.6. DRUG INTERACTIONS WITH SOME ANTIARRHYTHMIC AGENTS

Propafenone increases serum digoxin concentrations 35% to 85% and increases the prothrombin time by about 25% in patients taking warfarin. Propafenone is converted to its active metabolite by CYP2D6, so inhibitors of this isoenzyme, such as quinidine, decrease formation of the metabolite.

Understanding the pathways of elimination of antiarrhythmic agents and the pharmacology of potential interactants allows anticipation of drug interactions and appropriate modification of dosing strategies.

ANTIANGINAL AGENTS

Disposition and Effect

Nitrates, b-blockers, and calcium channel antagonists are the mainstays of therapy for angina. Numerous nitrate preparations are available, as previously discussed ([Table 90.1](#)). Their use in patients with angina follows the same pharmacologic principles as for treatment of those with CHF.

b-Adrenergic antagonists decrease myocardial oxygen demands primarily by decreasing heart rate and particularly by blocking exercise- or stress-induced increases in rate. b-Blockers can be conveniently grouped according to their pharmacologic characteristics: nonselective, cardioselective, or with intrinsic sympathomimetic activity (ISA). Nonselectivity implies the ability to block all b-receptors. Cardioselectivity means that at low doses the agent has a relative selectivity to block b₁-receptors, which mediate chronotropy and renin release; at higher doses, selectivity disappears. ISA indicates that the drug has partial agonist activity; at low levels of endogenous sympathetic activity, these drugs have agonist properties; when endogenous activity increases, these b-blockers become antagonists. Clinically, these agents do not diminish (and in fact may increase) resting heart rate, but they block exercise- or stress-induced increases in heart rate.

Clinically, the most useful means for discriminating among these agents, other than selectivity and ISA, is the primary route of elimination. Some obey primary renal

excretion (nadolol, atenolol, acebutolol), and others are eliminated predominantly by the liver (propranolol, timolol, metoprolol). Pindolol is eliminated by both routes. The importance of this characteristic is in predicting the need for dose modification in patients with disease. For example, patients with renal insufficiency require decreased doses of nadolol, and patients with liver disease require dose modification of propranolol. Alternatively, if a patient has renal disease, a b-blocker eliminated by the liver can be used.

Pharmacokinetic data for b-adrenergic antagonists are presented in [Table 90.7](#). Propranolol, metoprolol, and atenolol have active metabolites, but they probably contribute negligibly to the overall pharmacologic effect. In contrast, the metabolite of acebutolol, which is also cardioselective and has ISA, contributes substantially to the activity of this agent; in fact, the dosage modification required in patients with renal disease is due to changed handling of the metabolite rather than of the parent drug. Similarly, the long half-life of the metabolite allows less frequent dosing than would be necessary with the parent compound alone.

Drug	Bioavailability (%)	Renal Clearance (ml/min)	Active Metabolites	LD ₅₀ (mg/kg)	Half-life (hr)	Effect of Disease
Alprenolol	10-20	<10	None	2.0-3.0	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Atenolol	50-60	10	None	1.0-1.5	6-10	Clearance 10-20% normal in liver disease; renal clearance 25-50% normal in renal disease; half-life normal
Bisoprolol	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Carvedilol	25-35	10-20	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Esmolol	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Metoprolol	50-60	10	None	1.0-1.5	6-10	Clearance 10-20% normal in liver disease; renal clearance 25-50% normal in renal disease; half-life normal
Nadolol	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance 25-50% normal in renal disease; half-life normal
Propranolol	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Timolol	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Verapamil	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Diltiazem	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal

TABLE 90.7. PHARMACOKINETIC PARAMETERS OF SOME b-ADRENERGIC ANTAGONISTS

One of the convenient features of the b-blockers is that response can be easily evaluated clinically. Whether a dose has been administered sufficiently to cause b-blockade can be determined simply by assessing whether the heart rate increases with exercise. In a formal evaluation, exercise on a treadmill can be used. However, testing also can be accomplished easily in an office setting by having the patient walk up and down stairs or by determining whether the transient increase in heart rate with standing is blocked. If any of these tests show that increases in heart rate are not blocked, the patient can be given larger doses of the b-blocker. It is important to note that b-blockade usually cannot be documented reliably by assessing effects on resting heart rate because in most patients, the contribution of b-adrenergic tone to resting heart rate is negligible. Proper assessment, therefore, entails evaluation of the effects on exercise-induced increases in heart rate.

Calcium channel antagonists have proved useful in treating patients with angina, not only to block a coronary vasospastic component of the syndrome but also to reduce afterload and thus diminish myocardial oxygen demands. Although verapamil, diltiazem, and the various dihydropyridines share the feature of calcium channel blockade, these drugs also manifest a spectrum of pharmacologic effects. Simplistically, verapamil is at one end of the spectrum, having the greatest slowing of atrioventricular nodal conduction and the least effect of lowering peripheral vascular resistance. The dihydropyridines are at the opposite end, being the most potent in terms of decreasing resistance and having negligible effects on cardiac conduction. Diltiazem is intermediate in both regards.

Pharmacokinetic parameters for the calcium antagonists are presented in [Table 90.8](#). All depend on hepatic elimination, and verapamil and diltiazem are converted to active metabolites. The contribution of norverapamil to the overall pharmacologic effect is unknown. Desacetyldiltiazem appears to contribute substantially to the overall effects of diltiazem; it reaches serum concentrations of about half that of the parent drug, and it is about one-third as potent.

Drug	Bioavailability (%)	Renal Clearance (ml/min)	Active Metabolites	LD ₅₀ (mg/kg)	Half-life (hr)	Effect of Disease
Verapamil	10-20	<10	None	2.0-3.0	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Diltiazem	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Nifedipine	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Flunarizine	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Isradipine	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Levamisole	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Gallopamil	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Flunarizine	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Verapamil	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal
Diltiazem	10-20	<10	None	1.0-1.5	10-15	Clearance 10-20% normal in liver disease; renal clearance normal; half-life normal

TABLE 90.8. PHARMACOKINETIC PARAMETERS FOR CALCIUM CHANNEL ANTAGONISTS

In addition to formation of an active metabolite, the pharmacology of verapamil is made more complex by the fact that it exists as two stereoisomers, of which the 1-form is active. When given orally, stereoselective first-pass metabolism of the active isomer occurs, so that relatively more of the inactive form reaches the systemic circulation. This phenomenon accounts for the finding that after oral dosing, greater total serum concentrations of verapamil are required to produce the same effect as with intravenous dosing. After intravenous dosing, the total concentration represents half-active and half-inactive drug. In contrast, after oral dosing, the total verapamil concentration is predominantly inactive drug. The relation between the active 1-isomer and response is the same for both routes of administration. A corollary of this stereoselective pharmacology is that measurement of total serum concentrations of verapamil is not helpful and is likely to be misleading.

Effects of Disease

Clear patterns are evident when assessing the impact of different diseases on the disposition of b-blockers. Those with predominant elimination by the liver show striking changes in disposition in patients with cirrhosis. For example, with propranolol and metoprolol, clearance is about half normal in such patients. Presystemic elimination also is decreased, which increases the bioavailability of both drugs. These two changes have a multiplier effect on serum drug concentrations: thus, if the bioavailability doubles together with a decrease in clearance to half normal, the average serum concentration quadruples ([Chapter 55](#)). Substantial decreases in dose must be made to compensate for these effects. If the dose is given intravenously so that bioavailability is not a factor, the magnitude of dose adjustment needed depends solely on changes in clearance. Although timolol has not been studied in patients with cirrhosis, its disposition is so similar to that of propranolol and metoprolol that one would expect similar qualitative changes.

Hyperthyroidism affects the disposition of propranolol and metoprolol, and one would predict similar effects with other hepatically eliminated b-blockers. Both the volume of distribution and the clearance double in hyperthyroid patients, so the loading dose should be twice the usual amount. In addition, on average such patients require a maintenance dose twice normal. As the hyperthyroidism is treated and the patient returns to the euthyroid state, disposition parameters regress toward normal, and doses of these b-blockers should be diminished. The disposition of atenolol is not affected by hyperthyroidism, making it a desirable b-blocker in such patients. Effects of thyroid dysfunction on disposition of other b-blockers is unknown.

The b-blockers eliminated predominantly by the kidney require decreased maintenance doses in patients with renal insufficiency. On average, patients with severe renal impairment require maintenance doses 25% to 50% of normal. In such patients, the half-life is prolonged (e.g., up to 40 hours for atenolol), so that the time needed to reach steady state may be lengthy. Alternatively, in patients with renal disease, a b-blocker eliminated by hepatic routes can be used so that no dose adjustment is needed.

Pindolol has substantial elimination by both renal and hepatic routes, so neither renal nor hepatic disease affects its overall disposition. One would predict that

patients with combined renal and hepatic disease will need dosage modification of this drug.

Because the calcium channel antagonists are eliminated by hepatic metabolism, it can be predicted that renal dysfunction will not affect their elimination. Conversely, liver disease has been shown to affect the disposition of a number of these drugs ([Table 90.8](#)). With cirrhosis, the bioavailability of a number of these agents roughly doubles, similar to the effects observed with b-blockers eliminated by hepatic metabolism. Clearance of these drugs is also reduced in patients with hepatic disease. Because of the multiplier effect, patients with cirrhosis should receive substantially decreased maintenance doses. By mechanisms that are not understood, the volume of distribution of verapamil is decreased to about half normal in patients with cirrhosis, so they should receive proportionally lower loading doses.

Drug Interactions

Drug interactions described with b-blockers and calcium antagonists are listed in [Table 90.9](#). Propranolol and metoprolol are affected by other drugs that influence hepatic metabolism. These drugs are metabolized by CYP2D6, and their metabolism is predictably decreased by drugs such as quinidine, which inhibit this isoenzyme. Although timolol has not been studied, one would expect it to be subject to similar interactions because it is also metabolized by this isoenzyme. Interactions have not been described for those b-blockers eliminated by the kidney.

Drug	Interaction
β-Adrenergic Antagonists	
Propranolol	Decrease clearance of diazepam and fentanyl Absorption decreased by antacids and cholestyramine Clearance decreased by chlorpromazine, cimetidine, diltiazem, and quinidine
Metoprolol	Decrease clearance of lidocaine Clearance increased by rifampin Clearance decreased by cimetidine, oral contraceptives, propofolone, and diltiazem
Calcium Channel Antagonists	
Verapamil	Decrease clearance of substrates for cytochrome P450A1, including carbamazepine, quinidine, cyclosporine, lovastatin and simvastatin; decreases renal secretion of substrates for P-glycoprotein such as digoxin
Diltiazem	Similar to verapamil
Dihydropyridine calcium antagonists	Clearance decreased by inhibitors of cytochrome P450A1 including ketoconazole, itraconazole, erythromycin, amiodarone, and others

TABLE 90.9. DRUG INTERACTIONS WITH β-ADRENERGIC ANTAGONISTS AND CALCIUM CHANNEL ANTAGONISTS

Calcium antagonists are metabolized by CYP3A4; verapamil and diltiazem also inhibit this isoenzyme. Thus, these two drugs inhibit other substrates for this isoenzyme, such as cyclosporine. Of particular note is the effect of verapamil and diltiazem on the metabolism of lovastatin and simvastatin. Both calcium antagonists can dramatically increase serum concentrations of these two hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (also called statins) sufficient to cause rhabdomyolysis. Other HMG-CoA reductase inhibitors are not subject to this interaction and should be used instead.

Antianginal agents are an excellent example of the ability to use predictable pharmacodynamic interactions to the patient's advantage by combining them. The effects of antianginal drugs on the determinants of myocardial oxygen demand are presented in [Table 90.10](#). Logical combinations of these drugs can be used for additive efficacy; for example, reflex tachycardia caused by nitrates or dihydropyridines can be blocked by β-adrenergic antagonists. Similar additional pharmacodynamic interactions that occur with these drugs are predictable, based on the known pharmacology of the interactants.

Determinant	Nitrates	β-Blockers	Verapamil	Diltiazem	Dihydropyridine Calcium Antagonists
Heart rate	↑	↓	—	—	↓
Contractility	↑	↓	↓	↓	—
Wall tension	—	—	—	—	—
Perioid	↓	—	—	—	—
Atrial rate	↓	—	↓	↓	↓

—, no effect.
*Nitrates will increase, will affect with anticholinergic, nitrate; will give long nitric oxide/vascular activity.

TABLE 90.10. EFFECTS OF ANTIANGINAL AGENTS ON DETERMINANTS OF MYOCARDIAL OXYGEN DEMANDS

ANTIHYPERTENSIVE AGENTS

Disposition and Effect

Previous sections have discussed nitroprusside, hydralazine, ACE inhibitors, angiotensin antagonists and β-adrenergic and calcium channel antagonists, all of which are effective antihypertensives ([Table 90.2](#), [Table 90.7](#), and [Table 90-8](#)). Pharmacokinetic parameters for additional antihypertensive drugs are presented in [Table 90.11](#).

Drug	Route of Administration	Half-life (hr)	Clearance (L/min)	Volume of Distribution (L)	Effect of Renal Failure	Effect of Hepatic Failure
Hydralazine	Oral	8-12	1.5-2.5	10-15	Decreased	Decreased
Nitroglycerin	Sublingual	1-2	1.5-2.5	10-15	Decreased	Decreased
Verapamil	Oral	4-12	1.5-2.5	10-15	Decreased	Decreased
Diltiazem	Oral	3-5	1.5-2.5	10-15	Decreased	Decreased
Enalapril	Oral	11	1.5-2.5	10-15	Decreased	Decreased
Lisinopril	Oral	12	1.5-2.5	10-15	Decreased	Decreased
Losartan	Oral	2	1.5-2.5	10-15	Decreased	Decreased
Clonidine	Oral	12	1.5-2.5	10-15	Decreased	Decreased
Methyldopa	Oral	12	1.5-2.5	10-15	Decreased	Decreased
Moxonidine	Oral	12	1.5-2.5	10-15	Decreased	Decreased
Guafacine	Oral	12	1.5-2.5	10-15	Decreased	Decreased
Urapidil	Oral	12	1.5-2.5	10-15	Decreased	Decreased

TABLE 90.11. PHARMACOKINETICS OF ANTIHYPERTENSIVE AGENTS

The central α₂-adrenergic agonists decrease blood pressure by suppressing the concentration of circulating catecholamines, thereby decreasing peripheral vascular resistance. Methyldopa, clonidine, and moxonidine have a substantial component of renal elimination; in contrast, guanabenz and guanfacine depend exclusively on hepatic function. Despite the short half-lives of guanabenz and methyldopa, their duration of effect is long enough to allow dosing twice a day.

Doxazosin, prazosin, terazosin, trimazosin, and urapidil block α₁-adrenergic receptors in the periphery. The selectivity of this effect still allows catecholamines to activate α₂-receptors, suppressing their release. Hence, in contrast to nonselective peripheral adrenergic antagonists such as phentolamine and phenoxybenzamine,

administration of these drugs is not associated with increases in circulating catecholamine concentrations. This effect may account, at least in part, for the usual absence of reflex tachycardia in association with their use. Prazosin is metabolized to two compounds that are active. They are eliminated by secretion into the bile and do not attain sufficient systemic concentrations to exert an effect. Although the half-lives of prazosin and trimazosin are short, they can be administered twice a day for the treatment of hypertension. Doxazosin and terazosin usually can be given once a day.

Diazoxide can be administered orally, but it is usually given intravenously for hypertensive emergencies. An early hypothesis was that diazoxide was so avidly bound to serum proteins that large, rapid intravenous bolus doses were required to attain enough unbound drug at the arteriolar site of action to be effective. As such, early guidelines suggested initial doses of 300 mg, with repeated administration as needed. Subsequent studies proved the initial postulate to be false and also noted that the large doses that had been recommended too often resulted in hypotension. Doses of 1 mg per kilogram should be given; they can be repeated every 10 to 15 minutes until desired blood pressures have been reached.

Two interesting aspects of the pharmacology of diazoxide are its propensities to cause hyperglycemia and to cause sodium retention. These effects are somewhat paradoxical, because diazoxide is derived from a sulfonamide structure, just as are oral sulfonylureas and thiazide diuretics. Patients with non-insulin-dependent diabetes are particularly susceptible to the hyperglycemic effects of diazoxide and should be monitored closely. Sodium retention is usually not problematic and does not occur unless sodium is given to the patient. If it does occur, diuretics may be needed.

Minoxidil, an extremely potent vasodilator, is reserved for patients with refractory hypertension. It is not used in mild or moderate hypertension because its potent vasodilating effects predictably cause reflex tachycardia, requiring concomitant use of β -blockers, and fluid retention sufficient to mandate use of diuretics. Hence, multidrug therapy is always needed. In addition, minoxidil causes hair growth, and the hirsutism can be a particularly worrisome cosmetic problem in women. When used as an ointment to stimulate hair growth, less than 5% of a dose is absorbed. Although minoxidil has a short half-life, it can be administered twice a day.

Labetalol has both nonselective β - and α -adrenergic antagonist effects ([Table 90.7](#)). The ratio of these separate pharmacologic activities is about 7:1. Labetalol has two asymmetric carbon atoms in its structure. It is administered as a racemate, which therefore contains four structurally distinct stereoisomers (RR, RS, SR, and SS). The RR isomer accounts for the β -blocking activity, the SR isomer is responsible for the α -blockade, and the other two configurations are inactive. As a result, the pharmacology of labetalol is little different from separate but concomitant administration of two drugs with the same pharmacologic activity of the active stereoisomers of labetalol.

Treatment of Malignant Hypertension

The choice of antihypertensives differs, depending on whether the patient has mild hypertension or accelerated or malignant hypertension. The approach in the former case is discussed in [Chapter 30](#); the latter represents a special use of these agents.

Nitroprusside is the gold standard for hypertensive emergencies because of its potency and short duration of action. It is effective in virtually all patients, and the short duration of effect allows precise control of the degree of lowering of the blood pressure. This drug is particularly useful in patients with hypertensive encephalopathy or in those with cerebrovascular disease in whom the goal is to lower the diastolic blood pressure quickly to about 110 mm Hg, with subsequent gradual lowering to normal. Rapid attainment of normal blood pressures in such patients can result in cerebrovascular compromise. Although nitroprusside is the ideal agent for treating these patients, it requires an infusion pump and intra-arterial monitoring of blood pressure.

Other drugs used for hypertensive emergencies include intravenous diazoxide and labetalol and oral clonidine. Labetalol can be administered as either intermittent bolus injections or as a continuous intravenous infusion. With the former method, an initial dose of 20 mg is administered as a bolus dose over 2 to 5 minutes. Ten to 15 minutes later, 40 mg can be administered, with additional 80-mg doses every 10 to 15 minutes until the goal blood pressure or a total dose of 300 mg is reached. This dosing strategy is aimed at using small doses initially to prevent a too-pronounced fall in blood pressure, thus allowing gradual titration of the pressure to desired levels. If an infusion pump is available, labetalol can be administered at a rate of 2 mg per minute, with end points the same as with intermittent dosing. This method also results in controlled titration of blood pressure.

Although the use of labetalol and repeated small doses of diazoxide allows controlled pressure lowering in most patients, the longer duration of action of these drugs is undesirable if an adverse effect occurs or if the antihypertensive effect is greater than desired. Hence, these drugs do not supplant nitroprusside in patients at greatest risk, but they are useful alternatives when nitroprusside cannot be used or if the precise degree of titration that occurs with nitroprusside is not needed.

Clonidine offers the advantage of oral administration, thus avoiding the expense of intravenous dosing, but it is not appropriate for all patients. The use of clonidine entails the administration of 0.2 mg initially, followed by 0.1 mg every hour until a total dose of 0.8 mg or the desired blood pressure is reached. This oral titration allows gradual lowering of the blood pressure. Such doses of clonidine frequently cause patients to be sleepy, however, and the drug therefore should not be used in patients in whom one is closely monitoring end points of cerebral perfusion, such as alertness.

The efficacy of oral nifedipine has been described in patients with severe hypertension. Administration of a 10-mg capsule orally or sublingually can cause prompt lowering of blood pressure in 15 to 30 minutes. Although this regimen is attractive in its simplicity, too many adverse effects occur and this therapy should be abandoned.

Effects of Disease

The effects of disease on the disposition of a number of the antihypertensives were discussed in prior sections, and the effects on additional agents are presented in [Table 90.11](#). Of the centrally acting α_2 -adrenergic agonists, clonidine, moxonidine, and methyldopa have substantial renal elimination. Patients with severe renal insufficiency require maintenance doses of clonidine and moxonidine one-third to one-half of those normally used. Studies with methyldopa have been equivocal in terms of demonstrating clinically relevant changes in clearance related to renal disease; on the other hand, patients with renal disease have greater blood pressure lowering from methyldopa than do those with normal renal function. The mechanism by which an increased effect occurs is not understood, but such patients should receive lower doses of methyldopa.

Guanabenz and guanfacine are eliminated exclusively by the liver, and disposition is predictably altered in patients with cirrhosis. Pronounced declines in the clearance of guanabenz to 20% of normal occur, mandating decreased maintenance doses. By unknown mechanisms, the volume of distribution is also about one-third of normal in patients with cirrhosis. Because loading doses of guanabenz are rarely if ever administered, this change has little clinical relevance. With the pronounced alterations in the disposition of guanabenz that occur in cirrhosis, clonidine, methyldopa, or moxonidine should be used in such patients if a centrally acting α_2 -agonist is to be given.

Prazosin clearance is decreased in patients with CHF to one-half to two-thirds of normal. Elderly patients appear to eliminate prazosin normally but have an increased volume of distribution. Because a loading dose strategy is not used with this drug, no change in dosing is needed. Conversely, the clearance of doxazosin, terazosin, and urapidil is reduced in elderly patients, and they should receive half the usual dose.

Although both diazoxide and minoxidil are primarily eliminated by the liver, the response to both drugs is increased in patients with renal disease. Changed protein binding is a postulated mechanism for the effect with diazoxide, but no data support (or refute) this hypothesis. Initial doses of both drugs should be decreased in patients with renal insufficiency, with subsequent increases dictated by clinical endpoints. One would expect liver disease to affect the disposition of diazoxide and minoxidil; although studies have not been published that address this question, it would seem reasonable to exercise cautious dosing in such patients.

Drug Interactions

Drug interactions with β -adrenergic antagonists and calcium channel antagonists were presented previously ([Table 90.9](#)). Of the remaining antihypertensive agents, clinically important drug interactions are pharmacodynamic. These drugs frequently are used in combination for their additive effects. For example, potent vasodilators such as hydralazine, dihydropyridine calcium antagonists, and minoxidil frequently cause reflex tachycardia and fluid retention, which can be sufficient to negate their pressure-lowering effect (pseudotolerance). In this setting, the addition of β -blockers or diuretics restores antihypertensive efficacy. Understanding the pharmacology of the various antihypertensives allows rational combination of these agents to achieve a beneficial drug interaction.

Adverse pharmacodynamic drug interactions also occur with these agents. For example, nonsteroidal anti-inflammatory drugs can blunt the natriuretic effect of most diuretics and the antihypertensive effect of b-blockers and ACE inhibitors.

ANTICOAGULANT, THROMBOLYTIC, AND ANTIPLATELET AGENTS

Disposition and Effect

Drugs that affect hemostasis are among the most exciting drugs for cardiovascular disorders. New drugs are being developed at a rapid pace, many of which are biologic agents. These, in turn, spawn frenzied development of nonbiologic agents with the same pharmacologic effects. For example, the first available agent that blocks platelet glycoprotein IIb/IIIa receptors is a hybridized monoclonal antibody. Its efficacy has resulted in intense efforts to develop nonpeptide inhibitors of this receptor that provide more flexibility in terms of route of administration, ability to dose chronically, and so on. The pharmacokinetics of anticoagulants, thrombolytics, and platelet inhibitors are listed in [Table 90.12](#).

Drug	Renal Clearance (%)	Half-life (hr)	Active Metabolites	PK (S ₁) ^a (hr)	PK (S ₂) ^a (hr)	PK (S ₃) ^a (hr)	Effect of Disease
Anticoagulants							
Heparin	0	50-90		0.5	2.5	2-3	Renal disease: 10 normal (1) Hemodialysis: 12 normal (2) Colloids: no change
Low-molecular-weight heparins	0	3-24		0.5-1.5	1.5-3	1.5-3	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Warfarin	0	36		0.1-0.25	0.5-0.8	20-40	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Fibrinolytics							
Streptokinase	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Urokinase	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
alteplase	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Antiplatelet Agents							
Aspirin	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Ticlopidine	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Clopidogrel	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change
Other							
Abciximab	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change

Tirofiban	0	15-30		1.5-2.5	5-10	10-15	Renal disease: 10 normal (1) Colloids: no change Hemodialysis: 12 normal (2) Colloids: no change

TABLE 90.12. PHARMACOKINETICS OF ANTICOAGULANTS, FIBRINOLYTICS, AND INHIBITORS OF PLATELET FUNCTION

The pharmacokinetics of heparin are difficult to evaluate because of imprecision of assays for heparin. Heparin consists of many different polymeric constituents, it follows saturable elimination kinetics, and there is great variability in its effect among patients. As a result, reported values for heparin disposition parameters vary over a tenfold range. This variability has been the stimulus for developing low-molecular-weight heparins, which are far less variable in their kinetic profile. This lower variability accounts for their equal and sometimes superior efficacy with less toxicity compared with conventional heparin. Conventional heparin has an average molecular weight of 15,000 (range, 3,000 to 30,000), whereas that for low-molecular-weight heparins is 4,000 to 5,000. This low molecular weight allows these heparins to be filtered by the glomerulus, causing them to depend on the kidney for elimination in contrast to conventional heparin.

Excluding the use of low doses of subcutaneously administered heparin for prophylaxis, the usual goal of therapy is to maintain an activated partial thromboplastin time (aPTT) 1.5 to 2.5 times the control value. To do so, conventional heparin can be given in several ways. If a continuous intravenous infusion is used, a loading dose of 70 to 75 U per kilogram should be given, followed by an infusion rate of 1,000 U per hour. The anticoagulant effect should be measured in about 6 hours, at which time most patients will have reached steady state. If the aPTT is not in the desired range, the infusion rate can be adjusted by increments (or decrements) of 100 to 200 U per hour, with assessment of anticoagulant effect 6 hours after the change in regimen. When the desired anticoagulant effect is obtained, follow-up monitoring should occur on a daily basis.

A less preferable mode of administration is intermittent intravenous injections of heparin. With this method, a dose of 70 to 100 U per kilogram is administered every 4 hours. Doses are adjusted based on aPTT measurements obtained about 30 minutes before a dose. This method is inferior to continuous intravenous infusion of heparin because the level of anticoagulation vacillates within the dosing interval, and the time at which peak effects occur is associated with greater-than-needed anticoagulation. This probably accounts for the greater incidence of side effects that occurs with intermittent intravenous administration.

Heparin also can be administered subcutaneously as 7,000 to 10,000 U every 8 hours or 10,000 to 15,000 U every 12 hours. With this route, doses should be adjusted to maintain an aPTT 2 to 2.5 times control 6 hours after a dose. This method is preferred only when intravenous access is problematic or impossible.

Unfractionated heparin is highly heterogeneous, making its clinical pharmacology complex. Low-molecular-weight heparins (enoxaparin, dalteparin, and ardeparin) have been developed, which have more predictable pharmacokinetics. These preparations do not require monitoring of aPTT; rather, they are administered subcutaneously in fixed doses. Because they are primarily eliminated by the kidney, doses need to be decreased in patients with diminished renal function. These preparations have been shown to be effective for prevention and treatment of deep venous thrombosis and in pulmonary embolism. In the former condition, they allow treating some patients on an ambulatory basis, avoiding hospitalization. Recently, enoxaparin was also approved for use in patients with acute coronary syndromes.

A variety of thrombin inhibitors have been and are still being tested. Most of these agents are either hirudin itself or modifications thereof. Hirudin is the anticoagulant in leech saliva. Early trials with hirudin and its analogs were disappointing, but in retrospect the reason therein was because they were designed ignoring fundamental principles of clinical pharmacology. As a consequence, wrong doses were used. These drugs may eventually prove to live up to their previous expectations. Currently, lepirudin is approved for anticoagulation in patients who have had heparin-induced thrombocytopenia. Its dose is based on a desired aPTT 1.5 to 2.5 times normal. Since lepirudin depends on the kidney for elimination, lower doses are needed in patients with decreased renal function.

Warfarin depends exclusively on hepatic metabolism for elimination. Warfarin obeys stereoselective metabolism in that the clearance of the active S(-) isomer is about 1.5 times as great as that of the inactive isomer. Because the volume of distribution is the same for each stereoisomer, the half-life for the active isomer is shorter (24 to 33 hours) than that for the inactive isomer (35 to 58 hours). The goal of therapy with warfarin is to maintain a prothrombin time 1.5 times control, using the international normalized ratio (INR). A loading dose is usually administered as 10 mg per day for 2 or 3 days. A large single loading dose should not be given because it can cause precipitous falls in clotting factor VII, with risk of bleeding. Maintenance doses average 5 mg per day, but because there is considerable variability among patients, the dose should be titrated to obtain the desired INR. Because of the half-life of the active isomer of warfarin, attaining a steady state requires about 1 week of dosing.

Streptokinase and urokinase are thrombolytic agents used to lyse clots in peripheral and pulmonary veins, in peripheral and coronary arteries, and in shunts. Although the two agents have different mechanisms of action, their ultimate effect is to initiate fibrinolysis. Streptokinase differs from urokinase in being a foreign protein; thus, it is antigenic, and an initial loading dose must be administered that is sufficient to overwhelm circulating antibodies that are present in anyone who has had a previous streptococcal infection (i.e., virtually everyone). In addition, the antigenicity requires a 6- to 12-month lapse of time between exposures to streptokinase. With these drawbacks, urokinase would seem to be a preferable agent. Unfortunately, it is more expensive, rendering it the usual second choice.

For systemic intravenous administration, both streptokinase and urokinase initially require loading doses to attain a therapeutic effect (streptokinase, 250,000 U in 20 to 30 minutes; urokinase, 4,400 U per kilogram over 10 minutes). This streptokinase dose is sufficient to overcome endogenous antibodies in 85% to 90% of patients. Maintenance doses are streptokinase, 100,000 U per hour for 24 to 72 hours, and urokinase, 4,400 U per kilogram per hour for 12 to 24 hours, with the duration of infusion, depending on the entity being treated.

Various regimens have been used for regional infusion. Some use a loading dose (10,000 to 20,000 U of streptokinase) and others do not. Infusion rates have ranged from 1,000 to 5,000 U per minute, with durations of infusion usually of up to 1.5 hours.

With systemic and even with regional administration, streptokinase and urokinase result in a systemic thrombolytic state and the risk of bleeding. A thrombolytic agent specifically directed to a thrombus therefore would be desirable and would offer a theoretical therapeutic advantage. As such, attention has focused on modifying streptokinase to make it more clot-specific (e.g., anisoylated plasminogen streptokinase activator complex, anistreplase) and using tissue plasminogen activator ([tPA]

and similar agents). Both restore patency in thrombotically occluded coronary arteries but unfortunately do not obviate the risk of bleeding.

Several types and dosing regimens of tPA are available, with considerable debate as to advantages and disadvantages. All tPA agents are pharmacologically the same. Differences are in their pharmacokinetics and, hence, their dosing regimens. Alteplase is approved for use in acute myocardial infarction, acute stroke, and massive pulmonary embolus. Studies are ongoing to assess its benefit in acute coronary syndromes. For myocardial infarction, accelerated dosing is preferred wherein an initial intravenous bolus of 15 mg is administered. Subsequent infusion rates are based on body weight. For patients weighing more than 67 kg, 50 mg is administered over 30 minutes followed by another 35 mg over 60 minutes. For patients \leq 67 kg, 0.75 mg per kilogram is infused over 30 minutes followed by another 0.5 mg per kilogram over 60 minutes. For treatment of stroke, 0.9 mg per kilogram (maximum dose = 90 mg) is administered over 60 minutes, with 10% of the dose given as an initial bolus. Reteplase is administered as two separate 10-U bolus doses 30 minutes apart. The bolus doses are administered over 2 minutes.

Choice of these thrombolytics is largely driven by cost, a component of which is convenience of dosing.

Low-dose aspirin, ticlopidine, clopidogrel, dipyridamole, inhibitors of the glycoprotein IIb-IIIa receptor, and drugs in development that are either prostaglandin analogs or block thromboxane receptors are used to inhibit platelet aggregation. The activity of aspirin (acetylsalicylic acid) depends on the acetyl moiety; hence, nonacetyl salicylate derivatives are ineffective. Once aspirin is absorbed across the gastrointestinal epithelium, the acetyl group is cleaved and irreversibly binds to platelet cyclooxygenase, thus preventing thromboxane A_2 synthesis and inhibiting platelet aggregation. The dose required for this effect is minuscule. At very low doses, platelets are most likely acetylated in the portal circulation rather than systemically. Low doses of aspirin are sufficient to inhibit platelet aggregation, and if aspirin is used for this purpose, doses of one adult aspirin per day should not be exceeded. This admonition particularly applies to the use of aspirin for prophylaxis against myocardial infarction. Ticlopidine is as efficacious as aspirin, but because it is more expensive and causes more adverse effects, it is reserved for patients who cannot take aspirin. Clopidogrel is similar in effects to ticlopidine but does not have the same risk of neutropenia. Thus, its therapeutic margin seems greater.

Dipyridamole is used more frequently than compelling data would indicate. It causes increased concentrations of cyclic adenosine monophosphate in the platelet and thus inhibits aggregation. Because this mechanism differs from that of aspirin, it has been postulated that the combination would have a synergistic, or at least additive, effect. Efficacy has been demonstrated in some conditions. The half-life of dipyridamole is long enough to allow twice-daily dosing.

Prostaglandin I_2 inhibits platelet aggregation, whereas thromboxane is a potent aggregant and vasoconstrictor. Iloprost is a PGI₂ analog and sulotroban and vapiprost are thromboxane inhibitors that are under development.

The final common pathway in platelet aggregation involves activation of the platelet glycoprotein IIb/IIIa receptor. The first inhibitor of this receptor to be approved for use is a humanized monoclonal antibody, abciximab. It has been studied in the setting of angioplasty, where it prevents the rethrombosis that occurs in many patients, particularly those at high risk. Because this agent is a protein, it must be given intravenously. Intense efforts have focused on developing other IIb/IIIa antagonists, in particular seeking nonpeptide, orally available agents. To this end, tirofiban and eptifibatid have recently become available. Abciximab and eptifibatid are approved for use in high-risk patients with percutaneous transluminal coronary angioplasty (PTCA) plus patients undergoing acute coronary syndromes. Tirofiban is approved for the latter. All are used in combination with aspirin and heparin and are being actively studied for broader indications.

Effects of Disease

Several attempts to assess the influence of hepatic and renal disease on the disposition of heparin have been reported, with conflicting results. Such patients may have disease-induced alterations in hemostasis that make them more susceptible to bleeding with heparin. It does not appear, however, that changes in pharmacokinetics are of concern. Because low-molecular-weight heparins are primarily excreted by the kidney, doses need adjustment in patients with renal insufficiency.

Warfarin is eliminated exclusively by hepatic metabolism and would be expected to be subject to altered disposition in patients with hepatic dysfunction. Neither patients with liver disease nor those with viral hepatitis, however, have been shown to have altered pharmacokinetics. Patients with liver disease are more sensitive to the anticoagulant effects of warfarin, however, probably because of decreased synthesis of vitamin K. A similar phenomenon occurs in patients with CHF, in whom warfarin disposition is normal but the congestive hepatopathy causes decreased synthesis of clotting factors. In hyperthyroid patients, the degradation of clotting factors increases, similarly increasing sensitivity to warfarin but via a different mechanism. Hence, several clinical conditions affect the sensitivity to warfarin, but none is associated with pharmacokinetic changes.

Patients with renal disease have diminished protein binding of warfarin because of accumulation of endogenous organic acids that displace the anticoagulant from binding sites on albumin. The unbound pharmacologically active concentration, however, remains the same. Therefore, any increased sensitivity to warfarin in patients with renal disease is due to the bleeding diathesis that occurs in such patients.

Disease-induced effects on the disposition of streptokinase, urokinase, tPA, and dipyridamole have not been described. Increased sensitivity to their effects is predictable in diseases associated with clotting abnormalities.

Doses of iloprost need adjustment in patients with hepatic or renal disease. Sulotroban doses need to be substantially lower in patients with renal disease, whereas with ticlopidine, elderly patients require lower doses.

Drug Interactions

No definitive pharmacokinetic drug interactions have been described with heparin. The antiplatelet effects of large doses of penicillins and the hypoprothrombinemic effects of cephalosporins containing the methylthiotetrazole side chain (cefamandole, moxalactam, cefoperazone, and others) increase the risk of bleeding during heparin administration.

Numerous drug interactions have been described with warfarin, not only because of the frequency of their occurrence but also because of their potential severity (Table 90.13). The effect of cholestyramine on absorption can be obviated by administering warfarin 1 hour before a dose of this resin. The protein-binding interactions are transient. After displacement from albumin, the free concentration of warfarin reaches a new steady-state concentration the same as before the interaction; as such, no change in dose is required. Numerous drugs induce hepatic metabolism of warfarin, thus requiring increased doses of the anticoagulant. This interaction requires about 2 weeks to reach its full effect and dissipates slowly. Dosing adjustments should be based on the measured INR. Several drugs also inhibit the metabolism of warfarin. In contrast to the slow onset of induction, these inhibitory effects occur quickly. As a consequence, if any of the inhibiting drugs listed in Table 90.13 are added to a stable regimen, the warfarin dose should be halved in anticipation of the effect, with further adjustments based on INR. The dissipation of the inhibitory effect depends on the rate of elimination of the inhibiting drug. For example, owing to the prolonged half-life of amiodarone, its effects persist for months. Conversely, the effects of cimetidine dissipate within 2 or 3 days.

Absorption

Decreased absorption caused by cholestyramine and presumably colestipol

Protein Binding

Decreased binding caused by chloral hydrate, clofibrate, diazoxide, ethacrynic acid, mefenamic acid, phenylbutazone, phenytoin, and salicylates

Metabolism

Increased metabolic degradation caused by carbamazepine, chronic ethanol intake, glutethimide, griseofulvin, phenobarbital, phenytoin, and rifampin

Decreased metabolism caused by amiodarone, chloramphenicol, cimetidine, clofibrate, disulfiram, acute ethanol intake, oral contraceptives, propafenone, and sulfinyprazole

TABLE 90.13. DRUG INTERACTIONS WITH WARFARIN

LIPID-LOWERING DRUGS

DISPOSITION AND EFFECT

The binding resins cholestyramine and colestipol are not absorbed. By binding bile acids, they decrease the absorption of cholesterol. An indirect effect—increasing low-density lipoprotein receptor numbers (up-regulation)—also serves to lower serum cholesterol concentrations. The binding properties of these resins are nonspecific, and they can interact with many drugs. To avoid such interactions, dosing with other agents should precede administration of the resin by at least 1 hour or should be delayed until at least 4 hours afterward.

Little is known about the disposition of most lipid-lowering drugs. Clofibrate is the most studied. It is not active but is rapidly metabolized to *p*-chlorophenoxyisobutyric acid (CPIB), the active moiety, which in turn is either excreted in the urine or conjugated in the liver, with renal excretion of the conjugates. This metabolite can cause a severe myopathy, so considerable caution must be exercised with its use in patients in whom CPIB may accumulate.

The development of gemfibrozil, another derivative of fibric acid, was motivated by the adverse effects of clofibrate. Its half-life (7.5 hours) allows twice-daily administration. Gemfibrozil disposition is normal in patients with renal disease, and it should be used in preference to clofibrate in such patients.

Doses of nicotinic acid (niacin) must be titrated gradually upward in patients to minimize the common side effects related to cutaneous vasodilation. Beginning doses are usually 50 to 100 mg three times a day, with gradual increases to 1 to 3 g three times daily. Because the adverse effects seem to be related to rapidly increasing serum concentrations, they can be minimized by taking the nicotinic acid with food, which slows its rate of absorption without affecting bioavailability.

Probucol is eliminated slowly, with a half-life of 20 to 50 days. With this long half-life, once-daily dosing is sufficient.

Lovastatin and similar agents (simvastatin, pravastatin, fluvastatin, cerivastatin, and atorvastatin) are the most effective lipid-lowering agents. Lovastatin and simvastatin are converted to numerous active metabolites, which probably account for their effectiveness. The others are primarily active as the parent compounds. By inhibiting HMG-CoA reductase, these drugs increase the number of low-density lipoprotein (LDL) receptors, thereby lowering LDL 30% to 40%. The statins are particularly effective when combined with bile acid-binding resins. Atorvastatin has greater efficacy than the other statins in that at maximally effective (and tolerated) doses it lowers LDL more than the other drugs in the class.

It has recently been discovered that the isoenzyme responsible for metabolism of lovastatin and simvastatin is cytochrome P4503A4 (CYP3A4). In turn, inhibitors of CYP3A4 such as verapamil, diltiazem, ketoconazole, and others cause substantial increases in concentration of parent drug with risk of myopathy. Alternative statins should be used if substrates or known inhibitors of CYP3A4 are to be coadministered.

Effects of Disease

The disposition of clofibrate is considerably affected by both renal and hepatic disease. In renal insufficiency, CPIB accumulates in a disproportionate fashion because excretion of the metabolite itself is decreased; the conjugates of CPIB also accumulate and then are hydrolyzed back to CPIB *in vivo*. Because of the severe myopathy that can occur from clofibrate, it is best to avoid it in this setting; gemfibrozil is a better alternative. Patients with cirrhosis also have diminished clearance of clofibrate. If its use cannot be avoided, maintenance doses in such patients should be about half of normal doses.

For the remaining lipid-lowering drugs, the paucity of data makes their use in patients with hepatic or renal disease potentially hazardous. Nicotinic acid is eliminated by hepatic routes, and its disposition is thereby unchanged in patients with renal disease. Although no data are available concerning its handling in patients with liver disease, nicotinic acid can cause elevated liver function tests in such patients and should be avoided. Because of the slow elimination of probucol, which depends on hepatic metabolism, this drug is best avoided in patients with liver disease.

Atorvastatin serum concentrations are markedly increased in patients with cirrhosis (up to 15-fold). This drug should be avoided in patients with liver disease. Fluvastatin also accumulates in such patients but to less degree. If used in patients with liver disease, doses should be one-third to one-half normal. Both lovastatin and simvastatin accumulate in elderly patients, who should receive doses that are half those of younger patients.

Drug Interactions

Cholestyramine and colestipol can bind many drugs in the gastrointestinal tract and thus decrease their bioavailability. Physicians should have a high index of suspicion that the binding resins will affect the absorption of any drug. Some drugs undergo biliary secretion followed by reabsorption, a process called *enterohepatic circulation*. With such agents, the resins can interrupt this recycling and sequester drug in the gut. The overall effect is increased elimination of the drug. This process occurs with cardiac glycosides, and the binding resins have been advocated as potential therapeutic agents in overdoses of digoxin and digitoxin. Similar effects would be expected with other drugs that undergo enterohepatic cycling.

Clofibrate is avidly bound to serum albumin and can displace warfarin from binding sites. Because this interaction is transient, no change in warfarin dosing is needed due to this effect alone. In contrast, clofibrate also inhibits the hepatic metabolism of warfarin, decreasing clearance and mandating a decrease in the maintenance dose to about half of normal. This inhibition is stereoselective. As discussed previously, warfarin is administered as a racemate, whereas only the S(-) isomer is active. Clofibrate selectively decreases the metabolism of the active isomer.

Gemfibrozil and probucol do not interact with oral hypoglycemics and warfarin. Whether they affect disposition and response to other drugs is unknown.

Lovastatin and simvastatin are metabolized by CYP3A4. Inhibition of this isoenzyme by drugs such as ketoconazole, erythromycin, verapamil, and diltiazem can cause substantial increases in concentration of both the parent drugs and their active metabolites. This effect enhances the risk of myopathy and rhabdomyolysis. If potential inhibitors of CYP3A4 are a necessary part of therapy, then alternative HMG-CoA reductase inhibitors should be used.

Parenteral anticoagulation is usually achieved with heparin, which was first identified in 1916 by McLean, a medical student. Warfarin was first used in humans in 1953. Chronic anticoagulation requires the oral administration of warfarin. It acts by directly competing with vitamin K, thereby inhibiting synthesis of vitamin K-dependent coagulation factors.

HEPARIN

STRUCTURE AND COMPOSITION

Heparin is made up of a heterogeneous group of highly sulfated glycosaminoglycan molecules of different sizes and structures that are highly negatively charged. Heparin molecules vary according to (a) size, depending on the number of disaccharide residues; (b) constituents, depending on whether glycuronic or iduronic acid is present; and (c) sulfation and charge, depending on the extent and positioning of sulfate residues. All these factors contribute to functional heterogeneity between heparin molecules. Commercial preparations of heparin are heterogeneous. Their components have molecular weights ranging from 3,000 to 30,000 (mean, 15,000). Only about one-third of the heparin molecules have the specific pentasaccharide sequence required for binding with antithrombin III (ATIII). This fraction is responsible for most of its anticoagulant effect. Commercial heparin is most commonly obtained from the lungs or intestinal mucosa of cows or pigs, from which it is extracted as either the sodium or calcium salt.

MECHANISMS OF ACTION

The anticoagulant effect of heparin is mediated largely through its ability to bind to and catalyze ATIII. At high concentrations, heparin also catalyzes the inhibition of factor IIa. At concentrations at which heparin is used clinically, this interaction is thought to be of little importance. More important, the heparin-ATIII complex inhibits the activated coagulation enzymes X, XI, XII and IX (Xa, XIa, XIIa, and IXa). Thrombin and Xa are the coagulation factors that are most sensitive to inactivation; on average, inhibition of thrombin is about ten times greater than the inhibition of Xa, but relative sensitivities vary.

ACTIONS

The synthesis of heparin by mast cells, which are present in the perivascular tissues, suggests that heparin is not involved in maintaining blood fluidity. However, vascular endothelial cells synthesize heparin-like heparan sulfate molecules, suggesting that the heparin-antithrombin system plays an important physiologic role in the prevention of intravascular thrombosis.

Congenital deficiency states for heparin have not been described. Congenital deficiency of ATIII does occur and is associated with a hypercoagulability state. ATIII deficiency is inherited as an autosomal dominant disorder in which carriers have ATIII levels between 40% and 60% of normal. Affected persons have a high prevalence (30%–80%) of thromboses, which often occur before the fifth decade, are recurrent, may occur in unusual locations, and are associated with a positive family history of thrombosis.

Heparin may increase vessel wall permeability and activation of lipoprotein lipase. It may inhibit platelet function, reduce proliferation of vascular smooth muscle cells, inhibit delayed hypersensitivity reactions, and suppress aldosterone secretion and angiogenesis.

All heparin fractions can interfere with platelet function. There is evidence that large heparin molecules that have no or low affinity for ATIII are particularly potent inhibitors of platelets. Platelet inhibition, combined with increases in vascular permeability, probably accounts for dissociations between the antithrombotic and hemorrhagic effects of heparin.

PHARMACOKINETICS

Heparin is not absorbed after oral administration and therefore must be given by injection. The preferred routes of administration are intravenous and subcutaneous. Intramuscular injection may produce large hematomas by accidental puncture of an intramuscular vein. There is evidence that heparin administration by intermittent intravenous injection is associated with more bleeding than is administration by continuous intravenous infusion.

The efficacy and safety of heparin administered by either continuous infusions or subcutaneously are comparable, provided that the dosages used are adequate. However, if the subcutaneous route is selected, the initial dose must be sufficiently high to counteract the reduced bioavailability associated with this method of administration. If an immediate anticoagulant effect is required, the initial subcutaneous dose should be accompanied by an intravenous bolus injection to avoid the 1- to 2-hour delay in anticoagulant effect that occurs with subcutaneous heparin alone.

After its injection and passage into the bloodstream, heparin binds to a number of plasma proteins that can reversibly neutralize its anticoagulant activity and so reduce its bioavailability. Heparin also binds to endothelial cells and macrophages, further complicating its pharmacokinetics. Differences between individuals in protein- and cell-binding capacity for heparin contribute to the variability of the anticoagulant response commonly seen in patients with thromboembolic disorders and to the laboratory phenomenon of heparin resistance (see discussion later in this chapter).

Neither liver nor renal disease appears to influence heparin pharmacokinetics at standard therapeutic concentrations. Similarly, there is no convincing evidence that heparin pharmacokinetics is influenced by concomitant use of other medications. Heparin elimination is, however, increased in patients with acute pulmonary embolism by a mechanism that is poorly understood. Bleeding while on heparin therapy is increased by any process that additionally impairs hemostatic mechanisms. Such a process may include reduction in platelet numbers (e.g., lymphoproliferative disorders, therapeutic agents) or function (e.g., polycythemia rubra vera, aspirin) or reduction in the concentration of coagulation proteins (e.g., hepatic disease, oral anticoagulants). Pregnancy, malignancy, acute thrombosis, and major surgery may be associated with heparin resistance owing to an increase in procoagulant activity.

There appears to be no clinically important difference in the bioavailability of sodium or calcium heparin. When the two salts have been directly compared in clinical trials assessing subcutaneous heparin prophylaxis for deep venous thrombosis, antithrombotic efficacy and hemorrhagic side effects have been similar.

After administration of an intravenous bolus of heparin, activity falls rapidly as equilibration occurs with binding to plasma proteins and cellular constituents, particularly endothelial cells. This is followed by a more gradual clearance that can best be explained by a combination of a saturable and a nonsaturable mechanism. The saturable phase of heparin clearance appears to be due to uptake by endothelial cells and macrophages, with depolymerization and metabolism to smaller less sulfated derivatives. The nonsaturable mechanism obeys first-order kinetics—the rate of clearance is linearly related to dose and can be accounted for by renal elimination.

The relative contribution of each of these mechanisms to clearance of heparin depends on the dose and size of the heparin fractions administered. Low doses of standard heparin are eliminated predominantly by the highly efficient but low-capacity saturable mechanism. With larger doses of heparin, capacity of the saturable

mechanism is exceeded, so that at high doses renal clearance predominates. Larger heparin molecules are preferentially cleared by the saturable mechanism; this has important implications for dose-response relations and for differences between the pharmacokinetic properties of standard and low-molecular-weight heparins.

MONITORING HEPARIN THERAPY

Because there is no suitable chemical assay for heparin, the investigation of its kinetics has depended on measurements of its biologic activity. Currently used methods for measuring heparin activity are summarized in [Table 91.1](#).

Method	Procedure	Therapeutic Range
Heparin assay	Thrombin or factor Xa is added to plasma sample; measure time to clotting	0.3-0.7 U/mL
Protamine titration of thrombin time	Protamine is added to thrombin-treated plasma sample; measure amount needed to inhibit clot formation	0.3-0.4 U/mL
Activated partial thromboplastin time (aPTT)	Kaolin and cephalin are added to a decaclified plasma sample; measure clotting time on recalcification	1.5-2.5

TABLE 91.1. MEASUREMENT OF HEPARIN ACTIVITY

CLINICAL USE OF HEPARIN

The results of randomized controlled trials confirm that a relation exists between the clinical effectiveness of heparin and its ex vivo effect on the activated partial thromboplastin time (aPTT) for the following conditions; prevention of recurrent thrombosis in patients with proximal vein thrombosis; prevention of mural thrombus in patients with acute myocardial infarction; prevention of recurrent ischemia in patients who have had streptokinase therapy for acute myocardial infarction; and prevention of coronary artery reocclusion after tissue plasminogen activator.

Maintaining the aPTT ratio above 1.5 is associated with protection against thrombosis, but bleeding complications may occur within the therapeutic range. The risk of bleeding is increased by a number of factors, which include both the heparin dose and the degree of prolongation of the aPTT. A satisfactory approach is to give an initial bolus of 5,000 U intravenously unless contraindicated (e.g., surgery within 24 hours) followed by an infusion of 32,000 U over 24 hours. This is the average infusion rate required to achieve optimal anticoagulation. Because of the short half-life of heparin at therapeutic doses, infusion rates should be adjusted on the basis of aPTTs performed as closely as 6 hours apart, with the first performed 6 hours after heparin is initiated. A heparin dose adjustment nomogram has been developed for aPTT reagents for which the therapeutic range is 1.9 to 2.7 times control (based on a protamine titration heparin level of 0.2 to 0.4 U). With this protocol, an aPTT above the lower limit of the therapeutic range was reached in 82% of patients after 24 hours and in 91% after 48 hours. This nomogram is not applicable to all aPTT reagents and should be adapted to the heparin responsiveness of the local thromboplastin in use.

In postmyocardial infarction patients who have received thrombolytic therapy, particularly streptokinase, a systemic lytic state may be observed with prolongation of clotting parameters. When intravenous heparin is given in this situation, the same 5,000-U intravenous bolus may be given, followed by 24,000 U over a 24-hour period (for the first 24 hours only adjusted upward if aPTT values are below the therapeutic range).

When the subcutaneous route is used for therapeutic anticoagulation, a suitable initial heparin dosage is 17,500 U every 12 hours. The dosage should be reduced to 12,500 U every 12 hours after thrombolytic therapy; at this lower dose, the heparin level does not exceed 0.1 anti-Xa U per milliliter and therefore coagulation monitoring is not required. For patients at particularly high risk, three studies have demonstrated that the efficacy of low-dose heparin is improved without compromising safety by adjusting the dose to achieve a minimal heparin effect. One of these studies, which aimed for an aPTT at the upper limit of normal, used a mean daily dose of 15,000 U of heparin; the other two prolonged the aPTT ratio to 1.1 to 1.2 with a mean daily dose in excess of 18,000 U. The adjusted dose regimen has limitations for routine use because it requires careful monitoring and the use of a responsive aPTT system.

SIDE EFFECTS

Bleeding

Four variables have been reported to influence bleeding during heparin treatment: (a) the dose of heparin; (b) the method of heparin administration; and patient factors such as (c) concurrent illness and (d) concurrent medication ([Table 91.2](#)). Pooled analysis of randomized trials comparing different methods of heparin administration yields an average incidence of major bleeding of 6.8% in the continuous-infusion group and 14.2% in the intermittent intravenous group (odds ratio 0.42; p .01). However, the comparison is confounded by the difference in the 24-hour heparin dose, which was greater in the intermittent intravenous group in five of the six studies. Thus, the observed increase in bleeding could be contributed to by the higher dose of heparin in the intermittent intravenous group.

Doses of heparin
Concurrent illness and medication
Method of heparin administration
Interindividual differences in protein and cell binding

TABLE 91.2. FACTORS INFLUENCING BLEEDING RISKS OF HEPARIN

For studies comparing continuous intravenous heparin with subcutaneous heparin, there was a similar bleeding incidence of 5.2% and 4.1%, respectively (odds ratio 1.1). Other factors that predispose to anticoagulant-induced bleeding are a serious concurrent illness, chronic heavy alcohol consumption, and a reduced functional capacity.

The concomitant use of aspirin has long been identified as a risk factor for heparin-induced bleeding. This observation bears close examination because the combination of heparin and aspirin is used often in the initial treatment of acute coronary artery syndromes. Aspirin increases operative and postoperative bleeding in patients who receive the very high doses of heparin required during open heart surgery. However, the risk of adding aspirin to a short course of regular therapeutic doses of heparin does not appear to be excessive.

Renal failure and patient age and gender also have been implicated as risk factors for heparin-induced bleeding. The reported association with female gender has not been consistent among studies and remains in question. The influence of patient-related factors on heparin-associated bleeding is illustrated by a recent study of patients with proximal vein thrombosis. Patients received an initial intravenous bolus of 5,000 U of heparin followed by a continuous infusion of 30,000 U per 24 hours

for patients with clinical risk factors for bleeding and of 40,000 U per 24 hours in patients free of risk factors for bleeding. The incidence of major bleeding was 11% in the high-risk group (who received the lower starting dose) and 1% in the low-risk group (who received the higher starting dose).

Bleeding during an intravenous infusion usually can be managed with supportive measures and by stopping the infusion, because the half-life for heparin therapeutic levels is approximately 60 minutes, and heparin effect is rapidly lost. It may be necessary to reverse heparin effect more rapidly if bleeding is life threatening (e.g., massive gastrointestinal or intracranial bleeding) or if a heparin overdose has occurred when heparin elimination will be markedly delayed. The anticoagulant effects of heparin can be reversed with protamine sulfate, which binds firmly with heparin. The dose of protamine sulfate is determined by the amount of circulating heparin, which in turn depends on the amount of heparin that was administered and the time elapsed since the last heparin dose. The full neutralizing dose is 1 mg of protamine sulfate for 100 U heparin; this must be reduced to half of this at 1 hour and to one-fourth of this at 2 hours. Protamine should be infused over 10 minutes to avoid hypotension and may need to be repeated because of its rapid clearance. Smaller repeated doses of protamine will be required to reverse therapeutic doses of heparin that have been given subcutaneously.

Thrombocytopenia

The reported incidence of heparin-associated thrombocytopenia varies widely. Thrombocytopenia is more common with heparin derived from bovine lung than that derived from porcine gut. Pooled analysis of recent prospective studies of full-dose intravenous heparin (thrombocytopenia defined as a platelet count less than 100×10^9 per liter) yielded a prevalence of thrombocytopenia of 5.4% for bovine and 1.3% for porcine heparin. The prevalence of thrombocytopenia in association with low-dose subcutaneous heparin appears to be lower than with full-dose intravenous therapy. Arterial thrombosis as a complication of heparin-induced thrombocytopenia (HIT) is also rare (0.18%). Arterial thrombosis occurs as a consequence of platelet aggregation *in vivo*, but venous thrombosis could result from heparin resistance caused by the neutralizing effect of heparin-induced release of platelet factor 4.

Thrombocytopenia usually begins between 3 and 15 days after the commencement of heparin therapy (median 10 days), but it has been reported within hours of commencing heparin in patients who have been exposed to heparin previously. The platelet count usually returns to baseline levels within 4 days after stopping heparin. Heparin-associated thrombocytopenia is thought to be caused by an IgG–heparin immune complex involving both the Fab and Fc portions of the IgG molecule. If the platelet count falls progressively or precipitously to less than 100,000 per milliliter, heparin should be stopped and an alternative management strategy instituted. If warfarin treatment has already been started and the international normalized ratio (INR) is approaching or in the therapeutic range, warfarin can be continued without the addition of alternative treatment (Table 91.3). If warfarin has not been started and heparin is being used to treat venous thromboembolism, a caval filter can be inserted or an alternative antithrombotic agent used. Two alternative antithrombotic agents have been evaluated in descriptive studies. These are the snake venom ancrod and the heparinoid Lomoparin (Organon).

Lack of reliability at the onset of warfarin therapy
Loss of accuracy and precision when thromboplastins with high
ISI values are used.
Loss of accuracy with automatic clot detectors
Lack of reliability of the ISI result provided by the manufacturer
Incorrect calculation of the INR because an inappropriate normal
control plasma is used to calculate the patient's prothrombin
time ratio

INR, international normalized ratio; ISI, international sensitivity
index.

TABLE 91.3. POTENTIAL PROBLEMS WITH THE INTERNATIONAL NORMALIZATION RATIO

The diagnosis of suspected HIT can be confirmed by laboratory tests. A test based on ^{14}C serotonin release of washed donor platelets plus heat-treated patient serum in the presence of therapeutic (0.1 U and high 100 U per milliliter) heparin concentrations has been shown to be both sensitive and specific.

Osteoporosis

The incidence of osteoporosis occurs as a complication of heparin therapy has been difficult to determine, because the need for long-term heparin treatment is rare. When it occurs, randomization to heparin or alternative therapy is usually not clinically justifiable. In one randomized trial that did address this question, 1 of the 20 women allocated to long-term antenatal heparin prophylaxis (10,000 U twice daily) developed clinical osteoporosis, whereas no patients in the control group did. A number of other descriptive series and case-controlled studies have also evaluated clinical or radiologic end points. Taken in combination, these studies suggest that heparin-induced osteoporosis is largely confined to patients who receive moderately high doses ($\geq 20,000$ U per 24 hours) for more than 5 months.

OTHER SIDE EFFECTS

Heparin has been reported to produce two distinct types of skin lesions—urticarial lesions and skin necrosis. *Urticarial lesions* occur at the site of subcutaneous injection and may be caused by a contaminant in heparin. Changing to a different preparation (i.e., a different salt or different animal origin) may resolve this problem. *Skin necrosis* usually occurs as a complication of subcutaneous heparin but has also been observed in association with the intravenous route of administration. The mechanism of skin necrosis is uncertain; it is inconsistently associated with thrombocytopenia but may be caused by a heparin-associated immune reaction. Histologic studies have found hemorrhagic infarction of skin and subcutaneous fat with acute necrotizing angitis, in keeping with a hypersensitivity reaction. Skin necrosis seems to be unrelated to the source of the heparin, and, consequently, a different preparation of standard heparin is unlikely to be tolerated. The heparinoid Lomoparin, which has minimal cross-reactivity with standard heparin, may be a safe alternative in these patients, but this has yet to be demonstrated equivocally. Generalized hypersensitivity reactions may also occur as a result of heparin. Symptoms include urticaria, conjunctivitis, rhinitis, bronchospasm, angioneurotic edema, and anaphylactic shock.

Selective hypoaldosteronism is a rare but probably real side effect of heparin administration, which appears to be caused by inhibition of 18-hydroxycorticosterone synthesis from corticosterone. It is usually of no clinical importance, although significant metabolic derangements and death have been reported in a few cases.

LOW-MOLECULAR-WEIGHT HEPARINS

Smaller heparin molecules bind less to plasma proteins and endothelial cells, are cleared predominantly by nonsaturable renal mechanisms rather than by the rapid saturable cellular route, inhibit platelet function to a lesser extent, have little effect on vascular permeability, and have a higher anti-Xa to anti IIa ratio than larger heparin molecules. A number of low-molecular-weight heparins (LMWHs) have been approved for use in North America.

Biochemistry and Anticoagulant Effects of LMWHs

LMWHs are fragments of heparin produced by either chemical or enzymic depolymerization. LMWHs are approximately one-third of the size of heparin with a molecular weight distribution of 1,000 to 10,000 and a mean molecular weight of 4,000 to 5,000. Depolymerization of heparin results in a change in the anticoagulant profile of the resulting low-molecular-weight fractions, with a progressive loss of their ability to catalyze thrombin inhibition. In addition to LMWHs produced by depolymerization, two other glycosaminoglycans have been developed for clinical use. These are dermatan sulfate and the heparinoid Lomoparin, which is a mixture of heparan sulfate (80% of the mixture), dermatan sulfate, and chondroitin sulfate.

LMWHs produce their anticoagulant effect by binding to ATIII through the same unique pentasaccharide sequence as standard heparin, which is present on less than one-third of LMWH molecules. Because a minimum chain length of 18 saccharides (including the pentasaccharide sequence) is required for ternary complex formation (heparin–ATIII–thrombin), only the larger molecules in each preparation are able to inactivate thrombin. In contrast, all LMWH fragments that contain the high-affinity pentasaccharide sequence catalyze the inactivation of factor Xa. Almost all standard heparin molecules contain at least 18 saccharide units, whereas

gastrointestinal bleeding. The risk of clinically important bleeding is increased when high doses of aspirin are used in combination with high-intensity warfarin therapy (INR 3.0 to 4.5). In contrast, a recent study has reported that low doses of aspirin (100 mg per day), which retain their antithrombotic efficacy and have only minimal gastric side effects, increase the efficacy of warfarin without significantly increasing the risk of major bleeding.

Sulfonamides and many broad-spectrum antibiotics may augment the anticoagulant effect of warfarin by eliminating bacterial flora and thereby producing vitamin K deficiency. However, these agents potentiate the anticoagulant effect of warfarin only in patients on a vitamin K–deficient diet. It is prudent to take special care when treatment with any new drug is necessary in patients who are being treated with oral anticoagulants and to monitor the INR time more frequently during the initial stages of combined drug therapy, with dose adjustments made when appropriate.

MONITORING ORAL ANTICOAGULANT THERAPY

The PT test is the most common method for monitoring oral anticoagulant therapy. The PT is responsive to depressions of three of the four vitamin K–dependent procoagulant clotting factors (factors II, VII, and X). These are reduced by warfarin at a rate proportional to their respective half-lives. The PT is performed by adding calcium and thromboplastin to citrated plasma. The term “thromboplastin” refers to a phospholipid–protein extract of tissues, usually lung, brain, or placenta, which contains both the tissue factor and the phospholipid necessary to promote the activation of factor X by factor VII. During the first few days of warfarin therapy, the PT reflects primarily the depression of factor VII, which has a half-life of approximately 6 hours. Subsequently, the test is prolonged also by depression of factors II and X. The responsiveness of a given thromboplastin to warfarin-induced changes in clotting factors mirrors the strength of the activation of factor X by factor VII as the levels of both of the clotting factors decrease. An unresponsive thromboplastin produces accelerated stimulation of factor X, resulting in a lesser prolongation of the PT for a given reduction in clotting factors than that caused by a less responsive thromboplastin.

A calibration model adopted in 1982 is used to standardize the reporting of the PT by converting the PT ratio observed with the local thromboplastin into an INR, calculated as follows:

$$\text{INR} = \frac{\text{observed ratio}_{\text{Patient Pt}}}{\text{Control PT}}^C$$

where C is the power value that represents the international sensitivity index (ISI). The ISI is a measure of the responsiveness of a given thromboplastin to reduction of the vitamin K–dependent coagulation factors compared with the international reference preparation; the lower the ISI, the more responsive is the reagent. The INR system loses accuracy and precision when thromboplastins with high ISI values are used ([Table 91.3](#)).

PRACTICAL DOSING

After administration of coumarin, an observable anticoagulant effect is delayed until newly synthesized dysfunctional vitamin K–dependent clotting factors replace the normal clotting factors as the latter are cleared from the circulation. Depending on the dose administered, the delay may range from 2 to 7 days. An approach to warfarin dosing and monitoring is as follows: if a rapid anticoagulant effect is required, an initial dose is administered in combination with heparin, which is then discontinued when the INR has been in the therapeutic range for at least 2 days. If treatment is not urgent (e.g., chronic stable atrial fibrillation) and the patient is under the age of 70 years, treatment can be commenced with an anticipated maintenance dose of 4 to 5 mg per day, which achieves a steady-state anticoagulant effect in 5 to 7 days. PT (INR) monitoring is usually performed after 5 to 7 days after institution of therapy, then weekly for 1 to 2 weeks, and then less often, depending on the stability of INR results. If the INR response remains stable, testing can be drawn out to intervals as long as every 4 to 6 weeks. If adjustments to the dose are required or clinical situations or drug changes occur, then the cycle of more frequent monitoring is repeated until a stable dose response is again achieved.

Some patients on long-term coumarin therapy are difficult to manage because they have unexpected fluctuations in dose response. The unexpected fluctuations in dose response could be due to changes in diet, inaccuracy in PT testing, undisclosed drug use, poor patient compliance, surreptitious self-medication, or intermittent alcohol consumption. We recommend an initial dose of 3 mg daily for patients over 70 years of age. For these patients particularly, concomitant monitoring of blood pressure is essential to reduce the incidence of intracranial bleeding.

MANAGEMENT OF PATIENTS WITH HIGH INR VALUES

An approach to managing patients with high INR values has been developed. The following guidelines are suggested:

1. If the INR is above the therapeutic range but below 6.0, if the patient is not bleeding, and if rapid reversal is not indicated for reasons of surgical intervention, the next few doses can be omitted and warfarin therapy can be resumed at a lower dose when the INR is in the therapeutic range.
2. If the INR is above 6.0 but below 10.0 and the patient is not bleeding or when rapid reversal is required because the patient requires elective surgery, vitamin K₁ can be given subcutaneously in a dose of 0.5 mg to 1 mg with the expectation that a demonstrable reduction of the INR will occur at 8 hours and that in many patients the INR will be in the therapeutic range of 2.0 to 3.0 within 24 hours. If the INR remains high at 24 hours, an additional dose of 0.5 mg vitamin K₁ can be given. Warfarin treatment can then be resumed at a lower dose.
3. If the INR is above 10.0 but below 20.0 and the patient is not bleeding, a higher dose of vitamin K (3 mg to 5 mg) should be given subcutaneously with the expectation that the INR will be reduced substantially at 6 hours. The INR should be checked in 6 hours and vitamin K can then be repeated, if necessary. Subcutaneous injection of vitamin K is preferred over intravenous injection in these circumstances because rapid intravenous infusion of vitamin K can produce anaphylactoid reactions.
4. If a very rapid reversal of an anticoagulant effect is required because of serious bleeding or major warfarin overdose (e.g., INR more than 20.0), vitamin K in a dose of 10 mg should be given by slow intravenous infusion (e.g., over 20 to 30 minutes) and the INR checked every 6 hours. It may be necessary to repeat vitamin K at 12-hour intervals and supplement with plasma transfusion or prothrombin complex concentrate, depending on the urgency of the situation.
5. In case of life-threatening bleeding or serious warfarin overdose, replacement with prothrombin complex concentrate is indicated, supplemented with intravenous vitamin K (10 mg), which should be repeated as necessary, depending on the INR.
6. If continued warfarin therapy is indicated after high doses of vitamin K administration, heparin can be given until the effects of vitamin K have been reversed and the patient becomes responsive to warfarin.

CLINICAL INDICATIONS

PREVENTION OF VENOUS THROMBOEMBOLISM

Oral anticoagulants are effective in preventing venous thrombosis after hip surgery and major gynecologic surgery when used at a targeted INR of 2.0 to 3.0 ([Table 91.5](#)). Benefit has been demonstrated when treatment is commenced a number of days before surgery, the evening before surgery, or on the first postoperative day. The risk of clinically important bleeding with the less intense regimen is small, but because warfarin prophylaxis is more complicated to use than fixed low-dose heparin, warfarin is generally reserved for very-high-risk patients such as those with previous venous thrombosis or those having major orthopedic procedures. For patients undergoing elective hip replacement or major knee surgery, low-molecular-weight heparins have been shown to be more effective than warfarin commenced postoperatively or the night before surgery.

INR Range	Management
> 6.0 and < 10.0	Stop warfarin. Give vitamin K ₁ 0.5-1 mg subcutaneous. Recheck INR in 8-24 hours.
> 10.0 and < 20.0	Stop warfarin. Give vitamin K 3-5 mg subcutaneous. Recheck INR in 6 hours.
> 20.0	Stop warfarin. Give vitamin K 10 mg intravenous over 20-30 minutes. Consider plasma transfusion or prothrombin complex concentrate. Recheck INR in 6 hours.

TABLE 91.5. ANTITHROMBOTIC REGIMENTS TO PREVENT VENOUS THROMBOEMBOLISM

Very low fixed doses of warfarin (1 mg daily) have been reported to be effective in one small study in patients having gynecologic surgery and in a larger study in which 1 mg of warfarin per day was effective in preventing subclavian vein thrombosis in cancer patients with indwelling subclavian catheters. It is surprising that the very-low-dose warfarin was associated with an increase in fibrinolysis in the gynecologic patients. One recent randomized study demonstrated that warfarin in a fixed dose of 1 mg is ineffective in preventing postoperative venographically proven venous thrombosis in patients having hip and knee surgery. The other studies in hip surgery—one uncontrolled and another based on fibrinogen uptake studies—produced similar findings. Although it is attractive because of its safety and simplicity, the 1-mg dose is now clearly ineffective in patients having hip and knee replacements and should not be used for those with these high-risk conditions. Levine and associates reported that low-dose warfarin with a targeted INR of 1.5 is effective in preventing thrombosis in patients with stage IV breast cancer.

TREATMENT OF DEEP VENOUS THROMBOSIS

Initial therapy is with heparin or low-molecular-weight heparin. Caution is advised in patients having spinal or epidural anesthesia because of the risk of bleeding and paraplegia. Antithrombotic therapy should be commenced only when the needle has been removed and contraindicated if bleeding has occurred. Oral anticoagulant therapy is indicated for up to 3 months in patients with proximal vein thrombosis and in patients with symptomatic calf vein thrombosis. A less intense regimen (INR 2.0 to 2.5) is as effective as the more intense regimen (INR 3.0 to 4.5) but is associated with a much lower incidence of bleeding. More recently, studies in patients with proximal vein thrombosis evaluating short-course compared with long-course heparin treatment have confirmed the initial observation that moderate-dose warfarin is associated with a low rate of recurrent venous thromboembolism and a low incidence of bleeding.

ACUTE MYOCARDIAL INFARCTION

Intravenous heparin or low-molecular-weight heparin is indicated in the acute phase of myocardial infarction. There is evidence that less intense warfarin therapy (INR 2.0 to 3.0) is effective in preventing stroke and venous thromboembolism in patients with acute myocardial infarction and that a higher intensity (INR 3.0 to 4.5) is effective in reducing recurrent infarction, stroke, and death.

The early evidence that oral anticoagulants are effective for the early treatment of acute myocardial infarction comes from studies performed in the 1960s and 1970s, which reported that a low-intensity warfarin regimen (presumptive INR 1.5 to 2.5) is effective for preventing stroke and pulmonary embolism. Three randomized trials evaluated the effectiveness of oral anticoagulants in patients with acute myocardial infarction. Two of these, the MRC study and the Veterans Affairs Cooperative Study, showed a significant reduction in stroke; the third, the Bronx Municipal Study, reported a nonsignificant trend. The Bronx Municipal Study showed a significant reduction in mortality, whereas the other two showed no effect on mortality. All three studies showed a reduction in the incidence of clinically diagnosed pulmonary embolism.

The early evidence that oral anticoagulants are effective in the long-term management of acute myocardial infarction comes from analysis of pooled data from seven randomized trials published between 1964 and 1980, which showed that oral anticoagulant therapy during a 1- to 6-year treatment period reduced the combined end points of mortality and nonfatal reinfarction by approximately 20%.

The question of the value of oral anticoagulants has been reopened by the results of three more recent studies. The study by the Sixty-Plus Reinfarction Study Group was limited to patients over the age of 60 who had been treated with oral anticoagulants for at least 6 months. Although there was a significant reduction in reinfarction and in stroke in patients randomized to receive continuing anticoagulant therapy, the findings were limited by its lack of generalizability as a “stopping trial” in a select age group. The study by Smith and associates had no age restriction and showed a 50% reduction in the incidence of the combined outcomes of recurrent infarction, stroke, and mortality. The most recent study, Anticoagulants in the Secondary Prevention of Events in Coronary Thrombosis (ASPECT) trial, also had no age restriction and reported a higher than 50% reduction in reinfarction and a 40% reduction in stroke.

All three contemporary studies used high-intensity regimens (INR of 2.7 to 4.5 in the first; 2.8 to 4.8 in the other two), and all reported an increased incidence of bleeding with anticoagulants. Indirect support for the efficacy of oral anticoagulants in patients with coronary artery disease comes from a randomized trial of patients with peripheral arterial disease. Compared with an untreated control group, a relatively high-intensity oral anticoagulant regimen (INR 2.6 to 4.5) produced a significant (50%) reduction in mortality (6.8% to 3.3% per year). Studies are ongoing, evaluating the role of warfarin and aspirin in combination among survivors of myocardial infarction.

PROSTHETIC HEART VALVES

There have been no clinical trials comparing oral anticoagulants with an untreated control group in patients with prosthetic heart valves (for ethical reasons); however, a trial with aspirin as the comparator found that the bleeding in the warfarin group was significantly less than in those who received antiplatelet drugs (relative risk reduction 60% to 79%). The incidence of bleeding was highest in the warfarin group. The minimum effective intensity of anticoagulant therapy has been evaluated in three studies that compared the efficacy and safety of two levels of intensity of warfarin therapy. The first included only patients with tissue heart valves and showed that the less intense regimen (INR 2.0 to 2.25) was as effective but produced less bleeding than the more intense regimen (INR 2.5 to 4.0). The second study, which included patients with mechanical prosthetic heart valves, compared a very-high-intensity regimen prothrombin ratio (INR 7.4 to 10.8) with a lower-intensity regimen (INR 1.9 to 3.6). There was no difference in effectiveness between the two regimens, but the higher-intensity regimen produced significantly more bleeding. A third study, which included patients with mechanical prosthetic valves, all of whom received aspirin and dipyridamole, compared the efficacy and safety of a low-intensity regimen (INR 2.0 to 3.0) with a high-intensity regimen (INR 3.0 to 4.5). No difference in efficacy was found between those in the two regimens, but, as in the previous studies, the high-intensity regimen was associated with a statistically significant increase in bleeding.

Thus, two studies have now demonstrated that moderate-intensity warfarin treatment is as effective as a high-dose regimen, although in one, all patients also received aspirin and dipyridamole. A recently completed randomized trial has shown that the addition of aspirin in a dose of 100 mg per day to warfarin (INR 3.0 to 4.5) results in a marked improvement in efficacy when compared with warfarin (INR 3.0 to 4.5) plus placebo. The combined low-dose aspirin and high-intensity warfarin regimen produced a significant and clinically impressive reduction in general mortality, in cardiovascular mortality, and in stroke, without a significant increase in major bleeding or cerebral hemorrhage.

ATRIAL FIBRILLATION

Five primary prevention trials, all with relatively similar study designs, were performed. Three were carried out in the United States—the Stroke Prevention in Atrial Fibrillation trial (SPAF), the Boston Area Anticoagulation Trial for Atrial Fibrillation (BAATAF), and the Stroke Prevention in Atrial Fibrillation trial (SPINAF). One trial was carried out in Denmark—the Copenhagen Atrial Fibrillation, Aspirin, Anticoagulation study (AFASAK); and the other was performed in Canada—the Canadian Atrial Fibrillation Anticoagulation study (CAFA). In two of the trials (AFASAK and SPAF), a third group of subjects was randomized to aspirin therapy. To be eligible for enrollment in these studies, patients were required to be good candidates for anticoagulant therapy. All five trials reached consistent conclusions, with a pooled 68% risk reduction on intention-to-treat analysis. All trials reached a statistically significant difference ($p < 0.05$) except for the Canadian study, which was stopped prematurely after the results of other trials became available. In patients who remained on treatment with warfarin, the reduction of stroke risk was greater than 80%. The rates of hemorrhagic complications were low, with little difference between the rate of major or intracranial hemorrhage in the warfarin, aspirin, or control groups. Minor hemorrhage was increased by approximately 3% per year in the warfarin group. Results from the aspirin treatment arms of the two original studies that randomized patients to aspirin therapy were consistent with a small benefit. In the AFASAK study, which used a 75-mg daily dose of aspirin, the 14% reduction in stroke was not statistically significant, whereas in the SPAF trial a 325-mg daily dose of aspirin was associated with a 44% reduction of risk of stroke.

The European Atrial Fibrillation Trial (EAFT) study compared anticoagulant therapy, aspirin, and placebo in patients with atrial fibrillation who had sustained a stroke or transient ischemic attack within the preceding 3 months. There was a 68% reduction in stroke risk with anticoagulant therapy and a 16% stroke risk reduction in the aspirin group. Of interest, the reduction in stroke risk with an aspirin dose of 300 mg per day was comparable to the reduction observed in the AFASAK study, which used an aspirin dose of 75 mg per day. None of the patients in the anticoagulant group of the EAFT suffered an intracranial hemorrhage.

In the second phase of the Stroke Prevention in Atrial Fibrillation (SPAF II) trial using an intention-to-treat analysis, warfarin was slightly more effective than aspirin for preventing ischemic stroke. This difference was almost entirely offset, however, by a higher rate of intracranial hemorrhage in the warfarin group, in patients over 75 years of age who had a rate of intracranial hemorrhage 1.8% per year compared with approximately 0.3% in the other trials. The intensity of anticoagulant therapy was higher in the SPAF II trial than in the primary prevention studies. In addition, most patients who suffered an intracranial hemorrhage during any of the trials had relatively high levels of anticoagulation, with estimated INRs greater than 3.0 at the time of the hemorrhage. Therefore, the high rate of cerebral hemorrhage observed in the anticoagulant group in the SPAF 2 study was possibly related to the high intensity of anticoagulation in the elderly patients who may be at particularly high risk for intracranial hemorrhage when INR values are greater than 3.0. In addition, when an on-treatment analysis was performed, the benefit of warfarin over aspirin in both the under- and over-75-year group was about 50%.

In a pooled analysis of the primary prevention trials, it was determined that increasing age, history of hypertension, history of diabetes mellitus, and a previous transient ischemia attack or stroke are independent predictors of a higher risk of stroke in patients with atrial fibrillation. Accordingly, in patients under the age of 65 without risk factors, anticoagulation does not seem to be of benefit. However, in patients under the age of 65 with risk factors and over the age of 65 with or without risk factors, anticoagulation significantly reduces the risk of stroke, particularly in women.

EVALUATION OF WARFARIN AND ASPIRIN IN COMBINATION

The SPAF III study evaluated 1,044 patients with atrial fibrillation who also had at least one prespecified risk factor for thromboembolic disease. The prespecified risk factors increased were congestive heart failure or left ventricular fractional shortening less than 25%, previous thromboembolism, systolic pressure greater than 160 mm Hg, or being a woman over 75 years of age. Patients were randomly assigned either to a combination of low-intensity, fixed-dose warfarin adjusted to an INR of 1.2 to 1.5 for initial dose adjustment and aspirin 325 mg per day or to adjusted-dose warfarin for an INR of 2.0 to 3.0. The mean INR in the combination group was 1.3 compared with 2.4 for those taking adjusted-dose warfarin. The trial was terminated after a mean follow-up of 1.1 years when the rate of ischemic stroke and systemic embolization in the combination therapy group was 7.9% per year, compared with 1.9% per year in the dose-adjusted group (RR 7.4%; $p > 0.0001$). The rates of major bleeding were similar in both treatment groups. Thus, following the regimen of low-intensity, fixed-dose warfarin plus aspirin was not sufficient for stroke prevention in patients with nonvalvular atrial fibrillation who were considered to be at high risk for thromboembolic complications. This study further confirmed the benefit of therapeutic dose warfarin over aspirin; the dose of warfarin was below the therapeutic level.

PATIENTS CONSIDERED AT LOW RISK ON ASPIRIN

A separate component of the SPAF III study identified patients with atrial fibrillation considered at low risk because of the absence of four prespecified thromboembolic risk factors (recent congestive heart failure or left ventricular fractional shortening less than 25%, previous thromboembolism, systolic blood pressure higher than 160 mm Hg at study enrollment, or being a woman over 75 years of age). It is noteworthy that a history of diabetes mellitus was not used as a risk factor. All were given aspirin at 325 mg per day with an ischemic stroke rate of 1.4% per year. For such patients, treatment with warfarin was (1.1% per year) and may not justify the risk, expense, and inconvenience of life-long anticoagulation. Thus, it appears that these patients would be protected with either aspirin or warfarin.

STROKE PREVENTION IN PATIENTS WITH ATRIAL FIBRILLATION: SUMMARY

Patients without risk factors for hypertension, diabetes, previous transient ischemic episodes, or stroke who are under the age of 65 do not require either warfarin or aspirin prophylaxis. Patients between the ages of 65 or 75 without risk factors can be treated with aspirin or warfarin. All patients over 75 or those of any age with risk factors would benefit from warfarin. Any patient with poor ventricular function and atrial fibrillation would benefit from warfarin.

IDEAL THERAPEUTIC RANGE FOR ANTICOAGULATION

From the results of several studies, it appears that anticoagulation therapy with warfarin should be monitored carefully, and an INR between 2.0 and 3.5 is the optimum range for most indications. Among elderly patients, however, an upper limit to the INR of approximately 3.0 is appropriate.

SILENT CEREBRAL INFARCTION

Cerebral infarction in patients with atrial fibrillation may vary from being clinically silent to catastrophic. The prevalence of silent cerebral infarction and its effect as a risk factor for symptomatic stroke are important considerations for the evaluation of patients with atrial fibrillation.

The Veterans Affairs Cooperative Study was a double-blind, controlled trial designed primarily to determine the efficacy of warfarin for the prevention of stroke in neurologically normal patients with nonrheumatic atrial fibrillation. It also was designed to evaluate patients with silent cerebral infarction. Computed tomography scans of the head were performed at entry, at the time of any subsequent stroke, and at termination of follow-up on all patients who completed the study without a neurologic event. Of 516 evaluable scans performed at entry, 76 (14.7%) had evidence of one or more silent infarcts. Age ($p < 0.011$), a history of hypertension ($p < 0.003$), active angina ($p < 0.012$), and elevated mean systolic blood pressure ($p > 0.001$) were associated with the presence of this finding. Silent cerebral infarction occurred during the study at rates of 1.01% and 1.57% per year for the placebo and warfarin treatment groups, respectively (RR, 1.55, 95% CI 0.40 to 6.11 NS). Silent cerebral infarction at entry was not an independent predictor of later symptomatic stroke, but active angina was a significant predictor; 15% of the placebo-assigned patients with angina developed a stroke compared with 5% of the placebo-assigned patients without angina.

ADVERSE EFFECTS OF ANTICOAGULATION

Bleeding is the main complication of oral anticoagulant therapy. The risk of bleeding is influenced by the intensity of anticoagulant therapy, by the patient's underlying clinical disorder, presence of hypertension and by the concomitant use of high doses of aspirin, which both impair platelet function and produce gastric erosions.

Four randomized studies have demonstrated that the risk of clinically important bleeding is reduced by lowering the therapeutic range from 3.0–4.5 to 2.0–3.0. Although this difference in anticoagulant intensity is associated with a reduction of the dose of warfarin of only approximately 1 mg, the effect on bleeding is profound.

The risk of major bleeding has been reported to be increased by age over 65 years, a history of stroke or gastrointestinal bleeding, atrial fibrillation, and the presence of serious comorbid conditions such as renal insufficiency or anemia. Bleeding that occurs when the INR is less than 3.0 is often associated with an obvious underlying cause or an occult gastrointestinal or renal lesion.

The most important nonhemorrhagic side effect of warfarin is skin necrosis. This uncommon complication, usually observed on the third to eighth day of therapy, is caused by extensive thrombosis of the venules and capillaries within the subcutaneous fat. An association has been reported between warfarin-induced skin necrosis and protein C deficiency and, less commonly, protein S deficiency, but this complication can also occur in nondeficient persons.

The pathogenesis of this striking complication is unknown. A role for protein C deficiency seems probable and is supported by the similarity of the lesions to those seen in neonatal purpura fulminans, which complicates homozygous protein C deficiency. The reason for the unusual localization of the lesions remains a mystery. The treatment of patients with coumarin-induced skin necrosis who require lifelong anticoagulant therapy is problematic. Warfarin is relatively contraindicated, and long-term heparin is inconvenient and associated with osteoporosis. A reasonable approach in such patients is to restart warfarin at a low dose, such as 2 mg, under the coverage of therapeutic doses of heparin and to increase the warfarin gradually over several weeks. This approach should prevent an abrupt fall in protein C levels before a reduction in the levels of factors II, IX, and X and has been shown to be free of recurrence of skin necrosis in a number of recent case reports.

Oral anticoagulants cross the placenta and can produce a characteristic embryopathy, central nervous system abnormalities, or fetal bleeding. Warfarin should not be used in the first trimester of pregnancy and should, if possible, be avoided throughout the entire pregnancy. Heparin is preferred when anticoagulants are indicated in pregnancy. There is convincing evidence that warfarin does not induce an anticoagulant effect in the breast-fed infant when the drug is administered to a nursing mother.

CHAPTER 92: PRINCIPLES AND APPLICATIONS OF CARDIAC SURGERY

JOHN G. BYRNE, RAYMOND H. CHEN AND DAVID H. ADAMS

[Indications for Cardiac Surgery](#)
[Surgical Strategies](#)
[Estimating the Risks of Cardiac Surgery](#)
[Summary](#)

Surgical intervention for cardiovascular disorders is indicated when the outcome of the planned operation is expected to be superior to medical treatment. Cardiac surgery is usually indicated when symptoms are refractory to medical management but may also be indicated to provide survival benefit.

The modern era of cardiac surgery can be summarized by the events of recent decades. The 1950s were notable for the development of cardiopulmonary bypass and early attempts at correction of congenital abnormalities. During the 1960s, the surgical treatment of congenital abnormalities and valve replacement surgery became commonplace. The 1970s were characterized by the widespread growth of coronary artery bypass graft (CABG) procedures for the treatment of coronary artery disease. During the 1980s, cardiac transplantation and valve reparative procedures became accepted treatment options. The 1990s have been notable for the development of minimally invasive and video-assisted techniques for cardiac surgery, and the new millennium may bring the development of "robotic" computer-assisted cardiac surgery.

INDICATIONS FOR CARDIAC SURGERY

ISCHEMIC HEART DISEASE

Elective or Urgent Surgery

The inability to medically control severe anginal symptoms is the most common indication for elective or urgent cardiac surgery in ischemic heart disease. Transarterial catheter dilatation techniques, with or without intra-arterial stents, are now widely used as first-line invasive therapy for patients with disabling angina and relatively limited coronary obstructions who fail to improve with medical therapy. Early recurrent obstructions after balloon dilatation, or stent restenosis, however, are relatively common, and many patients ultimately require CABG for symptomatic relief.

An important factor to measure, when considering CABG, is the magnitude of inducible myocardial ischemia, as reflected both by the patient's symptoms and by the response to exercise stress testing. Other important considerations include the nature and condition of the coronary arteries, as well as the many patient-related factors that determine the patient's risk profile for surgery. Patients with several comorbidities, such as generalized atherosclerosis, diabetes mellitus, respiratory insufficiency, and renal failure, have a much higher risk for surgery. For obvious reasons, it is inappropriate to recommend CABG in patients whose life expectancy is limited due to coexisting major medical illnesses or terminal cancer.

Patients with multivessel disease and good ventricular function have similar survival when managed by percutaneous transluminal coronary angioplasty (PTCA) or CABG, but freedom from reintervention and return of angina is much better with CABG (Fig. 92.1). Patients with multivessel coronary artery disease or significant left main coronary artery disease or both in the setting of depressed left ventricular function have improved long-term survival with CABG over medical management (Fig. 92.2 and Fig. 92.3). This may be especially true for diabetics, as documented in the Bypass Angioplasty Revascularization Investigation (BARI) trial. Long proximal left coronary artery obstruction also generally precludes safe and effective PTCA/stent procedures, and patients with diabetes are best managed with surgical revascularization.

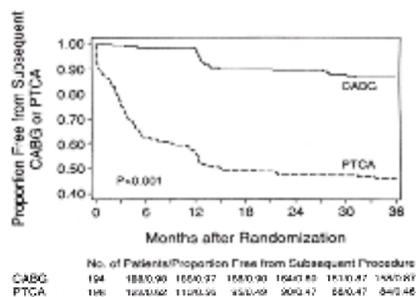

FIGURE 92.1. Proportion of patients remaining free from subsequent intervention (CABG or PTCA) after the initial revascularization procedure. (From King SB III, Lembo NJ, Weintraub WS, et al. A randomized trial comparing coronary angioplasty with coronary bypass surgery. *N Engl J Med* 1994;331:1044.)

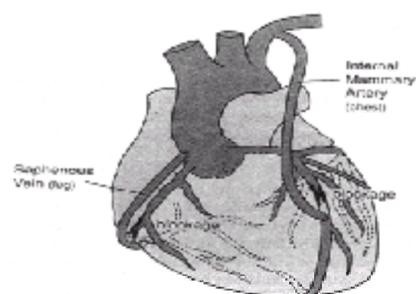

FIGURE 92.2. Anatomical depiction of two-vessel bypass operation, using the LIMA graft to the left anterior descending artery and aorto-coronary saphenous vein graft to the posterior descending artery. (From Burrows SG, Gassert CA. *Moving right along after open heart surgery*. Atlanta: Pritchett & Hull Associates, 1990:43.)

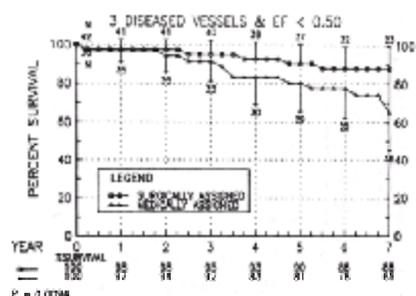

FIGURE 92.3. Survival in the CASS randomized trial of patients with three-vessel disease and ejection fractions less than 0.50. After seven years of follow-up, 88% of patients assigned to surgical treatment versus 65% of those assigned to medical treatment are alive ($p = 0.0094$). (From Killip T, Passamani E, Davis K, et al. Coronary Artery Surgery Study: a randomized trial of coronary bypass surgery: eight years follow-up and survival in patients with reduced ejection fraction. *Circulation*. 1985;72:102.)

Emergency Surgery

Patients who develop mechanical complications of acute myocardial infarction (MI) are candidates for emergency cardiac surgery. These include patients with (a) ruptured ventricular free wall resulting in tamponade, (b) ruptured ventricular septum resulting in a ventricular septal defect, (c) ruptured papillary muscle resulting in severe mitral regurgitation, and (d) severe pump impairment resulting in cardiogenic shock. Needless to say, the operative risk in these patients is very high, but in general their only chance for survival involves surgical therapy. An acute MI without cardiogenic shock is not usually an indication for undertaking CABG. However, patients who develop postinfarct angina have an increased risk for reinfarction, either in the original infarct zone or in another portion of the heart supplied by a second coronary artery with severe obstruction, and are generally best served by transcatheter or surgical intervention. Patients who require emergency CABG are usually best served by all-vein bypass grafting, because of the concerns regarding early decreased flow in the internal mammary artery (IMA) in the setting of potential high inotropic requirement.

Long-Term Considerations

The major potential adverse long-term outcome of CABG is saphenous vein graft stenosis due to intimal proliferation. This risk is especially high in saphenous vein grafts to the left anterior descending coronary artery (LAD). Patients with greater than 50% stenosis in these grafts had worse 7- and 10-year survival rates than did patients with greater than 50% stenosis of the native LAD. The problem of late stenosis can be avoided to some extent by grafting one or both of the IMAs, rather than saphenous veins, to the LAD (Fig. 92.4). IMA grafts have improved late graft patency compared with saphenous vein grafts. In addition, patients receiving IMA grafts have improved early and late survival compared with patients receiving saphenous vein grafts alone. The late survival benefit extends to patients older than age 70 for the left internal mammary (LIMA) graft. The improved patency and the improved early and late survival for IMA grafts have resulted in routine use of the LIMA graft, making it the gold standard for elective CABG operations, and have ameliorated somewhat the long-term risk of saphenous vein graft stenosis in CABG. Furthermore, "all-arterial" reconstruction, by use not only of both IMA, but also of free radial arteries, has gained favor because of presumed improved patency of the arterial conduits. Use of bilateral IMA grafts in diabetics, however, increases the risk of deep sternal wound infection.

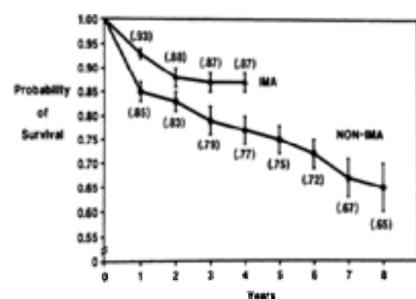

FIGURE 92.4. Actuarial Kaplan–Meier survival estimates for coronary artery bypass patients 70 years of age and older. The NON-IMA group had only vein grafts, whereas the IMA group included patients who had one internal mammary artery graft and at least one vein graft. The projected survival for up to 4 years was statistically significant ($p < 0.001$). (From Gardner TJ, Greene PS, Rykiel MF, et al. Routine use of the left internal mammary graft in the elderly. *Ann Thorac Surg* 1990;49:188.)

VALVULAR HEART DISEASE

Deformities of the cardiac valves, resulting in valvular stenosis or regurgitation generally culminate in chronic and progressive cardiac functional deterioration. Pressure or volume overloading of the heart results, with cardiac enlargement and progressive deterioration of contractile function. Although congenital bicuspid aortic valve and rheumatic mitral valve disease were once the most common indication for valve surgery, the most common indication for valvular heart surgery is degenerative calcific aortic stenosis and degenerative mitral regurgitation.

Aortic Valve Disease

Patients with critical aortic stenosis often benefit dramatically from aortic valve replacement (AVR). The indication for valve replacement is based primarily on symptoms, but occasionally patients with asymptomatic high-grade aortic stenosis (systolic gradient more than 100 mm Hg) are also candidates for surgery (Fig. 92.5). In fact, most patients in this subgroup have symptoms with forced exertion. In aortic regurgitation, symptoms usually direct surgical therapy, but asymptomatic patients with echocardiographic documentation of severe cardiac dilatation (end-systolic dimension greater than 55 mm Hg) or dysfunction (ejection fraction less than 0.30) are also appropriately referred for AVR.

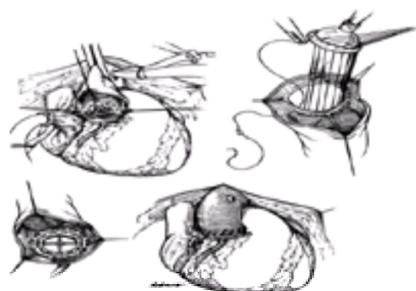

FIGURE 92.5. Aortic valve replacement. The sclerotic leaflets are excised, and the new valve is secured to the native annulus with the interrupted sutures. (From Cooley DA. *Techniques in cardiac surgery, second edition*. Philadelphia: W.B. Saunders, 1984:179.)

Mitral Valve Disease

Another common condition for which cardiac valve surgery is indicated is chronic progressive mitral regurgitation. Many such patients need valve surgery to prevent clinical heart failure. The indication for surgery in most patients is also related to symptoms, but asymptomatic patients with echocardiographic documentation of cardiac dysfunction are also appropriately referred. If these patients develop significant cardiac dilatation, cardiac functional recovery may not occur after valve replacement or repair. Mitral valve repair is generally preferred over replacement and is usually possible except in the case of severe rheumatic mitral disease (Fig.

92.6). Successful repair obviates the need for later valve re-replacement owing to bioprosthetic structural valve degeneration and the need for life-long anticoagulation in the case of mechanical valves.

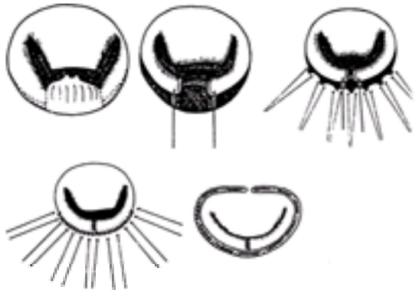

FIGURE 92.6. Mitral valve repair is generally preferred over replacement and is usually possible except in the case of severe rheumatic mitral disease. Successful repair obviates the need for later valve re-replacement.

HEART FAILURE

Patients with severe heart failure refractory to medical management may be candidates for surgical therapy. Heart transplantation is reserved for patients without other major medical comorbidities. Ventricular assist devices (VADs) may be used as “bridge to transplant,” “bridge to recovery,” or possibly as permanent devices (Fig. 92.7). Given the limited number of available donor hearts, nontransplantation procedures such as high-risk CABG or mitral valve repair with VAD backup may be the only suitable option. Ventricular volume reduction surgery has also been suggested as an option for end-stage dilated cardiomyopathy but remains highly controversial.

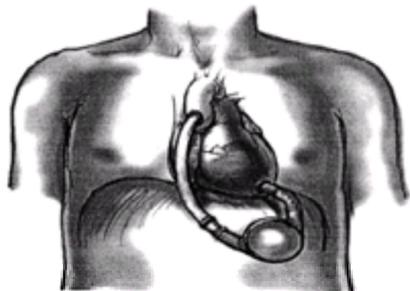

FIGURE 92.7. Ventricular assist devices (VADs) may be used as “bridge to transplant,” “bridge to recovery,” or possibly as permanent devices.

OTHER INDICATIONS FOR CARDIAC SURGERY

The many other possible indications for open heart surgery include congenital deformities of the heart, such as ASDs and aneurysmal disease of the thoracic aorta resulting in dilatation, dissection, or rupture. Primary cardiac tumors, although rare, almost always require surgical removal and reconstruction of the affected portion of the heart. Surgical treatment of atrial fibrillation by the Cox–Maze procedure may also benefit selected patients.

SURGICAL STRATEGIES

ISCHEMIC HEART DISEASE

Most CABGs are performed using conventional sternotomy, cardiopulmonary bypass (CPB), aortic clamping, and cardioplegia. Recently, however, efforts to develop safe methods to perform surgery without CPB, so-called “beating heart” surgery, have evolved. When performed by means of a full sternotomy, off-bypass CABG is termed *OPCAE* or *off-pump coronary artery bypass*. When performed through a small anterior left thoracotomy, off-bypass CABG is termed *MIDCAB* or *minimally invasive direct coronary artery bypass*. Many centers have embarked on programs to bypass not only single-vessel disease but also multivessel disease by use of various cardiac stabilizers. The technical results of these methods appear to be improving, but the long-term results are unknown. Our current indications for OPCAB include situations in which CPB poses increased risk in poor-option patients. Such patients include those with severe atherosclerotic disease of the ascending aorta and cerebral circulation, in which CPB with aortic cannulation or clamping or both pose increased risk of stroke. Another indication for OPCAB is severe renal insufficiency in which CPB may worsen renal function. Other methods at minimally invasive CABG include the Heartport system, which uses transfemoral cannulation for CPB and a small left submammary incision for single- and multivessel CABGs. A transfemoral aortic balloon occluder is used to clamp the aorta and deliver cardioplegia. Robotic, video-assisted, and computer-assisted techniques, using thorascopic instruments, may also prove beneficial in the future.

VALVULAR HEART DISEASE

Minimally invasive techniques are now widely applicable to isolated valve surgery. Isolated aortic valve replacement can be safely performed through an upper hemisternotomy, and isolated mitral valve repair or replacement can be safely performed through a small right thoracotomy, a parasternal incision, or an upper or lower hemisternotomy. In our practice, a minimally invasive approach to isolated valve surgery is the standard of care for selected patients. In contrast to minimally invasive CABG surgery, in which we recommend OPCAB for high-risk patients, in valve surgery, we recommend minimally invasive surgery for good-risk patients. Higher-risk patients should be offered the most efficient and expeditious operation to improve their symptoms—the open sternotomy approach.

HEART FAILURE

Transplantation

The classic Shumway technique of left and right atrial cuff anastomoses is still used today but is limited because it fails to effectively transplant the atria and because it essentially represents a ventricular transplant with a loss of atrioventricular (AV) synchrony. Many transplantation surgeons today favor the bicaval technique, in which a complete heart transplantation is performed by excising the recipient atria and performing separate left atrial and bicaval anastomoses so that the complete donor heart is transplanted, not just the ventricles. This preserves AV synchrony and long-term function (Fig. 92.8).

FIGURE 92.8. The bicaval technique, in which a complete heart transplantation is performed by excising the recipient atria and performing separate left atrial and bicaval anastomoses so that the complete donor heart is transplanted, not just the ventricles.

Ventricular Assist

VADs fall into two categories: short-term postcardiotomy failure assist devices and more long-term devices. We currently use the ABIOMED system for short-term support and the HeartMate, TCI, for long-term support. Both can be used for bridge to recovery and bridge to transplant, but most frequently the short-term devices are used for bridge to recovery and the long-term devices are used for bridge to transplant. The ABIOMED system can be used for both left (LVAD) and right (RVAD) support and requires systemic anticoagulation. The HeartMate system is an LVAD only and is generally implanted on a semielective basis. It does not require systemic anticoagulation. Current trials are evaluating VADs for use as permanent devices.

ESTIMATING THE RISKS OF CARDIAC SURGERY

PATIENT-RELATED FACTORS

The presence of diabetes mellitus, renal insufficiency, intrinsic lung disease, and neuropsychiatric factors may influence the decision for cardiac surgical intervention. Patient characteristics that influence the risk of surgery include the patient's age, with elderly patients having higher surgical risks for all types of cardiac procedures. Women have an increased operative mortality after CABG in most reported series. Another factor influencing risk and outcome is previous cardiac surgery. Outcomes are generally worse when the operation is performed as an emergency procedure or because of hemodynamic instability.

OPERATIVE FACTORS

Effects of Cardiopulmonary Bypass

Exposure of the patient's blood to an extracorporeal circuit initiates a cascade of inflammatory changes and complement activation. Experimentally, this type of inflammatory response results in end-organ injury to the lungs, liver, and kidneys. Another consideration when a patient is placed on CPB is the need to prime the circuit with up to 2 L of fluid and to provide anticoagulation to avoid clotting when the blood comes in contact with the extracorporeal system. Use of relatively large doses of heparin prevents microthrombosis but may result in a protracted disruption of the patient's coagulation function, even after the usual attempts to reverse the heparinization effect with drugs such as protamine sulfate. Thus, bleeding complications remain a major threat with open heart surgery.

Myocardial Protection

The most significant challenge, however, with cardiac surgical procedures that involve total bypass of the heart results from the need to interrupt blood flow to the heart and to induce complete ischemia while the surgery is performed. Although rare, inadequate myocardial protection can lead to surgical mortalities owing to cardiac pump failure, or to cardiogenic shock, which develops immediately after the operation as a result of the heart's intolerance to the protracted anoxic interval required for performing the procedure. Various techniques have evolved to allow surgeons to work in and on a still and bloodless environment by developing solutions and administration techniques that allow both induced arrest and metabolic support of the arrested heart during protracted periods of cardiac anoxia. These cardioplegic techniques, as well as a host of later refinements and additions, have become a mainstay for protecting the heart from ischemic injury during long and complicated cardiac surgical operations. The other important development in reducing injury to the heart during cardiac surgery began with the experimental work of Shumway and others, who investigated techniques to protect donor hearts to be used for cardiac transplantation. The benefit of significant cooling, by markedly reducing myocardial metabolic demands especially in the arrested heart, was clearly demonstrated and has become an accepted adjunct to myocardial protection.

Avoidance of Intraoperative Cerebrovascular Accidents

Patients with peripheral vascular disease, especially those with significant intracranial cerebrovascular disease, may have inadequate brain perfusion on CPB with focal or generalized central nervous system injury as a result. Although extracorporeal bypass circuits generally approximate the normal mean perfusion pressure, the phasic pulsatile component of normal circulatory hemodynamics is not duplicated. Patients with significant obstructive vascular disease may be especially susceptible to the loss of phasic blood flow. If the patient is cooled systematically, however, the body's tolerance to less adequate perfusion may be enhanced, but bypass perfusion flow support may still be inadequate. In addition, there may be embolization of aortic atherosclerotic material from perfusion cannulas, which injure such end organs as the brain. Intraoperative epi-aortic echocardiography is one way to identify potential mobile debris. Avoidance of manipulation of an aorta with mobile debris or heavily calcified aorta may also help reduce the incidence of intraoperative CVA. When a "porcelain aorta" is encountered, circulatory arrest without aortic cannulation may be the only option to ensure that no atheroma forms an embolism to the brain.

Extracorporeal perfusion technology and its physiologic foundations have become highly sophisticated, but many patients, especially elderly ones with generalized atherosclerosis, continue to sustain complications as a result of the need for extracorporeal CPB during surgery.

POSTOPERATIVE FACTORS

Primary lung injury can be caused by exposure to CPB, with the resultant activation of inflammatory mediators and with edema formation. Long operations are characterized by the significant accumulation of body fluid, with weight gains often exceeding 10% of a patient's normal body weight as a result of hemodilution and the circulatory support provided by bypass. Furthermore, embolization of atheromatous material can affect the brain and also the lungs, gut, kidneys, and liver. In addition to these factors, there is significant risk of systemic or wound infections because of prolonged intraoperative exposure of the mediastinum, pericardium, and pleura. Patients with an immune or vascular insufficiency, especially those with severe diabetes, may have an increased risk of surgery-related infection.

SUMMARY

Surgical therapy for cardiovascular disease continues to be an important adjunct to medical treatment. In patients who have not benefited from medical management, cardiac surgery may be the only option for symptomatic relief. In addition, surgery can provide significant survival benefit in selected groups of patients. Continued collaboration between cardiologists and their surgical counterparts will result in further refinement in referral strategies for patients with significant cardiovascular disease.

CHAPTER 93: MEDICAL MANAGEMENT OF THE CARDIAC TRANSPLANT PATIENT

KEITH AARONSON AND ROBERT CODY

[Immunosuppressants and Their Complications](#)
[Rejection](#)
[Infection](#)
[Coronary Allograft Vasculopathy](#)
[Malignancies](#)

Cardiac transplantation is the most successful treatment available for patients with truly end-stage heart disease. Nearly 85% of patients survive the first postoperative year, with a subsequent mortality rate of only 4% per year. Compared with larger centers, survival is worse at low-volume transplantation centers (less than nine transplantations per year). For patients who meet the strict selection criteria, survival is much greater than would be expected for the natural history of their disease. Severe heart failure is the reason for undergoing transplantation for nearly all recipients. For ambulatory patients, disease severity is commonly documented by a severe reduction in oxygen consumption during exercise testing, but other indicators of severity of illness should also be considered. Implantable defibrillators and improved surgical and catheter-based techniques have substantially reduced the need for transplantation as a treatment for refractory angina or recurrent malignant ventricular arrhythmias. Despite the growing number of patients placed on the transplant waiting list, the restricted availability of donor hearts has limited the annual number of transplantations to approximately 2,400 in the United States and 3,500 worldwide. Given this severe organ shortage, every effort is made to ensure that patients accepted for the transplant waiting list are free of comorbid conditions (including advanced age) that would further limit post-transplant survival.

Periodic follow-up of the transplant recipient should be performed by an experienced cardiac transplantation team. However, the frequency and intensity of routine follow-up with the transplant center are reduced as the time from transplantation increases. As the number of transplantation survivors grows, an increasing number of internists will encounter these patients in their daily practice. Therefore, a basic knowledge of cardiac transplantation and immunosuppression and its complications is important for the practicing internist, who will often be the initial point of contact for patients who have returned to their communities. With the appropriate knowledge of the altered physiology of the transplanted heart, and of immunosuppressant drug interactions, many of the common problems encountered by these patients (e.g., colds, hypertension, hyperlipidemia, diabetes) can be well treated by an internist. In some managed care settings, internists have been increasingly called on to evaluate all recipient problems before the patient may be seen at the transplant center. The threshold for contacting the transplantation team must be low, and access to specialized care for this small but fragile population should be readily available. For their part, the transplantation cardiologist, coordinator, and surgeon must be highly accessible and should attempt to coordinate their care with the internist, whenever possible.

The post-transplantation management of the heart transplant recipient reflects the constant tensions inherent in the use of immunosuppressant therapies: inadequate immunosuppression risks organ rejection, whereas overvigorous immunosuppression increases the risk of infection, malignancies, and other drug complications (discussed in the following text). Optimal management attempts to balance these conflicting risks by individualizing immunosuppressant therapy to each recipient's needs.

IMMUNOSUPPRESSANTS AND THEIR COMPLICATIONS

Most heart transplant recipients initially receive a three-drug regimen for chronic maintenance immunosuppression: cyclosporine (or, less commonly, tacrolimus), azathioprine or mycophenolate mofetil, and prednisone.

CYCLOSPORINE AND TACROLIMUS

By inhibiting the enzymatic action of calcineurin, cyclosporine reduces the transcription of inflammatory cytokines, most notably interleukin-2, thereby inhibiting T-cell activation and proliferation. Cyclosporine dosing is guided by trough blood levels, with higher targeted levels early after transplantation or when rejection is present or frequent ([Table 93.1](#)). Cyclosporine is metabolized by the liver through the cytochrome P4503A4 system. Because many other drugs either compete for use of this enzyme system or increase its activity, their coadministration with cyclosporine markedly affects its blood levels ([Table 93.2](#)). Physicians must be aware of these potential drug interactions, and blood levels should be closely monitored whenever a change in cyclosporine levels is anticipated.

Time After Transplantation (mo)	MC-TDx Level (ng/mL)	HPLC Level (ng/mL)
0-3	300-400	250-300
3-6	250-350	200-250
6-12	200-250	150-200
>12	150-200 ^a	100-150 ^a

HPLC, high-pressure liquid chromatography; MC-TDx, monoclonal fluorescence polarization immunoassay.

^a Possibly lower in long-term recipients with low risk of rejection.

TABLE 93.1. TARGET THERAPEUTIC CYCLOSPORINE LEVELS

Increased Cyclosporine and Tacrolimus Levels	Decreased Cyclosporine and Tacrolimus Levels
Calcium channel blockers	Anticoagulants
Diltiazem	Phenobarbital
Nifedipine	Carbamazepine
Verapamil	Phenytoin
Antibiotics	Antituberculars
Clarithromycin	Rifabutin
Erythromycin	Rifampin
Amikacin	Neuroleptics
Chloramphenicol ^a	Phenothiazines

Nonsteroidal antiinflammatories	

^a Decreases tacrolimus only (not cyclosporine).

TABLE 93.2. EFFECTS OF COMMONLY USED DRUGS ON CYCLOSPORINE AND TACROLIMUS LEVELS

Cyclosporine use is associated with numerous unwanted side effects, most of which appear to result from calcineurin inhibition. The most serious adverse drug effects include renal dysfunction (decreased glomerular filtration rate, hyperkalemia, hypermagnesemia), hypertension, hyperlipidemia, diabetes, gout, osteoporosis, and cholelithiasis. Common neurotoxicities include tremulousness and peripheral neuropathy; seizures generally occur only when cyclosporine levels are high or when patients predisposed to them. Hirsutism is common and may be a troubling side effect for women. Gum hyperplasia may require periodontal attention to prevent oral infections. Hepatotoxicity is infrequent. As transplant physicians have gained greater familiarity with cyclosporine, targeted drug levels and dose-related toxicities have decreased.

Although structurally different, tacrolimus (previously called FK-506) also inhibits calcineurin activity. It is routinely used in preference to cyclosporine at some centers.

Increased doses of tacrolimus alone (without increased corticosteroids) have been successfully used to treat cellular rejection. Neurotoxicity and nephrotoxicity appear to be more common with tacrolimus than with cyclosporine, but this may in part reflect less familiarity with the drug and more aggressive immunosuppression. However, hypertension appears to be less common, whereas diabetes may be more common. Hirsutism does not occur with tacrolimus and generally resolves when patients are switched to it from cyclosporine.

AZATHIOPRINE AND MYCOPHENOLATE MOFETIL

Both azathioprine and mycophenolate mofetil (MMF) reduce DNA synthesis. MMF selectively inhibits inosine monophosphate dehydrogenase, a critical enzyme in the de novo purine synthesis pathway, on which T- and B-lymphocyte biosynthesis depend. Azathioprine blocks numerous enzymes required for DNA synthesis and so less selectively inhibits immune cell proliferation than does MMF. MMF also inhibits growth factors that may be important in the development of coronary allograft vasculopathy. In studies of both heart and kidney transplant recipients, patients on MMF tend to have fewer serious rejection episodes but more infections. Both drugs may cause leukopenia, and dose adjustments may be required to prevent this. Because both azathioprine and allopurinol are metabolized by xanthine oxidase, azathioprine doses must be reduced by one-third to one-half when allopurinol is given. Other potential adverse effects of azathioprine include hepatitis and pancreatitis. Abdominal discomfort, vomiting, diarrhea, and gastrointestinal hemorrhage may occur with MMF use.

CORTICOSTEROIDS

Corticosteroids inhibit the production of T-cell lymphokines, which amplify macrophage and lymphocyte responses and cause lymphocytolysis. Corticosteroid side effects are legion. High doses are used early after transplantation, with prednisone doses commonly reduced to 0.3 mg per kilogram at 1 month and 0.1 mg per kilogram by 3 months after transplantation in patients not experiencing frequent rejection. Many patients ultimately can be weaned from corticosteroids and successfully maintained on a two-drug regimen.

REJECTION

Rejection is the most common cause of death in the first year after heart transplantation. Hyperacute rejection manifests within hours of transplantation as a result of preformed recipient antibodies directed against the donor graft. Fortunately, the use of ABO blood group-compatible donors and prospective donor-specific cross-matching for recipients with preformed anti-HLA (human leukocyte antigen) antibodies has made this a rare, though usually fatal, event.

Acute cellular rejection occurs far more commonly. About two-thirds of patients experience at least one rejection episode in the first post-transplant year, with the greatest risk occurring in the early post-transplant months. The risk is substantially lower after the sixth month and is very low after 1 year. Rejection is more common in younger patients and in multiparous women, in recipients of female donors, in those who develop anti-HLA antibodies or experience a cytomegalovirus infection or a previous rejection episode, and when immunosuppression is decreased either by the physician or by a poorly compliant patient. Perioperative treatment with either polyclonal (antithymocyte or antilymphocyte globulins) or monoclonal (OKT3) antibodies reduces early rejection but increases infections and may increase future development of post-transplant lymphoproliferative disorder (see Malignancies). Newer monoclonal antibodies directed against the interleukin-2 receptor are under study for this indication.

Rejection may present as episodes of undue fatigue or malaise, palpitations, a mild reduction in exercise capacity, or even frank heart failure, but most episodes are asymptomatic. Noninvasive methods of detecting rejection are still neither sensitive nor specific enough to supplant endomyocardial biopsy, which remains the standard approach (although limited experience with serial monitoring of intramyocardial electrograms from pacemakers implanted at the time of transplantation is encouraging). Therefore, surveillance right ventricular endomyocardial biopsies are performed routinely on all patients regardless of symptoms, with extra biopsies performed whenever rejection is suspected clinically. A typical schedule would be to perform weekly biopsies for the first month, biweekly biopsies for the next 2 months, monthly biopsies for the 4th to 6th months, and bimonthly biopsies for the 7th through 12th months. Biopsy frequency subsequently decreases to every 3 to 12 months as the time from transplantation lengthens. If any biopsy shows rejection, the frequency of subsequent biopsies increases until the rejection is no longer present. Because the decision to institute antirejection treatment reflects not just the histologic grade of rejection but the effect of rejection on cardiac function, some measure of cardiac function (either echocardiography or measurement of right heart and pulmonary wedge pressures and cardiac output by pulmonary artery catheterization) is performed with each biopsy.

Rejection is graded by the International Society of Heart and Lung Transplantation (ISHLT) scale from grade 0 (none) to 4 (severe). Experts differ on the threshold for treating asymptomatic rejection. Patients with milder grades of asymptomatic rejection may be treated by increasing the level of background immunosuppression; or, when they occur late in the post-transplantation period, they may not require specific treatment. Those with higher grades of rejection, with rejection associated with a reduction in ventricular function or poor hemodynamics, and with rejection occurring closer to the time of transplantation are treated more aggressively. Treatment, when indicated, generally includes high-dose glucocorticoids. More severe rejection episodes and corticosteroid-refractory episodes are treated with either antithymocyte/antilymphocyte globulins or OKT3. A follow-up biopsy is required 1 to 2 weeks after a course of treatment to ensure that the rejection has resolved. Treatment of right or left ventricular dysfunction, when present, is the same as for the nontransplant recipient.

Humoral rejection is an antibody-mediated process directed against HLA class II antigens present on the donor vascular endothelium. The diagnosis is suspected when a recipient has ventricular dysfunction without cellular rejection, which is confirmed by immunofluorescence staining of biopsy specimens showing deposition of IgG, C3, and C4 on coronary endothelium. Humoral rejection generally occurs in the first 3 months after transplantation, appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis and is associated with an increased fatality rate and a higher incidence of cardiac allograft vasculopathy. Affected persons are treated with high-dose intravenous glucocorticoids, antithymocyte globulin, cytoxan, plasmapheresis, and heparin.

INFECTION

Infections are a constant risk for the post-transplant patient. The lungs are the most common site of infection, followed by the blood, urine, gastrointestinal tract, and operative wounds. Corticosteroids may make the signs of infection subtle. Prompt clinical evaluation of the recipient with low-grade fever, malaise, or a nonproductive cough is essential. A careful history and physical is often supplemented with a chest radiograph and a low threshold for pursuing other diagnostic testing as appropriate. As immunosuppressive medications are reduced over time, the overall risk of infection decreases.

Common pathogens and sites differ by post-transplantation period. In the first few months after transplantation, bacterial infections predominate, with the usual nosocomial pathogens resulting in intravascular catheter-induced bacteremias, urinary tract infections, pneumonias, and mediastinitis. Prophylactic treatment with oral nystatin or clotrimazole troches is required to prevent oral and esophageal candidiasis, but candidemia may also occur. Without prophylaxis, herpes simplex virus is common from 2 to 4 weeks after transplantation, but routine use of acyclovir can eliminate this risk. In the second and third months after transplantation, aspergillosis may cause pneumonia with frequent hematogenous dissemination.

The most important pathogen in the third through sixth months cytomegalovirus (CMV). CMV-negative recipients of a CMV-positive donor have the highest risk and progress to the most severe illness (primary infection), but CMV-positive recipients are also at risk for clinical illness. CMV may cause a mononucleosis-like febrile illness (CMV syndrome) or tissue-invasive disease (pneumonia, hepatitis, esophagitis, or colitis). CMV infection is associated with the development of allograft vasculopathy, and persistent CMV replication is associated with severe coronary disease. CMV infection up-regulates major histocompatibility antigens and is associated with an increased risk of subsequent rejection. Patients at risk are given ganciclovir either prophylactically or preemptively (after detection of CMV by antigen assay or polymerase chain reaction [PCR] but before clinically manifested illness) to prevent CMV illness and as treatment for established disease. Oral valganciclovir effectively prevents CMV disease in renal transplant recipients and may be an attractive alternative to ganciclovir, but it has not yet been approved by the Food and Drug Administration for this indication.

Although far less common, toxoplasmosis also may occur during this period, with encephalitis, hepatitis, and myocarditis the typical presentations. Toxoplasmosis only occurs in toxoplasmosis-negative recipients of a positive donor and can be completely prevented by prophylaxis with pyrimethamine for the first 6 weeks after transplantation. *Pneumocystis carinii* pneumonia previously occurred in about 20% of recipients, with the peak incidence in the third through sixth months, but prophylaxis with trimethoprim-sulfamethoxazole for the first year after transplantation has made this illness uncommon. *Legionella* (pneumonia) and *Listeria* (meningitis and bacteremia) should be considered in the appropriate settings.

After the first 6 months, recipients remain at risk for the usual community-acquired bacterial infections, but parasitic and fungal infections and herpes zoster are also

encountered. A nodular pulmonary infiltrate should prompt consideration of nocardiasis.

CORONARY ALLOGRAFT VASCULOPATHY

Development of coronary artery disease in the transplanted heart is the single most common cause of death in patients who survive the first post-transplantation year. Although classically described as a diffuse, concentric process, focal lesions may occur as well. Complete obliteration of secondary and tertiary epicardial vessels may occur, and the development of collaterals is unusual. Angiographic evidence of coronary allograft vasculopathy (CAV) is present in 50% of patients by 5 years after transplantation, but the more sensitive intravascular ultrasonography (IVUS) technique detects CAV in 80% to 100% of patients at 5 years. That CAV is limited to the transplanted heart attests to its immunologic nature, but hypercholesterolemia, hypertriglyceridemia, obesity, glucose intolerance, possibly smoking, and CMV infection all play a role. Denervation renders most patients incapable of experiencing angina (although partial reinnervation with atypical presentations of angina may occur), so CAV presents most commonly as heart failure, ventricular arrhythmias, or sudden death, if not first detected by annual surveillance coronary angiography or IVUS.

Coronary artery bypass surgery or catheter-based interventions may be performed with good short-term success if the anatomy is suitable, but this is often not the case, and progression of disease may be rapid. In one study, the 1-year survival rate after the demonstration of any 40% proximal or mid-vessel lesion was only 63%, with only 23% of heart failure patients surviving 1-year. Treatment and prevention of CAV are based on attention to the reversible risk factors just noted.

HMG-CoA reductase inhibitors (statins) reduce the incidence of both CAV and fatal rejection and should therefore be pursued in all patients, with a goal low-density lipoprotein (LDL) level of less than 100 mg per deciliter. However, myositis is more common in patients receiving statins with cyclosporine, so careful monitoring is warranted. Lovastatin, in particular, should be avoided. Diltiazem was shown to reduce the incidence of angiographically detectable CAV in a randomized trial and many centers use this routinely, with appropriate decreases in cyclosporine dosing. Some centers substitute MMF for azathioprine in patients with established CAV, based on limited clinical data suggesting that mycophenolate may decrease the incidence of CAV in new transplant recipients. Retransplantation is the most successful treatment for this condition, but it is controversial, considering the poorer survival for second-transplant recipients and the persistent shortage of donor organs. Those centers that perform retransplantation (about 50% of US centers) do so in only young and otherwise ideal candidates.

MALIGNANCIES

Nearly 12% of all deaths after heart transplantation result from malignancy. Most of the common malignancies (e.g., those of the lung, breast, colon, prostate, and cervix) are not appreciably increased in solid organ transplant recipients. When present, these cancers respond to therapy as would be expected in nonimmunosuppressed patients.

Two types of malignancies occur with particular frequency in heart and other solid organ transplant recipients. Post-transplant lymphoproliferative disorder (PTLD) occurs in nearly 2% of transplant recipients. Lymphotropic effects of the Epstein–Barr virus are thought to underlie this condition. Its development is related to the aggressiveness of immunosuppression and particularly to the prolonged use of prophylactic OKT3. Tumors are frequently present in extranodal sites, particularly in the gastrointestinal tract, lung, and central nervous system. The spectrum of disease runs from localized, benign lesions that respond to a reduction in immunosuppression to much more aggressive tumors that may be fatal despite lesion excision (when feasible), chemotherapy, and radiation.

The incidence of skin cancers is increased about 20-fold in cardiac transplant recipients. Locally invasive cancers may be fatal. An increased incidence is seen with all immunosuppressive regimens, but azathioprine may especially enhance this risk. Patients must be encouraged to use effective techniques to reduce sun exposure. All suspicious lesions should be biopsied, and yearly dermatologic screening is advisable.

The cardiac transplant recipient trades one set of problems for another. Post-transplant success requires frequent monitoring and constant vigilance on the part of both the patient and the treatment team. In most cases, these efforts are rewarded with good recipient survival and a substantially improved quality of life.

EVIDENCE LEVEL: B. Reference: AGA Medical Position Statement on Management of Oropharyngeal Dysphagia. *Gastroenterology* 1999;116:452-478.

The physical examination usually reveals a neurologic or neuromuscular condition contributing to the symptoms. Hemiparesis secondary to a previous cerebrovascular accident, palpebral ptosis and end-of-the-day weakness indicative of myasthenia gravis, or a fenestrating gait and paucity of movement characteristic of Parkinson's disease can lead to a precise diagnosis. Specific deficits of the cranial nerves involved in swallowing may also aid in the evaluation.

Oropharyngeal dysphagia should not be confused with globus, a sensation of a lump or tightness in the throat. It is a more constant symptom that usually does not interfere with swallowing and actually may be relieved during deglutition. It can be associated with or aggravated by stress and gastroesophageal reflux.

COMMON CAUSES

Neuromuscular diseases are responsible for about 80% of cases of oropharyngeal dysphagia. Strokes are the most common neurologic condition in the elderly. Symptoms are typically abrupt in onset and are usually associated with other neurologic deficits, particularly those of the cranial nerves. However, small lacunar infarcts, deep in the brain, may produce dysphagia as a sole primary symptom. Cerebral and brain stem cerebrovascular accidents can produce oropharyngeal dysphagia. The mechanism producing the former is probably brain stem distortion secondary to cerebral edema; the latter results from direct brain stem injury caused by vertebralbasilar artery disease. Bilateral brain stem involvement is more severe and less likely to show recovery than unilateral involvement. If recovery occurs, it usually does so within the first 6 to 9 months after the stroke.

Some degree of oropharyngeal dysphagia is present in up to 50% of patients with Parkinson's disease; 95% show abnormalities on video-esophagography. Clinically significant dysphagia may appear early in the course of Parkinson's disease, but it usually is a late manifestation. Tongue tremor and hesitancy in initiating a swallow are well-recognized features of this disease.

Inflammatory myopathies (polymyositis and dermatomyositis) present with oropharyngeal dysphagia in 60% to 70% of patients. These patients may show dramatic improvement with steroid therapy. Two forms of muscular dystrophy involve the striated muscles of the pharyngoesophageal region. Myotonic dystrophy is a familial disease characterized by myopathic facies, myotonia, swan-neck deformity, muscle wasting, frontal baldness, testicular atrophy, and cataracts. Oculopharyngeal dystrophy is an autosomal dominant disorder occurring after age 60 in patients of French-Canadian ancestry. Dysphagia followed by ptosis is a common presentation.

Myasthenia gravis is characterized by weakness on repetitive use of voluntary muscles. Typically, muscle strength tends to worsen toward the end of the day, partially returns with rest, and improves dramatically with administration of anticholinesterase drugs. Myasthenia gravis has a peak incidence in the third decade for women and the seventh decade for men. Dysphagia occurs in nearly two-thirds of patients; the first manifestation is often nasal regurgitation of fluids and weakness in chewing. Other common symptoms include generalized weakness, ptosis, diplopia, and dysarthria characterized by a fading voice that becomes more nasal after sustained conversation or when the patient is challenged with repetitive phrases.

Oropharyngeal dysphagia can also occur with a steroid myopathy and hyper- or hypothyroidism.

Anatomical abnormalities causing mechanical obstruction and oropharyngeal dysphagia include neoplasms, infections (e.g., retroperitoneal abscesses), thyromegaly, lymphadenopathy, and, rarely, cervical osteophytes. UES dysfunction may be associated with a Zenker's diverticulum or cricopharyngeal bar. Once thought to be related to discoordination of UES relaxation (cricopharyngeal achalasia), recent studies show that the UES relaxes appropriately but opens incompletely because of reduced muscle compliance resulting from myositis and fibrosis. To compensate for this decrease in cross-sectional area, intrabolus pressure and hypopharyngeal pressure increase, leading to dysphagia and diverticula formation. Patients usually present after age 50 with variable symptoms, including regurgitation of previously eaten foods, solid and liquid dysphagia, cough, and halitosis. Cricopharyngeal myotomy is the treatment of choice.

DIAGNOSTIC STUDIES

Barium examination of the oropharynx and esophagus during swallowing is the most useful test ([Fig. 94.2](#)). The extremely rapid sequence of events in this area cannot be evaluated adequately by standard barium techniques. Examination of the oropharyngeal area should include videotaping and the use of both liquids and different consistencies of semisolid and solid boluses. Playback of the videotape allows careful evaluation of the swallowing mechanism and identification of subtle abnormalities resulting from neurologic or muscular diseases. The administration of various consistencies of barium and food products helps identify patients who can swallow safely without aspiration and assists in the formulation of therapeutic interventions. Conventional esophageal manometry is less helpful. Appropriate evaluation of the oropharyngeal region requires self-contained intraluminal transducer systems and on-line computer analysis to assess UES and pharyngeal dynamics accurately. These techniques require special facilities and expertise and are not routinely done. Endoscopic visualization of vocal cord movement and ultrasound are useful for imaging tongue movements and laryngeal transport.

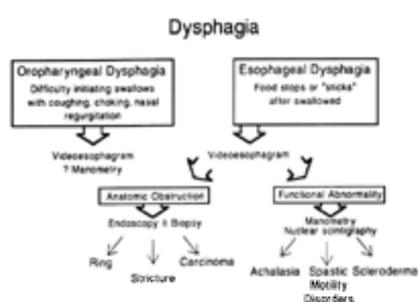

FIGURE 94.2. Algorithm for the appropriate use of diagnostic tests in evaluating the patient with dysphagia. The barium esophagogram, preferably using the video technique, is the initial diagnostic test for patients presenting with either oropharyngeal or esophageal dysphagia.

EVIDENCE LEVEL: B. Reference: AGA Medical Position Statement on Management of Oropharyngeal Dysphagia. *Gastroenterology* 1999;116:452-478.

ESOPHAGEAL DYSPHAGIA

PRESENTATION

Esophageal dysphagia is caused by various mechanical or neuromuscular (motility) defects that prohibit the passage of food down the esophagus. The patient often describes this problem as food "hanging up" somewhere behind the sternum. Localized to the lower sternum or the epigastric area, the lesion is most likely in the distal esophagus. Localization to the lower part of the neck may indicate dysfunction in this area, but often the symptoms are referred from a more distal blockage.

[Figure 94.1](#) shows a simple algorithm for the evaluation of patients with dysphagia. After obtaining a general medical history, including medication use, a detailed history of swallowing should emphasize the duration of the symptoms and the types of food and liquids that cause them. Patients reporting dysphagia that occurs with both solids and liquids are most likely to have an esophageal motility disorder. If the dysphagia occurs only after swallowing a solid bolus, such as a large piece of meat, but never when the patient initially drinks a beverage, the physician should consider the possibility of a mechanical obstruction. Intermittent solid food dysphagia, particularly for bread or steak in an otherwise healthy person, should suggest a lower esophageal (Schatzki's) ring. Dysphagia is the rule if the luminal diameter is less than 13 mm but is unlikely if the diameter is larger than 20 mm. Progressive solid food dysphagia may be associated with a peptic stricture or carcinoma. Patients with peptic strictures usually have a long history of heartburn and regurgitation and no weight loss. Although the esophagus may be markedly

narrowed, these patients have a good appetite and will modify their diet to maintain their weight. On the other hand, patients with cancer of the esophagus tend to be older men with marked weight loss, as much from anorexia as from esophageal luminal narrowing.

Intermittent dysphagia for solids and liquids associated with chest pain should suggest spastic motility disorders. Progressive solid and liquid food dysphagia may be associated with scleroderma or achalasia. Scleroderma of the esophagus generally is seen in women giving a long history of heartburn. On the other hand, patients with achalasia are equally distributed between men and women, and they complain of bland regurgitation, choking, coughing, and weight loss. All of these disorders are discussed in further detail in [Chapter 106](#).

The physical examination is usually of limited value. Patients with esophageal cancer may have cervical and supraclavicular lymphadenopathy and marked weight loss. Patients with scleroderma may present with the CREST syndrome: digital calcinosis, Raynaud's disease, esophageal dysmotility, sclerodactyly, and telangiectasia.

DIAGNOSTIC STUDIES

A barium esophagogram should be the initial test performed ([Fig. 94.2](#); [Chapter 106](#)). Barium outlines irregularities in the esophageal lumen, defines sites of anatomical obstruction, and assesses liquid transit through the body of the esophagus. In patients with dysphagia for liquids and solids, this test accurately defines achalasia and diffuse esophageal spasm. In patients with solid food dysphagia, a barium swallow performed with tablets of various sizes (6, 8, 12.5 mm), marshmallows, or food products may help identify anatomical abnormalities such as subtle rings, strictures, or segmental regions of poor motility. An upper gastrointestinal series is not a suitable substitute for a barium esophagogram when esophageal disease is suspected because this study focuses on the stomach, with only spot films of the pharynx and limited full-column examination of the esophagus.

There is a good correlation between radiographic findings and subsequent endoscopic examination. If the barium studies reveal an obstructing lesion, endoscopy with biopsy and brush cytology can establish the diagnosis. Immediate therapeutic intervention can be accomplished with the use of dilators over a wire or blunt bougie dilators. Endoscopy should not be the initial test for patients presenting with dysphagia. The use of a narrow endoscope and light sedation tends to miss rings and strictures, particularly if the luminal diameter is greater than 13 mm, as a result of poor esophageal insufflation and distention.

If the barium studies are normal or suggest a motility disorder, esophageal manometry is the next step ([Chapter 106](#)). Motor abnormalities of the esophagus can be intermittent, and manometry allows more prolonged evaluation of the esophagus than barium studies. Manometric studies are diagnostic of achalasia and spastic motility disorders and may suggest the presence of a scleroderma esophagus.

CHAPTER 95: APPROACH TO THE PATIENT WITH NONCARDIAC CHEST PAIN

HENRY P. PARKMAN

[Differential Diagnosis](#)
[History and Physical Examination](#)
[Diagnostic Tests](#)
[Strategies for Optimal Care](#)
[Complications and Pitfalls](#)
[Conclusion](#)

Chest pain is a common clinical problem. The symptom of chest pain is frightening for patients due to the possibility of cardiac disease and its mortality. However, of the 750,000 patients with chest pain undergoing cardiac catheterization each year, normal coronary arteries are demonstrated in 20% to 30%. These patients have noncardiac, or unexplained, chest pain (NCCP). It is estimated that 4% of the population have frequent episodes of NCCP.

Patients with NCCP may be seen by a variety of physicians including internists, family practitioners, cardiologists, and gastroenterologists. Evaluation and treatment of patients with NCCP is a major clinical challenge, since the cause of the chest pain can often be elusive and the patients can remain extremely symptomatic with resultant poor functional status and repeated visits to physicians and emergency rooms. A significant proportion of patients (44%) with NCCP actually continue to believe that they have heart disease. Patients with NCCP have a good prognosis with mortality rate similar to that of the general population. Several studies have suggested that a definitive diagnosis of the cause of the patient's NCCP helps to reassure the patient, improve quality of life, and reduce the number of urgent office and emergency room visits.

DIFFERENTIAL DIAGNOSIS (TABLE 95.1)

TABLE 95.1. CAUSES OF CHEST PAIN

CARDIAC DISORDERS

Coronary artery disease is the most important cause of chest pain due to the risk of myocardial infarction and death. Patients with recurrent chest pains should be evaluated for coronary artery disease first, often entailing exercise stress with thallium testing and/or coronary arteriography. If these suggest underlying coronary artery disease, the patients are then treated appropriately. However, patients with underlying coronary artery disease may also have NCCP. Up to 36% of patients with recurrent chest pains and known coronary artery disease may have gastroesophageal reflux disease (GERD) precipitating their symptoms. Ischemic heart disease and GERD can coexist in the same patient and may produce identical symptoms. Acid suppression can lead to marked improvement in the chest pain in some patients.

Chest pain is commonly associated with mitral valve prolapse and usually described as a brief sharp or sticking pain, but it may be a dull ache over the chest that may last for hours. Breathlessness, palpitations, faintness, and fatigue may be associated symptoms. Esophageal motor abnormalities, primarily diffuse esophageal spasm (DES), and panic disorder have been described in many patients with mitral valve prolapse, which may also cause chest pains.

Microvascular angina refers to abnormalities in the small endocardial vessels without lesions in the larger epicardial vessels. These patients have chest pain despite normal coronary arteriograms. Diagnosis requires sophisticated cardiac catheterization. Increased microvascular resistance is the hallmark of the disease. The prevalence of this disorder among patients with recurrent chest pain and normal coronary arteries in the general population is unknown, since evaluation for this disorder is not usually performed. It has been suggested that stress thallium or exercise gated blood pool scintigraphy might be used as a screening test for this disorder. The diagnosis would be suggested by ischemic ST segment response and/or abnormal left ventricular ejection fraction in response to exercise associated with the patient's typical chest pain in the absence of coronary artery disease. Patients with microvascular angina have also been found to have coexistent esophageal motility abnormalities, making it unclear as to whether the chest pain symptoms are from the esophagus or heart. The long-term prognosis for these patients appears to be excellent, with little evidence of heart attacks or cardiac deaths.

ESOPHAGEAL DISORDERS

Esophageal disorders are probably the most common cause of NCCP, accounting for 20% to 60% of cases. The common causes of esophageal chest pain are esophageal motility disorders and GERD. Esophageal hyperalgesia (hypersensitivity) has been suggested as a third mechanism.

Esophageal Motor Abnormalities

Diffuse esophageal spasm is an esophageal motor disorder that is clinically manifested by substernal chest pain and/or dysphagia (see [Chapter 94](#)). Chest pain, usually the most prominent symptom, is generally retrosternal and may have radiation pattern similar to that of angina. Symptoms are intermittent and nonprogressive. Esophageal manometric findings are high-amplitude, nonperistaltic contractions that are interspersed with normal peristaltic contractions. Although this disorder is occasionally thought to be synonymous with esophageal chest pain, DES actually accounts for less than 5% of patients with NCCP.

The "nutcracker" esophagus describes manometric findings of high-amplitude peristaltic esophageal contractions (see [Chapter 106](#)). In contrast to DES, the esophageal contractions are always peristaltic. This finding is present in 12% of patients with NCCP. It is unclear as to whether this entity has true clinical or pathophysiologic significance, since often the high-pressure contractions correlate poorly with the occurrence of chest pain. When these patients are treated with the calcium channel blocker nifedipine, to reduce the amplitude of esophageal contractions, there is little symptomatic improvement in the chest pain. Moreover, the patient's symptoms may improve on low-dose trazodone, an antidepressant, without a change in the manometric abnormalities. Nutcracker esophagus may also be associated with GERD and symptoms of chest pain may improve with antireflux treatment.

Gastroesophageal Reflux Disease

Although heartburn is the classic symptom, GERD may cause atypical symptoms such as chest pain (see [Chapter 106](#)). Prolonged esophageal pH monitoring has allowed better recognition of GERD as one of the most common identifiable causes of NCCP. It is possible that in some patients acid-sensitive receptors in the esophagus interpret the reflux as chest pain. Occasionally, the reflux of acid into the esophagus may precipitate esophageal spasm.

Esophageal Hyperalgesia

Esophageal hyperalgesia has recently been suggested as a cause of unexplained chest pain. Graded distention of an intraesophageal balloon in patients with NCCP has been used to show that they are more sensitive to esophageal distention, with patients reporting an exaggerated perception of pain compared to controls. Esophageal balloon distention can produce chest pain in approximately 50% of patients with NCCP compared to only 10% to 20% of normal subjects. Furthermore, the volumes used to elicit chest pain in patients are relatively low compared to the higher volumes needed in normal subjects. The chest pain may be related to lower pain threshold to balloon distention, suggesting that there is enhanced sensitivity to distention (hyperalgesia) as a result of a lower visceral pain threshold. In some patients with NCCP, intraesophageal balloon distention produces nonperistaltic esophageal contractions consistent with spasm distal to the balloon simultaneously with reproduction of patients' chest pain.

MUSCULOSKELETAL DISORDERS

Musculoskeletal causes may account for 10% to 30% of patients with NCCP. The pain is often a dull, aching, or nagging pain with variable intensity and duration. Alternatively, it may be a sharp pain that is accentuated by movement especially on arising in the morning. The diagnosis of musculoskeletal chest pain involves eliciting tenderness on palpation of trigger points on the chest wall, which is similar to the spontaneously occurring pain.

Tietze's syndrome is characterized by pain, tenderness, and swelling of a costal cartilage usually involving the second, left costosternal or sternoclavicular joints. Trauma to the cartilage from repeated coughing or sudden movements is proposed as mechanisms for this disorder. Costochondritis is similar to Tietze's syndrome, although it more commonly affects multiple junctions with frequent symmetry, especially of the lower ribs.

PSYCHIATRIC/PSYCHOGENIC DISORDERS

Patients with NCCP have a high prevalence of depression, anxiety disorders, and somatization disorders. Panic disorder is the most common anxiety-related disorder in NCCP. Up to one-third of patients with chest pain and normal coronary arteries have panic disorder. Panic disorder is characterized by frequent (at least three attacks in 3 weeks) periods of intense fear or discomfort accompanied by shortness of breath, palpitations, chest pain or discomfort, sweating, faintness, choking, and fear of losing control, "going crazy," or dying. Chest pain in panic disorder may be an important factor in the health care seeking of these patients. It is an important disorder to recognize since some patients may have depression and suicidal ideation.

HISTORY AND PHYSICAL EXAMINATION

Information obtained during the history and physical examination, carefully selected diagnostic tests, and therapeutic trials of medications are used to evaluate the patient for the different cardiac, esophageal, musculoskeletal, and psychiatric causes of chest pain ([Table 95.2](#)).

History and physical examination
Initial baseline testing
Chest radiography
Electrocardiography
Evaluate for cardiac cause
Stress thallium test
Coronary arteriography
Reevaluate for musculoskeletal causes
Physical examination
Therapeutic trial with nonsteroidal anti-inflammatory drug
Evaluate for esophageal disorders
Diagnostic testing
Esophageal manometry
Esophageal pH monitoring
Therapeutic trial
Proton pump inhibitors
Evaluate for psychological causes

TABLE 95.2. EVALUATION OF NONCARDIAC CHEST PAIN

A detailed description of the chest pain, including aggravating and alleviating factors, is important. Esophageal disorders giving rise to chest pain can be perceived as chest pain similar to that of angina. In many cases, it is not possible from the history to distinguish between cardiac and esophageal causes of chest pain. This is not surprising in view of the close proximity of these two organs and the fact that both organs are innervated by similar distribution of the vagus nerve (parasympathetic) and sympathetic nervous system. Associated symptoms of dysphagia (difficulty swallowing), odynophagia (pain on swallowing), and heartburn may be helpful to direct the etiology of chest pain to the esophagus. However, these associated symptoms are not always present in patients with esophageal chest pain; furthermore, they can be present to some degree by chance occurrence in patients with cardiac pain. Esophageal discomfort is usually not brought on by exertion or relieved by rest. At times, however, GERD can be triggered by exercise, as angina can. Features suggesting an esophageal origin include pain that continues for hours, pain related to meals, and pain relieved with antacids. Chest pain due to esophageal spasm can be associated with deglutition, especially with foods that are cold or hot. Similar to patients with angina, patients with esophageal spasm may also obtain relief with sublingual nitroglycerin and calcium channel blockers.

Besides inquiring about the common risk factors for coronary artery disease, one needs to inquire about the use of cocaine. Cocaine use may also induce myocardial ischemia.

Patients with atypical chest pain should be screened for generalized anxiety states, panic disorder, and depression. Chest pain associated with intense fear or discomfort and the sense of impending doom or dying should raise the suspicion of panic attacks. These patients often have other somatic complaints.

The physical examination is occasionally helpful to detect cardiac valvular disease, such as aortic stenosis and mitral valve prolapse. Eliciting tenderness on palpation of the chest wall, as well as reproduction of the patient's typical pain, is helpful in the detection of a musculoskeletal cause. Cutaneous signs of scleroderma may suggest GERD as a cause of chest pain.

DIAGNOSTIC TESTS

The initial diagnostic phase of the evaluation involves ruling out the possibility of cardiac disease. Most patients with chest pain should have initial evaluation for a cardiac source because the presence or absence of coronary disease cannot be reliably established from symptoms alone. Depending on the patient's age and gender, the cardiac evaluation may involve an electrocardiogram, exercise stress testing with thallium imaging, and coronary arteriography. Once coronary artery disease is excluded, evaluation proceeds for other, more benign causes of chest pain. Evaluation of NCCP is often tailored to the individual patient. The evaluation may include upper gastrointestinal radiologic examination or upper endoscopy, esophageal manometry, and 24-hour esophageal pH monitoring.

ENDOSCOPY OR X-RAYS

The upper gastrointestinal tract (esophagus and stomach) is evaluated for mucosal disorders (esophagitis, ulcer, mass lesions) with either barium studies or upper gastrointestinal endoscopy (esophagogastroduodenoscopy). Although these tests are frequently normal, important therapeutic information is obtained if they are positive. It should be remembered that a normal study does not rule out an esophageal cause for chest pain.

If dysphagia is an associated symptom, a barium esophagram is the procedure of choice to detect structural lesions of the esophagus such as strictures, achalasia, or even esophageal cancer. Careful observation of esophageal function during fluoroscopy is important, since esophageal aperistalsis, spasm, or GERD may be demonstrated. A hiatal hernia on barium swallow has been found to correlate poorly with GERD.

Upper endoscopy can also identify a significant number of patients with NCCP with acid-peptic disorders (esophagitis, gastritis, duodenitis, or ulcer disease). In one

study of 100 patients with NCCP, esophagitis was present in 24 patients and gastroduodenal ulcer in 6. However, other studies have suggested that endoscopic evidence of esophagitis is seen in fewer than 10% of patients with NCCP. The advantage of endoscopy over radiology is the better mucosal detail that endoscopy provides and the ability to perform biopsies directly. Endoscopy is more reliable in detecting reflux esophagitis, pill-induced esophagitis, and Barrett's esophagus, a complication of long-standing GERD. Endoscopy is thus generally preferable over barium studies in evaluation of patients with NCCP. However, upper endoscopy gives little information about the physiologic function of the esophagus.

ESOPHAGEAL MANOMETRY AND PROVOCATIVE TESTING

Esophageal manometry is used to evaluate patients with NCCP primarily for spastic motility disorders of the esophagus (see [Chapter 106](#)). Esophageal manometry is useful to specifically diagnose achalasia and DES. However, most of the time esophageal manometry will be normal or show nonspecific findings. The two major esophageal motor abnormalities, DES and achalasia, are found in only 3% and 1%, respectively, of patients undergoing esophageal manometry for NCCP. Other manometric diagnoses, such as nutcracker esophagus and nonspecific esophageal motor disorders, are present more frequently in patients with chest pain; however, the relationship of these nonspecific findings to chest pain has been questioned. Occasionally, evidence of low LES pressure or low-amplitude esophageal contractions may suggest GERD, which can be verified by subsequent esophageal pH monitoring. Due to the high prevalence of normal or nonspecific findings on esophageal manometry in patients with NCCP, it has been suggested that esophageal manometry not be used as one of the initial tests in patients with unexplained chest pain.

Acid perfusion of the esophagus (Bernstein's test), intravenous infusion of edrophonium, and esophageal balloon distention are provocative tests that have been used during esophageal manometry to correlate abnormal findings (such as acid in the esophagus or esophageal dysmotility) with the clinical symptoms of chest pain. If positive, they may help to reassure the patient that there is an esophageal and not a cardiac cause of the chest pain. These provocative tests do not determine cause and effect, and they might not help to direct therapy confidently.

AMBULATORY ESOPHAGEAL pH MONITORING

Ambulatory 24-hour monitoring of esophageal pH is helpful in determining the presence of GERD (see [Chapter 106](#)). This is the best test for quantifying abnormal amounts of acid reflux and/or demonstrating a causal relationship between the acid reflux and chest pain. During the study, diary cards and event markers are used to time the patient's symptoms and can be used to correlate atypical symptoms of reflux, such as chest pain, to episodes of acid reflux. The symptom index is calculated as the percentage of chest pain episodes that occurred when the esophageal pH was less than 4. The higher the symptom index, the more likely the chest pain is secondary to reflux. Often a symptom index of greater than 50% is used to demonstrate a correlation of symptoms to acid reflux. The value of the symptom index is that it directly associates the chest pain events with acid reflux. Furthermore, it can be positive even when the esophageal acid exposure is normal. Patients with a positive symptom index but normal acid exposure represent a group that may be hypersensitive to physiologic amounts of acid reflux. The symptom index can also be useful when the test is being performed on gastric acid suppressant medications or if a patient has several different types of symptoms.

THERAPEUTIC TRIAL

An alternative approach to esophageal pH monitoring in the evaluation of a patient for GERD as a cause of chest pain is with a therapeutic trial of a gastric acid suppressant medication. This has been gaining popularity, especially with the availability of effective gastric acid suppression with the proton pump inhibitors and for physicians without easy access to esophageal pH monitoring testing. With this approach, one places a patient on an acid suppressant treatment for 2 to 4 weeks and monitors the frequency of chest pain episodes. A reduction in the number of chest pain episodes suggests that GERD was the cause. Usually proton pump inhibitors, such as omeprazole 20 mg PO b.i.d. or lansoprazole 30 mg PO b.i.d., are used to ensure that gastric acid secretion is suppressed and that elimination of acid reflux has occurred. If there is response to the therapeutic trial, the patient may be placed on the medication that helped his or her symptoms. If there is not a response, esophageal and gastric pH monitoring on medication is often used to determine if gastric acid secretion was suppressed.

STRATEGIES FOR OPTIMAL CARE

ESOPHAGEAL CHEST PAIN

Gastroesophageal Reflux Disease–induced Chest Pain

Treatment of GERD initially includes nonsystemic therapy with dietary modifications and postural measures (see [Chapter 106](#)). Antacids may be useful to acutely relieve the symptoms. Stopping drugs that reduce LES pressures may be helpful. These include anticholinergics, nitrates, calcium channel blockers, b-adrenergic agents, and certain tranquilizers. Fatty foods, chocolate, and alcohol also reduce LES pressure and may contribute to GERD.

Antisecretory agents are the main treatment for NCCP caused by GERD. These include H₂-receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) and proton pump inhibitors (omeprazole and lansoprazole). Chest pain resulting from GERD appears to be harder to treat than conventional symptoms of GERD, such as heartburn. Patients often need intensive therapy with t.i.d./q.i.d. or double-dose b.i.d. H₂ receptor agonists, or up to b.i.d. dosing of proton pump inhibitors.

Prokinetic agents, such as cisapride and metoclopramide, increase LES pressure and increase gastric emptying, both of which may improve symptoms of reflux. Although prokinetic agents are useful in mild symptoms of GERD, they have not been studied in NCCP resulting from GERD. Usually for NCCP, they are used as adjunctive therapy to gastric acid suppressants.

The final type of antireflux treatment is surgery (see [Chapter 106](#)). The most common antireflux operation is the Nissen fundoplication, which involves wrapping the fundus around the gastroesophageal junction to augment LES pressure. With the introduction of potent antisecretory agents, surgical treatment is required in only a minority of patients (less than 3% of patients). Surgery should be attempted in patients with NCCP only with objective evidence of reflux as a cause of symptoms, preferably by both esophageal pH monitoring and some response to gastric acid–suppressive therapy.

Spastic Esophageal Motor Disorders

Treatment of spastic esophageal motility disorders has not been as successful as that for GERD (see [Chapter 106](#)). Treatment for esophageal motility disorders such as DES and nutcracker esophagus centers on smooth muscle relaxants to reduce the high-amplitude esophageal contractions. If dysphagia is also a problem, reduction of LES pressure may also improve the chest pain. Medications used for spastic esophageal motility disorders include nitrates, calcium channel antagonists, and anticholinergic agents. Oral or sublingual nitrates, such as isosorbide dinitrate (Isordil), has been shown to reduce the frequency of symptoms and lower the high-amplitude contractions in the esophageal body. The frequency of side effects, most notably headache and hypotension, usually precludes increasing the dosage of nitrates to effectively relieve the chest pain. The calcium channel antagonists nifedipine and diltiazem both reduce esophageal contraction amplitude, but demonstrations of symptomatic improvement have been inconsistent. Anticholinergic agents, such as hyoscyamine (Levsin) or dicyclomine (Bentyl), reduce the amplitude of esophageal contractions; however, their effectiveness in treating esophageal motility disorders is unknown. In patients with recalcitrant DES, pneumatic dilatation of the lower esophageal sphincter may be tried. Surgical therapy, such as long esophageal myotomy, although tried in the past, is best avoided.

INCREASED VISCERAL NOCICEPTION

Treatments for functional gastrointestinal disorders, including NCCP, have often included psychotropic medications. It is likely these therapies are mediated through visceral analgesic action that alters abnormal nociception (visceral hypersensitivity). Often tricyclic antidepressants are used at doses lower than those for treatment of depression. Imipramine 25 to 100 mg taken at bedtime has been reported to result in significant improvement in patients with NCCP who do not have reflux disease. The antidepressant trazadone 25 to 100 mg per day (at night) has been shown to be beneficial in decreasing symptoms associated with abnormal esophageal motility. The conventional antidepressant amitriptyline (Elavil) may also be useful but has anticholinergic side effects.

MUSCULOSKELETAL DISORDERS

Treatment of patients with musculoskeletal chest pain includes local therapy, nonsteroidal anti-inflammatory drugs, and, occasionally, corticosteroid–lidocaine

injections.

PANIC DISORDER

Panic disorder can be approached with cognitive behavior therapy and pharmacologic therapy. The tricyclic antidepressants are often considered first-line therapy. Imipramine administration is beneficial; however, it may take up to 24 weeks for response. Benzodiazepines, such as alprazolam, may be used for initial control and have been used for this disorder. Serotonin uptake inhibitors, such as fluoxetine, have shown promising results.

COMPLICATIONS AND PITFALLS

A pitfall in the approach to patients with NCCP is a failure to recognize that GERD and panic disorder may cause chest pain. Today there is specific treatment available for chest pain due to GERD. Furthermore, patients with known underlying coronary artery disease can have noncardiac causes, especially GERD, accounting for some of their chest pain. GERD as a cause of chest pain in patients with coronary artery disease is also important to recognize because medications used to treat ischemic heart disease, especially nitrates and calcium channel blockers, can decrease the LES pressure and predispose patients to more reflux. If chest pain symptoms are chronic (more than 5 to 10 years duration) and due to GERD, the patient may be at risk for Barrett's metaplasia, which is best evaluated with endoscopy.

Indications for HOSPITALIZATION

Usually hospitalization in patients with NCCP occurs when there is still the concern that the pain is from cardiac ischemia. This occurs in patients who have not been adequately evaluated for cardiac disease or patients with a change in their typical pain episodes.

Indications for REFERRAL

Patients may be referred to gastroenterologists for several reasons, including (a) upper endoscopy procedure; (b) esophageal pH monitoring and/or esophageal manometry; (c) consultation to determine if the chest pain is of gastroenterologic origin; (d) aggressive treatment for GERD and spastic esophageal motor disorders. Patients may be referred to a psychiatrist or a psychologist for psychological disorders. Generally speaking, panic attacks are best treated by a specialist.

CONCLUSION

Through appropriate evaluation, many patients with NCCP may be found to have a reason for their symptoms. Esophageal disorders, musculoskeletal disorders, and panic disorders can often be diagnosed. With esophageal manometry and esophageal pH monitoring, an esophageal etiology can be demonstrated in 50% of patients with NCCP, with GERD being more prevalent than esophageal motor disorders. Occasionally, empiric treatment, especially for GERD, is undertaken both for therapeutic and diagnostic reasons. Patients with esophageal hyperalgesia (altered sensory perception) or panic disorder may respond to psychotropic medication.

CHAPTER 96: APPROACH TO THE PATIENT WITH ABDOMINAL PAIN

ROBERT B. STEIN AND GARY R. LICHTENSTEIN

[Anatomical Basis of Abdominal Pain](#)
[Stimulants of Abdominal Pain](#)
[Types of Abdominal Pain](#)
[History](#)
[Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Modifiers of Clinical Presentation of Abdominal Pain](#)
[Strategies for Optimal Care](#)

The approach to the patient with abdominal pain is one of a physician's greatest challenges. Abdominal pain is a common symptom that involves the patient's subjective reaction to a stimulus. It is essential that treating physicians have an understanding of the pathophysiologic basis of abdominal pain so that they may be better able to determine its cause and prescribe appropriate therapy. This chapter reviews the physiologic aspects of abdominal pain, as well as the methods most suitable for evaluation and management of acute and chronic abdominal pain.

ANATOMICAL BASIS OF ABDOMINAL PAIN

The perception of pain (nociception) most commonly begins at the level of the pain neuroceptors (nociceptors). The free peripheral ends of these fibers are ubiquitous and may respond to a variety of stimuli, such as stretch, spasm, inflammation, or ischemia. Two types of fibers transmit painful impulses: A δ fibers and C fibers. Type A δ fibers are found predominantly in skin and muscle. They are myelinated, rapidly conducting, and yield sharp, well-localized pain. Type C fibers are unmyelinated and are distributed in muscle, mesentery, abdominal viscera, and peritoneum. Compared to type A δ fibers, type C fibers conduct stimuli slowly and produce a poorly localized, dull or burning pain. Acute injury often leads to sharp pain transmitted by type A δ fibers, followed by a dull ache or discomfort transmitted by type C fibers.

The majority of nociceptors in the abdominal viscera are type C fibers. Thus, it is common for patients with abdominal pain to present with a dull, poorly localized pain. Nociceptors within the abdominal viscera are less sensitive and fewer than those within the skin. The fact that endoscopic biopsies and polypectomies can be performed without causing any discomfort to the patient supports this fact. However, mucosa that is inflamed or interrupted may cause significant pain, likely resulting from the release of a variety of chemical substances (e.g., bradykinin).

Visceral afferent (sensory) fibers penetrate the serosa of hollow abdominal organs to enter the submucosa and muscularis layers. This is in contrast to solid organs such as the liver, which only have nociceptors on their surfaces and capsules. This explains why large hepatomas may not elicit abdominal pain until they involve or stretch the liver capsule.

There are three orders of neurons that transmit pain signals from the abdominal organs to the brain. Viscera afferent neurons leave the abdominal organs and travel via splanchnic nerves to regional ganglia (e.g., celiac, superior mesenteric). The cell bodies of the visceral afferent fibers are located in the dorsal root ganglia of spinal afferent nerves (Fig. 96.1). Fibers then carry impulses to the dorsal horn of the spinal cord where they synapse with the second-order neurons. These neurons then cross the anterior commissure and ascend the spinal cord via the contralateral lateral spinothalamic tract. Upon entering the brain stem, synapse occurs with the third-order neurons, which carry painful impulses to the somatosensory cortex of the cerebrum via the thalamus, and to the limbic system and frontal cortex. The somatosensory cortex makes possible the discrimination of painful stimuli, whereas the limbic system and frontal cortex provide the emotional aspects of pain.

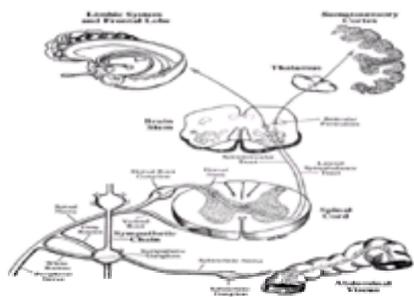

FIGURE 96.1. Neuronal pathways mediating abdominal visceral pain sensation. Three orders of neurons carry pain signals from the abdominal organ to the brain. The first-order neuron travels from the abdominal organ to the regional splanchnic ganglion along the corresponding splanchnic nerve, through a ganglion of the sympathetic chain, and then by way of the white ramus communicans to the spinal nerve. From there, it traverses the dorsal root (its cell body lies in the dorsal root ganglion) to enter the dorsal horn of the spinal cord, where it synapses predominantly within laminae I and V. The second-order neurons leave the dorsal horn, cross the midline, and ascend primarily in two tracts. The spinothalamic tract neurons travel through the brain stem to various nuclei within the thalamus, where they synapse with third-order neurons that go predominantly to the somatosensory cortex. This area mediates the sensory and discriminative aspects of pain. Spinoreticular tract neurons synapse within reticular formation nuclei located primarily in the pons and medulla. From there, third-order neurons travel predominantly to the limbic system and frontal cortex, mediating aspects of pain that have to do with feelings and actions. (Yamada T, ed. *Textbook of Gastroenterology*. 2nd ed. Philadelphia: JB Lippincott 1995:752).

Inhibitory fibers descend from the cerebral cortex and connect to the dorsal horn via the thalamus and brain stem. These inhibitory fibers allow modulation of painful stimuli and release important neurotransmitters, which effect the interpretation of pain.

STIMULANTS OF ABDOMINAL PAIN

Sensory receptors are generally of two distinct types: mechanoreceptors and chemoreceptors. Mechanoreceptors are primarily located in the walls of the hollow organs, within the muscle layers, and between the muscularis mucosa and submucosa. Visceral mechanoreceptors are most sensitive to stretch (e.g., as occurs during bowel obstruction) and are not responsive to cutting or crushing. This is in sharp contrast to somatoparietal receptors, which are exquisitely sensitive to the latter. Visceral mechanoreceptors are also located on the surfaces of solid abdominal organs and within the mesentery. Stretching or torsion of the mesentery, as occurs during sigmoid volvulus, usually leads to marked abdominal pain. Pathologic processes within solid organs such as the liver or spleen may not cause any pain until the process causes stretching of the capsule.

Abdominal visceral receptors also respond to a variety of chemicals and neurotransmitters. Inflammation, ischemia, mechanical injury, and tissue necrosis are some of the conditions that result in the release of substances such as bradykinin, substance P, histamine, prostaglandins, and serotonin. Accumulation of these chemicals activates nociceptors and has other direct and indirect effects on the circulation and tissues adjacent to the involved area. Additionally, the endorphins that usually are released are important stimulants of inhibitory pathways.

TYPES OF ABDOMINAL PAIN

There are three major types of abdominal pain: visceral, parietal, and referred. Visceral pain is perceived as dull, gnawing, or burning pain that is poorly localized. It is often described as an "uncomfortable" feeling rather than pain. Visceral pain may be elicited by numerous stimuli such as muscle contractions or spasm, mural distention, ischemia, or necrosis. Visceral pain is often accompanied by autonomic disturbances, including nausea, vomiting, pallor, and diaphoresis. Patients often

feel restless and attempt to move about to relieve the discomfort.

In contrast to visceral pain, parietal pain is sharp, well localized, and more intense. Parietal pain often indicates the anatomical site of the stimulus (e.g., right upper quadrant pain in a patient with acute cholecystitis). Parietal pain is not usually associated with autonomic disturbances. Patients experiencing parietal pain attempt to lie still as even small movements often exacerbate the pain.

Referred pain combines features of both visceral and parietal pain and is felt at sites distant to the involved organ, usually along cutaneous dermatomes whose afferent nerve roots enter the same levels of the spinal cord as the affected organ ([Table 96.1](#)). Referred pain is usually well localized, and it increases in intensity as organ damage progresses.

Abdominal Viscera	Segmental Distribution of Cutaneous Hyperalgesia
Esophagus (lower)	T4–T7
Stomach	T5–T10
Liver, gallbladder	T5–T10
Pancreas	T6–T9
Small intestine	T5–T10
Colon, rectum	T8–L1, S1–S4
Kidney, ureter	T8–L2
Urinary bladder	T10–L2, S2–S4
Ovary, fallopian tube	T9–L1
Uterus	T9–L2, S1–S4
Cervix	T10–T12, S2–S4
Testicle, epididymis	T9–T12

TABLE 96.1. SEGMENTAL DISTRIBUTIONS OF CUTANEOUS HYPERALGESIA RESULTING FROM PAIN IN ABDOMINAL VISCERA

HISTORY

MODE OF ONSET

Often the key to the correct diagnosis of abdominal pain is found in the patient's historical account of his or her symptoms. The mode of onset of the pain is one such piece of the history that may be of paramount importance. Acute abdominal pain is commonly predated by prodromal symptoms, which may be helpful in determining the diagnosis of more acute pain. For example, a patient may report several months of biliary colic prior to the development of acute right upper quadrant pain of gangrenous cholecystitis. Conversely, the sudden onset of severe abdominal pain without prior symptoms may be more difficult to diagnose and often is the result of an intra-abdominal catastrophe, such as mesenteric infarction or perforated viscus.

Abdominal pain may begin after an injury (e.g., acute pancreatitis after blunt abdominal trauma), and it is useful to ask what the patient was doing when the pain began. Obtaining a menstrual history in women is also important, as acute lower abdominal pain may be the result of intrauterine or ectopic pregnancy.

LOCATION

The location of abdominal pain is often helpful in constructing a differential diagnosis to determine its cause ([Table 96.2](#)). However, it must be remembered that abdominal pain can be diffuse or localized. In addition, the pain may be referred to a dermatomal distribution distant from the involved organ. Pain from gastric or duodenal ulcers is usually localized to the epigastrium, whereas peri-umbilical pain is often small intestinal in origin. Pain below the umbilicus may be related to a colonic process, such as diverticulitis, or tubal or ovarian disorders. Gallbladder and biliary pain is often localized to the right upper quadrant but may be referred to the right shoulder or right scapula.

Abdominal Viscera	Location	Character	Onset	Relieving Factors	Referred Pain	Severity	Pattern
Esophagus (lower)	Epigastrium	Localized	Acute	None	None	Mild to moderate	Steady and constant
Stomach	Epigastrium	Localized	Acute	None	None	Mild to moderate	Steady and constant
Liver, gallbladder	RUQ	Localized	Progressive	None and relief by leaning forward	Right shoulder, right scapula	Mild to moderate	Steady and constant
Pancreas	Epigastrium	Diffuse	Progressive	None	None	Mild to moderate	Steady and constant
Small intestine	Periumbilical	Diffuse	Acute	None	None	Mild to moderate	Steady and constant
Colon, rectum	Periumbilical to RLQ	Localized	Acute	None	None	Mild to moderate	Steady and constant
Kidney, ureter	Flank	Localized	Acute	None	None	Mild to moderate	Steady and constant
Urinary bladder	Suprapubic	Localized	Acute	None	None	Mild to moderate	Steady and constant
Ovary, fallopian tube	Lower abdomen	Localized	Acute	None	None	Mild to moderate	Steady and constant
Uterus	Lower abdomen	Localized	Acute	None	None	Mild to moderate	Steady and constant
Cervix	Lower abdomen	Localized	Acute	None	None	Mild to moderate	Steady and constant
Testicle, epididymis	Lower abdomen	Localized	Acute	None	None	Mild to moderate	Steady and constant

(From Cervero F, Morrison JFB, eds. *Visceral sensation*. Amsterdam: Elsevier, 1996:87, with permission.)

TABLE 96.2. COMMON CAUSES AND CHARACTERISTICS OF ACUTE ABDOMINAL PAIN

It is also important to realize that abdominal pain may migrate over time. One well-described example is pain that occurs during the course of acute appendicitis. Initially, the pain begins in the mid-abdomen, but over time the pain moves toward the right lower quadrant and McBurney's point. This should be distinguished from referred pain, where pain is felt at locations remote from the involved organ (e.g., phrenic irritation referred to the shoulder region).

RELIEVING OR AGGRAVATING FACTORS

An important part of the history is determining which factors improve or aggravate the pain. The patient's position often provides a clue to the diagnosis. Peritonitis often results in the patient's lying still, as even small movements may exacerbate the pain. Alternatively, the visceral pain that accompanies mesenteric ischemia often leads the patient to writhe around in an attempt to find a comfortable position. Pancreatitis is associated with worsening pain when the patient lies supine, leading these patients to sit upright or lean forward to relieve pressure and irritation on the posterior peritoneum. Psoas muscle irritation, as may occur in Crohn's disease complicated by a psoas abscess, often results in the patient's lying supine with the right leg flexed at the hip and knee. Diaphragmatic irritation from a subphrenic abscess or hepatic congestion may result in avoidance of deep breathing or coughing.

The relationship of abdominal pain to food is also important. Uncomplicated duodenal ulcer pain is often relieved by the ingestion of food, whereas gastric ulcers are aggravated during meals. Patients with small intestinal obstruction usually complain of postprandial pain. More proximal obstruction leads to symptoms shortly after meals, whereas terminal ileal disease may lead to pain that occurs hours after food ingestion. Patients with mesenteric ischemia classically complain of periumbilical pain after meals, resulting in anorexia and weight loss. Patients with pancreatitis avoid eating, as ingestion of any food or liquid may exacerbate their pain. Acute cholecystitis is also commonly associated with right upper quadrant pain shortly after a meal. Patients with irritable bowel syndrome often complain of lower abdominal cramping following meals, although a detailed account of the types of foods that seem to provoke symptoms is usually unrewarding. The patient's use of medications may also be helpful in diagnosing certain disorders. Patients who take large doses of antacids or histamine-2 receptor antagonists for relief of symptoms may have esophagitis, hiatal hernia, or peptic ulcer disease. Alternatively, patients with gastritis or peptic ulcer disease who attempt self-medication for analgesia may exacerbate their pain by taking high doses of nonsteroidal anti-inflammatory drugs (NSAIDs).

TEMPORAL RELATIONSHIP OF ABDOMINAL PAIN

The timing and duration of abdominal pain are also important in determining its cause. Pain that is acute in onset and well localized may point to a more severe process such as ruptured appendix or ectopic pregnancy, whereas dull, intermittent pain is more characteristic of mesenteric ischemia. Colicky pain, or pain that comes and goes over time, classically is reported by patients with cholelithiasis or nephrolithiasis. Pain from gallstones may occur following meals but commonly develops in the evening hours, lasts from minutes to hours, and occurs intermittently in an unpredictable manner. Determining the progression of the pain is also helpful, as pancreatitis or appendicitis may take hours to reach peak intensity, whereas patients with intra-abdominal catastrophes, such as a ruptured abdominal aortic aneurysm, present with immediate onset of severe pain.

Determining the duration of abdominal pain is also important. Patients who present within hours of the onset of pain are more likely to have an acute process such as mesenteric infarction. Conversely, those who seek attention after weeks of pain are less likely to have a life-threatening process, and more likely to have a more chronic process, such as inflammatory bowel disease or irritable bowel syndrome.

QUALITY/CHARACTER

Determining the character or quality of the perceived pain is also helpful in delineating its source. Dull pain is more characteristic of visceral irritation, whereas somatoparietal pain usually leads to more severe, well-localized pain. Oftentimes, patients use a variety of terms to help depict their pain, such as burning, stabbing, gnawing, cramping, or aching. Depth of the pain may also be reported. A patient with pancreatic cancer may present with a feeling of deep aching in the midepigastrium and back, whereas acute appendicitis presents as a relatively superficial anterior pain that is more easily reproducible on physical examination. Cramping pain may be associated with distention of a hollow viscus secondary to obstruction, whereas burning midepigastriac pain is classically reported by patients with peptic ulcer disease.

INTENSITY

The intensity of the pain is often characterized as mild, moderate, or severe. However, pain is a subjective experience and depends on a variety of factors, including perception of pain, personality, and prior painful experiences. What one person describes as severe pain another may describe as trivial. Close visual evaluation of a patient in pain is often very helpful, as a patient sitting comfortably likely has less intense pain than one writhing in distress. Grading pain on a scale (e.g., scale from 1 to 10) has limited value at one point in time but may be useful in measuring the intensity of pain over time.

OTHER SIGNS AND SYMPTOMS

Many conditions causing abdominal pain are associated with other systemic signs and symptoms. Nausea and vomiting are commonly associated with abdominal pain, and their temporal relationship to the onset of the pain should be noted. Acute viral gastroenteritis is usually associated with nausea and vomiting early in its course. Alternatively, patients with small-bowel obstruction often develop abdominal pain that precedes the onset of vomiting. Colonic obstruction usually leads to later vomiting; however, reflex vomiting may occur as a result of conditions such as cecal volvulus. Anorexia commonly occurs as an early symptom of appendicitis, and patients with mesenteric ischemia often have persistent anorexia and subsequent weight loss.

Diarrhea and constipation also commonly are associated with abdominal pain. Gastroenteritis and colitis often are accompanied by diarrhea. Bloody diarrhea usually suggests more severe colitis secondary to infection, ischemia, NSAIDs, or inflammatory bowel disease. Frank rectal bleeding accompanying abdominal pain may suggest more severe ischemia or bowel infarction. Alternating diarrhea and constipation is a classic presentation of irritable bowel syndrome. Lower abdominal pain and constipation may be a sign of colonic neoplasm, although these patients may develop a paradoxical diarrhea.

Pyrexia accompanying abdominal pain presents a broad differential diagnosis. Patients with gastroenteritis may develop fevers early in the course of illness, whereas patients with walled-off abscesses may develop late, intermittent fevers. High fevers and rigors combined with right upper quadrant pain are suggestive of cholangitis, whereas left lower quadrant pain and a fever is characteristic of diverticulitis.

Acute onset of jaundice, abdominal pain, vomiting, dark urine, and clay-colored stools suggests biliary tract disease or hepatitis. Pancreatic carcinoma involving the head of the pancreas typically presents with painless jaundice. Abdominal pain in association with neurologic disturbances and photosensitivity suggests porphyria. Inflammatory bowel disease, lupus, and vasculitis may all cause abdominal pain and associated skin disorders.

Abdominal pain may also be associated with urogenital signs or symptoms. Colicky flank pain radiating to the groin is likely to be secondary to renal calculi and is often accompanied by hematuria. Abdominal pain and pneumaturia suggests an enterovesicular fistula complicating diverticulosis or Crohn's disease. A careful menstrual history should always be obtained, as lower abdominal pain may be the result of ectopic pregnancy, ovarian cyst, or ovulation.

PAST MEDICAL HISTORY

Evaluation of the patient's past medical and surgical history may provide additional information as to the etiologic factors involved in their abdominal pain. Patients who have had prior abdominal surgeries are likely to develop adhesions, which may be the cause of small-bowel obstruction. Abdominal aortic aneurysm repair often results in compromise of the arterial supply to the left colon, resulting in ischemic colitis. A patient with cholelithiasis who presents with distal small-bowel obstruction may have a gallstone ileus.

Patients with concomitant coronary artery disease or arrhythmias are prone to develop small intestinal ischemia. Additionally, congestive heart failure may lead to hepatic congestion and subsequent diaphragmatic irritation. In patients with a history of cirrhosis, the onset of diffuse abdominal pain should raise the concern for spontaneous bacterial peritonitis. Furthermore, abdominal pain may be a result of medications taken to treat underlying illnesses, as gastric or duodenal ulcers should be suspected in patients with chronic arthritis taking large doses of NSAIDs.

FAMILY AND SOCIAL HISTORY

A detailed review of the patient's family and social history may reveal other important clues to the cause of their symptoms. The diagnosis of inflammatory bowel disease is more likely in an individual with one or more affected family members. Excessive use of alcohol is a common cause of pancreatitis, hepatitis, and gastritis. Cocaine abuse may lead to vascular compromise, resulting in mesenteric ischemia. Recent foreign travel or camping trips raise the possibility of intestinal parasite infection.

PHYSICAL EXAMINATION

The general appearance of a patient in abdominal distress may reveal obvious or subtle clues to their diagnosis. A patient's expressions, position, breathing pattern, and gestures are often as important as the abdominal exam itself. Following a review of their general appearance, vital signs should be checked. The presence of fever or tachycardia may point to an acute process, such as cholangitis or diverticulitis. Acute onset of pain and hypotension often is a clue to an abdominal catastrophe, such as ruptured aortic aneurysm. Elderly patients or those on high-dose steroids mask fevers and require even closer attention. Atrial fibrillation may predispose patients to mesenteric ischemia as a result of left atrial emboli. Patients with hepatitis or common bile duct obstruction often are icteric or jaundiced. Spider angiomas suggest chronic liver disease. Patients with vascular disease may have weak distal pulses resulting from poor peripheral perfusion.

ABDOMINAL EXAMINATION

Prior to palpation it is important to inspect the abdomen for the presence of surgical scars, distention, hernias, or abnormalities of the overlying skin such as ecchymoses or engorged veins. Following inspection, auscultation should be performed, allowing for sufficient time to determine the quality and character of the bowel sounds. Diffuse peritonitis usually leads to absent bowel sounds, whereas early intestinal obstruction results in "tinkling," high-pitched sounds. A succussion splash, which can be elicited by placing the stethoscope on the abdomen and moving the patient from side to side, may be detectable in a patient with gastric outlet obstruction. A bruit may be audible over the mid-abdomen in a patient with an aortic aneurysm, whereas auscultation over the liver may reveal a hepatic bruit in a patient with a large hepatoma.

Palpation of the abdomen should begin with light palpation at an area distant from the region of greatest pain. This allows the patient to “get comfortable” with the examination rather than be fearful that the examiner will cause more pain. Percussion is useful to detect fluid or gas within the abdomen. Shifting dullness suggests the presence of ascites or blood within the abdominal cavity. Percussion is also used to determine the size of the liver and spleen. Once palpation is begun, it is important to slowly increase pressure rather than use sudden or abrupt movements. Rebound tenderness suggests peritoneal irritation, as does guarding, which can be localized or generalized. It is also often useful to gently shake the bed from side to side, which may be a more subtle way to detect peritonitis.

GENITAL, RECTAL, AND PELVIC EXAMINATIONS

Rectal, genital, and pelvic examination should be part of every physical examination in patients with acute abdominal pain. Intra-abdominal disorders may not initially involve the anterior abdominal wall and may first be detected during rectal examination (e.g., appendicitis). Stool should be tested for occult blood. External genital examination is useful and may lead to a diagnosis of an inguinal hernia—a common cause of small-bowel obstruction. In women, a pelvic examination is essential as it may lead to discovery of disorders of the fallopian tubes or ovaries, whereas the presence of cervical motion tenderness suggests pelvic inflammatory disease.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

BLOOD AND OTHER LABORATORY TESTS

A complete blood count with differential should be obtained from every patient with acute onset of abdominal pain. Anemia often points to gastrointestinal bleeding, which may be occult. Microcytic anemia suggests a more chronic process, such as colonic polyps or neoplasm. Leukocytosis and bandemia may suggest an ominous process, such as gangrenous cholecystitis, whereas more minor elevations in the white blood cell count are often present in patients with less serious disorders, such as viral gastroenteritis. Conversely, severe leukopenia may indicate overwhelming infection and sepsis syndrome. Eosinophilia may point to an allergic reaction or parasitic infection, whereas lymphopenia may be the result of a viral infection (e.g., cytomegalovirus). Thrombocytopenia, secondary to splenic sequestration, is often seen in patients with cirrhosis and may lead to bleeding diatheses.

Urinalysis should always be performed in patients complaining of abdominal pain. The urine specimen can be examined for glucose, bile, blood, protein, and ketones. Microscopic examination for white and red blood cells, bacteria, and crystals may lead to a diagnosis of pyelonephritis or renal calculi. A urine pregnancy test should also be performed in all women of childbearing age who present with acute abdominal pain.

Serum electrolytes and glucose should be obtained, as well as blood urea nitrogen (BUN) and creatinine. An elevated BUN-to-creatinine ratio suggests dehydration but may be seen in patients with upper gastrointestinal bleeding or renal insufficiency. Elevated serum amylase and lipase are suggestive of pancreatitis. Measurement of liver-associated enzymes is often helpful and should be evaluated in all patients who present with upper abdominal pain or jaundice. Obstructive jaundice usually results in hyperbilirubinemia and elevations of alkaline phosphatase and g-glutamyltranspeptidase. The presence of abdominal pain accompanied by elevations of alanine aminotransferase and aspartate aminotransferase indicates hepatocellular injury, perhaps secondary to viral or alcoholic hepatitis. Mild abnormalities are common, however, and minor elevations may be a result of a variety of causes such as minor infections, congestive heart failure, or drug reactions. An elevated prothrombin time (PT, international normalized ratio) is commonly found in patients with cirrhosis. Hypoalbuminemia may also be a manifestation of cirrhosis, but it can also be the result of other chronic abdominal processes such as inflammatory bowel disease or neoplasm. Patients with ascites who develop abdominal pain should undergo diagnostic paracentesis to rule out spontaneous bacterial peritonitis.

RADIOGRAPHIC EXAMINATION

Determination of the type of radiologic evaluation to be performed should be guided by the historical presentation, physical examination, and laboratory results. A plain abdominal series, including upright and supine views of the abdomen, is essential in all patients who present with acute onset of abdominal pain. In patients who cannot stand, a later left decubitus film may supplant the upright view. These radiographs can detect free intraperitoneal air secondary to perforated viscus and are sensitive in the detection of abnormal gas patterns (e.g., small-bowel obstruction). Pneumobilia, although rarely identified, suggests the presence of a fistula between the small bowel and the biliary tree. A “ground glass” appearance suggests the presence of ascites. Gallstones are usually not visualized on plain abdominal radiographs, whereas up to 70% of renal calculi are opaque and can be seen on the plain abdominal series. A chest radiograph may detect pneumonia or effusion, accounting for abdominal or flank pain in some patients. Furthermore, an upright chest radiograph can usually rule out the presence of even small amounts of free intraperitoneal air.

In addition to plain radiographs, ultrasonography and computed tomography (CT) examinations should be performed when appropriate and may even be the tests of first choice in certain situations. Ultrasonography is particularly advantageous for detection of cholelithiasis or biliary ductal dilatation. Ultrasound examination is also beneficial in diagnosing pelvic disorders such as ovarian cysts and ectopic pregnancy. Abdominal CT scan is significantly more expensive than ultrasonography but is the best method of detecting many intra-abdominal processes (e.g., appendicitis). CT is particularly sensitive for evaluation of retroperitoneal abnormalities, such as pancreatic neoplasm or retroperitoneal hemorrhage/abscess, and can often detect changes that occur within the mesentery (e.g., fat stranding secondary to diverticulitis) or intestinal wall (e.g., ischemia). CT is useful for evaluation of vascular structures as well, and can diagnose such problems as dissecting aortic aneurysm and portal or splenic vein thromboses. CT is beneficial following abdominal trauma, as lesions such as splenic rupture and liver laceration may be detected and managed quickly.

ENDOSCOPY

The use of endoscopy to evaluate abdominal pain depends on the timing and nature of the pain, in combination with the patient's other comorbidities. For example, a patient who develops acute abdominal pain may be suffering from a perforated duodenal ulcer, in which case endoscopy is contraindicated. Alternatively, it would be appropriate to perform upper endoscopy in a patient with more chronic epigastric pain suggestive of an uncomplicated gastric ulcer. Flexible sigmoidoscopy and/or colonoscopy are often indicated in patients with lower abdominal pain accompanied by rectal bleeding to rule out the presence of colitis secondary to ischemia, infection, NSAIDs, or inflammatory bowel disease. Colonoscopy may also be required to decompress a sigmoid volvulus. Cholangitis secondary to an obstructing gallstone or mass is characterized by fever, chills, and acute right upper quadrant pain, and may best be treated by emergency endoscopic retrograde cholangiopancreatography (ERCP) with stone extraction or biliary stenting.

LAPAROSCOPY

Diagnostic laparoscopy is an invasive procedure that may be useful in a subset of patients who have abdominal pain of uncertain origin. Laparoscopy may be performed on an emergency basis in an extremely ill patient, or on an elective basis in patients with more chronic abdominal pain where the diagnosis remains elusive despite all other noninvasive tests. Additionally, laparoscopy can be therapeutic, as a patient diagnosed with appendicitis during laparoscopy can often undergo a laparoscopic appendectomy rather than the more invasive open procedure.

MODIFIERS OF CLINICAL PRESENTATION OF ABDOMINAL PAIN

An individual presenting with abdominal pain may under special circumstances have specific factors, which modify the approach that the health care deliverer takes to diagnose the problem. In particular, individuals who are very young or very old, who are pregnant, or who are immunocompromised present a special challenge in the diagnosis of abdominal pain.

AGE

The diagnosis of abdominal pain in individuals who are either very young or very old is often challenging since the clinical history may be difficult to ascertain or may be unreliable. Despite having significant abdominal pathology, laboratory parameters can be misleadingly normal.

Several etiologies of acute abdominal pain need to be considered in infants and children. In infancy, the development of the abdominal wall has not occurred, and splinting of the recti musculature in response to peritoneal irritation does not readily occur. In infants who present with abdominal pain, the following etiologies should be strongly suspected in the differential diagnosis: small intestinal intussusception, pyelonephritis, Meckel's diverticulitis, gastroesophageal reflux disease, acute

appendicitis, and infectious intestinal enteritides. Slightly older children presenting with acute abdominal pain may have bacterial cystitis, mesenteric lymphadenitis, Meckel's diverticulitis, acute appendicitis, or inflammatory bowel disease, whereas in adolescents pelvic inflammatory disease, inflammatory bowel disease, acute appendicitis, and other disorders that are commonly encountered in the adult population should be considered. In children of all ages the presence of abdominal pain as a sequel of abuse is common and must be included among the differential diagnostic possibilities. In the elderly adult population with acute abdominal pain, the differential diagnostic spectrum encompasses other specific causal factors, such as biliary tract disease, malignancy, bowel obstruction, complications of peptic ulcer disease, and hernia-related pain.

In light of the lack of standard clinical and laboratory findings in this patient population, astute clinical judgment with aggressive intervention is imperative to help reduce the often-late diagnoses that occur in these patients at extremes of age, with resultant increased morbidity.

PREGNANCY

Pregnancy increases the challenge for the diagnostician who is attempting to uncover the cause of acute abdominal pain. Abdominal discomfort may arise from the presence of uterine enlargement and its sequelae. Additionally, attempts to perform radiographic examinations are typically avoided (especially early on in pregnancy) due to potential teratogenic fetal effects. Furthermore, pregnancy abrogates the body's ability to ward off infection. Finally, the abdominal examination itself is more difficult during pregnancy. The specific causes of abdominal pain in the pregnant patient are similar to those in age-matched nonpregnant controls. During pregnancy, common causes for abdominal pain include acute appendicitis, pyelonephritis, cholecystitis, ovarian (such as torsion or cyst rupture) and adnexal disease.

Anatomical variations due to displacement of abdominal viscera from the gravid uterus require knowledge of typical pregnancy-associated presentations of these common disorders. The position of the appendix after the fifth month of gestation is positioned superior to the right iliac crest with its tip positioned more medially subsequent to displacement by the enlarged uterus. As pregnancy progresses, the appendiceal tip becomes displaced more superiorly, such that at 8 months of gestation its position approximates the right subcostal margin. During pregnancy the presence of fever is less commonly seen despite the presence of significant abdominal pathologic processes. Additionally, leukocytosis is frequently encountered during pregnancy, thus making its interpretation in the presence of abdominal pain more difficult. This becomes important when evaluating the patient for the presence of appendicitis, since rapid diagnosis with early surgical intervention has been demonstrated to reduce morbidity and rate of fetal loss.

IMMUNOCOMPROMISED HOST

The presence of an immunocompromised host is certainly a potential modifier of disease presentation. Immunocompromised patients comprise those individuals with congenital immunodeficiency syndromes (e.g., common variable immunodeficiency) or those with acquired immunodeficiency syndromes [such as medication-induced states (e.g., corticosteroids or other immunosuppressants, or chemotherapeutic agents), or disease-related states (e.g., AIDS)]. In general, these individuals are susceptible to diseases that may occur commonly in the general population (e.g., appendicitis, cholecystitis, and diverticulitis), or disease states that occur specifically in the immunocompromised population (such as graft-versus-host disease, cytomegalovirus infection, or neutropenic enterocolitis). Regardless of the cause of the immune compromised status, the typical signs and symptoms of peritonitis (fever, guarding, rebound, and abdominal pain) may be minimal or absent. Patients may not appear acutely ill and white blood counts may not be elevated; however, a left shift to immature forms is commonplace and should be sought. The primary methods for detection of abnormalities that may develop are frequently endoscopic and/or radiographic. Radiographic assessment might include CT scans or plain abdominal radiographs. In general, these examinations should be performed more frequently in this patient population than in nonimmunocompromised hosts.

ACUTE ABDOMINAL PAIN

The term *acute abdominal pain* refers to a disorder of less than 24 hour's duration presenting with signs and symptoms of pain localized to the abdominal region. Regardless of the acuity of the situation, it is critical to provide an early, efficient, and accurate diagnosis so that appropriate specific therapeutic intervention can occur. If the pain is chronic, the diagnostician should ascertain if there has been an acute worsening of a chronic condition requiring urgent intervention. An astute clinician may also detect signs that the patient being evaluated has a psychological basis of abdominal pain. If discovered, this may prevent the need for unnecessary, sometimes costly, and possibly risky procedures.

Whatever the acuity of the situation, the history and physical examination remain the most important elements extracted in the determination of an accurate early diagnosis. A precise evaluation of the location, severity, character, chronology, exacerbating and relieving factors, other associated symptoms, and associated other medical history is essential. A complete and thorough physical examination enables the diagnostician to verify diagnostic suspicion raised while taking the history. Subsequently, by using specific laboratory and imaging modalities, the establishment of a precise diagnosis frequently is successful.

Several areas of particular importance that often help the physician to determine the urgency of the situation include the vital signs (especially the presence of hypotension, orthostatic hypotension, fever, tachycardia, bradycardia, tachypnea, or hypopnea). Additionally, diaphoresis, pallor, clamminess, mental confusion, and restlessness serve as indicators of a possible pending catastrophe. At the other end of the spectrum, less subtle findings include respiratory arrest, coma, shock, and cardiovascular arrest. In assessing patients with acute abdominal pain, detailed laboratory evaluation may signify the presence of acute pathology and help to establish its cause. Several tests, including liver enzymes, bilirubin, amylase, lipase, white blood cell count with differential, hemoglobin, and urinalysis with microscopic evaluation, should be done. Leukocytosis with the presence of polymorphonuclear leukocytes or bands is an important finding, but its presence does not necessarily indicate the need for surgical intervention (e.g., acute cholecystitis). Additionally, individuals with acute clinical deterioration, such as a perforated appendix, requiring emergency surgical intervention may present with a normal white blood cell count.

In evaluating patients with acute abdominal pain there are several commonly encountered diagnoses that should be considered, including acute appendicitis, diverticulitis, acute cholecystitis, acute pancreatitis, perforated gastric or duodenal ulcer, small-bowel obstruction, acute mesenteric ischemia, endometriosis, acute salpingitis, abdominal aortic aneurysm ectopic pregnancy, tubo-ovarian abscess, gastroenteritis, viral hepatitis, inflammatory bowel disease, nonulcer dyspepsia, gastroesophageal reflux disease, and ovarian cysts or torsion. Characteristics of some of these disorders are listed in [Table 96.2](#) and [Table 96.3](#).

TABLE 96.3. INTRA-ABDOMINAL AND EXTRA-ABDOMINAL CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN

CHRONIC ABDOMINAL PAIN

Clinicians in nearly all specialties and subspecialties are commonly faced with treating a patient who acknowledges the presence of chronic abdominal pain ([Table 96.3](#)). The majority of incidents are short-lived and minor in nature, and in some estimates occur in up to 15% of individuals. Individuals afflicted with chronic abdominal pain due to any specific cause may experience significant disruption of their lives (e.g., work, family function, and other social interactions), a higher rate of narcotic/analgesic use and dependency, and lowered self-esteem.

Chronic Intermittent Abdominal Pain

Individuals afflicted with chronic intermittent abdominal pain are not infrequently erroneously regarded as having “functional abdominal pain.” The pain may be present for several hours to several days at a time with intervening periods of complete relief. The critical solution to discerning the particular etiology of patients with chronic intermittent abdominal pain is extracting a careful medical history.

The cause of chronic abdominal pain can be established by ascertaining the factors that trigger its onset. Onset of pain in terms of proximity to meals is often helpful. Patients with mesenteric ischemia, gastroesophageal reflux disease, peptic ulcer disease, and chronic pancreatitis often complain of pain after meals. Individuals who note the onset of abdominal pain occurring at monthly intervals might include patients with endometriosis or ovulation-related pain. Pain that has its onset in specific positions is suggestive of the presence of a nerve root irritation by a neoplasm, vertebral pathologic process, or compression or entrapment of a nerve. If jaundice is present in the presence of intermittent abdominal pain, the presence of a gallstone occluding the common bile duct or recurrent pancreatitis due to gallstone disease should be considered. In a person with perineal disease, such as severe hemorrhoids, fissures, or fistulas, the consideration of Crohn's disease should be entertained. The presence of an “abdominal mass” that comes and goes should raise the suspicion of intestinal intussusception or an abdominal hernia. If an individual has a distended abdomen with visible peristalsis, bowel obstruction should be considered. The presence of a rash such as palpable purpura should suggest the presence of a vasculitis, which can be seen in disorders such as systemic lupus erythematosus, polyarteritis nodosa, or Henoch–Schönlein purpura. These disorders may affect the bowel by causing a small-vessel vasculitis with subsequent abdominal pain.

Pain relieved by defecation may signify the presence of colonic obstruction secondary to a colonic neoplasm or may occur in persons with irritable bowel syndrome. Intermittent lower abdominal pain radiating to the back or flank area associated with hematuria may signify the presence of nephrolithiasis. The presence of suprapubic pain relieved by urination may signify bladder outlet symptoms resulting from prostatitis, benign prostatic hypertrophy, or use of medications such as anticholinergics.

Upper abdominal pain worsened by the ingestion of food and relieved by vomiting suggests the presence of a partial functional or organic obstruction of the upper luminal digestive tract and may result from peptic ulcer disease, duodenal carcinoma, gastroparesis, duodenal Crohn's disease with stricturing, surgical stricture of the proximal small bowel, and other similar obstructive factors.

There exist several disorders that are difficult to differentiate from underlying intestinal pathology. A common source of such confusion is from the “slipped-rib syndrome,” a disorder in which the intercostal nerve, and not the abdominal viscera, is the source of pain. In this disorder the patient is noted to experience recurrent left upper quadrant or right upper quadrant pain that may or may not radiate to the back. On physical examination, superior retraction of the inferior portion of the lowest rib will frequently reproduce the pain. In addition, the patient may relate that certain positions relieve or exacerbate the pain. The performance of an intercostal nerve block relieves the pain temporarily and serves as a diagnostic test. Similarly, it is sometimes difficult to differentiate abdominal wall pain from that of an intra-abdominal cause. To help differentiate these specific factors, Carnett's test can be performed. This test is performed by first asking the patient to fold his or her arms. The examiner then determines the site of maximal discomfort when abdominal palpation is performed. The patient is asked to attempt to sit up partially—a maneuver that places tension on the abdominal wall. The patient is then asked to attempt to sit up once again while the examiner palpates in the same area as previously. If the palpation in this region elicits more pain than the initial examination, then this is felt to be consistent with abdominal wall–related pathology as the source of pain. Several specific diagnoses may cause the Carnett's test to be positive including cutaneous nerve entrapment, hernias of the abdominal wall, and rectus sheath hematomas. A similar source of commonly overlooked pain is the presence of abdominal pain at sites of previous surgery (e.g., scars or trocar sites). These sites require special attention during the performance of a physical examination. Hernias may become obvious when an increase in abdominal pressure occurs with careful examination of the local areas of pain. Local nerve blocks may be successful in elimination of pain at former surgical sites if hernias are not present.

In the evaluation of patients who have chronic abdominal pain of unknown cause it is important to pay attention to details. Simple laboratory tests may reveal the source of pain in some patients with an unrevealing physical examination. The presence of abnormal liver tests suggests the need to image the hepatobiliary system via transabdominal ultrasound, abdominal CT, abdominal magnetic resonance imaging (MRI), endoscopic ultrasound, or ERCP. If iron-deficient anemia is present, disorders such as Crohn's disease, ulcerative colitis, peptic ulcer disease, gastric or duodenal neoplasms, colonic or small-bowel neoplasm, or ischemic bowel disease might be considered. In evaluation for the presence of such disorders, endoscopic evaluation of the luminal gastrointestinal tract (e.g., esophagogastroduodenoscopy, sigmoidoscopy, colonoscopy, enteroscopy), small-bowel radiography (e.g., enteroclysis or small-bowel meal), or imaging of the mesenteric vasculature (e.g., mesenteric angiography or magnetic resonance angiography) might be considered for diagnostic evaluation. If the patient reports intermittent abdominal distention and a change in bowel habit, an obstruction series or CT evaluation when symptoms are present might diagnose the presence of intermittent small-bowel obstruction, intussusception, or an intermittent obstructing internal hernia. Hematuria or urinary tract infection detected on urinalysis should be followed by appropriate imaging or evaluation of the genitourinary system in selected patients (e.g., cystoscopy, intravenous pyelogram, transcutaneous ultrasonography, or CT). The use of abdominal and pelvic ultrasonography and CT imaging is helpful for the evaluation of lower abdominal or pelvic pathology. If these are unsuccessful in establishing a specific diagnosis, hormonal therapy and laparoscopy are sometimes required.

Chronic Persistent Abdominal Pain of Known Cause

Individuals afflicted with incurable, chronic, persistent abdominal pain of known cause often present great challenges to health care providers. Patients with abdominal cancers (e.g., colon cancer, gastric cancer, pancreatic cancer, lymphoma) or cancers that are metastatic to abdominal organs or lymph nodes (e.g., pancreatic cancer with lymph node or hepatic metastases) frequently suffer from chronic abdominal pain. In individuals with chronic pancreatitis, chronic abdominal pain often plagues their ability to perform their activities of daily living. Furthermore, patients with mesenteric ischemia frequently complain of postprandial abdominal pain.

Therapy of these disorders is focused on treatment of the underlying pathologic process and relief of the abdominal pain. The relief of pain may require drug treatment, nerve blocks or destruction, or nerve stimulation. The use of NSAIDs may help with musculoskeletal pain syndromes but is less effective for chronic abdominal pain. Anxiolytics are not effective for the treatment of chronic abdominal pain but rather function to lessen the anxiety associated with the pain. Dependency may be problematic if long-term anxiolytic use is attempted. Antidepressants (e.g., nortriptyline, amitriptyline, and doxepin) have also been used successfully in individuals who have chronic pain states and have analgesic efficacy independent of their antidepressant effects. Opioids have also been used for the treatment of chronic abdominal pain; however, the potential for dependency must be realized when initiating therapy. In addition, techniques have been used for chemical and surgical nerve destruction. For example, the use of a celiac plexus block may be performed by injecting a nerve-destroying substance (e.g., ethanol) into the celiac nerve ganglia in individuals with pancreatic adenocarcinoma, often with encouraging results. In individuals with short life spans (typically less than 6 months) it is similarly appropriate to consider surgical techniques such as rhizotomy or cordotomy for pain relief; however, the clinician needs to be cognizant of the possible complications that can occur as a result of this technique (such as bowel and bladder dysfunction or worsening of pain). In addition, transcutaneous electrical nerve stimulation and dorsal column stimulation are relatively safe and simple procedures that may provide moderate pain relief to some individuals.

Chronic Functional Abdominal Pain

Chronic intractable abdominal pain or chronic undiagnosed (functional) abdominal pain is defined as abdominal pain that has been present for at least 6 months without any identifiable cause despite appropriate diagnostic evaluation. This disorder occurs more commonly in women than men and is frequently associated with a history of sexual or physical abuse. Functional abdominal pain needs to be differentiated from other similar common disorders (e.g., nonulcer dyspepsia) that may require quite different therapies. Patients with functional abdominal pain often have pain elsewhere (not only abdominal pain). Despite repeated histories and physical examinations, there is no evidence for another cause that would explain the symptom complex. Typically the pain does not change in intensity, location, or character in response to physiologic states (such as eating or defecation), or, if it does vary, it does so in an unpredictable fashion. The pain is often worse during times of stress and is often associated with many other somatic complaints. The pain responds poorly to standard therapies; thus, patients may undergo many unnecessary procedures.

In general, individuals afflicted with functional abdominal pain may have many psychological impairments, including depression, sleep alterations, anxiety, diminished activity, loss of sexual desire, and preoccupation with the abdominal pain. Depression is especially common and can be quite debilitating in certain individuals with functional abdominal pain.

Unless there are specific indications for performing more involved and perhaps more invasive diagnostic procedures than those that have already been performed for individuals with chronic abdominal pain of more than 6 month's duration, the testing is unlikely to be fruitful. Frequently, abnormalities identified are of little or no importance in terms of their relationship to the patient's complaints. Certainly, if a patient has not had an adequate etiologic evaluation, the appropriate workup should

be performed.

Similar to many other chronic disorders, there is presently no cure for functional abdominal pain. Thus, it is important to discuss this with the patient and to help establish realistic therapeutic expectations. In caring for the patient with functional abdominal pain, frequent contact is important with continued reassurance. The goal should be to improve the quality of life of the patient by discussing improvement in patient functioning, not necessarily elimination of pain (since such a goal is in all likelihood unachievable). Patients should also be encouraged to take an active role in their care. A multidisciplinary approach is recommended, incorporating the fields of psychiatry or psychology, neurology, pain management, physical therapy, relaxation therapy, and other similar ancillary treatments (such as biofeedback and hypnosis).

STRATEGIES FOR OPTIMAL CARE

COMPLICATIONS AND PITFALLS

Establishment of an accurate diagnosis as quickly and efficiently as possible helps to minimize the patient's suffering and may avoid complications. The rapidity with which the diagnosis must be established varies with the presentation. Few conditions require immediate operative intervention to the extent that an orderly procedure cannot be followed in the workup and evaluation of patients with abdominal pain. Some exceptions to this are exsanguinating hemorrhage, vascular catastrophe, and perforated viscus, which require urgent evaluation and diagnosis. Thus, the clinician should approach nearly all patients in a logical fashion, with particular attention to the history and physical examination. All individuals who present with abdominal pain should have rectal and pelvic examinations performed because significant pathology can be uncovered by these examinations.

In evaluating individuals with abdominal pain there are several points that should be emphasized: (a) Disorders of the chest can mimic abdominal disorders and need to be considered in the evaluation of patients. (b) Acute mesenteric ischemia and infarction may be difficult to diagnose since there are typically nonspecific abdominal findings. (c) Don't assume that the location of the pain is of no consequence. Upper abdominal pain is a common complaint in individuals with cholecystitis, pancreatitis, or peptic ulcer disease. Midabdominal pain may represent appendicitis, intestinal obstruction, or mesenteric vascular occlusion, whereas lower abdominal pain may represent appendicitis, diverticulitis, ureteral colic, ectopic pregnancy, or ovarian cyst torsion. (d) Don't assume that observing the patient's actions is not helpful. As a rule of thumb, if a patient prefers to lie still in bed, peritoneal pain (e.g., peritonitis) may be present, whereas a patient moving about restlessly likely has visceral pain (e.g., intestinal or ureteral obstruction, biliary colic). (e) Physical examination must include a thorough evaluation of all hernias, especially in obese patients because small hernias are especially difficult to palpate in such individuals.

Indications for HOSPITALIZATION

Although there are established guidelines for determining when an individual needs to be admitted to the hospital, there have been very few randomized controlled trials to determine when this is necessary in patients with abdominal pain. When dealing with the very young, the elderly, or immunocompromised patients with acute abdominal pain, admission should be considered even in the presence of normal vital signs and normal laboratory parameters. These patients may not mount the same response to severe insult (e.g., bowel perforation, mesenteric ischemia) that is commonly seen in other individuals. Patients with chronic recurrent abdominal pain presenting with similar symptoms to their baseline pain often can be managed as outpatients. If, on the other hand, a patient with chronic abdominal pain has a sudden onset of severe acute abdominal pain on top of his or her chronic abdominal pain, admission should be contemplated to rule out more serious diagnoses. Patients who have abdominal pain in association with fever, vomiting, orthostatic hypotension, tachycardia, abdominal guarding, abdominal rebound, leukocytosis, a new finding of hyperbilirubinemia, or mental confusion should be strongly considered for admission to firmly establish a quick diagnosis and to closely observe their response to treatment.

signs of peritoneal irritation—pain, guarding, rebound tenderness, and absent bowel sounds—thus become established.

In addition to pain sensed in the abdomen, visceral disease often is associated with characteristic patterns of pain sensed in areas anatomically distinct from the abdomen. The patterns of radiation of pain often can provide a useful clue to the organ involved ([Fig. 97.1](#)). In gallbladder disease, the radiation is to the right scapular region. In pancreatitis, the radiation is to the middle of the back in the region of L1 and to the left of this vertebra when the body or tail of the pancreas is involved. When a duodenal ulcer penetrates posteriorly, the radiation is straight through to the back to the area of L1. Diaphragmatic irritation is referred to the shoulder region in the distribution of dermatomes C3, C4, and C5. Renal colic radiates from the flank to the groin or testicle.

ASSOCIATED GASTROINTESTINAL SYMPTOMS

Anorexia

Anorexia is a nonspecific symptom that accompanies many acute abdominal disorders. It is almost invariably present in acute appendicitis, and the diagnosis should be questioned if the patient does not have anorexia. Anorexia is less prominent for the gynecologic or urologic causes of the acute abdomen.

Vomiting

Vomiting usually develops in the course of acute abdomen as a reflex consequence of activation of visceral afferent fibers to the medullary vomiting center. Such reflex vomiting usually is not progressive, nor are unpleasant symptoms ameliorated by vomiting. In contrast, vomiting due to mechanical obstruction of the GI tract is progressive. Vomiting caused by obstruction may lead to intravascular fluid depletion. Electrolyte imbalance characterized by hypochloremic, hypokalemic alkalosis occurs when the obstruction is proximal in the small intestine. More distal intestinal obstruction causes delayed vomiting and distention and may lead to hypovolemia but rarely to electrolyte imbalance.

Abdominal Distention

Abdominal distention is caused by accumulation of swallowed air, the gas of bacterial metabolism, and fluids secreted from the GI tract above the level of obstruction. Distention denotes mechanical intestinal obstruction or paralytic ileus. When distention is caused by ileus, bowel sounds are absent on auscultation of the abdomen. Distention caused by mechanical obstruction is accompanied by hyperactive, high-pitched bowel sounds except in the late stages, when vascular compromise of the GI tract and peritonitis develop.

Constipation

Constipation may be present as a symptom of an underlying disease, such as cancer of the sigmoid colon, that has produced a complication such as perforation. Constipation also may be caused by paralytic ileus. An important indication of mechanical intestinal obstruction is obstipation, the absence of bowel movements or flatus.

Diarrhea

Copious watery diarrhea suggests gastroenteritis. GI ischemia caused by mesenteric venous thrombosis is associated with dark, bloody diarrhea. Bloody diarrhea also may be associated with chronic inflammatory bowel disease.

Jaundice

The presence of jaundice in patients with acute abdominal pain usually indicates a hepatobiliary disorder as the cause of acute abdomen (see [Chapter 103](#)). As indicated in [Table 97.1](#), prehepatic causes of jaundice also can occasionally cause acute abdomen. Jaundice also can be caused by hepatic dysfunction from abdominal sepsis.

Urologic Symptoms

Frequency, dysuria, hematuria, and suprapubic or flank pain indicate a lesion in the kidneys, ureter, bladder, or urethra and necessitate investigation and treatment.

HISTORY AND PHYSICAL EXAMINATION

HISTORY

Past Illness

A complete record of all previous surgical procedures is crucial. A history of previous appendectomy or cholecystectomy allows one confidently to exclude disorders of the appendix or gallbladder as causes of symptoms. A history of peptic ulcer may be an important clue in the diagnosis of a perforated peptic ulcer. A history of previous attacks of renal calculi, inflammatory bowel disease, or abdominal aortic aneurysm is important.

Family History

Family history is particularly important in ruling out medical causes of acute abdomen such as familial Mediterranean fever and sickle cell anemia.

Drug Therapy

The cause of acute abdomen may be directly related to the use of drugs. Use of estrogen-containing oral contraceptives may lead to development of hepatic adenoma, which can bleed and precipitate acute abdominal pain. Patients taking anticoagulant drugs are susceptible to intramural hematoma of the intestine and to retroperitoneal hemorrhage. Corticosteroids may be important in two ways. First, sudden withdrawal of corticosteroids after long-term therapy may precipitate an Addisonian crisis, which may be manifest as abdominal pain. Second, the presence of corticosteroids masks development of the typical signs and symptoms of acute abdomen.

Menstrual History

The correct and expeditious diagnosis of the cause of acute abdominal pain is most difficult among women of childbearing age. For this reason, an accurate and detailed history of menstrual function and sexual activity is critical in the care of young women. Particular attention must be paid to timing of symptoms relative to anticipated menstrual periods, previous episodes of pelvic inflammatory disease, and the possibility of pregnancy.

PHYSICAL EXAMINATION

An unhurried and systematic approach to the physical examination of a patient with acute abdomen is extremely important. In most instances, the results of a careful history and physical examination suggest the correct diagnosis. Confirmation is needed with only a few selected laboratory and radiographic tests.

A patient with an acute abdomen often has an anxious, pale, sweaty face and dilated pupils. Patients with irritation of the parietal peritoneum characteristically lie quietly and minimize movement. Sneezing, coughing, or sudden movement exacerbates pain. The state of hydration is assessed, and the respiratory rate, temperature, and blood pressure determined.

The abdominal examination includes the area from nipples to mid thigh, front and back. All clothing is removed from the abdomen for adequate inspection. The patient

often lies supine or on the side with knees and hips flexed. In the presence of peritoneal irritation, the abdomen is either flat or scaphoid, and respiration is shallow and intercostal. Surgical scars, masses, and potential sites of hernias are evaluated.

After inspection, auscultation is performed before palpation. All four quadrants are auscultated, and the presence and character of bowel sounds are assessed. Bowel sounds are considered absent if no tones are audible over at least a 2-minute period of auscultation. A silent abdomen, if associated with pain and tenderness, is an ominous finding. If hyperactive bowel sounds are present, pitch and association with waves of abdominal pain are evaluated. Vascular bruits are assessed.

After auscultation, gentle percussion is performed to elicit rebound tenderness. Percussion starts in the quadrant farthest from the site of pain; percussion of the painful quadrant is performed last. Gentle palpation to assess the tone of the abdominal wall ensues. Deep palpation is performed last. Intentional attempts to elicit rebound tenderness by means of rapid release of the abdominal wall after deep palpation usually are not helpful and eliminate the possibility of sequential examinations. The sine qua non of an inflammatory process such as appendicitis is localized or *point tenderness*, best elicited by means of gentle, one-finger palpation. If the inflamed appendix is deep in the pelvis, point tenderness may be elicited only by means of rectal or vaginal examination.

Digital rectal examination is performed on all patients. The stool on the examining finger is tested for guaiac positivity. Pelvic examination is performed on all female patients. Any external ostomies or fistulas are examined digitally.

MODIFIERS OF CLINICAL PRESENTATION

Several factors modify the appreciation of pain and the development of signs of peritoneal irritation in an acute abdomen ([Table 97.3](#)). The two extremes of age, infancy and old age, inhibit the full expression of peritoneal irritation, particularly the development of guarding. Patients undergoing corticosteroid therapy and those with Cushing's syndrome may have deceptively few signs of peritoneal irritation even though they have well-developed peritonitis. Diabetes mellitus inhibits expression of the signs and symptoms of acute abdomen to a lesser degree. Patients with diabetes, however, may rapidly experience gangrenous cholecystitis and may have relatively less pain and tenderness than patients without diabetes who have a similarly advanced abnormality. Abdominal signs are less well developed when the abnormality is retroperitoneal. Retroperitoneal perforation of the duodenum often is not diagnosed promptly because of the lack of explicit abdominal signs. Patients with severe acute pancreatitis also may have severe pain and abdominal tenderness but relatively less guarding or rebound tenderness. For reasons that are not well understood, patients with vascular compromise of the intestine and even intestinal infarction have pain out of proportion to the abdominal signs of guarding and tenderness.

Endocrine or metabolic factors
Corticosteroid therapy
Cushing's syndrome
Diabetes
Extremes of age
Infancy (<2 y)
Old age (>70 y)
Retroperitoneal abnormality
Vascular compromise of the intestine
Postoperative status
Central nervous system disorder
Coma
Paraplegia
Pregnancy
Neutropenia

TABLE 97.3. FACTORS THAT MAY LIMIT THE EXPRESSION OF THE SIGNS AND SYMPTOMS OF THE ACUTE ABDOMEN

Acute abdominal abnormality is difficult to diagnose immediately after operations performed for another abdominal condition. Pain, abdominal tenderness, and fever are common and are expected after any abdominal operation, thus the presence of these signs and symptoms delays the diagnosis of acute abdominal disease. Patients in a coma or who have paraplegia do not have abdominal signs or symptoms. In both conditions, systemic signs (fever, hypotension, leukocytosis) are the usual, and often late, indicators of abdominal disease. Among patients with paraplegia, abdominal pain may be limited to diaphragmatic irritation that causes shoulder pain in the distribution of C3, C4, and C5.

AGE

The diagnosis of acute abdominal conditions can be difficult in the two extremes of age. In infancy, the abdominal wall is not well developed, and splinting of the rectus muscles in response to an intra-abdominal inflammatory process does not occur. Infants are unable to communicate well, and the cardinal signs of peritoneal irritation may be difficult to elicit. Systemic signs of fever and dehydration, although they tend to occur early, are not helpful because they are common among children. Elderly patients may not have systemic manifestations even in the presence of well-developed generalized peritonitis. Leukocytosis may not be apparent, and abdominal signs may be misleading. In the two extremes of life, the management of acute abdominal pain calls for the best clinical judgment and the judicious use of early laparotomy.

CORTICOSTEROID THERAPY

Patients taking corticosteroids who have acute abdominal disorders of any cause often do not have full expression of the usual manifestations of acute abdomen. It is common, for example, for findings at physical examination of the abdomen to be relatively normal among patients with toxic megacolon and multiple colonic perforations if the patient is taking corticosteroids. The findings at examination also are relatively normal among corticosteroid-treated patients with acute perforation of a duodenal ulcer. The signs of peritonitis (pain, guarding, and rebound tenderness) may be poorly developed, and fever is suppressed. The patient may not appear acutely ill despite rapid progression of infection. The white blood cell (WBC) count may not be elevated, but usually a marked shift to immature forms is present. Radiologic examination, either plain radiography of the abdomen or computed tomography (CT), is performed more frequently than it is for other patients.

PREGNANCY

Diagnosis of the cause of acute abdomen during pregnancy is complicated. The pain may originate from the pregnant uterus, and uterine enlargement displaces organs from their normal positions. Abdominal examination is difficult, and radiologic evaluation is avoided. Acute appendicitis, acute cholecystitis, and acute pyelonephritis are the most common causes of the acute abdomen among pregnant women. The point tenderness of appendicitis in pregnancy often is shifted away from McBurney's point to a more lateral position in the right upper quadrant of the abdomen. Two specific causes of acute abdomen that occur frequently during pregnancy are rupture of splenic artery aneurysm and rupture of subcapsular hematoma of the liver. The former becomes manifest as severe epigastric pain associated with hypotension and without tenderness of the uterus. Immediate surgical exploration is life saving. Subcapsular hematoma of the liver typically occurs among multiparous woman in the third trimester of pregnancy and is associated with toxemia and disseminated intravascular coagulation. In both disorders hemoperitoneum and shock often are followed by death of the fetus. In the evaluation of acute abdominal abnormalities among pregnant patients, a useful rule is to examine and treat the patient as aggressively as and for the same conditions as nonpregnant patients. The best guarantee of a healthy infant is a well mother.

NEUTROPENIA

Acute abdominal pain is frequent among patients with severe neutropenia (fewer than 100 cells per microliter). Patients with acute leukemia or aplastic anemia and those undergoing bone marrow transplantation before engraftment or aggressive systemic chemotherapy are at particular risk. Among these patients, a syndrome of fever, diffuse abdominal pain, and watery diarrhea may mimic an abdominal disorder. These symptoms often are caused by neutropenic colitis, a pathologic entity characterized by mucosal ulceration, invasive bacterial infection, and sepsis. The terminal ileum and ascending colon are most commonly affected. Cecal edema may occur among many such patients. Laparotomy is indicated if the presence of perforation or full-thickness necrosis is suggested.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A careful history interview and physical examination suggest the correct diagnosis in most cases of acute abdomen. Laboratory and radiologic or ultrasonographic examinations have to be selective and are directed at confirming the diagnosis suggested by the history and physical findings ([Fig. 97.2](#)).

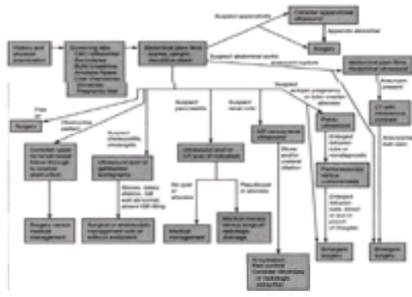

FIGURE 97.2. Evaluation of acute abdomen.
EVIDENCE LEVEL: C. Expert Opinion.

All patients with acute abdomen need a complete blood cell count, including hemoglobin, hematocrit, and WBC count with differential. Leukocytosis with a shift to the left indicates acute inflammation, usually a bacterial infection. Leukopenia suggests a viral infection. A low WBC count with severe shift to the left (increase in immature forms or in cells with toxic granulation) occurs among elderly persons or in the presence of an abscess, but elderly patients may show little change in the number or shift of the WBC count.

All patients with acute abdomen need urinalysis. The results rapidly rule out diabetic ketoacidosis and urinary tract infection. The presence of gross or microscopic blood in the urine suggests renal or ureteral calculi and is an indication for intravenous pyelography. A urine pregnancy test rules out pregnancy as a confounding factor. Serum amylase is measured if pancreatitis is suggested. Liver enzyme tests are performed if cholecystitis, cholangitis, or hepatitis is included in the differential diagnosis. Serum electrolytes, urea, and creatinine are measured for elderly patients, when a patient has vomiting or diarrhea, and when the pathologic process has existed for a prolonged period.

Plain radiographs of the abdomen are obtained when generalized peritoneal irritation is present or when the presence of intestinal obstruction or infarction or renal calculi is suggested. When a perforated viscus is a possibility, three views of the abdomen are obtained—supine, upright, and right or left decubitus. The views include both sides of the diaphragm and the pelvis so that the presence of free air and free peritoneal fluid can be detected. About 75% of patients with perforated peptic ulcer have free air under the diaphragm or evidence of free air on decubitus radiographs. The extent of pneumoperitoneum, however, usually is much more pronounced in colonic perforation. The presence of gas in the biliary tree is ascertained. The presence of gas indicates abnormal communication between the GI tract and the biliary system. Pneumatosis, the presence of gas within the intestinal wall or in the portal vein, usually is a grave sign in the context of acute abdominal pain; it indicates intestinal infarction.

Specialized tests include ultrasonography, radionuclide scanning, CT of the abdomen, GI contrast studies, endoscopic examination of the upper or lower GI tract, and laparoscopy. Ultrasonography is the preferred primary method for examination of the gallbladder and biliary tract. Radionuclide scanning is quite sensitive for confirming the presence of acute cholecystitis. Ultrasonography is preferred as a first method for examination of the liver, the reproductive organs, and retroperitoneal structures such as the aorta. CT is preferred for examination of the pancreas and for detection of localized intra-abdominal or retroperitoneal inflammatory processes. An increase in the availability of abdominal CT has reduced the number of abdominal explorations for pancreatitis. CT also has become the preferred examination to evaluate complications of acute diverticulitis.

Not all patients need all of the listed tests. A young man with typical signs and symptoms of appendicitis and normal findings of urinalysis usually needs no additional testing and needs an emergency operation. Many patients, however, need more involved investigations than those listed earlier. Laparoscopy has a rapidly developing role in the diagnosis of acute inflammatory abdominal conditions. In many instances it allows minimally invasive surgical treatment. For example, laparoscopy is a valuable procedure for young women because a gynecologic condition cannot be easily distinguished from appendicitis or right upper quadrant pain may be caused by the Fitz-Hugh–Curtis syndrome, in which perihepatic inflammation is a complication of salpingitis.

DIFFERENTIAL DIAGNOSIS

The characteristic physical findings associated with acute abdominal abnormalities are summarized in [Table 97.4](#).

Condition	Characteristic Features
Peritonitis	Generalized guarding, tenderness, rebound tenderness, hypoactive or absent bowel sounds
Appendicitis	Right lower quadrant tenderness, guarding and rebound Discrete tenderness at McBurney's point
Acute cholecystitis	Right upper quadrant tenderness and guarding, positive Murphy sign
High small intestinal obstruction	Severe vomiting, dehydration, no distention
Low small intestinal obstruction	Distention, hyperactive and high-pitched bowel sounds, vomiting
Intestinal infarction	Pain out of proportion to tenderness, rectal bleeding if venous infarction
Ruptured aortic aneurysm	Palpable tender mass, hypotension, back pain
Diverticulitis	Left lower quadrant tenderness and mass, obstipation

TABLE 97.4. CHARACTERISTIC PHYSICAL FINDINGS OF ACUTE ABDOMEN

ACUTE APPENDICITIS

Acute appendicitis always is included in the differential diagnosis of abdominal pain. The patient typically has periumbilical pain and anorexia with or without nausea and vomiting. After a variable time, usually hours, the pain moves to the right lower quadrant as the parietal peritoneum becomes involved in the inflammatory process. Low-grade fever is usual. The most characteristic sign is point tenderness at McBurney's point, which is located one-third of the distance from the anterior superior iliac spine to the umbilicus. The exact point of maximal tenderness, however, depends on the anatomic location of the appendix. When the appendix is in a pelvic location, the point of maximal tenderness may be elicited best by means of rectal examination. In retrocecal appendicitis, tenderness often is higher and more lateral, toward the flank. If oriented medially, an inflamed appendix may cause pain with hip flexion—the *psoas sign*. Findings at urinalysis are normal, and there is mild elevation of the WBC count with a leftward shift. If the appendix lies posteriorly in approximation to the right ureter, microscopic hematuria or pyuria may occur in the absence of primary urinary tract disease.

In the care of young adults, if the diagnosis is in doubt, a period of observation may be planned during which the same examiner evaluates for the development of signs of peritoneal irritation. This approach is less safe in the care of infants and elderly persons because of the higher incidence and grave consequences of appendiceal rupture for these groups. In the evaluation of young women, pregnancy and other pelvic causes of pain must be excluded. The highest incidence of diagnostic error for appendicitis occurs among young women.

ACUTE CHOLECYSTITIS

The pain of acute cholecystitis occurs almost invariably in the right upper quadrant. Radiation to the right scapular region or the right shoulder is common. The pain frequently occurs 1 or 2 hours after a meal, quickly reaches maximum intensity, and may persist for a prolonged time. Pain relief usually necessitates narcotic analgesia. A history of intolerance of fatty foods or biliary colic often is elicited. Fever usually is low grade. The classic findings are guarding and tenderness in the right upper quadrant with or without a palpable, tender mass. Sudden arrest of inspiration occurs when the patient inspires deeply while the right upper quadrant is being palpated—*Murphy's sign*. The inspiratory arrest is caused by stimulation of parietal peritoneum by the inflamed gallbladder fundus.

Results of liver tests may be normal, and leukocytosis often is low grade. A mild rise in serum transaminase and bilirubin values may be present, although clinical jaundice is present in only 10% of cases. A serum bilirubin level above 5 mg per deciliter usually implies choledocholithiasis in addition to acute cholecystitis. The triad of right upper quadrant pain, jaundice, and fever with chills is consistent with acute cholangitis. The complete symptom complex, however, is present among only 60% of patients with cholangitis, and it may be difficult to differentiate acute gangrenous cholecystitis and cholangitis.

Although plain abdominal radiographs may contain evidence of gallstones if there is sufficiently high calcium content, the findings are abnormal in only 10% of cases. Ultrasonography and radionuclide cholangioscintigraphy provide the best diagnostic information. Ultrasonography shows the stone, thickening of the gallbladder wall, and pericholecystic edema and may show localized perforation. The size of intrahepatic and extrahepatic ducts and the status of the pancreas can be assessed. Radionuclide cholangioscintigraphy with a technetium Tc 99m derivative of iminodiacetic acid is useful when ultrasonographic findings are inconclusive. A positive result is that the gallbladder is not imaged. The obstruction of the cystic duct present in 95% of cases of acute cholecystitis prevents passage of radionuclide into the gallbladder. Radioactivity is present, however, in the duodenum.

Urgent (rarely emergency) cholecystectomy is the accepted form of management of acute cholecystitis. Intravenous antibiotics against gram-negative bacilli and anaerobes are used in the perioperative period. Most cases of acute cholecystitis can be managed by means of laparoscopic operative techniques.

ACUTE PANCREATITIS

The pain of acute pancreatitis typically is in the epigastrium and left upper quadrant with radiation to the upper lumbar area. Depending on the severity of the disease, the patient may have hypovolemia, hypotension, or respiratory distress. Abdominal tenderness out of proportion to accompanying abdominal wall rigidity often is observed. Because the peripancreatic phlegmon may dissect down either paracolic gutter, the clinical presentation may sometimes be confused with that of acute appendicitis or acute diverticulitis. Leukocytosis (15,000 cells per microliter) with a left shift often is present in acute pancreatitis. An elevated serum amylase level is present in more than 75% of cases. Plain abdominal radiographs may show dilatation of the stomach, air in the duodenum, an isolated dilated loop of proximal small intestine (sentinel loop), or dilatation of the transverse colon caused by ileus in intestinal segments that abut the inflamed pancreas.

The amount of air in the GI tract often militates against adequate evaluation of the pancreas by means of ultrasonography, and CT has become the most informative method of examining the pancreas for inflammation ([Fig. 97.3](#)). The availability of abdominal CT has markedly reduced the number of exploratory laparotomies performed on patients with pancreatitis. Other reliable diagnostic techniques include paracentesis with determination of amylase concentration in the peritoneal fluid when ascites is present.

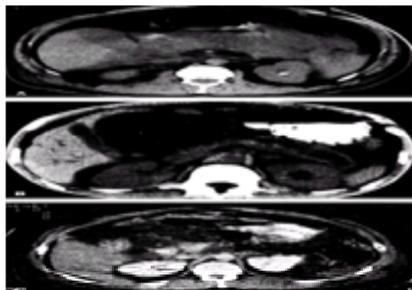

FIGURE 97.3. Computed tomographic scan of the upper abdomen shows pancreatic phlegmon associated with acute pancreatitis (A), pancreatic pseudocyst and associated dilatation of the pancreatic duct (B), and peripancreatic gas in the presence of pancreatic abscess (C).

ACUTE OBSTRUCTION OF THE SMALL INTESTINE

The most common causes of small-intestinal obstruction are adhesive bands from previous operations and hernias (inguinal, femoral, umbilical, incisional). The onset of complete small-intestinal obstruction is heralded by the development of visceral pain in the distribution of the midgut. Pain usually is felt in the midline around the umbilicus. The discomfort occurs intermittently in concert with periods of increased peristaltic activity. Soon after the onset of obstruction, patients may be nearly free of pain between periods of peristalsis. With the development of intestinal distention, however, residual discomfort remains between the episodes of intense colic. The pain of small-intestinal obstruction is severe and gnawing and yet vague and difficult to describe. If pain is not the first symptom, the diagnosis of small-intestinal obstruction should be questioned.

Abdominal distention, obstipation, and vomiting occur after the pain begins. Physical examination is directed at assessment of the completeness of obstruction and at detection of accompanying intraperitoneal inflammation. Information from plain abdominal radiographs is confirmatory in most instances. The loops of the small intestine usually are distended with fluid and swallowed air ([Fig. 97.4](#)). Upright radiographs contain air-fluid levels. In classic cases, the colon and rectum have a paucity of gas. A precise knowledge of the site of obstruction in the small intestine is not necessary in most cases of complete obstruction. *Barium contrast studies should not be performed* to obtain such information preoperatively.

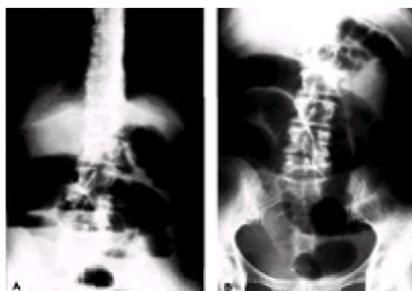

FIGURE 97.4. Plain supine (A) and upright (B) radiographs of the abdomen of a patient with complete intestinal obstruction show dilated loops of small intestine and air-fluid levels.

Two challenges confront surgeons treating patients with adhesive small-intestinal obstruction: differentiating simple and strangulated obstruction and differentiating partial and complete obstruction. With modern operative techniques and perioperative support, the perioperative mortality for simple mechanical obstruction is about

1%. The presence of intestinal infarction increases this risk to 5% to 10%. A delay in diagnosis or operative therapy of 12 hours, during which time strangulation may occur, increases mortality 50%. It follows, therefore, that impending strangulation should be sought strenuously and managed promptly. There are, however, no definite clinical criteria to differentiate simple and strangulated mechanical small-intestinal obstruction. Even experienced clinicians have difficulty detecting intestinal infarction. The classically taught clinical signs of strangulated obstruction, continuous abdominal pain, signs of peritonitis, abdominal mass, tachycardia, leukocytosis, and acidosis do not reliably confirm the presence of intestinal strangulation. The presence of erythema of the overlying skin of an incarcerated hernia is an advanced sign, but its absence does not rule out strangulation. Because of the difficulty in differentiating simple from complicated obstruction and the serious consequences of strangulation, prompt surgical treatment is considered when complete obstruction has been diagnosed.

It sometimes is difficult to determine whether obstruction is partial or complete. The finding of stool or gas in the colon at radiography or the passage of flatus after the onset of obstructive symptoms does not eliminate complete obstruction from consideration. Colonic gas and stool may already have been present at the time of obstruction. Symptomatic improvement that accompanies nasogastric decompression of the upper GI tract and restoration of intravascular volume also may be misinterpreted, because temporary relief may occur even if obstruction is complete.

Nonoperative treatment is indicated only if the obstruction is believed to be incomplete. Marked improvement of partial obstruction is expected within 1 or 2 days if nonoperative treatment is chosen. Serial radiographs should document distal passage of gas from the small intestine into the colon. Repeated clinical examinations should show clear and progressive improvement. Most important, a disciplined plan must be established. If patients do not meet criteria for improvement with nonoperative therapy, prompt surgical exploration should be undertaken.

PERFORATED PEPTIC ULCER

Patients with perforated peptic ulcer commonly have sudden onset of severe upper abdominal pain with or without radiation to the shoulders. The pain tends to diminish for 15 to 30 minutes, only to recur as constant, severe pain. A history of known peptic ulcer disease or dyspepsia is present among two-thirds of patients. The patient is anxious and appears acutely ill at examination. Tachycardia and fever are present, but hypotension rarely occurs early. If a patient with an acute abdomen has hypotension, other diagnoses, such as perforated colon, gangrene of the intestine, pancreatitis, cholangitis, or ruptured aortic aneurysm should be suspected.

Physical examination shows a flat or scaphoid, rigid abdomen. The patient lies immobile. With the abdominal wall splinted, respiration is shallow and intercostal. Abdominal rigidity, tenderness, and rebound tenderness are prominent. Bowel sounds usually are absent, and at percussion liver dullness may be diminished or absent because air is interposed between the liver and the abdominal wall. Plain abdominal radiographs are obtained with multiple views—supine, upright, and right decubitus (Fig. 97.5). Free air, however, is present in only about 75% of cases. Leukocytosis may be moderate, but anemia usually is absent. Serum amylase levels usually are within normal limits. If the serum amylase level is elevated, the value rarely exceeds three times the upper limit of normal. The accepted treatment is surgical. If the perforated ulcer is in the duodenum, closure of the perforation is accomplished with a direct suture technique or by means of suture closure over a buttressing piece of omentum (the Graham patch technique).

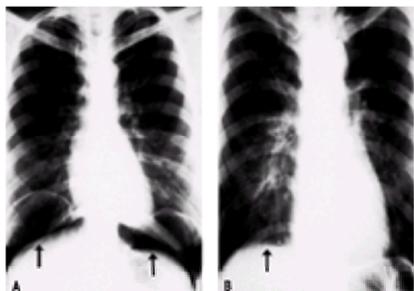

FIGURE 97.5. Upright chest radiographs of two patients with perforated peptic ulcer show massive (A) and minimal (B) amounts of free intraperitoneal air.

If the patient has a history of peptic ulcer or if perforation occurs during medical therapy, a definitive ulcer operation is undertaken if the patient has no other serious illness, the perforation is less than 48 hours old, and the patient has not experienced preoperative shock. When a decision is made to perform a definitive ulcer operation, proximal gastric (highly selective) vagotomy is the preferred procedure. When the perforated ulcer is gastric, the treatment of choice is antrectomy or excision of the ulcer and closure. Omental patch closure occasionally is performed for gastric perforation if the patient's condition is precarious.

COLONIC PERFORATION

Colonic perforation occurs as a complication of closed-loop obstruction, diverticulitis, or carcinoma. Impressive pneumoperitoneum often occurs, and septic shock develops quickly. In diverticular disease, perforation may occur as a primary event in the inflamed diverticulum or as a secondary event when a contained pericolic abscess from a previously inflamed diverticulum ruptures freely into the peritoneal cavity. A history of left lower quadrant pain and physical findings of a left-sided pelvic inflammatory mass are common.

Rapid resuscitation and broad-spectrum antibiotic coverage for the mixed aerobic and anaerobic colonic flora are instituted, and an operation is performed without delay. The goal of surgery is to resect the diseased colonic segment, to perform lavage of the peritoneum, and to construct a totally diverting colostomy. Primary colonic anastomosis under these conditions is unwise.

ACUTE DIVERTICULITIS

True colonic diverticula are uncommon. True diverticula are congenital, contain all the layers of the intestinal wall, and involve the right colon, usually as single lesions. Although true diverticula can be obstructed and become inflamed, they are rarely perforated. In most instances, the term *diverticulosis* refers to the presence of multiple pseudodiverticula in the colon. Pseudodiverticula contain only mucosa and submucosa as they penetrate the muscular layers of the colonic wall. Diverticulosis typically involves the sigmoid colon (95% of cases), but it can involve the descending colon or even the entire colon. The diverticula represent outpouchings of the mucosa and submucosa at points of weakness in the muscular wall at the site of perforating vessels. Most diverticula are adjacent to the longitudinal smooth-muscle bands of the taeniae coli, because these are the sites at which colonic vessels perforate the intestinal wall. The mucosal herniation is caused by an increase in intraluminal pressure.

Diverticulosis is common in western countries. It is a frequent problem among the elderly. In the absence of complications, diverticulosis does not necessitate specific treatment aside from common-sense admonitions to maintain appropriate fiber content in the diet. Diverticulosis occasionally has been associated with massive colonic bleeding caused by erosion of colonic arterioles subjacent to the mucosa of a diverticulum.

Diverticulitis is believed to occur when the ostium of one or more diverticula is obstructed with fecal material. Because the diverticula are outpouchings of the colon, obstruction and inflammation in effect constitute pericolic inflammation. An inflamed diverticulum can rupture either freely into the peritoneal cavity, causing generalized peritonitis, or, more commonly, intramesenterically with walling off by surrounding tissue, resulting in a pericolic abscess. Such a contained abscess can perforate and cause diffuse peritonitis. Colonic obstruction can be caused by a pericolic abscess as the result of mechanical obstruction or spasm. Colonic obstruction usually occurs when many diverticula in the same segment of intestine are inflamed. A peridiverticular abscess can rupture into an adjacent viscus, usually the bladder, to cause a colovesical fistula, which allows air into the urine and causes chronic urinary tract infection. Diverticulitis causes acute abdomen when free or localized perforation or colonic obstruction occurs.

When generalized peritonitis has occurred, emergency surgery is needed to remove the diseased segment of intestine. An end-colostomy is constructed, and the rectal stump is closed or exteriorized as a mucous fistula. A second operation, usually months later, is performed to close the colostomy. When perforation produces a localized abscess, the situation is less urgent. A period of nasogastric decompression and therapy with systemic antibiotics, sometimes combined with percutaneous

abscess drainage, may allow elective surgical therapy—resection and primary anastomosis—under optimal circumstances. Most patients with colonic obstruction caused by diverticulitis can be treated conservatively, and the need for an operation can be determined on the basis of clinical response within 7 to 10 days.

GYNECOLOGIC DISEASES

Gynecologic causes of acute abdomen, such as ruptured or twisted ovarian cyst, ectopic pregnancy, and acute salpingitis, often must be differentiated from acute appendicitis or another surgical condition. Menstrual and sexual histories are crucial. At pelvic examination, inflammatory disease of the uterus and fallopian tubes is indicated by tenderness when the cervix is moved, iliac fossa tenderness, or the finding of an adnexal mass at bimanual examination. Microscopic examination of any cervical discharge is mandatory, and any secretions from the cervix must be subjected to aerobic and anaerobic culture. The pouch of Douglas can be aspirated by means of colposcopy and the fluid examined for blood and bacteria. A pregnancy test is performed for all patients of childbearing age who have symptoms. When the findings on abdominal examination are impressive but the distinction between acute appendicitis and acute salpingitis is uncertain, laparoscopic examination may be performed through a small, subumbilical midline incision. The ovaries, fallopian tubes, uterus, and appendix can be visualized directly.

RUPTURED ECTOPIC PREGNANCY

An acute intra-abdominal crisis occurs when a tubal pregnancy ruptures into the peritoneal cavity. Sudden lower abdominal pain develops and is rapidly followed by generalized peritonitis and hypovolemic shock caused by intra-abdominal bleeding. At pelvic examination the cervix may look blue, and blood may be present at the cervical os. The uterus may be slightly enlarged, and a hematoma may be appreciated in the cul de sac. Laboratory studies show anemia and moderate leukocytosis. A pregnancy test result is positive. When necessary, peritoneoscopy or culdocentesis confirms the diagnosis. Emergency surgical intervention is needed to control hemorrhage.

RUPTURED ABDOMINAL AORTIC ANEURYSM

When abdominal aneurysms rupture, they do so most commonly posteriorly into the retroperitoneum. An initially contained retroperitoneal perforation may then rupture into the free peritoneum with sudden exsanguination. Ruptured aortic aneurysm must be kept high on the list of differential diagnoses, particularly when acute abdomen is associated with back pain and hypovolemic shock. The most important physical finding is a palpable, pulsatile mass in the abdomen. Plain abdominal radiographs in anteroposterior, lateral, and oblique projections, especially cross-table lateral, show aneurysmal calcification of the vessel wall. Ultrasonography is the most useful study for the diagnosis of aneurysm. When ruptured aortic aneurysm is suggested, any complex radiologic investigation needed, such as intravenous pyelography or aortography if a suprarenal aneurysm is suggested, is conducted in the operating room. An emergency operation is mandatory to control bleeding and to replace the aneurysmal segment with a synthetic graft.

STRATEGIES FOR OPTIMAL CARE

The essential questions to answer in the care of a patient with acute abdomen include the following: What is the nature of the pathologic process? Is hospitalization necessary for supportive care, observation, or further diagnostic testing? Is surgical evaluation indicated?

Indications for HOSPITALIZATION

For patients with acute abdominal pain, the need for hospitalization is related to the nature of the underlying pathologic condition found during the evaluation. If the underlying pathophysiologic condition necessitates surgical intervention, the timing of hospitalization is best determined in conjunction with the surgical consultant (see later). When medical therapy is indicated as the primary treatment, as for gastroenteritis, hepatitis, or endometritis, the need for hospitalization is dictated by the patient's physiologic condition when he or she comes to medical attention. Many of the potential causes of acute abdomen preclude or can be exacerbated by continued oral intake even if surgical intervention is not needed. The need to provide adequate analgesia, hydration, and nutrition while the patient takes nothing by mouth in situations such as acute pancreatitis, colonic diverticulitis, and flare-ups of chronic inflammatory bowel disease often necessitates hospitalization for supportive care. The need to monitor responses to medical therapy such as administration of antibiotics and electrolyte replacement also may dictate hospitalization.

Indications for REFERRAL

Indications for referral are related to the nature of the pathologic condition found during the primary evaluation. When critical intra-abdominal disorders such as ruptured abdominal aortic aneurysm, ectopic pregnancy, perforated viscus, or acute cholangitis are high on the list of possible diagnoses, immediate surgical consultation is indicated before extensive laboratory or diagnostic tests are initiated to prevent the considerable morbidity or mortality associated with any delay in definitive treatment. In less urgent situations, the history and physical examination and laboratory and diagnostic evaluations proceed to determine the cause of the underlying pathologic condition. If pathophysiologic processes that may necessitate surgical intervention remain on the list of diagnostic possibilities after this evaluation, surgical consultation is indicated. Most patients with acute abdominal pain need surgical evaluation.

SURGICAL MANAGEMENT

Once a referral has been made for surgical evaluation, the surgical consultant needs to answer the following questions: Is an operation needed immediately? If so, what amount of preoperative investigation is necessary? If an immediate operation is not indicated, what follow-up plan should be adopted, and what changes in the patient's condition indicate the need for an operation? The most common causes of acute abdomen are pathologic processes contained in the abdomen. Extra-abdominal causes are uncommon but must always be considered and excluded. Not all pathologic processes within the abdomen that cause acute abdomen are surgical conditions; examples include acute pancreatitis and acute salpingitis.

Immediate Operation

Rarely is an operation indicated so immediately that time cannot be devoted to performing necessary laboratory or radiographic tests. The most striking example of such an abdominal emergency is that of a patient with back or abdominal pain and a pulsatile abdominal mass. The single most important consideration in the differential diagnosis in such a case is leaking aortic aneurysm. Sending the patient to the radiology department for abdominal radiographs or intravenous pyelography can cause fatal delay. The patient is taken to the operating room immediately. If radiologic examination is considered critical, the examination can be performed in the operating room. Similarly, a young woman with a positive pregnancy test, peritonitis, and hemorrhagic shock needs immediate laparotomy to control bleeding from a ruptured ectopic pregnancy. Another, less urgent example is a patient with a perforated viscus and intestinal obstruction associated with septic shock (Table 97.5).

Gastrointestinal tract
Appendicitis
Perforated appendic ulcer
Subhepatic intraperitoneal obstruction
Intestinal perforation
Intestinal obstruction
Colonic diverticulitis
Inflammation of the appendix
Subhepatic obstruction
Pancreas, gallbladder, biliary tract, liver, spleen
Acute pancreatitis
Acute cholecystitis (cholelithiasis)
Acute cholangitis (choledocholithiasis)
Acute cholecystitis
Hepatic abscess
Hypertrophic pyloric stenosis
Spleenic rupture
Uterine tract
Rupture of uterine tube
Ectopic pregnancy
Tubo-ovarian abscess
Chorionic carcinoma
Ectopic rupture
Ruptured ovarian cyst or follicle
Hemoperitoneum
Abdominal aortic aneurysm rupture
Septic embolic pneumonia
Pneumothorax
Hemothorax
Acute myocardial infarction
Hemiparesis

TABLE 97.5. DIFFERENTIAL DIAGNOSIS OF ACUTE ABDOMEN THAT MAY NECESSITATE SURGICAL INTERVENTION

Immediate Operation Not Needed

For many patients with acute abdominal pain, the need for immediate surgical intervention is not evident. In such cases, it is imperative that a management plan be developed early. The plan must set prospective goals for clinical improvement that if not met prompt surgical exploration. The management plan includes repeated examination of the abdomen by the same observer at intervals determined by the severity of the signs and symptoms. In this way, the development of signs of peritoneal irritation can be detected early and a decision to operate made appropriately. If the patient's condition continues to improve, surgical intervention becomes unnecessary. Follow-up care can include repeated blood tests or abdominal ultrasonography or radiography. There are times, however, when no method of investigation provides enough information for a confident diagnosis, and exploratory laparotomy is needed. The importance of laparotomy for diagnosis must not be overlooked, but the decision to operate must be judicious.

CHAPTER 98: APPROACH TO THE PATIENT WITH NAUSEA AND VOMITING

WILLIAM L. HASLER

[Pathophysiology](#)
[Differential Diagnosis of Nausea and Vomiting](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Testing](#)
[Strategies for Optimal Care](#)

Nausea and vomiting are nonspecific symptomatic responses to a variety of conditions. *Nausea* is the subjective sensation of an impending urge to vomit, usually perceived in the throat or epigastrium. *Vomiting* is the forceful ejection of gastroesophageal contents from the mouth. Although usually preceded by nausea, vomiting may occur without nausea. *Retching* may precede vomiting but involves no discharge of gastric contents from the mouth.

Nausea and vomiting should be differentiated from other symptoms. *Regurgitation* is the effortless return of gastroesophageal contents into the mouth without nausea or somatic muscle contraction. *Rumination* is regurgitation with rechewing and reswallowing of food, often multiple times after a meal. *Anorexia* is loss of appetite, which may or may not be associated with nausea. *Early satiety* is a sensation of gastric fullness before completion of a meal. Nausea may be part of the general feeling of *indigestion*, which includes discomfort, heartburn, anorexia, and bloating.

Nausea and vomiting have socioeconomic effects on patients' lives. Most patients with nausea due to enteric infection restrict their activities. Pregnant women with first-trimester nausea report fatigue, sleep disturbances, and irritability. Nausea and vomiting after cancer chemotherapy or in the postoperative period reduce time spent on leisure activities, household tasks, and socializing. Employee productivity is markedly impaired by acute enteric infection, nausea of pregnancy, and cancer chemotherapy. Postoperative nausea and vomiting greatly increase the costs of the operation of outpatient surgical centers.

PATHOPHYSIOLOGY

Vomiting is caused by coordinated interaction of neural, humoral, somatic muscular, and gastrointestinal myoelectric and muscular phenomena. What is known about the pathways that mediate vomiting comes from studies involving ablation of neural structures in experimental animals. The mechanisms that result in nausea are less well understood. Whereas vomiting may be generated in decerebrate animals, nausea requires activation of selected corticocortical sites.

ACTIVATION OF THE EMETIC RESPONSE

Vomiting is initiated by stimulation of structures in the central (CNS) and peripheral nervous systems ([Fig. 98.1](#)). The area postrema in the dorsal medulla of the brainstem represents the chemoreceptor trigger zone in response to a number of neurochemical activators. Other CNS and peripheral afferent sites mediate emesis after other stimuli. Because of its location and lack of a tight blood-brain barrier, the area postrema is an interface to receive neural input and to sample chemical activators in the bloodstream and cerebrospinal fluid. The area postrema stimulant apomorphine, a dopamine D₂ receptor agonist, induces emesis when applied to the structure, and ablation of the area postrema prevents apomorphine-evoked emesis. Drugs (digoxin, opiates, nicotine, ergot alkaloids, some cancer chemotherapies), metabolic disorders (uremia, diabetic ketoacidosis, hypoxemia, hypercalcemia), radiation therapy, and exposure to bacterial toxins induce vomiting through activation of the area postrema. In addition to D₂ receptors, the area postrema is rich in muscarinic M₁, histaminic H₁, and serotonergic 5-HT₃ receptors; there are therapeutic roles for antagonists of these receptor subtypes.

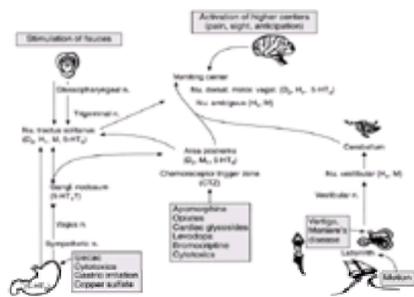

FIGURE 98.1. Afferent neural pathways and receptor populations involved in vomiting as determined by means of experimental studies with animals. Selected brainstem nuclei coordinate vomiting after activation of cortical, oral, vestibular, or peripheral afferents or the area postrema. (Mitchelson F. Pharmacological agents affecting emesis. *Drugs* 1992;43(3):295–315, with permission.)

Other CNS sites may provide stimuli for emesis. Cerebral pathways mediate vomiting caused by exposure to noxious odors, visual stimulation, somatic pain, and unpleasant tastes. Activated brainstem vestibular nuclei mediate emesis caused by motion sickness, labyrinthine infections or tumors, or Meniere's disease through pathways independent of the area postrema. Muscarinic M₁ and histaminergic H₁ but not dopaminergic or serotonergic pathways have important roles in motion sickness. Therefore use of antimuscarinic and antihistaminergic agents to manage this condition brings about an antiemetic response.

Gastric irritants such as copper sulfate, salicylate, and antral distention activate afferent nerves that project from the stomach. Nongastric intraperitoneal afferent stimuli that evoke emesis include distention of the colon, small intestine, and bile ducts, peritoneal inflammation, and mesenteric vascular occlusion. Stimuli also may originate from the heart and pharynx. These findings explain emesis induced by peritonitis, mesenteric ischemia, and myocardial infarction. Emetic responses to many peripheral stimuli are mediated by vagal pathways. Vagotomy prevents emesis after intragastric exposure to copper sulfate and reduces vomiting provoked by the chemotherapeutic agent cisplatin and by abdominal irradiation. Area postrema ablation, however, has little effect on copper sulfate-evoked vomiting. Serotonergic 5-HT₃ (and possibly 5-HT₄) receptors mediate the effects of many peripherally active emetic agents. Thus serotonin receptor antagonists are effective in controlling vomiting caused by selected peripheral exposure to stimuli such as cisplatin.

CENTRAL NERVOUS SYSTEM COORDINATION OF THE ACT OF VOMITING

Multiple brainstem sites mediate the act of vomiting in response to emetic stimuli from the activator sites. These include the nucleus tractus solitarius, the dorsal vagal and phrenic nuclei, medullary nuclei involved in respiration, the nucleus ambiguus, which supplies the laryngeal and pharyngeal musculature, and the trigeminal, facial, and hypoglossal nuclei, which serve the facial and tongue muscles. Once activated, these structures provide somatic stimulation to the diaphragm along cervical spinal pathways and to the external muscles through the thoracolumbar spinal nerves. Neurotransmitters involved in these processes are poorly understood.

PERIPHERAL RESPONSES TO INITIATION OF VOMITING

Somatic Muscular Events Associated with Vomiting

Emesis is caused by a stereotypical series of somatic muscle actions. During retching, inspiratory thoracic, diaphragmatic, and abdominal muscles contract concurrently against a closed glottis. The resulting high positive intra-abdominal pressure forces gastric contents into the esophagus and herniates the gastric cardia into the thorax. High negative intrathoracic pressure prevents expulsion of luminal contents into the mouth. In contrast, both intra-abdominal and intrathoracic pressures are positive during vomiting because of a lack of diaphragmatic contraction in the crural region that allows transmission of the high positive abdominal

pressure into the thorax. With vomiting, the high positive intrathoracic pressure is the force for expulsion of luminal contents into the mouth. Oral propulsion of the vomitus is facilitated by movement of the hyoid bone and larynx up and forward. Glottic closure prevents pulmonary aspiration of gastroesophageal contents. Elevation of the soft palate prevents passage of the vomitus into the nasal cavities.

Gastrointestinal Myoelectric and Motor Events Associated with Nausea and Vomiting

Gastrointestinal motility is regulated by oscillatory electrical activity known as the *slow wave*, which controls the maximal frequency and the direction of contractions (see [Chapter 129](#)). In the stomach, a pacemaker in the gastric body generates slow waves at three cycles per minute that propagate to the pylorus. Small-intestinal slow waves originate in the proximal duodenum at 11 to 12 cycles per minute. Patients with nausea from pregnancy, gastroparesis, nonulcer dyspepsia, and motion sickness have abnormalities of gastric slow-wave frequency, including accelerated (tachygastria) or decelerated (bradygastria) cycling. Because slow-wave amplitudes are very low with tachygastria, this condition causes gastric atony. Bradygastria produces chaotic but infrequent slow waves that produce uncoordinated and ineffective gastric contractions. The causative relation between gastric dysrhythmias and the sensation of nausea is unclear.

With vomiting, gastrointestinal myoelectric and motor events are more pronounced. Before emesis, intestinal slow waves are abolished and followed by bursts of electrical spikes that propagate orally. A retroperistaltic contractile complex begins in the middle small intestine and propagates into the stomach, causing enterogastric reflux. Pyloric closure, antral contraction, and lower esophageal sphincter relaxation facilitate evacuation of the intragastric contents. Blockade of these motor events by atropine does not prevent emesis, indicating that they are not strictly needed for vomiting to occur but enhance evacuation of luminal contents.

Endocrinologic and Autonomic Responses to Induction of Nausea and Vomiting

Levels of circulating hormones and neurotransmitters are altered with nausea and vomiting. Vasopressin levels increase during motion sickness and after administration of apomorphine and cisplatin. Among monkeys, vasopressin V_1 antagonists prevent motion-induced emesis. This finding suggests a possible pathogenic role of vasopressin. Levels of other transmitters such as epinephrine, β -endorphin, and cortisol change during nausea and vomiting, but the pathogenic importance of these alterations is uncertain. Autonomic neural disturbances are caused by the proximity of brainstem nuclei that mediate vomiting to those that control respiratory, vasomotor, cardiac, and salivary activity. Pallor, diaphoresis, hypersalivation, defecation, tachycardia, and hypotension may occur with nausea. Bradycardia, blood pressure variations, and respiratory interruption may occur with retching or vomiting.

DIFFERENTIAL DIAGNOSIS OF NAUSEA AND VOMITING

The differential diagnosis of nausea and vomiting is extensive. It includes a broad range of pathologic and physiologic conditions that affect the gastrointestinal tract, peritoneal cavity, central nervous system, and endocrine and metabolic functions ([Table 98.1](#)).

TABLE 98.1. DIFFERENTIAL DIAGNOSIS OF NAUSEA AND VOMITING

MEDICATIONS

Drug reactions are among the most common causes of nausea and vomiting and usually occur soon after initiation of therapy. The most extensively studied medications that evoke emesis are cancer chemotherapeutic agents. Emesis from chemotherapy may be acute, delayed, and anticipatory. Potent agents that induce acute vomiting within hours of administration include cisplatin, nitrogen mustard, and dacarbazine, which act by activating 5-HT₃ receptors on vagal afferent fibers and the area postrema. In contrast, acute vomiting from less emetogenic agents such as cyclophosphamide and delayed and anticipatory nausea are mediated by serotonin-independent pathways. Analgesics such as aspirin or nonsteroidal anti-inflammatory drugs induce nausea through direct irritation of mucosal afferent fibers. Other drugs with emetic properties include cardiac antiarrhythmics, antihypertensive agents, diuretics, antidiabetic drugs, contraceptives, antibiotics such as erythromycin, and gastrointestinal medications such as sulfasalazine.

INFECTIOUS AND TOXIC CAUSES

Infectious illness produces nausea and vomiting that usually is of acute onset. Acute enteric infection is most prevalent among children younger than 3 years and often occurs in the autumn and winter. Viral gastroenteritis may be caused by rotaviruses, reoviruses, adenoviruses, and the Hawaii, Snow Mountain, and Norwalk agents. Bacterial infection with *Staphylococcus aureus*, *Salmonella* organisms, *Bacillus cereus*, and *Clostridium perfringens* also produces nausea and vomiting, in many cases through the action of toxins on the area postrema. Nausea among immunosuppressed patients is caused by gastrointestinal infection with cytomegalovirus or herpes simplex virus. Nongastrointestinal infections that produce nausea include otitis media, meningitis, and hepatitis.

DISORDERS OF THE GASTROINTESTINAL TRACT AND PERITONEAL CAVITY

Gastrointestinal and peritoneal disorders represent prevalent causes of nausea and vomiting. Gastric or small-intestinal obstruction produces prominent nausea that may be relieved by vomiting. Gastric outlet obstruction often is intermittent, whereas small-intestinal obstruction usually is acute and associated with abdominal pain. Superior mesenteric artery syndrome is a rare condition in which the duodenum is compressed by the overlying superior mesenteric artery as it originates from the aorta, producing anatomic obstruction. This syndrome occurs among patients who have had profound weight loss, a recent surgical procedure, or prolonged bed rest.

Motility disorders such as gastroparesis or chronic intestinal pseudoobstruction produce nausea due to an inability to clear retained food. Gastroparesis is caused by diabetes, scleroderma, systemic lupus erythematosus, amyloidosis, or pancreatic adenocarcinoma. It also can develop after vagotomy or in the absence of other diseases. Idiopathic gastroparesis may be preceded by a viral prodrome of diarrhea, fever, headache, or myalgia. Chronic intestinal pseudoobstruction may be hereditary or caused by a systemic disease that produces gastroparesis. Paraneoplastic pseudoobstruction occurs with some malignant tumors such as small-cell carcinoma of the lung. Nausea may be prominent among patients with nonulcer dyspepsia who also may have delayed gastric emptying.

Abdominal radiation therapy produces emesis among as many as 80% of patients by means of effects on the structure and function of the gastrointestinal tract. Involvement of serotonergic pathways is indicated by the ability of 5-HT₃ receptor antagonists to reduce emesis evoked by abdominal irradiation.

Abdominal disorders that do not involve the gastrointestinal lumen may produce nausea and vomiting. Inflammatory conditions such as pancreatitis, appendicitis, and cholecystitis activate afferent pathways from the peritoneum. Biliary colic in the absence of inflammation produces nausea through activation of afferent fibers from distention of the biliary tree. Fulminant hepatic failure results in nausea, presumably because of retention of unknown emetic toxins and increased intracranial pressure.

CENTRAL NERVOUS SYSTEM CAUSES

Many emetic stimuli produce symptoms through action on the cerebrum or brainstem. Increased intracranial pressure from malignant tumors, infarction, hemorrhage, or infection may produce emesis with or without nausea. Emotional responses to unpleasant smells, tastes, or memories may induce vomiting. Psychogenic vomiting occurs most commonly among young women, often with a history of psychiatric illness or social difficulties. Other psychiatric conditions accompanied by nausea include anxiety disorders, depression, anorexia nervosa, and bulimia.

Labyrinthine disorders such as labyrinthitis, tumors, and Meniere's disease produce nausea and vomiting, often with vertigo. Motion sickness is evoked by repetitive movements that activate the vestibular nuclei and is associated with extensive autonomic activation that produces pallor, diaphoresis, and salivation. Space sickness, experienced by most astronauts in zero gravity, is related to motion sickness but may not have the associated autonomic phenomena.

ENDOCRINOLOGIC AND METABOLIC CONDITIONS

Endocrinologic and metabolic causes of nausea include uremia, diabetic ketoacidosis, hyper- and hypoparathyroidism, hyperthyroidism, and Addison's disease. Pregnancy is the most common endocrinologic cause of emesis, which occurs among about 70% of pregnant women. The condition peaks in the ninth week of gestation and is not deleterious to either mother or fetus. Hyperemesis gravidarum, however, a condition of intractable vomiting that complicates 1% to 5% of pregnancies, may produce dangerous fluid and electrolyte abnormalities. The cause of nausea of pregnancy is unknown but is believed to be hormone-related. Acute fatty liver of pregnancy, a condition distinct from first trimester nausea, produces third-trimester emesis and can be complicated by liver failure, disseminated intravascular coagulation, and fetal or maternal death.

MISCELLANEOUS CONDITIONS

Nausea and vomiting complicate 17% to 37% of operations, more commonly among women. Postoperative nausea and vomiting occur more frequently after general anesthesia and abdominal and orthopedic procedures, rather than after laparoscopic and extra-abdominal procedures other than orthopedic operations. Cyclic vomiting syndrome produces discrete attacks of intractable vomiting. The mean age at onset is 5 years; the syndrome occurs very rarely among adults. Children with this syndrome typically have eight attacks per year that last an average of 20 hours. The pathogenesis is likely multifactorial, but a strong association with migraine headaches has been reported and some patients respond to antimigraine therapy. Posterior myocardial infarction produces nausea due to diaphragmatic irritation. Nausea may occur in congestive heart failure from passive congestion of the liver and gastrointestinal tract. Excess ethanol induces vomiting through local action on the gastrointestinal tract and through action on the brainstem. Jamaican vomiting sickness occurs after one eats unripe akee fruit. Excess vitamin intake and extended fasting or starvation also may cause nausea.

HISTORY AND PHYSICAL EXAMINATION

HISTORICAL FEATURES

A detailed history provides useful diagnostic information about the cause of unexplained nausea and emesis. Acute vomiting (1 to 2 days) most often is caused by infection, a medication or toxin, or accumulation of endogenous toxins, as in uremia or diabetic ketoacidosis. Chronic vomiting (more than 1 week) usually is caused by a long-standing medical or psychiatric condition.

Timing of Nausea and Vomiting

The timing of symptoms provides clues to the underlying disease. Vomiting soon after a meal occurs with gastric obstruction from ulcer disease or a malignant tumor. Psychogenic vomiting also occurs soon after eating, but most patients control the act of emesis until a convenient receptacle is available. Patients with gastroparesis may report nausea within 5 minutes of eating, but most have symptoms more than 1 hour after a meal. Nausea and vomiting from inflammatory conditions such as cholecystitis and pancreatitis may occur in the first postprandial hour. With some cases of esophagitis or ulcer disease, nausea may abate with eating. Vomiting early in the morning is characteristic of first-trimester pregnancy, uremia, and chronic alcoholism.

Character of the Vomitus

The characteristics of the vomitus can assist in diagnosis. Return of undigested food suggests achalasia or Zenker's diverticulum. Vomiting of partly digested food hours or days after ingestion suggests gastric obstruction or gastroparesis. Bile in the vomitus excludes obstruction proximal to the ampulla of Vater, whereas blood or coffee-ground material suggests a process with mucosal damage such as an ulcer or malignant tumor. However, retching and vomiting can induce hematemesis from Mallory–Weiss tears across the gastroesophageal junction. Voluminous, clear, acidic vomitus suggests gastric hypersecretion from Zollinger–Ellison syndrome. Feculent emesis occurs with distal intestinal or colonic obstruction, intestinal bacterial overgrowth, and gastrocolic fistula. Odorless emesis may be found with gastric achlorhydria.

Symptoms Associated with Nausea and Vomiting

Abdominal pain occurs with ulcer disease, intestinal obstruction, and inflammatory disorders such as cholecystitis and pancreatitis. Vomiting may relieve nausea and pain in ulcer disease and intestinal obstruction but has no effect in inflammatory conditions. The presence of diarrhea, fever, or myalgia suggests enteric infection. Weight loss and malnutrition occur with chronic illness, but psychogenic vomiting rarely produces weight loss. Meningitis or CNS lesions are suggested by headaches, visual changes, altered mentation, and neck stiffness. In these disorders, emesis may be effortless, there may be no nausea, or emesis may be projectile. Labyrinthine diseases become manifest with tinnitus or vertigo. Chest pain, dysphagia, or jaundice suggests pregnancy or cardiac, esophageal, or hepatobiliary disease. Associated symptoms also indicate the severity of the underlying condition and help to direct treatment. Prolonged vomiting may produce substantial fluid and electrolyte loss, which may be manifested as postural light-headedness, rapid heart rate, and mouth dryness.

Complications of Nausea and Vomiting

Gastrointestinal hemorrhage may be caused by retch-induced mucosal tears across the gastroesophageal junction, known as Mallory–Weiss tears. A more severe complication, Boerhaave's syndrome, occurs when retching or vomiting produces complete esophageal rupture with mediastinitis or peritonitis. Among patients with impaired consciousness, emesis may be complicated by pulmonary aspiration of acidic material that leads to severe chemical pneumonitis.

PHYSICAL EXAMINATION FINDINGS

The physical examination assists in the diagnosis and management of nausea and vomiting. Fever suggests infection or inflammation. Tachycardia or orthostatic hypotension indicates dehydration, which is supported by finding a loss of skin turgor or dry mucous membranes. Skin examination may show sclerodactyly in scleroderma or jaundice with hepatobiliary disease. Oral examination may reveal loss of dental enamel, common in bulimia. Adenopathy raises the possibility of a neoplasm. Hepatomegaly also is found in malignant disease, as is benign hepatic disease. An absence of bowel sounds indicates ileus, whereas high-pitched hyperactive bowel sounds with a distended abdomen are a sign of intestinal obstruction. A succession splash on side-to-side movement occurs in gastric obstruction or gastroparesis. If abdominal tenderness or guarding is found, inflammation or infection such as an ulcer, cholecystitis, pancreatitis, or peritonitis is considered. The finding of gross or occult fecal blood at rectal examination prompts evaluation for an ulcer or neoplasm. At neurologic examination, focal signs, papilledema, and impaired mentation suggest a CNS process, whereas nuchal rigidity is consistent with meningitis. Asterix is present in metabolic diseases such as uremia or hepatic failure. Patients with gastrointestinal motility disturbances may have peripheral or autonomic neuropathy.

LABORATORY STUDIES AND DIAGNOSTIC TESTING

A thorough history interview and examination provide the information necessary for a diagnosis and for treatment of most patients with nausea and vomiting. However, some patients require blood studies, structural evaluations, or assessment of gastrointestinal function for diagnosis and treatment ([Fig. 98.2](#)).

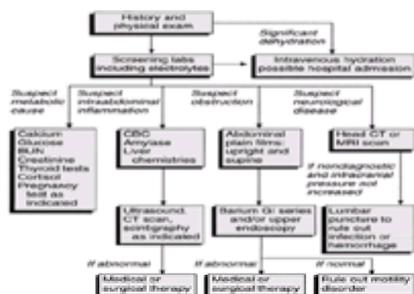

FIGURE 98.2. Evaluation of nausea and vomiting.
EVIDENCE LEVEL: C. Expert Opinion.

LABORATORY TESTING

Laboratory tests are ordered on the basis of findings in the history and physical examination. With long-standing symptoms or dehydration, serum electrolyte measurements can show hypokalemia or an elevated blood urea nitrogen level relative to creatinine level. Metabolic alkalosis may be caused by loss of hydrogen ions in the acidic vomitus and contraction of the extracellular space from dehydration. A complete blood cell count can be used to rule out anemia from inflammation or blood loss, leukocytosis from an inflammatory source, or leukopenia from a viral infection. Chronic blood loss also may be suggested by a low serum iron level and iron saturation of transferrin. Hypoalbuminemia occurs with some chronic diseases and in conditions with gastrointestinal protein loss. Amylase, lipase, and liver chemical analyses are performed when pancreatic or hepatobiliary disease is suspected. Endocrinologic and metabolic causes can be assessed through serum pregnancy testing, thyroid function testing, and measurement of blood urea nitrogen, creatinine, glucose, ketones, calcium, and plasma cortisol. Specific serologic markers can be obtained for presumed collagen vascular diseases such as lupus erythematosus, whereas antineuronal nuclear antibodies are present with paraneoplastic intestinal pseudoobstruction (usually from small-cell carcinoma of the lung). The presence of meningitis is confirmed by means of lumbar puncture.

STRUCTURAL EVALUATION

Structural investigation may be needed to exclude organic disease as a cause of emesis. Flat and upright abdominal radiographs are obtained as a screening examination. Air-fluid levels in the small intestine with an absence of colonic air suggests intestinal obstruction, whereas diffuse luminal distention with absent bowel sounds indicates ileus or chronic pseudoobstruction. Subdiaphragmatic free air indicates visceral perforation. Small-intestinal barium radiography may help confirm suspected partial intestinal obstruction. If symptoms are intermittent and intermittent obstruction is highly likely, enteroclysis may provide a more detailed assessment of the small-intestinal lumen. If colonic obstruction is a consideration, colonoscopy or barium enema radiography are performed before small-intestinal contrast studies. Upper gastrointestinal endoscopy or contrast radiography may be performed in cases of suspected ulcer disease or outlet narrowing. Endoscopy affords the advantage of allowing biopsy of abnormal mucosa. Endoscopy also may suggest gastroparesis, demonstrating retained food in the absence of outlet obstruction. For suspected pancreaticobiliary disease, ultrasonography or computed tomography may be useful. Biliary scintigraphy may provide findings that suggest acute cholecystitis. Computed tomography or magnetic resonance imaging of the head is indicated if the signs and symptoms indicate a CNS cause. If intestinal ischemia is a consideration, mesenteric angiography or magnetic resonance imaging of mesenteric flow may provide enough information for a diagnosis.

STUDIES OF GASTROINTESTINAL MOTOR AND MYOELECTRIC ACTIVITY

When luminal obstruction has been excluded, functional causes of nausea such as gastroparesis and pseudoobstruction are entertained. The clinician may treat the patient empirically with medication designed to stimulate gastrointestinal motility. An alternative is to test gastrointestinal motor and myoelectric activity to characterize the functional defects (see [Chapter 129](#)).

Quantification of Gastric Emptying

Gastroparesis is diagnosed through the demonstration of delayed gastric emptying of an ingested meal. Scintigraphic measures of the emptying rates of solid (such as technetium Tc 99m sulfur colloid in scrambled eggs) or liquid (such as indium In 111 diethylenetriamine pentaacetic acid [DTPA] in water) radionuclides are the most commonly used tests of gastric emptying. Gastroparesis affects solid-phase emptying to a greater extent than does liquid-phase emptying. Thus solid-phase scintiscans are more sensitive for diagnosis. Other means of quantifying gastric emptying are under investigation including magnetic resonance imaging and ultrasonography. A promising new technology is the carbon C 13 octanoate breath test. Because this test involves ingestion of a nonradioactive ligand, it may be used in examinations of children and pregnant women, for whom scintigraphy is relatively contraindicated.

Gastrointestinal Manometry

When scintigraphy does not provide enough information for a diagnosis of the cause of nausea, gastrointestinal manometry can be performed. Because of the discomfort involved and the personnel required, this test is performed only in specialized centers. Under fasting conditions, the stomach and small intestine exhibit a pattern known as the migrating motor complex, which consists of three phases that repeat every 90 to 120 minutes. The most propulsive phase, phase III, clears undigested debris from the upper gastrointestinal tract. Absence of gastric phase III, found in some cases of gastroparesis, is a predisposing factor for bezoar formation. Loss of intestinal phase III may lead to bacterial overgrowth. The postprandial period exhibits irregular, continuous contractions. The absence of this fed pattern in the stomach correlates with delayed solid-phase gastric emptying.

In addition to defining gastric dysmotility, manometry also is used to characterize small-intestinal motor disturbances. In intestinal pseudoobstruction, barium radiography may show intestinal dilatation and delayed transit. Manometry of the small intestine provides more specific information regarding the neuropathic or myopathic nature of the condition. Pseudoobstruction resulting from enteric nerve dysfunction, as with the familial visceral neuropathies or early scleroderma, produces intense, uncoordinated bursts of motor activity, whereas smooth-muscle dysfunction in familial visceral myopathy or late scleroderma produces contractions of very low amplitude. These patterns can be nonspecific, thus surgical full-thickness intestinal biopsy may be needed to document degeneration of nerve or muscle layers.

Electrogastrography

Gastric myoelectric disturbances are diagnosed in referral centers by means of electrogastrography, a technique with which slow waves are measured using cutaneous electrodes over the stomach. Recordings for healthy persons show a rhythm of three cycles per minute that increases in amplitude after eating. Patients with nausea may have symptoms that correlate with abnormally rapid (tachygastria) or slow (bradygastria) rhythms or with an absence of the postprandial signal increase. Because many patients with delayed gastric emptying have altered slow-wave activity, electrogastrography has been proposed as a nonradioactive means of diagnosing gastroparesis. Electrogastrographic findings also may be abnormal among some patients with nausea who have normal gastric emptying. The suggestion is that this test may help define patient populations with primary slow-wave dysrhythmia.

STRATEGIES FOR OPTIMAL CARE

Care of a patient with nausea and vomiting involves assessment of the cause and the severity of the condition and initiation of therapy to prevent complications.

Indications for HOSPITALIZATION

The first decision in treating a patient with vomiting is to determine whether intravenous resuscitation is needed. Poor skin turgor or orthostatic pulse or blood pressure changes indicate that more than 10% of body fluids have been lost, mandating intravenous infusion of saline solution (0.45% or 0.9%). Potassium supplements may be started for hypokalemia if urine output is adequate. Intravenous fluids can be given in the emergency department or outpatient clinic if the patient is expected to resume adequate oral intake at home. If prospects for oral replenishment are uncertain, hospitalization should be considered. Patients with mechanical obstruction or ileus may benefit from nasogastric suction. The threshold for hospitalization should be lowered for patients with diabetes, patients with concurrent diarrhea, persons with another chronic debilitating disease, and very young or very old patients; these persons become rapidly dehydrated.

DIETARY AND NONMEDICINAL CONSIDERATIONS

If the patient can return home, dietary advice is given. Because liquids empty more rapidly from the stomach than do solids, a liquid diet is recommended. Frequent, small meals should be prescribed; large volumes may worsen symptoms. Foods rich in fats and indigestible fiber are to be avoided because they may be retained in the stomach and increase nausea. Drugs that impair gastrointestinal motor function are discontinued if possible. Persons with diabetes should strive for good blood glucose control because hyperglycemia may delay gastric emptying and promote symptoms.

MEDICAL THERAPY FOR NAUSEA AND VOMITING

Medical or surgical management of nausea and vomiting are directed at the underlying disease whenever possible. However, many patients benefit from initiation of medications designed to suppress emesis and correct aberrant gastrointestinal function ([Table 98.2](#)).

TABLE 98.2. ANTIEMETIC AGENTS FOR SPECIFIC CLINICAL INDICATIONS

Antiemetic Medications

Antiemetic drugs that act on CNS muscarinic, cholinergic, histamine, or dopamine receptors reduce symptoms in many cases. Use of these agents is tailored to the underlying emetic stimulus. Antihistamines such as meclizine and dimenhydrinate are useful for vomiting with labyrinthine disorders, such as motion sickness or labyrinthitis. They also are effective in controlling nausea caused by uremia or the postoperative state. Antihistamines are safe, although sedation and dryness of the mouth may limit their use. Newer, less sedating antihistamines such as astemizole have limited antiemetic activity.

Drugs such as scopolamine that antagonize muscarinic receptors in vestibular pathways also are effective in controlling motion sickness when given orally or transdermally. Side effects from antimuscarinic agents such as dryness of the mouth and eyes, sedation, impaired concentration, headache, constipation, and urinary retention impair the usefulness of these drugs for some persons.

Dopamine antagonists, including phenothiazines (prochlorperazine, chlorpromazine) and butyrophenones (droperidol, haloperidol), are the most commonly prescribed antiemetics. These agents act on area postrema D₂ receptors and are effective against emesis caused by gastroenteritis, medications, and toxins and by some chemotherapeutic agents, abdominal irradiation, and surgery. Antidopaminergic agents produce many CNS side effects, including drowsiness, insomnia, anxiety, mood changes, confusion, dystonic reactions, parkinsonian symptoms, and irreversible tardive dyskinesia. Through effects on the pituitary gland, antidopaminergic agents may induce hyperprolactinemia that leads to breast engorgement, galactorrhea, and sexual dysfunction. Other side effects include blood dyscrasia and jaundice. Many antidopaminergic drugs have effects on other receptor subtypes and provoke antihistaminic and antimuscarinic side effects.

Prokinetic Agents for Gastroparesis and Intestinal Dysmotility

Gastrointestinal motility disorders may respond to drugs that stimulate gastric emptying and intestinal transit. These agents often are given before meals to enhance gastric emptying with a dose at bedtime to effect gastrointestinal clearance of undigested residue during sleep. Cisapride has become the initial drug of choice in the care of selected patients with gastroparesis and pseudoobstruction. Cisapride acts by means of 5-HT₄ receptor facilitation of gastrointestinal cholinergic transmission and potentially stimulates gastric emptying. Rare side effects include headache, abdominal cramps, and diarrhea due to colonic stimulation. Cisapride should be prescribed judiciously because of reports of potentially fatal cardiac arrhythmias among patients with cardiac disease or taking other medications.

Like cisapride, metoclopramide acts by means of 5-HT₄ receptor facilitation of gastric cholinergic function, but the drug also acts as a dopamine D₂ antagonist in the stomach and brainstem. The prokinetic properties of metoclopramide are limited to the proximal gastrointestinal tract, thus the drug is useful for gastroparesis but not for small-intestinal or colonic dysmotility. Because of central antidopaminergic side effects, metoclopramide is poorly tolerated by as many as 20% of patients.

Domperidone is a dopamine D₂ antagonist with prokinetic properties. It crosses only into CNS regions with porous blood-brain barriers such as the area postrema and thus exhibits a superior side-effect profile to that of metoclopramide. The drug is prescribed throughout much of the world but is not available in the United States. Because of a lack of enteric cholinergic stimulation, domperidone is a weaker prokinetic agent than are metoclopramide and cisapride, but the drug still has marked symptomatic efficacy in the treatment of patients with gastroparesis. Although dystonic reactions do not occur with domperidone, hyperprolactinemia is a problem because of the incomplete blood-brain barrier of the anterior pituitary gland.

Other prokinetic agents can be used to manage gastrointestinal motor dysfunction. The macrolide antibiotic erythromycin induces upper gastrointestinal contractions and promotes gastric emptying through action on receptors for the hormone motilin, the physiologic regulator of the migrating motor complex. Some patients with gastroparesis and pseudoobstruction respond to erythromycin, but this agent has a narrow dose range of efficacy that limits its utility: low doses have no effect and high doses induce abdominal pain, nausea, and diarrhea. Macrolide derivatives with no antimicrobial activity but with prokinetic properties are being developed. The direct muscarinic stimulant bethanechol has motor stimulatory properties in the upper gastrointestinal tract and on rare occasions is used to manage gastroparesis. However, because it induces spastic rather than propagative motility and because it produces side effects such as diaphoresis, abdominal pain, nausea, and chest pain, bethanechol is rarely prescribed for dysmotility syndromes. The somatostatin analog octreotide, which evokes small-intestinal complexes that resemble the migrating motor complex, may reduce nausea and vomiting among patients with scleroderma who have pseudoobstruction and bacterial overgrowth. The gonadotropin-releasing hormone analog leuprolide evokes propagative gastrointestinal motor complexes and reduces nausea and bloating among patients with small-intestinal dysmotility syndromes.

Management of Emesis Resulting from Cancer Chemotherapy

Extensive investigation has focused on antiemetic regimens to prevent or control nausea and vomiting that complicate cancer chemotherapy. Most programs include multiple drugs that act on distinct receptor sites. For highly emetogenic agents such as cisplatin, prophylactic regimens usually include 5-HT₃ antagonists such as ondansetron and granisetron. These agents also are effective against emesis induced by radiation therapy and the postoperative state. Side effects of 5-HT₃

antagonists include headache, constipation, and rare elevations in liver enzyme levels. Metoclopramide in high doses is useful for prophylaxis of chemotherapy-induced emesis, possibly stemming from weak 5-HT₃ antagonism. Other antidopaminergic agents such as prochlorperazine and domperidone are used with efficacy with some forms of chemotherapy. Corticosteroids have potent antiemetic effects against chemotherapeutic agents through unknown mechanisms. Intravenous benzodiazepines such as lorazepam are included in antiemetic regimens because they produce sedation and reduce anticipatory nausea. In prophylaxis against chemotherapy-induced emesis, cannabinoids such as tetrahydrocannabinol and nabilone are as efficacious as or slightly better than antidopaminergics. Cannabinoids, however, produce severe side effects such as somnolence, ataxia, syncope, seizures, and hallucinations, which are prominent in the elderly. The mechanisms of the antiemetic effects of cannabinoids are unknown.

Miscellaneous Antiemetic Therapies

Other medications are efficacious in selected instances. Tricyclic antidepressants are used to manage nausea associated with depression and have been shown to be effective in the treatment of patients with unexplained functional nausea. Patients with nausea due to opiate withdrawal have responded to opiate antagonists such as naloxone.

SURGICAL AND OTHER NONMEDICATION MANAGEMENT OF NAUSEA AND VOMITING

Nonmedication therapies have been proposed for some conditions of chronic emesis. Acupuncture and acustimulation have been used to control nausea of pregnancy, motion sickness, and postoperative nausea. Among patients with diabetes and gastroparesis, enteral feedings through a jejunostomy can reduce symptoms and decrease the number of hospitalizations. Intravenous hyperalimentation may be needed for severe pseudoobstruction. Patients with gastroparesis after vagotomy may improve after surgical removal of the stomach. Electrical pacing of the stomach has been reported to benefit some patients with severe gastroparesis, but this technology is unproved.

[History](#)
[Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Acute Diarrhea](#)
[Chronic Diarrhea](#)
[Strategies for Optimal Care](#)
[Cost-Effectiveness](#)

PRESENTATION

Diarrhea is a symptom that is extremely common and bothersome. It is one of the most common problems encountered by physicians in outpatient and inpatient settings and is a major cause of work absenteeism and medical expense. In developing countries, infectious diarrhea is a major cause of morbidity and mortality, predominantly among children, accounting for about 3 million deaths per year. In the United States, acute infectious diarrhea alone accounts for 2.2 million physician visits per year. The elderly have the highest mortality followed by adults who are immunocompromised or have cardiovascular disease. In the pediatric population, each child has an average of 7 to 15 episodes of diarrhea before the age of 5 years. In this age group, diarrhea accounts for 9% of all hospitalizations and causes 300 to 500 deaths a year. The morbidity and mortality from diarrheal disease in the United States could be reduced if inexpensive oral rehydration solutions were used earlier in the course of illness.

Although most cases of diarrhea are transient and benign, some are chronic and debilitating, and often associated with underlying disease. Diarrhea may be described as an increase in frequency, size or loosening of bowel movements. Because individual persons have different definitions of diarrhea, it is important to differentiate true diarrhea from conditions, such as fecal incontinence or functional bowel disease, associated with increased frequency or loose consistency of stool but a normal stool weight. Most adults who consume an average, low-residue western diet have less than 200 g of stool per day. Those with stool weights more than 200 g per day most likely have diarrhea. The average daily stool weight among infants is far less than that among adults; an output of 200 g per day represents diarrhea. Some patients with severe diarrhea have dehydration and metabolic disturbances, particularly if they are unable to take fluids orally. Findings such as fever, weight loss, and abdominal pain may be important clues to the cause of diarrhea. The context in which diarrhea occurs is an important factor in evaluation and management. The causes of diarrhea among hospitalized or intensive care patients differ from those among outpatients. The causes of diarrhea among immunocompromised hosts differ from those among normal hosts.

PATHOPHYSIOLOGY

Every day about 8 to 10 L of fluid enters the small intestine of an adult. About 2 L are from dietary intake, the rest are from salivary, gastric, pancreatic, biliary, and intestinal secretions. About 80% of this fluid is reabsorbed in the small intestine, and all but approximately 100 mL of the remaining fluid is absorbed in the colon. Water and electrolytes are absorbed in the intestine by a number of processes. Sodium is transported into absorptive (villous) small-intestinal epithelial cells predominantly by nutrient-dependent cotransporters. This results in the paracellular flow of Cl^- , K^+ , and water. In addition, water may be transported transcellularly in the small intestine by the sodium-glucose cotransporter. There also are nutrient-independent Na^+ transporters on the luminal surface of absorptive epithelial cells in the small intestine and colon. These include Na^+-H^+ exchange in the jejunum, coupled Na^+-H^+ and $\text{Cl}^--\text{HCO}_3^-$ exchange in the ileum and proximal colon, and Na^+ channels in the distal colon. Short-chain fatty acids (SCFAs) generated by bacterial degradation of unabsorbed carbohydrate and soluble fiber are absorbed with sodium in the colon, further promoting fluid absorption.

The intestine (small intestine and colon) also secretes water and electrolytes into the lumen. Apical chloride channels in crypt epithelial cells open when intracellular levels of cyclic nucleotides or calcium are increased in response to exposure to toxins, hormones, neurotransmitters, and immune mediators. When the apical chloride channels open, Na^+ and water are drawn paracellularly into the lumen. Bicarbonate is secreted in the ileum through a less well understood mechanism. The balance between absorptive and secretory processes in the intestine must be tightly regulated to avoid diarrhea. Net absorption of fluid and electrolytes normally far outweighs net secretion. Diarrhea occurs when the amount of fluid delivered to or secreted by the colon cannot be completely reabsorbed and stool output is more than 200 g per day.

Diarrhea arises from two basic pathophysiologic mechanisms—increased active anion secretion and decreased absorption of water and electrolytes ([Table 99.1](#)). In most diarrheal diseases, both processes are affected, resulting in net secretion, luminal fluid accumulation, and increased stool weight. Increased active anion secretion may have a number of different causes, including exposure to enterotoxins, hormones, neuropeptides, inflammatory mediators, bile salts, laxatives, medications, and insecticides. Examples include excessive stimulation of anion secretion by prosecretory agents such as vasoactive intestinal polypeptide (VIP), 5-hydroxytryptamine (serotonin; 5-HT), tachykinins, and prostaglandins. Prostaglandins are produced by inflammatory cells and stimulate sustained increases in levels of cyclic adenosine monophosphate (cAMP) in intestinal epithelial cells. As a result, anion secretion is stimulated and Na^+ and Cl^- absorption is inhibited, which leads to development of profuse watery diarrhea. Active secretion also is a component of diarrhea associated with celiac disease. In this disease, rapid epithelial cell turnover in the proximal small intestine causes crypt hyperplasia. Because crypt cells are believed to be the main sites of active anion secretion, these events give the celiac mucosa a secretory phenotype that is constantly active because of constant stimulation by inflammatory mediators.

Decreased absorption of water and electrolytes
Inhibited or defective absorption of water and electrolytes
Luminal presence of osmotically active agents
Increased propulsive motor activity that causes decreased contact time
Increased intestinal permeability
Increased secretion of water and electrolytes
Stimulated anion secretion
Secretion from hyperplastic crypts

TABLE 99.1. PATHOPHYSIOLOGIC MECHANISMS OF DIARRHEA

Decreased absorption of water and electrolytes is an equally important cause of diarrhea. It can be caused by several different mechanisms. Besides their effect on active anion secretion, bacterial enterotoxins, such as cholera toxin and *Escherichia coli* heat-stable toxin, and prosecretory agents, such as VIP and 5-HT, activate specific signaling pathways in villous epithelial cells that lead to functional inhibition of Na^+ and Cl^- absorption. Clinical studies with healthy human subjects suggest that secretagogues such as VIP appear to inhibit Na^+ and Cl^- absorption more so than they stimulate active anion secretion. Other mechanisms of decreased absorption of water and electrolytes in the intestine include (a) ingestion of a poorly absorbed, osmotically active solute such as magnesium or lactose by persons with lactase deficiency, (b) decreased absorptive surface area, as caused by mucosal damage, intestinal resection, or enteroenteric fistula, (c) hypermotility that causes decreased contact time between luminal fluid and absorptive mucosal surface area, and (d) impairment of mucosal barrier function (increased permeability) that causes back flux of water and electrolytes into the intestinal lumen.

MECHANISMS OF DIARRHEA

Mechanisms That Cause Specific Diarrheal Diseases

General Mechanisms of Inflammation-induced Diarrhea

Diarrhea is one of the cardinal manifestations of diseases that cause inflammation of the intestinal mucosa, including infection, celiac disease, or inflammatory bowel disease (IBD). Loss of surface area for water and electrolyte absorption due to mucosal damage is the main mechanism. However, diarrhea also occurs when the intestinal epithelium and mucosal architecture are intact but the lamina propria is expanded by infiltration of inflammatory cells. Inflammatory mediators such as prostaglandins, leukotrienes, platelet-activating factor, histamine, and hydrogen peroxide have been postulated on the basis of the results of in vitro studies to cause active intestinal secretion. However, studies performed on chronically inflamed intestine show selective decreases in secretory, absorptive, and barrier functions and increases in antigen-presenting surface molecules. These responses may represent a physiologic adaptation of the epithelium to down-regulate metabolic processes or undergo a phenotypic shift aimed at augmenting intestinal mucosal defense functions. Inflammatory mediators also may induce, directly or through neural activation, hypermotility that causes rapid intestinal transit and reduced contact time between luminal fluid and the absorptive surface area. Changes in splanchnic and mesenteric capillary blood flow and lymphatic drainage also may be contributing factors.

Diarrhea Due to Inflammatory Bowel Disease

Diarrhea associated with IBD is proportional to the extent and degree of mucosal inflammation and can have numerous causes ([Table 99.2](#)). In ulcerative colitis, inflammation and ulceration of the colonic mucosa can cause exudation of protein, blood, and pus into the intestinal lumen that results in bloody diarrhea. If diarrhea is voluminous, however, it is usually caused by decreased absorption of fluid and electrolytes across the diseased mucosa and stimulation of fluid secretion by inflammatory mediators in both the colon and small intestine.

Mucosal injury and loss of digestive and absorptive functions
 Loss of absorptive surface area
 Increased mucosal permeability
 Ulcerations with plasma-like exudate
 Impaired or down-regulated enterocyte transport functions
 Decreased mucosal digestive functions
 Increased net secretion
 Anion secretion stimulated by inflammatory mediators
 Inhibited absorption by inflammatory mediators
 Increased epithelial turnover and immaturity of villous function
 Anion secretion stimulated in the colon by unabsorbed bile salts and fatty acids
 Intestinal dysmotility
 Rapid transit
 Decreased luminal fluid–mucosa contact time
 Anatomic alterations
 Short bowel from surgical resection
 Enterocutaneous fistula
 Paradoxical diarrhea caused by partial intestinal obstruction
 Bacterial overgrowth caused by strictures or an incompetent ileocecal valve
 Pouchitis
 Other potential mechanisms
 Mucosal atrophy from prolonged parenteral hyperalimentation
 Antibiotic-associated colitis (*Clostridium difficile*)
 Identification

TABLE 99.2. PATHOPHYSIOLOGIC MECHANISMS OF DIARRHEA IN INFLAMMATORY BOWEL DISEASE

Along with the inflammation-induced effects on mucosal function and integrity described earlier, persons with Crohn's disease and small-intestinal involvement may have impaired mucosal digestive function caused by increased cellular turnover and a greater proportion of immature villous cells along the crypt-villus axis. Thus the expression of brush border hydrolases such as lactase, sucrase–isomaltase, and aminopeptidases can be markedly decreased, reducing the overall mucosal capability to digest oligosaccharides and oligopeptides. Chronic inflammation also is associated with decreased expression or function of critical nutrient-transporting proteins, such as sodium glucose transporter 1 (SGLT1). The net effect of the presence of incompletely digested and nonabsorbed nutrients is to increase the osmolar load of the colon. When the capacity of the colon to reabsorb water and electrolytes is overwhelmed, diarrhea occurs.

Among persons with Crohn's disease who have inflammation of or have undergone resection of the terminal ileum, malabsorption of bile salts or fat may cause diarrhea. If less than 100 cm of ileum is involved, bile salts but not fats are malabsorbed. Malabsorption of a-hydroxy bile acids, in particular, stimulates colonic secretion and increases mucosal permeability. This results in watery diarrhea, which can be alleviated with the binding resin cholestyramine. When more than 100 cm of ileum is involved, fat malabsorption frequently develops. In this case, the extent of bile-salt wasting exceeds the synthetic capacity of the liver, resulting in negative bile salt balance and depletion of the body's total bile-salt pool. As a result, there are insufficient bile salts in the intestinal lumen for proper micelle formation, which is necessary for fat digestion and absorption. Unabsorbed long-chain fatty acids reach the colon and are hydroxylated by bacteria. In this form they stimulate net fluid secretion, increase mucosal permeability, and induce colonic hypermotility. This results in diarrhea, which may be lessened by a low-fat diet. Administration of cholestyramine in this case may make diarrhea worse by further increasing bile-salt losses and fat malabsorption.

Other causes of diarrhea in Crohn's disease include bacterial overgrowth due to stricture-related stasis or an incompetent ileocecal valve, paradoxical diarrhea from partial intestinal obstruction, and intestinal hypermotility with rapid transit. Some patients with Crohn's disease have diarrhea from complications of altered intestinal anatomy. An enteroenteric fistula may bypass large amounts of small intestine. Extensive resection of the small intestine may cause short-bowel syndrome. In both cases diarrhea is caused mainly by an insufficiency of absorptive surface area. Immediately following resection some patients have hypersecretion of acid caused by hypergastrinemia that may exceed the absorptive capacity of the remaining intestine and cause diarrhea.

Disturbances in SCFA acid metabolism and absorption in the colon of patients with IBD also may contribute to diarrhea. SCFAs have several important functions in the colon. They promote vectorial Na⁺ and water absorption, are a leading source of energy for colonocytes, and have trophic effects on the mucosa. Decreased availability of SCFAs has been associated with the development of diversion colitis and may aggravate ulcerative colitis. Both the availability and absorption of SCFAs may be markedly impaired in ulcerative colitis. For example, the bacterial flora can be altered by medications such as antibiotics, steroids, and immunomodulatory agents that adversely affect the production of SCFAs. This may decrease colonic Na⁺ absorption, make the mucosa unable to withstand injury and heal itself, further compromise fluid absorption, and cause diarrhea.

In some patients with continent reservoir ileostomies, ileorrhea may develop from partial obstruction and overgrowth of anaerobic bacteria caused by fecal stasis. Patients with an ileoanal anastomosis after colectomy and mucosal proctectomy may have diarrhea caused by intestinal spasms and diminished absorptive capacity. This usually resolves 6 to 12 months later, after ileal adaptation (villous hyperplasia and increased nutrient transporters) and enlargement of the ileal reservoir. These patients also can have pouchitis (inflammation of the ileal reservoir) that causes bleeding and diarrhea. Net fluid secretion in this instance is thought to be caused by a decrease in absorptive function related to partial villous atrophy, bacterial overgrowth, and increased mucosal permeability of the pouch. Iatrogenic causes should be considered when a patient with IBD has diarrhea. Antibiotic-associated and medication-induced diarrhea can occur but are often overlooked.

Diarrhea Caused by Transmissible Agents

In most instances of infectious diarrhea, pathogens are acquired through the fecal-oral route. Enteric pathogens ([Table 99.3](#)) fall into three groups—bacterial, viral, and parasitic (see [Chapter 113](#)).

Watery diarrhea
 Enterotoxigenic (*Escherichia coli* toxins, *Vibrio cholerae* toxin)
 Enteroadherent (entero-adherent *E. coli*, cryptosporidia, giardia)
 Food-borne toxins* (*Bacillus cereus*, *Clostridium perfringens* and *C. botulinum*, *Staphylococcus aureus*, *V. parahaemolyticus*, ciguatera, scombroid toxin)
 Invasive (rotavirus, Norwalk agent, *Salmonella* species, enteroinvasive *E. coli*)
 Organisms of the immunocompromised (Mycobacterium avium intracellulare complex, cryptosporidia, *Isospora belli*, microsporidia, cyclospora, HIV enteropathy)
Bloody diarrhea
 Invasive (*Campylobacter jejuni*,[†] *Aeromonas organiana*,[‡] *Yersinia enterocolitica*, *Vibrio parahaemolyticus*,[§] *Vibrio vulnificus*)
 Destructive (*Shigella* organisms,[¶] enterohemorrhagic *E. coli*, *C. difficile*,^{**} *Entamoeba histolytica schistosomiasis*)
 Organisms of the immunocompromised host (cytomegalovirus)

* Symptoms usually occur several hours after the ingestion of contaminated food. Vomiting is common.
 † Diarrhea may be watery or bloody.
 ‡ Some strains both produce an enterotoxin and invade; may initially manifest as watery diarrhea, which then turns bloody.
 §

TABLE 99.3. PATHOGENS THAT CAUSE INFECTIOUS DIARRHEA**Bacterial Pathogens**

Several mechanisms are responsible for diarrhea caused by bacterial pathogens. *Vibrio cholerae* and *E. coli* (enterotoxigenic *E. coli* [ETEC]) colonize the intestine and produce enterotoxins that disturb water and electrolyte transport in the absence of mucosal damage. Cholera toxin and the heat-labile enterotoxin of *E. coli* bind to the Gm1 ganglioside of the luminal surface of enterocytes, gain entry into the cell, activate adenylate cyclase, and increase intracellular cAMP levels. This results in direct stimulation of active Cl⁻ secretion and inhibition of nutrient-independent Na⁺ and Cl⁻ absorption in epithelial cells. These enterotoxins also indirectly stimulate secretion by binding to receptors on enterochromaffin cells that release hormones that activate the enteric nervous system. Heat-stable *E. coli* toxin (STa) also causes secretory diarrhea and is a frequent cause of traveler's diarrhea. This agent binds to intestinal guanylate cyclase (GCC) (the receptor for the gastrointestinal hormone guanylin) present in the brush border membrane of enterocytes. Activation by STa increases intracellular cyclic guanosine monophosphate (cGMP), which like cAMP stimulates anion secretion and inhibits Na⁺ and Cl⁻ absorption.

These enterotoxins cause high-volume diarrhea without fecal leukocytes or blood. Loss of fluid and electrolytes into the intestinal lumen may cause hypovolemia, acidosis, and decreased perfusion to vital organs—the main cause of morbidity and mortality. Because nutrient-dependent sodium cotransporters are not affected by these toxins, oral rehydration solutions containing Na⁺ and glucose or glucose polymers are very effective in promoting intestinal fluid absorption and preventing death.

Oral rehydration solutions that contain glucose polymers, such as rice-based solutions, lessen diarrhea. For the same osmotic load, glucose polymers are digested by amylase and hydrolases at the brush border membrane into many more glucose monomers than are present in standard glucose-containing solutions. Because absorption of glucose monomers occurs immediately upon digestion, this results in absorption of both the fluid ingested and some of the enteric secretions. The small-intestinal epithelium must be relatively intact for polymeric solutions to be beneficial. If not, the polymers are digested in the lumen but not absorbed; the result is an increase in luminal osmols and worsening diarrhea.

Campylobacter, *Salmonella*, *Shigella*, and enteroinvasive *E. coli* (EIEC) are invasive organisms that injure the intestinal mucosa and cause diarrhea with fecal leukocytes and often blood. *Campylobacter* is the most common species of these organisms on a worldwide basis. The degree of mucosal injury, inflammation, and exudate depends on the virulence of the pathogen and on host susceptibility. Although most of these diseases are self-limited, relapses can occur among patients with *Campylobacter* infection. Enterohemorrhagic *E. coli* (EHEC) infection, as with *E. coli* O157:H7, is associated with ingestion of undercooked meats and raw milk. The organism elaborates Shiga-like cytotoxins that cause bloody, but noninflammatory diarrhea (absence of fecal leukocytes). In a small number of cases, EHEC and *Shigella* organisms can cause hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura.

Enteroadherent *E. coli* (EAEC) organisms cause diarrhea through a mechanism that is not fully understood. As implied by the name, these organisms are not invasive and do not stimulate appreciable mucosal inflammation. They adhere to the luminal surface of enterocytes and disrupt the glycocalyx and cause effacement of the microvillous membrane, disorganization of the terminal web, crypt hyperplasia, and villous atrophy. These changes decrease brush border hydrolase activity, and the decrease may cause substantial nutrient malabsorption and osmotic diarrhea. EAEC infection is a cause of diarrhea in infancy.

A number of bacterial pathogens contaminate foods and elaborate toxins. *Staphylococcus aureus* infection is one of the most common causes of food poisoning. The organisms elaborate several toxins that cause profuse vomiting and stimulate net intestinal fluid secretion. Symptoms may occur within several hours of ingestion of preformed toxin. Some strains of *Bacillus cereus* that contaminate fried rice produce an illness characterized by nausea and vomiting. Other *Bacillus* species that contaminate meats, baked goods, and salads cause abdominal cramps and diarrhea. *Clostridium perfringens* multiplies in unrefrigerated foods and when ingested binds to the intestinal mucosa and elaborates an enterotoxin that stimulates net fluid secretion and causes motility abnormalities. Crampy abdominal pain is therefore a prominent feature that differentiates this illness from diarrhea caused by other enterotoxigenic bacteria. *Vibrio parahaemolyticus* infection is associated with food poisoning from raw or spoiled shellfish. It produces several enterotoxins, some of which stimulate net intestinal fluid secretion and others that are cytotoxic and proinflammatory. Persons with this disorder have watery diarrhea or dysentery.

Viral Pathogens

Infection with rotaviruses and Norwalk virus causes acute, self-limited diarrhea. Rotavirus infection is a leading cause of diarrhea among children younger than 2 years. Norwalk virus primarily infects older children and adults. These viruses injure the small-intestinal mucosa and cause villous blunting, shortening of microvilli, and mononuclear infiltration of the mucosa. Decreased brush border hydrolase activity is common and may seriously impair nutrient absorption. Diarrhea is caused by decreased fluid absorption related to loss of villous surface area and an increase in luminal osmols. A rotavirus enterotoxin NSP4 has been identified that stimulates intestinal fluid secretion by a calcium-dependent signaling pathway and may contribute to the development of diarrhea. Rotavirus also stimulates intestinal fluid secretion by activation of the enteric nervous system.

Parasitic Pathogens

Chronic diarrheal diseases occasionally are caused by intestinal parasites such as helminths (cestodes, nematodes, trematodes) and protozoa, particularly among persons from areas where these organisms may be endemic or public sanitation is poor. Diarrhea is not always a manifestation of helminthic infection. Most cestodes, for example, cause few gastrointestinal symptoms even when worm loads are large. Helminthic organisms that colonize the small intestine are more likely to produce diarrhea and nutrient malabsorption and usually cause eosinophilia. Of the intestinal nematodes, *Capillaria philippinensis*, *Ascaris lumbricoides*, *Trichinella spiralis*, *Ancylostoma* (hookworms), and *Strongyloides stercoralis* may cause diarrhea. Trematodes such as *Schistosoma* species deposit eggs in the intestinal mesenteric venules and incite a host inflammatory response that may cause diarrhea.

Protozoa that cause diarrhea include *Giardia lamblia*, *Cryptosporidium* species, and *Amoeba* species. *Giardia lamblia* is a major cause of waterborne outbreaks of diarrhea and traveler's diarrhea. Person-to-person transmission also occurs, particularly in day care centers, in guardian institutions, and among homosexuals. After ingestion of cysts, trophozoites develop and multiply in the small intestine, where they adhere to the mucosal surface and cause effacement of the brush border microvillous membrane, partial villous atrophy, and reduction of brush border hydrolase activity. Diarrhea is caused by impaired fluid absorption. Malabsorption of carbohydrate and peptides can contribute to the development of diarrhea.

Cryptosporidium infection is an important cause of waterborne diarrheal illness among humans and domestic animals. Transmission also can occur by the fecal-oral route from infected animals and persons. *Cryptosporidium* infection usually produces acute, often severe, crampy, watery diarrhea that is self-limited and lasts several days to weeks. The organisms attach to small-intestinal epithelial cells, but the mechanism by which they cause diarrhea is not well understood.

Entamoeba histolytica is transmitted in contaminated water and by the fecal-oral route. *E. histolytica* cysts multiply in the small intestine and mature into trophozoites, which penetrate the mucosa of the large intestine. Severe mucosal inflammation and ulceration develop from the acute inflammatory response of the host and the innate cytotoxic properties of the organisms. The histologic lesion of amebic infection is characteristically a flask-shaped ulcer that features a small mucosal ulcer and a large submucosal area of tissue necrosis. Chronic complications of amebic infection involve most commonly the liver and lung. A hepatic abscess (typically single and in the posterior aspect of the right lobe) when aspirated yields a dark, odorless, and thick necrotic material that resembles anchovy paste. Pulmonary amebic abscesses or bronchopleural fistulas develop in some patients with hepatic amebiasis; they are caused by amebic emboli or contiguous spread.

Diarrhea Caused by Opportunistic Pathogens or Developing in a Susceptible Host**Antibiotic-associated Colitis**

Antibiotic-associated colitis is caused by *Clostridium difficile*, a common nosocomial pathogen in health care and long-term care facilities. The disease is caused by poor hand washing by health care workers who spread the organism and alteration of intestinal flora by antibiotics to favor growth of *C. difficile*. Although any antibiotic can cause antibiotic-associated colitis, clindamycin, cephalosporins, and ampicillin are most commonly involved. Diarrhea is caused by two exotoxins. Toxin A is a

potent stimulator of intestinal fluid secretion, increases intestinal permeability, and activates a profound inflammatory response in the lamina propria. Toxin B is cytotoxic and causes epithelial and mesenchymal cell destruction.

Diarrheal Pathogens in Immunocompromised Hosts

Immunocompromised hosts are vulnerable to common diarrheal pathogens as well as opportunistic pathogens. *Giardia lamblia* infection is an important cause of diarrhea among persons with AIDS and common variable hypogammaglobulinemia. Unusual pathogens such as *Legionella* organisms and *Candida albicans* also can cause diarrhea among immunocompromised hosts. Opportunistic pathogens including *Cryptosporidium* species, *Isospora belli*, *Mycobacterium avium-intracellulare* complex, Microsporidia, and cytomegalovirus (CMV) are important causes of diarrhea among patients with AIDS. CMV infection can cause profuse watery diarrhea or bloody diarrhea due to mucosal inflammation and ulceration. *Cryptosporidium* infection causes intractable watery diarrhea among persons with AIDS. There is no effective treatment.

Other Diseases

Tropical sprue and Whipple's disease cause intestinal inflammation, villous blunting, and crypt hyperplasia similar to celiac disease. The process causes decreased fluid absorption and diarrhea. Tropical sprue occurs among persons who live in or travel to the tropics. It is associated with overgrowth of predominantly coliform bacteria in the small intestine. Whipple's disease is an infectious disease of the small intestine caused by the organism *Tropheryma whippelii*. Those with the *HLA B27* genotype may be more susceptible to this disease.

Noninfectious Diarrheal Diseases Associated with an Abnormal Mucosa

Diseases of the intestine such as IBD, celiac disease, microscopic colitis, eosinophilic and allergic gastroenteritis, and acute radiation enteritis are associated with inflammation of and usually injury to the intestinal mucosa. These diseases cause diarrhea by several different mechanisms, including loss of surface area, nutrient malabsorption, increased intestinal permeability, and stimulation of secretion by inflammatory mediators.

In microscopic colitis (collagenous and lymphocytic) the endoscopic appearance of the colon is normal (see [Chapter 114](#)). Diagnosis can be made only by means of colonic biopsy, which characteristically shows normal crypt architecture but increased numbers of intraepithelial lymphocytes and of lymphocytes and plasma cells in the lamina propria. Collagenous colitis is differentiated from lymphocytic colitis by the additional presence of a thickened subepithelial collagen layer. Microscopic colitis causes watery and sometimes high-volume diarrhea. It occurs predominantly among older women and is associated with celiac disease, autoimmune disease, and arthritis. In most cases, mucosal inflammation is diffuse, causing pancolitis. The diagnosis is made from multiple biopsy specimens obtained at flexible colonoscopy.

Diarrhea is a frequent complication of bone marrow transplantation. Soon after transplantation diarrhea usually is caused by the toxic effects of cytoreductive therapy on rapidly dividing cells in the intestinal epithelium. Graft versus host disease (GVHD) is another cause of diarrhea among these patients. In mild cases, the intestinal mucosa appears endoscopically normal, but biopsy specimens obtained from the stomach, small intestine, colon, or rectum contain apoptosis of crypt or gastric gland cells. In more severe cases, exploding crypts (crypts filled with cell debris), chronic inflammation, and villous flattening are found, and they account for watery diarrhea. In the most severe cases, the intestinal epithelium is denuded with exudation of protein, pus, and blood; the result is bloody diarrhea. Chronic GVHD occurs more than 3 months after transplantation and has clinical and radiologic features similar to those of visceral scleroderma. These patients often have diarrhea and nutrient malabsorption.

Noninfectious Diarrheal Diseases Associated with a Normal Mucosa

Diarrhea associated with a normal intestinal mucosa is most likely functional. Functional diarrhea can be caused by (a) the presence of osmotically active substances in the lumen, (b) a decrease in contact time for fluid absorption, as in rapid intestinal transit, (c) defects in specific ion or nutrient transporters, or (d) defects in the regulation of intestinal water and electrolytes.

Osmotic Diarrhea

The presence of poorly absorbed solute in the intestinal lumen can cause diarrhea and limit the ability of the intestine to efficiently absorb water and electrolytes. Both exogenous ([Table 99.4](#)) and endogenous factors can cause osmotic diarrhea. Magnesium-containing antacids, bowel lavage solutions (polyethylene glycol), and sorbitol (chewing gum, elixir preparations) represent exogenous sources of luminal osmolytes. Endogenous causes include small-intestinal conditions in which nutrient digestive or absorptive capability is impaired and nutrient, water, and electrolyte malabsorption and diarrhea occur; examples are primary or acquired lactase deficiency and rare defects in sugar transport proteins. Lactose intolerance due to acquired lactase deficiency is the most common endogenous cause of osmotic diarrhea. Its prevalence is highest among Asians, Native Americans, and African Americans. Symptoms due to lactose malabsorption depend on the amount ingested. Unabsorbed lactose is metabolized by colonic bacteria to CO_2 , H_2 , and SCFAs. Ingestion of a small amount of lactose may cause gas and bloating but not diarrhea. Diarrhea does not occur because SCFAs are absorbed along with sodium and water in the colon. However, ingestion of larger amounts of lactose overwhelms the capacity of the colon to absorb SCFAs and results in acidic osmotic diarrhea.

TABLE 99.4. MEDICATIONS AND DIETARY PRODUCTS ASSOCIATED WITH DIARRHEA

Decreased Contact Time for Fluid Absorption

Rapid intestinal transit occurs in most cases of diarrhea. It is caused by reflexive propulsive activity in response to an increase in luminal volume or the effect of the disease on intestinal smooth muscle. In only rare instances is a primary motility disorder thought to cause diarrhea. Some children with toddler's diarrhea and adults with painless diarrhea (irritable bowel syndrome [IBS] variant) may have continuous propulsive migrating motor complexes that are not halted with eating. This causes rapid intestinal transit, wasting of carbohydrates in the colon, and an osmotic diarrhea. Persons with IBS may have diarrhea of other causes, such as microscopic colitis, celiac disease, or laxative abuse. Many persons with IBS do not have true diarrhea but rather frequent, loose stools of normal weight.

Congenital Diarrhea

Infants with rare congenital ion transport disorders have watery diarrhea at birth. Congenital chloride diarrhea is associated with metabolic alkalosis and chloride-rich, acidic stools. The genetic defect resides in the down-regulated in adenoma (*DRA*) gene, which codes for an anion exchanger normally expressed in the ileum and colon. The defect impairs $\text{Cl}^-/\text{HCO}_3^-$ or Cl^-/OH^- exchange in the intestine. Congenital sodium diarrhea is associated with metabolic acidosis and sodium-rich, alkaline stools. These infants appear to have defective Na^+/H^+ exchange in jejunal brush border membranes. The genetic defect has not yet been identified. In both diseases, patients need aggressive oral fluid replacement therapy for life. In microvillous inclusion disease, brush border membranes do not reach the luminal surface (or are

invaginated from the apical surface) of villous epithelial cells and are found intracellularly or misplaced in the basolateral membrane. The result is a devastating loss of surface area for nutrient and fluid absorption and the need for lifelong parenteral nutrition.

Defective Regulation of Intestinal Water and Electrolytes

The intestine normally is maintained in a net absorptive state by the sympathetic nervous system. However, when extrinsic adrenergic nerves are cut, as occurs during transplantation of the small intestine, diarrhea develops but resolves. This phenomenon suggests local factors in the intestine also regulate water and electrolyte absorption. Enteric nerves, endocrine cells, immune cells, and mesenchymal cells in the intestine all are capable of releasing proabsorptive and prosecretory substances that may influence water and electrolyte transport. In rare instances, tumors produce one or more of these prosecretory substances and cause secretory diarrhea. These patients usually have high-volume, watery diarrhea that does not resolve with fasting. Examples include tumors that produce VIP (VIPoma, watery diarrhea, hypokalemia, achlorhydria syndrome or pancreatic cholera), 5-HT, and bradykinin (carcinoid syndrome), gastrin (gastrinoma or Zollinger–Ellison syndrome), and calcitonin (medullary carcinoma of the thyroid). Nutrient malabsorption also may occur among persons with gastrinoma due to denaturation of pancreatic enzymes and precipitation of bile salts by the large acid load presented to the duodenum.

Defective regulation of intestinal water and electrolyte transport also occurs in diabetic diarrhea. Persons with diabetes often have severe watery diarrhea (more than 500 g per day), dehydration, and nocturnal incontinence. Among a subset of persons with diabetes, autonomic neuropathy appears to be a contributing factor because treatment with the α_2 -adrenergic agonist clonidine lessens the diarrhea. This diagnosis requires clinical signs of autonomic neuropathy and the exclusion of fecal incontinence and other causes of diarrhea, such as bacterial overgrowth.

Other Diarrheal Diseases

Nosocomial diarrheal diseases are caused by iatrogenic factors such as medication (e.g., antibiotics or sorbitol-containing elixirs), tube feeding, and *C. difficile* infection related to poor hand washing. They most commonly occur in hospitals, nursing homes, and guardian institutions. Persons who reside in institutions and nursing homes also are susceptible to food poisoning and infectious diseases that are transmitted by the fecal-oral route.

Factitious chronic diarrhea is caused by the secretive use of laxatives or diuretics that either stimulate anion secretion or cause osmotic diarrhea ([Table 99.4](#)). In some cases of chronic diarrhea, no cause can be found despite an extensive evaluation. When referred to tertiary care centers, some patients are found to have fecal incontinence, microscopic colitis, and bile-acid induced diarrhea. For other patients no cause of diarrhea is found (chronic idiopathic diarrhea). These persons should be treated symptomatically. For many, the diarrhea resolves spontaneously.

HISTORY

The following questions should be answered when any patient comes to medical attention with diarrhea: Is it truly diarrhea? Is the diarrhea acute (less than 2 to 3 weeks' duration) or chronic (more than 4 weeks' duration)? What are the other symptoms? What are the circumstances? Routine questions should be asked about stool texture and frequency, blood in the stool, fever, vomiting, abdominal pain, weight loss, travel, diet, drug use, alcohol, abdominal operations, chemotherapy, radiation therapy, incontinence, immune status, and underlying disease.

To determine whether a patient truly has diarrhea, questions should be asked about consistency and frequency of stools relative to baseline bowel habits. Persons with IBS or fecal incontinence often have frequent, small stools of normal weight rather than diarrhea. Diarrhea that is of new onset, occurs daily or at night, or is associated with metabolic disturbances usually is caused by organic disease.

Acute diarrhea usually is infectious or related to use of new medications. Chronic diarrhea can be caused by a vast number of different diseases. Associated symptoms provide clues to the cause of diarrhea. Low-grade fever occurs with viral or toxigenic diarrhea, whereas high fever occurs with invasive bacterial infections, amebiasis, CMV colitis, or IBD. Fainting, dizziness on standing, or weakness suggests high-volume diarrhea. Weight loss with acute diarrhea indicates fluid loss, whereas with chronic diarrhea it usually indicates nutrient malabsorption. Nausea and vomiting are most often found with viral infections or food poisoning. Abdominal cramps may be caused by infection but can be caused by carbohydrate malabsorption. Severe abdominal pain occurs with invasive or cytopathic bacterial infection and intestinal ischemia. Blood in the stool indicates an infectious, inflammatory, or ischemic process. Associated neurologic symptoms occur with botulism and exposure to marine toxins (scombroid, ciguatera). Diarrhea sometimes occurs with a systemic illness such as hepatitis, legionnaires' disease, Rocky Mountain spotted fever, and toxic shock syndrome.

The setting in which diarrhea occurs provides important clues as to causation. Recent travel, restaurant dining, or ingestion of foods that were imported, poorly cooked, or left out at room temperature may point to an infectious cause of diarrhea. Diarrhea may occur with new use of medications, over-the-counter drugs, or herbal products or with changes in diet. Diarrhea due to *C. difficile* infection is common among patients in hospitals and nursing homes and those with a history of antibiotic use. Immunocompromised persons may have diarrhea caused by common organisms or those unique to the impaired host. Among the elderly and those predisposed to thrombosis, diarrhea with pain out of proportion to physical findings suggests intestinal ischemia.

PHYSICAL EXAMINATION

Attention is paid to vital signs, volume status in particular, and the findings of the abdominal and rectal examinations. High fever suggests the presence of invasive organisms. Hyperventilation may be a sign of metabolic acidosis caused by bicarbonate loss in the stool. Orthostatic vital signs (a drop in blood pressure greater than 10 mm Hg and a rise in pulse of more than 20 beats/min on standing) are reliable indicators of volume depletion except among persons taking cardiac medications, such as β -blockers or calcium channel blockers, and elderly persons with vascular disease. Skin tenting, dry mucous membranes, resting tachycardia, hypotension, sunken eyeballs, and a scaphoid abdomen are all signs of severe dehydration due to voluminous diarrhea.

Patients with chronic diarrhea are evaluated for signs of malnutrition and vitamin and mineral deficiency caused by malabsorption. These signs include weight loss, muscle wasting, tetany, oral and skin lesions, peripheral neuropathy, ataxia, and edema. Edema may indicate protein-losing enteropathy.

The abdomen is examined for distention, bowel sounds, tenderness, and masses. A stool swab for culture, when necessary, is obtained before the rectal examination because lubricants contain bacteriostatic agents that can interfere with bacterial growth. The rectum is examined for stool texture, masses, and sphincter tone. Rectal villous adenoma and carcinoid tumor may be detected during the examination. Most persons with diarrhea do not have solid stool in the rectum except for those with diarrhea associated with fecal impaction. Stool should be tested for occult blood. Persons with high-volume diarrhea are often incontinent of stool. Among those with cholera, fluid with mucous flecks (rice-water stools) pours out of the rectum.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

STOOL TESTS

Stool Tests for Intestinal Inflammation

Stool studies for the presence of intestinal inflammation are readily performed but lack specificity. Fecal lactoferrin (an iron-binding glycoprotein released from leukocytes during an inflammatory reaction) is the most sensitive (about 90%) but least specific test in supporting a diagnosis of invasive bacterial enteritis. Microscopic examination for fecal leukocytes is the least sensitive test (about 50%) but has the greatest specificity. A negative result of a fecal occult blood test has the same negative predictive value for an invasive bacterial enteritis as does a negative fecal lactoferrin test.

Stool Culture

Stool culture results are positive in only 40% to 60% of cases of dysentery. Special culture techniques are needed for the diagnosis of *Yersinia*, *Campylobacter*, and *V. cholerae* infections. Growth of colonies on sorbitol–MacConkey agar indicates EHEC infection, but confirmation by means of vero cell toxin testing or strain-specific serotyping is critical for diagnosis.

Stool for Ova and Parasites

Microscopic analysis of stool for parasites is performed before any barium studies, because barium interferes with depiction of parasites for weeks. In ideal circumstances, one stool test for *Giardia* antigen should be performed in cases of chronic diarrhea because with chronic infection *Giardia* organisms adhere to the small-intestinal mucosa and few are found in the stool. *Cryptosporidium* organisms are not detected by means of routine microscopic examination of the stool. Special staining is needed for detection.

Stool for *Clostridium difficile* Toxin

The test for toxin B (cytotoxin) is performed by means of adding a sterile stool filtrate to human fibroblasts grown in culture and observing for cell death within 2 to 3 days. A more rapid test that has about the same sensitivity is an enzyme immunoassay to detect toxin A. The sensitivity is about 90% when three stool samples are tested.

Stool Sudan Stain for Fat

Sudan staining is a qualitative test for fat in the stool that is valid only if the patient is eating a high-fat diet. The test is 90% sensitive with fat malabsorption of more than 10 g per day. The result sometimes is positive in the presence of high-volume secretory diarrhea, in which as much as 14 g per day of fat can be passed in the stool.

Stool Alkalinization and Cathartic Screen

Addition of NaOH or KOH turns stool pink when phenolphthalein-containing laxatives are present. The test is easy to perform, and a positive result leads to an inexpensive and rapid diagnosis. If the result is negative and laxative abuse is highly likely, stool and urine are tested for anthraquinones, docusate salts, magnesium, SO_4 , PO_4 , and diuretics. Although stool magnesium output can increase to 50 mmol per liter with diarrhea, levels higher than this suggest laxative abuse.

Stool Electrolytes

Stool electrolyte measurements are useful in differentiating secretory diarrhea from osmotic diarrhea (Table 99.5). Secretory diarrhea is characterized by high stool sodium and bicarbonate concentrations and the absence of a stool osmotic gap. Osmotic diarrhea is characterized by a low stool sodium concentration and the presence of a stool osmotic gap more than 100 mOsm per kilogram H_2O . Direct measurement of stool osmolality may be falsely elevated when stool specimens are not processed immediately; the delay allows colonic bacteria to generate large amounts of SCFAs from unabsorbed carbohydrates and soluble fibers. This occurs even in stool samples that are refrigerated. To avoid this problem, plasma osmolality rather than stool osmolality is used in the following calculation:

Plasma osmolality	=	Stool osmotic gap
or		
$290 \text{ mOsm/kg H}_2\text{O} - 2([\text{Na} + \text{K}] \text{ mmol/L})$		
Stool $[\text{Na}] > 50 \text{ mmol/L}$	=	Secretory diarrhea or osmotic diarrhea
and		caused by Na_2SO_4 or Na_2PO_4 ingestion?
Osmotic gap $< 50 \text{ mOsm/kg H}_2\text{O}$		
Stool $[\text{Na}] < 40 \text{ mmol/L}$	=	Osmotic diarrhea; if stool volume does not
and		return to normal with fasting, suspect
Osmotic gap $> 100 \text{ mOsm/kg H}_2\text{O}$		symptomatic Mg ingestion?
Stool $[\text{Na}] > 100 \text{ mmol/L}$		
and		
Stool osmolality $> 375\text{--}400 \text{ mOsm/kg H}_2\text{O}$	=	Suspect contamination of specimen with
		deionized water
Stool osmolality $> 290\text{--}350 \text{ mOsm/kg H}_2\text{O}$	=	Suspect contamination of specimen with
		distilled water or water

* Normal stool SO_4 and PO_4 are usually $< 10 \text{ mmol/L}$; exact value not established. In Na_2SO_4 or Na_2PO_4 -induced diarrhea, stool Cl⁻ concentrations are $< 20 \text{ mmol/L}$.
† Normal stool Mg is negligible (but is 10–15 mmol/L during fasting; the concentration should be $< 10 \text{ mmol/L}$ in Mg-induced diarrhea; stool Mg²⁺ concentration is usually < 50 and often $< 100 \text{ mmol/L}$.
‡ Source: Powell 1997. Approach to the patient with diarrhea. In: Kamada T, ed. The book of gastroenterology. 2nd ed. Philadelphia: JB Lippincott, 1998, with permission.

TABLE 99.5. STOOL OSMOTIC GAP AS A GUIDE TO THE PATHOPHYSIOLOGIC PROCESS AND DIAGNOSIS OF DIARRHEA

$$\text{Stool osmotic gap} = 290 \text{ mOsm/kg} - 2 \times (\text{stool } [\text{Na}] + [\text{K}])$$

The normal gap is usually less than 50 mOsm/kg H_2O , and plasma osmolality equals stool osmolality. When stool electrolyte concentrations are far less than those in plasma, surreptitious addition of water to the specimen must be considered.

Stool pH

A low stool pH (less than 7.0) can indicate carbohydrate malabsorption, due to the presence of SCFAs, or gastrinoma, due to hypersecretion of acid. This test is most helpful in the care of infants and children.

Fasting Stool Volume

A 24- to 48-hour measurement of stool volume while the patient is fasting provides useful information about whether diarrhea is functional (less than 250 mL per day), osmotic (low volume), or secretory (high volume more than 1 L per day). Intravenous fluids are administered during the fast.

Quantitative Stool Fat Test

A 72-hour stool collection for fat while the patient consumes a high-fat diet (70 to 100 g fat per day) is performed when (a) malabsorption is highly likely and the qualitative test result for stool fat is negative, (b) a qualitative test result for stool fat is positive and it is believed the positive result is caused by high-volume diarrhea, and (c) diarrhea is of undetermined origin. If the test result is positive, specific diagnostic tests are performed on the basis of the likelihood of pancreatic disease, bacterial overgrowth, mucosal disease, or lymphatic obstruction.

FLEXIBLE SIGMOIDOSCOPY

Examination with a flexible sigmoidoscope performed without intestinal preparation is useful in the detection of pseudomembranes, mucosal inflammation, and melanosis coli. Even if the mucosa appears normal, biopsy specimens are obtained to look for microscopic colitis, infiltrative disease, certain infectious diseases, and laxative abuse.

BLOOD HORMONE LEVELS

For patients with high-volume secretory diarrhea of undetermined origin, measurement of serum levels of gastrin, VIP, somatostatin, cortisol, neurokinins, and calcitonin may be considered. When carcinoid syndrome is suspected, serotonin and urine 5-hydroxyindoleacetic acid are measured.

ACUTE DIARRHEA

DIFFERENTIAL DIAGNOSIS

Normal Hosts

Acute diarrhea (less than 2 to 3 weeks' duration) may be caused by infection or ingested toxins, drugs, or dietary products. The most common cause is infection caused by viruses and food-borne toxins (Table 99.3). Viral diarrhea usually occurs among children, their family members, and day care workers. Diarrhea caused by food poisoning usually occurs within several hours of the meal. Associated symptoms include low-grade fever, vomiting, and abdominal cramps.

Pathogens that cause traveler's diarrhea usually are acquired through the fecal-oral route. They include enterotoxigenic bacteria (*E. coli*, *V. cholerae*), which cause high-volume watery diarrhea without blood or pus, and other organisms such as *Campylobacter*, *Shigella*, *Salmonella*, viruses, and parasites. Giardiasis is the most common parasitic infection in the United States. It is contracted through ingestion of contaminated water. Sporadic waterborne outbreaks of cryptosporidiosis also have occurred on farms and in cities.

Most acute infectious diarrheal diseases are self-limited, but some may persist for more than 3 or 4 weeks. In some instances the long duration may be caused by secondary lactase deficiency, and diarrhea improves with a lactose-free diet. Outbreaks of diarrhea lasting as long as a year occurred in Brainerd, Minnesota, and other rural areas. They were associated with ingestion of raw milk. No organism has yet been identified.

Bloody stool has a limited differential diagnosis that includes invasive bacterial enteritis (*Campylobacter*, *Shigella*, *Yersinia*), *E. histolytica*, cytopathic toxins (*C. difficile*, *E. coli*, or Shiga toxin), IBD, and intestinal ischemia. Persons with infection by invasive or cytopathic organisms often have severe abdominal pain and fever. Systemic manifestations of enteric bacterial infection include arthritis, urethritis and conjunctivitis (*Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*), and hemolytic-uremic syndrome (EHEC, *Shigella*).

A number of drugs and dietary products cause acute diarrhea (Table 99.4). Antibiotics are the most common cause. About 25% of antibiotic-associated diarrhea is caused by *C. difficile* toxin. *C. difficile* infection can cause watery or bloody diarrhea with fever and abdominal pain. In other cases of antibiotic-associated diarrhea the cause is unknown. Other drugs that commonly cause diarrhea include antacids, prokinetic agents (cisapride, metoclopramide), prostaglandins, and drug elixirs that contain sorbitol. Diarrhea caused by drugs usually is watery and without associated symptoms. Cholinergic poisoning with organophosphate insecticides may occur among migrant farmers, landscapers, or those who ingest medicinal teas. The classic presentation is diarrhea, severe abdominal cramps, copious salivation, and pulmonary edema. Dietary substances that cause diarrhea include lactose (among those with lactase deficiency), sorbitol (elixirs, dietetic candies, gum), fructose (pears, prunes, apple juice), and Olestra (a nondigestible fat substitute).

Immunocompromised Hosts

Although many new anti-retroviral drugs, especially protease inhibitors, cause diarrhea, the development of these compounds has resulted in a marked decrease in infectious diarrhea among persons with HIV infection in developed countries (see Chapter 114). Nevertheless, persons with HIV disease and a CD4 cell count less than 150 cells per cubic millimeter and other immunocompromised hosts are still at risk of diarrhea caused by common infectious organisms and by CMV, *M. avium-intracellulare* complex, *Cryptosporidium* organisms, *I. belli*, *Microspora*, and *Cyclospora* organisms.

Diarrhea is common among recipients of bone marrow and intestinal transplants. Soon after bone marrow transplantation, diarrhea usually is caused by cytoreductive therapy (Table 99.4). Twenty to 80 days after transplantation, diarrhea usually is caused by GVHD or infection. Persons with GVHD also may have a skin rash, jaundice, buccal mucositis, and abdominal pain, which help secure the diagnosis. Endoscopic intestinal biopsy, however, often is necessary to differentiate GVHD from infection. Immediately after small-intestinal transplantation, diarrhea appears to be caused by disruption of adrenergic neurons. Later it is caused by rejection, GVHD, or infection. A patient with neutropenia who has a fever, diarrhea, and abdominal pain may have neutropenic colitis (typhlitis), which can be fatal unless colonic resection is performed.

Patients with Cancer

Diarrhea is common among patients who undergo chemotherapy (Table 99.4) or radiation therapy to the abdomen. It usually is caused by the toxic effects of chemotherapy or radiation therapy on the gastrointestinal tract. Interleukin-2, 5-fluorouracil plus leucovorin, and irinotecan (CPT-11) are the chemotherapeutic agents that most commonly cause diarrhea. Almost all patients have more frequent bowel movements after abdominal or pelvic radiation. Diarrhea also can occur many years after radiation therapy as the result of ischemia, enteroenteric fistula, or bacterial overgrowth. Radiation enteritis proctitis also can cause bloody diarrhea owing to ischemia.

Persons in Hospitals, Mental Health Facilities, or Nursing Homes

Diarrhea occurs among 30% to 50% of patients in intensive care units and can be caused by antibiotics, other drugs, fecal impaction, the underlying disease, or tube feeding. Among hospitalized patients *C. difficile* infection is the most common cause of diarrhea, whereas *Salmonella*, *Shigella*, or parasitic infection is extremely rare, especially in tertiary care hospitals. Among critically ill persons, increased mucosal permeability, low serum albumin levels, and dysmotility contribute to decreased intestinal fluid absorption. Tube feeding with formulas low in sodium content may contribute to diarrhea in this setting. Among nursing home residents, viral infections are the most common cause of diarrhea. About one-fourth of residents have *C. difficile* toxin in their stool. Sporadic outbreaks of *Salmonella* and EHEC infection also occur. In guardian institutions, patients are at increased risk for diarrhea caused by infection by *Shigella* species, *Giardia* species, *E. histolytica* and helminths.

EVALUATION

In cases of uncomplicated acute diarrhea among normal hosts (Fig. 99.1), no evaluation is necessary. Stool specimens are obtained for examination for ova and parasites only when the history suggests exposure to parasites or when diarrhea does not resolve. When diarrhea is associated with fever, a screening stool test (see earlier) is performed to differentiate inflammatory from noninflammatory diarrhea. A stool occult blood test is the easiest to perform, and the results are immediately available. If invasive bacterial enteritis is highly likely, stool culture is performed even if stool screening results are negative. If a patient has bloody diarrhea, a stool culture is performed; the microbiology laboratory should be notified about suspicious organisms for best diagnostic yield. If the culture result is negative, colonoscopy and biopsy are performed. IBD sometimes can be differentiated histologically from infectious enteritis and intestinal ischemia on the basis of the presence of irregular, branching crypts, a feature associated with chronic inflammation.

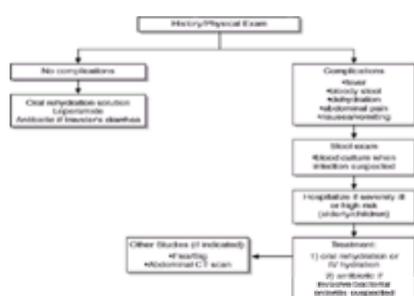

FIGURE 99.1. Approach to normal hosts with acute diarrhea.

Among immunocompromised hosts with diarrhea, stool is obtained for culture, examination for parasites, and detection of *C. difficile* toxin (Fig. 99.2). If fever is present, blood cultures are obtained for bacteria, *M. avium-intracellulare* complex in particular, and fungus. When the patient has a fever, blood is present in the stool, and initial stool test results are negative, full colonoscopy should be performed with a stool aspirate for culture, *C. difficile* toxin, parasites, and colonic biopsy

specimens. If the stool is watery, upper endoscopy with duodenal aspirate and biopsy is performed.

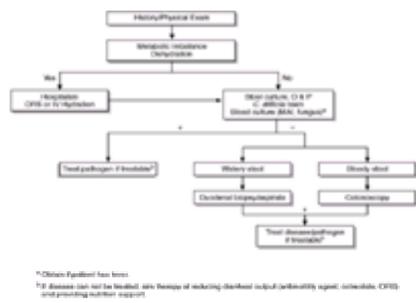

FIGURE 99.2. Approach to the immunocompromised host with diarrhea.

When a patient in the hospital experiences diarrhea, *C. difficile* infection must be excluded and medications scrutinized for those that may cause diarrhea (Fig. 99.3). For patients with blood in the stool and negative results of toxin tests, flexible sigmoidoscopy may be helpful for diagnosis if a pseudomembrane is present. Obtaining a stool sample for culture and parasite examination is not recommended when diarrhea develops in the hospital because these infections are extremely rare.

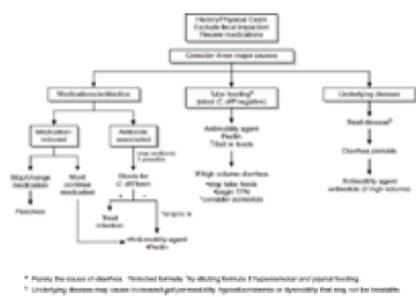

FIGURE 99.3. Approach to the hospitalized/ICU patient with diarrhea.

CHRONIC DIARRHEA

DIFFERENTIAL DIAGNOSIS

Chronic diarrhea (more than 4 weeks' duration) may be caused by malabsorption of nutrients or poorly absorbable solute, de- ranged water and electrolyte transport, or inflammatory diseases of the intestine (Table 99.6). In some cases of chronic diarrhea, the character of the stool correlates with the pathophysiologic mechanism (e.g., bulky steatorrhea in chronic pancreatitis, watery diarrhea after limited ileal resection due to bile salt wasting, and bloody diarrhea in ulcerative colitis), and a rapid diagnosis can be made. Most chronic diarrheal diseases, however, are caused by multiple mechanisms, making a clinical diagnosis difficult. A few guidelines are helpful. Diarrhea due to malabsorption of nutrients or poor absorption of solute usually is low volume (less than 1 L per day) and diminishes with fasting. Secretory diarrhea usually is high volume (more than 1 L per day) and does not improve with fasting. Inflammatory diarrhea with mucosal destruction is associated with blood and pus in the stool and edema. History, physical examination, and screening blood and stool tests can narrow the differential diagnosis so that the cause is found quickly and efficiently.

<p>Inflammatory disease Inflammatory bowel disease Microscopic colitis Enteropathic and allergic gastroenteritis</p> <p>Malabsorptive disease Impaired digestion (pancreatic insufficiency, bacterial overgrowth, extensive ileal resection) Impaired mucosal absorption (chronic infection, celiac disease, tropical sprue, radiation enteritis, lymphoma, Whipple's disease, amyloidosis) Lymphatic obstruction (lymphoma, Kaposi's sarcoma, severe congestive heart failure, constrictive pericarditis)</p> <p>Irritable bowel syndrome Medications (see Table 99.4)</p> <p>Radiation Abdominal surgery Cholecystectomy Truncal vagotomy Short bowel syndrome</p> <p>Ischemic bowel Laxative abuse (see Table 99.4)</p> <p>Endocrine (hyperthyroidism, adrenal insufficiency) Vitiligo adenoma Systemic mastocytosis Hormone-producing tumors (gastrinoma, carcinoid syndrome, VIPoma, medullary thyroid carcinoma) Heavy metals</p>

TABLE 99.6. CAUSES OF CHRONIC DIARRHEA

Malabsorption

Malabsorption can be caused by a number of diseases, drugs, or dietary products that impair intraluminal digestion, mucosal absorption, or nutrient delivery. Impairment of intraluminal digestion can be caused by pancreatic insufficiency, bacterial overgrowth, ileal resection, drugs (orlistat, cholestyramine), or hypersecretion of acid. Impairment in mucosal absorption can be caused by diseases associated with a normal intestinal mucosa (acquired lactase deficiency, abetalipoproteinemia) or with an abnormal intestinal mucosa (chronic intestinal infection, celiac disease, Crohn's disease, tropical sprue, Whipple's disease, radiation enteritis, lymphoma). Some drugs (colchicine, methotrexate, neomycin) also impair mucosal absorption. In short-bowel syndrome, the intestinal mucosa is normal, but the surface area for absorption is markedly decreased. Impairment in nutrient delivery usually is caused by diseases that cause lymphatic obstruction (lymphoma, tumor, tuberculosis, constrictive pericarditis, severe congestive heart failure). Hypoproteinemic edema is characteristic in these conditions.

Symptoms of nutrient malabsorption are predominantly related to impaired absorption of fat and carbohydrate. Steatorrhea (greasy, foul smelling stools that are difficult to flush) is the hallmark of malabsorption. Stools may be bulky or watery depending on whether triglycerides or fatty acids are malabsorbed. Watery steatorrhea is caused by fatty acid-induced stimulation of fluid secretion in the colon. Malabsorption of carbohydrate causes osmotic watery diarrhea, abdominal bloating, and cramps. Weight loss may be caused by nutrient malabsorption or decreased oral intake to avoid diarrhea. Poor absorption of carbohydrates, cations, or anions also causes osmotic watery diarrhea.

Poorly absorbed sugars include lactulose (used in therapy for hepatic encephalopathy), sorbitol (present in elixirs, dietetic candy, and chewing gum), and fructose (present in pears, prune juice, and apple juice). Magnesium, phosphate, and sulfate are present in laxatives. These poorly absorbed solutes exert an osmotic force in the lumen; they draw fluid and electrolytes from plasma to the lumen. An increased stool osmotic gap is found in all cases of osmotic diarrhea except for those caused by laxatives containing phosphate and sulfate. In the latter case, the stool osmotic gap is normal but stool Cl^- concentration is low because SO_4 and PO_4 anions

displace Cl^- to maintain stool osmolality equal to plasma.

Deranged Water and Electrolyte Transport

A number of different diseases cause watery diarrhea by altering water and electrolyte transport. In some of these diseases (bile acid diarrhea, diabetic diarrhea, microscopic colitis, laxative abuse, villous adenoma, hormone-secreting tumors, congenital transport disorders), diarrhea is caused by decreased absorption or stimulation of fluid secretion in the intestine. In others (IBS, toddler's diarrhea), dysmotility with rapid intestinal transit may play a role. In many of these diseases, the pathophysiologic mechanisms underlying the disorders are not well understood (postvagotomy syndrome, postcholecystectomy syndrome, binge drinking, idiopathic diarrhea).

Bile acid diarrhea may be caused by ileal disease or resection, primary malabsorption of bile salts, or postcholecystectomy or postvagotomy syndrome. Primary malabsorption of bile salts has been reported among infants and adults; it presumably is caused by defective intestinal bile acid transport proteins. Diarrhea due to primary bile salt malabsorption generally improves with fasting and cholestyramine treatment.

Diarrhea due to the presence of hormone-secreting tumors and congenital diarrhea are rare and are characteristically high volume and unresponsive to fasting. In VIPoma, VIP and other peptides are secreted from a pancreatic adenoma or neural crest tumor (in children) that causes watery diarrhea, hypokalemia, and achlorhydria. In the carcinoid syndrome, serotonin, bradykinin, prostaglandins, and other substances are secreted from metastatic tumors and cause diarrhea, flushing, abdominal cramps, bronchospasm, and right-sided heart valve lesions. Skin flushing and diarrhea also may be manifestations of systemic mastocytosis. Patients with the Zollinger–Ellison syndrome (gastrinoma) often experience diarrhea, in part because of the large gastric acid load presented to the small intestine.

There are two conditions in which high-volume diarrhea is associated with metabolic alkalosis—congenital chloride diarrhea and large villous adenoma of the intestine. The mechanism by which the latter causes diarrhea is unclear, although prostaglandins may play a role.

Diabetic diarrhea is associated with severe autonomic neuropathy, which perturbs water and electrolyte transport and motility. The incidence of celiac disease and pancreatic insufficiency also is reported to be higher among these patients. Thus the diagnosis of diabetic diarrhea rests on the exclusion of other identifiable causes.

In IBS, stools are more liquid and frequent, but the volume usually does not increase, and patients rarely lose weight. Dysmotility leading to carbohydrate wasting in the colon and food sensitivities may have a role in this disorder. Lactose intolerance, microscopic colitis, and celiac disease are considered in the differential diagnosis.

Laxative abuse is found in about 25% of patients evaluated for chronic diarrhea. It occurs most often among young women with eating disorders and among middle-aged women (often health care workers) who obtain secondary gain from ongoing medical attention. These patients often appear to have diarrhea while fasting, either self-induced surreptitiously or caused by manipulation of their stool collections. Over-the-counter laxatives containing phenolphthalein can be detected by means of alkalization of the stool. Other laxatives (anthraquinones, docusate salts, Mg^{2+} , SO_4 , Na_2PO_4 , Na_2SO_4 , diuretics) are detected only by means of laboratory stool and urine analysis. A room search, although complicated by ethical and legal issues, often is helpful in the diagnosis. This disorder is difficult to diagnose, and the patients are difficult to treat because they go to great lengths to hide their abuse. They often leave the care of physicians when they are confronted with the diagnosis.

Inflammatory Disease

Inflammatory diarrhea can be watery or bloody depending on whether there is destruction of the intestinal epithelium. Fever, abdominal pain, blood in the stool, and hypoproteinemia are characteristic signs of inflammatory destruction of the intestinal epithelium. The pattern of abdominal pain, the clinical situation, and the character of bloody stools provide clues to causation. Left-sided abdominal pain and frequent passage of small, bloody stools suggests left-sided colitis due to IBD. Among the elderly, this must be differentiated from ischemic colitis. Right-sided abdominal pain and bloody stool may be caused by Crohn's disease or chronic infection of the terminal ileum (tuberculosis, *Yersinia* infection, or histoplasmosis). Microscopic colitis causes watery diarrhea predominantly among middle-aged women. Some have associated celiac disease.

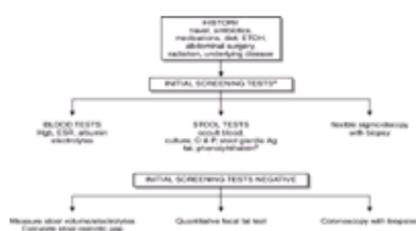

Patients with rectal inflammation, as in ulcerative and infectious proctitis, may have normal stool weight but experience tenesmus, incontinence, and increased stool frequency. These symptoms are caused by reduction in the capacity of the rectal vault from muscular irritation and decreased absorptive and barrier properties of the mucosa, making it difficult to form solid stool. Infectious proctitis due to gonorrhea, herpes, syphilis, chlamydiosis, or amebiasis is possible if there is a history of anal intercourse.

Eosinophilic gastroenteritis is caused by infiltration of the gastrointestinal tract with eosinophils. The cause is unknown. Some of these patients have allergic eosinophilic gastroenteritis. Any area of the gastrointestinal tract (esophagus to anus) can be involved, but the most common location is the stomach and small intestine. When the small-intestinal mucosa is involved, patients may have watery or bloody diarrhea. Allergic gastroenteritis is caused by specific food antigens that when ingested cause vomiting, abdominal cramps, and diarrhea. It most commonly occurs among infants and children.

EVALUATION

In most cases of chronic diarrhea, diagnostic evaluation is performed in the outpatient setting. Patients with dehydration, metabolic disturbances, or malnutrition may need admission to the hospital for a more expeditious evaluation. Before any tests are performed, a careful history must be obtained to ascertain the use of prescription drugs, over-the-counter drugs, or herbal preparations, dietary habits, and the presence of fecal incontinence. If lactose intolerance is likely or the patient has begun to use a new medication or dietary product, a lactose-free diet is tried or a change in medication is made before further evaluation.

An informative history can streamline tests that can establish a specific diagnosis. However, when this is not the case, initial screening tests (blood and stool) and flexible sigmoidoscopy are performed to differentiate organic disease from functional disease (dysmotility, laxative abuse) (Fig. 99.4). Initial screening tests include blood tests to look for electrolyte abnormalities, anemia, a low serum albumin level, and an elevated sedimentation rate—all signs of organic disease. Stool is tested first for occult blood, ova and parasites, *Giardia* antigen, fat, and phenolphthalein, and a stool culture is performed. Detection of *Giardia* antigen by means of enzyme-linked immunosorbent assay is as sensitive as examination of duodenal aspirate or biopsy in ascertaining the presence of chronic *Giardia* infection and is less invasive. Flexible sigmoidoscopy with biopsy can be useful in detecting inflammatory (IBD, microscopic colitis), infectious (shistosomiasis), infiltrative (amyloidosis), and cathartic (use of anthracene laxatives) lesions.

* If initial screening test positive, stool disease or obtain further tests for specific diagnosis as indicated.
 † If lactase abuse suspected, stool should also test for coliforms.
 ‡ If necessary, diarrhea stool should include function tests, stool tests for *Vibrio*, *Shigella*, *Campylobacter*, *Yersinia* and heavy metals.

FIGURE 99.4. Evaluation of chronic diarrhea.

A careful history, screening blood and stool tests, and flexible sigmoidoscopy provide specific diagnostic clues in about 80% of cases. The other 20% of persons with

chronic diarrhea may need inpatient evaluation. Measurement of stool volume in response to a 24- to 48-hour fast, quantitative fecal fat test, and colonoscopy with biopsy provide a specific diagnosis in many of these cases. The response of diarrhea to fasting, measurement of stool electrolytes, and calculation of the stool osmotic gap helps differentiate osmotic diarrhea from secretory diarrhea (Table 99.5). If the fecal fat test result is positive, specific tests for malabsorption are performed. Colonoscopy allows visualization of the right colon and terminal ileum, sometimes revealing Crohn's disease, collagenous colitis, or villous adenoma. If no diagnosis is made after these tests and diarrhea is secretory, blood is obtained for measurement of thyroid function and hormone levels.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

Fluid therapy is most important in the management of diarrhea, especially for infants and the elderly, because morbidity and mortality are caused by intravascular volume depletion. Persons with moderate to severe diarrhea lose large amounts of Na^+ , Cl^- , K^+ , HCO_3^- , and water in the stool; the result is hypokalemia, non-anion gap metabolic acidosis, and prerenal azotemia. When large diarrheal losses are replaced with water or oral solutions low in sodium content (juice, soda, sports drinks), hyponatremia results. Oral rehydration solutions (Table 99.7), in particular the rice-based solutions, are designed for maximal intestinal fluid absorption and must be started early in the course of moderate to severe diarrhea for optimal results. For patients with hypotension or who are unable to drink, an intravenous solution containing potassium and a base (Ringer's lactate) is started.

Solution	Na ⁺	K ⁺	Cl ⁻	Base [†]	Carbohydrate [‡]	Osmolality

TABLE 99.7. COMPOSITION OF ORAL SOLUTIONS

Patients with chronic, high-volume diarrhea lose zinc and magnesium in the stool. Failure to replace zinc losses may result in zinc deficiency, which may then worsen diarrhea. Because magnesium is poorly absorbed and can make diarrhea worse, intramuscular or intravenous replacement of magnesium often is necessary. Serum electrolytes, blood urea nitrogen, creatinine, and magnesium are monitored to guide therapy. Food can be taken as tolerated except perhaps for lactose by patients with secondary lactase deficiency.

Patients with acute infectious diarrhea should not be treated with antibiotics except those with traveler's diarrhea and those likely to have invasive bacterial enteritis. Antibiotic therapy for EHEC infection is controversial. For travelers, antibiotic treatment to prevent diarrhea is not generally recommended. A single oral dose of a quinolone and an antimotility agent at the onset of symptoms relieves traveler's diarrhea within 24 hours in most instances. For patients with severe diarrhea, high fever, or bloody stools, a quinolone taken orally twice a day for three days is recommended for adults. *Antimotility agents should not be used* because of concern about promoting bacterial invasion or prolonging intestinal infection. Persons with diarrhea caused by *C. difficile* toxin should stop taking the offending antibiotic (if possible) and be treated with metronidazole. Treatment with oral vancomycin is reserved for patients with severe or refractory infection. For hospitalized patients with persistent diarrhea and negative results of stool tests for *C. difficile* toxin, empirical antibiotic treatment can be tried. The use of *Saccharomyces boulardii* (*S. cerevisiae*) to prevent or control *C. difficile* infection has not been shown to be effective.

Management of chronic diarrhea consists of fluid repletion and specific therapy for the underlying condition. Lactase deficiency is managed with a lactose-free diet or Lactaid. Pancreatic insufficiency is managed with exogenous pancreatic enzymes. Celiac disease is managed with a gluten-free diet. Tropical sprue and bacterial overgrowth are managed with antibiotics. Patients with limited ileal resection are treated with cholestyramine, and those with extensive ileal resection are treated with a low-fat diet and an antimotility agent. Severe diarrhea due to GVHD is controlled with steroids and antithymocyte globulin or mycophenolate mofetil (CellCept) combined with parenteral nutritional support. When the underlying condition cannot be controlled or does not respond to available treatments, as in the case of chronic intestinal infections, cancer-related diarrhea, and GVHD, management is aimed at lessening diarrhea and maintaining adequate nutrition. Antimotility agents can be tried, but octreotide (often at high doses) often is more effective in lessening diarrhea. Anti-inflammatory agents are used in the treatment of patients with IBD and to maintain remission.

Antidiarrheal agents can be grouped into four categories: bismuth subsalicylate, antimotility agents, antisecretory agents, and anti-inflammatory agents. Bismuth subsalicylate has both antimicrobial and antisecretory properties and is used most often in the prevention or control of traveler's diarrhea. Antimotility agents (opiates) slow intestinal transit and increase contact time for fluid reabsorption. Loperamide does not cross the blood-brain barrier, and therefore use of this agent is associated with fewer side effects. Tincture of opium is the most potent drug, but it can cause sedation and induce drug dependence. Antimotility agents usually are reserved for those with mild to moderate diarrhea who do not have fever or blood in the stool. Antimotility agents should not be used or are used with caution to treat patients with high-volume diarrhea (use may cause underestimation of fluid losses), invasive bacterial enteritis (may enhance bacterial invasion and delay clearance), or ulcerative colitis (may precipitate toxic megacolon).

No specific agent inhibits intestinal fluid secretion. Octreotide, the long-acting somatostatin analog, inhibits all gastrointestinal secretions and is effective in decreasing secretory diarrhea from any cause. It is most often used to treat patients with severe diarrhea due to HIV disease, GVHD, or chemotherapy and those who have undergone extensive intestinal resection with an end jejunostomy. Octreotide or long-acting octreotide also are useful in the management of diarrhea due to hormone-producing tumors. It acts by inhibiting formation and secretion of these hormones. Undesirable side effects of octreotide include increased risk of gallstones, malabsorption (at doses higher than 300 µg per day), and pseudoobstruction. Patients with diabetes who have diarrhea have been reported to respond to treatment with α_2 -adrenergic agents (clonidine and lidamidine) and to treatment with octreotide. Proton-pump inhibitors are effective in decreasing diarrhea among patients with gastrinoma, short-bowel syndrome with acid hypersecretion, and congenital chloride diarrhea.

Steroids and 5-aminosalicylic acid decrease prostaglandin and leukotriene production, and the decrease results in decreased intestinal fluid secretion. Steroids also promote sodium and chloride absorption. These agents are effective in the management of IBD and microscopic colitis. Indomethacin inhibits production of prostaglandins but not of leukotrienes. It may decrease diarrhea in cases of radiation enteritis and villous adenoma but exacerbates diarrhea due to IBD.

COMPLICATIONS AND PITFALLS

Failure to recognize large diarrheal fluid losses contributes to morbidity and mortality, especially among infants and the elderly. Small diarrheal losses among infants rapidly lead to dehydration. Oral administration of rehydration solutions must be started early in the course of diarrhea. Solutions that contain glucose do not lessen diarrhea but keep up with fluid losses. Parents need to be instructed to continue giving oral solutions despite continued diarrhea. Oral solutions that contain glucose polymers (rice-based) do lessen diarrhea. Adults are told to monitor urine output as a gauge of adequate hydration. Standard oral solutions (Table 99.7) are appropriate only in mild cases of diarrhea.

Indications for HOSPITALIZATION

Any person with diarrhea accompanied by severe dehydration, inability to drink, metabolic disarray, severe abdominal pain, high fever, or a toxic appearance needs admission to a hospital for supportive care and diagnostic evaluation. There should be a lower threshold to admit patients with compromised immune function, elderly persons, or very young persons. These groups have the highest morbidity and mortality from diarrheal diseases.

Indications for REFERRAL

Severe diarrhea necessitates a more streamlined evaluation, which often includes endoscopic studies. Patients may need early referral to a specialist. Persons with chronic diarrhea of undetermined causation (idiopathic) are referred to a tertiary center that can perform specialized tests, such as tests for bile salt malabsorption and permeability studies.

COST-EFFECTIVENESS

The cost of a single positive result of a stool culture performed indiscriminately for patients with diarrhea is about \$1,200. The cost of a positive result of a stool culture can be drastically decreased if cultures are limited to patients with a positive result of a screening test for inflammation or when suspicion of invasive bacterial enteritis is high. Maximal diagnostic yield from a stool culture is obtained when the laboratory is notified to culture for specific organisms such as *Yersinia*, *Cholera*, or EHEC when these are suspected. Stool culture and examinations for parasites should not be performed when diarrhea develops while a patient is in the hospital unless there is reason to suspect an outbreak of *Salmonella* or *Campylobacter* infection. For patients with chronic diarrhea and no etiologic clues, a careful history and physical examination, limited blood and stool screening tests, and flexible sigmoidoscopy are performed before more expensive and invasive tests.

CHAPTER 100: APPROACH TO THE PATIENT WITH CONSTIPATION, FECAL INCONTINENCE, AND GAS

JEFFREY L. BARNETT

[Constipation](#)
[Fecal Incontinence](#)
[Gas](#)

Constipation implies difficulty extruding stool; fecal incontinence implies difficulty withholding it. At first glance, these symptoms appear completely unrelated, if not opposite. However, they share a common pathophysiologic mechanism and can even coexist in the same person. For example, long-standing constipation with straining predisposes to fecal incontinence later in life. Chronic fecal impaction among children or the elderly may manifest as overflow fecal incontinence. Irritable bowel syndrome (IBS) and various neuromuscular diseases may produce both constipation and fecal incontinence. Structural anorectal disorders such as rectal prolapse and hemorrhoids may be associated with both of these symptoms. Gaseousness, particularly bloating and flatulence, may accompany constipation and fecal incontinence or occur as an independent problem. Although belching and flatus production are universal, when taken to excess, these are particularly disturbing symptoms for many patients.

CONSTIPATION

Constipation can be defined as a symptomatic decrease in the frequency of bowel movements. Misconceptions persist about the need for daily evacuation. Normal stool frequency varies, but most persons pass at least two or three stools per week. Women and blacks are more likely to report infrequent defecation than are men and whites. To a patient, constipation may mean not only decreased stool frequency but also passage of dry stools, excessive straining, lower abdominal fullness, and a sense of incomplete evacuation. Although these symptoms are more difficult to assess objectively than is bowel movement infrequency, they deserve serious attention by the physician.

PATHOPHYSIOLOGY

Constipation is caused by one of two mechanisms—obstruction of the movement of luminal contents or poor colonic propulsive activity ([Table 100.1](#)). Obstruction of colonic flow may be caused by luminal narrowing or a functional disorder. Poor propulsive activity in the colon may be caused by inhibition of motility (drugs, electrolyte disturbances, metabolic diseases) or diffuse nerve and muscle diseases (multiple sclerosis, familial visceral myopathy).

TABLE 100.1. DIFFERENTIAL DIAGNOSIS OF CONSTIPATION

Several obstructing lesions cause constipation, the most important of which is carcinoma of the colon. Although carcinoma of the colon often becomes manifest with gross or occult blood in the stool, changes in bowel habit, ranging from a subtle decrease in stool frequency to constipation, also may occur. These symptoms usually occur over weeks or months but in rare instances are present for more than 1 year. Benign causes of colonic obstruction such as strictures caused by diverticular disease, colonic ischemia, or inflammatory bowel disease can produce similar symptoms. Anal strictures, foreign bodies, or sphincter spasm due to painful fissures or hemorrhoids may interrupt normal stool passage.

In the absence of an anatomic lesion, a disturbance in motility can produce functional colonic obstruction. A classic example of this is Hirschsprung's disease, or aganglionosis. This disorder is characterized by an absence of myenteric neurons in a segment of distal colon proximal to the sphincter. The aganglionic segment remains contracted, causing proximal obstruction and dilatation. This congenital condition occurs most often among infants with obstipation soon after birth, but in rare instances a short segment of aganglionosis can cause constipation among older children and adults. A more diffuse form of functional colonic obstruction may occur among patients with constipation associated with IBS. Hypersegmenting contractions of colonic circular muscle impede the forward movement of luminal contents in these patients. This spastic type of constipation may be associated with crampy abdominal pain and passage of scybalous (hard, dry) stools.

Constipation may be caused by drugs, metabolic abnormalities, and systemic diseases. Patients may suffer unknowingly if a physician fails to warn them about the constipating effects of such commonly prescribed medications as codeine, aluminum- or calcium-containing antacids, and iron compounds. Depressed patients often report constipation, a condition that may be exacerbated by the anticholinergic properties of antidepressants. Such metabolic disturbances as hypercalcemia and hypokalemia cause constipation by decreasing colonic smooth-muscle contractility. Constipation is a common gastrointestinal (GI) symptom among patients with diabetes mellitus, particularly those with autonomic neuropathy. Patients with progressive systemic sclerosis also may report constipation, but slow transit is caused by atrophy and fibrosis of colonic smooth muscle in this disease.

Neurogenic causes of constipation highlight the importance of both the extrinsic and intrinsic enteric nervous systems to normal colonic function. Central lesions due to Parkinson's disease, multiple sclerosis, or cerebrovascular accidents may cause constipation, although the symptoms may be caused in part by debilitation, inactivity, and poor bowel habits. Damage to the parasympathetic sacral nerves can lead to paralysis of the distal colon and rectum, making defecation an especially difficult problem for persons with spinal cord injuries. Chagas' disease, a parasitic infection, is an example of constipation caused by damage to the intrinsic enteric nervous system. The trypanosome organism infiltrates the GI tract and causes inflammation and degeneration of the myenteric plexus ganglion cells. Constipation associated with esophageal involvement suggests this infection among patients who have lived in or traveled to South America.

Changes in hormone levels have been associated with constipation. High levels of circulating catecholamines and low levels of thyroid hormone can depress GI motility and cause severe constipation among patients with pheochromocytoma and hypothyroidism, respectively. Elevated progesterone levels have been associated with increased intestinal transit time and reduced in vitro contractility of GI smooth muscle. Constipation during pregnancy and during the luteal phase of the menstrual cycle may be caused by increasing levels of this hormone.

Chronic idiopathic intestinal pseudoobstruction is a rare disorder characterized by recurrent episodes of intestinal obstruction without mechanical blockage. In addition to the small intestine, any other portion of the GI tract and occasionally the bladder can be involved. Although familial cases have been described, the underlying defect is unknown. Morphologic evidence of both neuropathy and myopathy has been reported.

Often no underlying cause of chronic constipation can be identified. Idiopathic constipation, a disorder more common among women, can be divided into two types: slow colonic transit (colonic inertia) and defecatory disorders (outlet obstruction). Colonic inertia involves poor transit of colonic contents throughout the colon and is demonstrated by delayed movement of radiopaque markers. Defecatory disorders are a heterogeneous group of conditions characterized by poor evacuation of contents from the rectosigmoid colon. These mechanisms overlap and may coexist in the same patient, but the division is useful in conceptualizing and treating patients with chronic symptoms. Slow transit of luminal contents can be caused by a weakly propulsive or a spastic hypersegmenting colon. These disorders may be

caused by abnormalities of the colonic smooth muscle or the myenteric plexus. Colonic inertia typically underlies severe constipation among young to middle-aged women who describe little pain but annoying bloating and marked stool infrequency. On the other hand, constipation among the elderly typically manifests as straining or evacuation difficulty rather than infrequency of stools.

Patients with long-standing constipation often have a disorder of the defecatory mechanism. Straining is common, and passage of even a large barium balloon or plastic sphere often is difficult. During attempted defecation, paradoxical contraction of the puborectalis and external sphincter muscles may produce functional outlet obstruction (anismus or rectosphincteric dyssynergia). Chronic straining itself is associated with increased descent of the perineal floor, which leads to a mechanically inefficient bulging motion of the anorectum. Abnormal perineal descent may cause chronic stretch injury to the pudendal nerve, which innervates the puborectalis muscle and external anal sphincter. This damage may cause incompetence of the anal sphincter and fecal incontinence. Occult and complete rectal prolapse may cause both partially obstructed defecation from rectal intussusception and, like perineal descent, chronic pudendal nerve injury. A large rectocele (anterior rectal herniation) may interfere with defecation because during straining, stool preferentially fills this sac and is therefore poorly expelled.

DIAGNOSTIC EVALUATION

The diagnostic evaluation of patients with constipation begins with a detailed history and physical examination. Important historical points include symptom duration and progression, a description of stool characteristics, and the presence of anorectal pain or bleeding. A directed history may uncover subtle symptoms suggesting hypothyroidism, collagen vascular disease, or esophageal or bladder dysfunction. A careful drug history must include such over-the-counter medications as antacids, vitamins, and bismuth compounds. The physical examination includes a thorough anorectal examination for tumors, hemorrhoids, and fissures. Anorectal neurogenic function is assessed by means of perianal cutaneous sensation, the anal wink reflex, and adequacy of anal canal tone. Examination during squeeze and straining maneuvers may uncover evidence of rectal prolapse, rectocele, and anismus. Appropriate laboratory studies can confirm suspected electrolyte or metabolic disturbances.

If the initial evaluation suggests the possibility of colonic obstruction, a structural study of the colon, such as barium radiography or endoscopy, is performed to exclude luminal narrowing. Flexible sigmoidoscopy or colonoscopy allows excellent visualization of the mucosa and tissue biopsy, which allow definitive diagnosis of anatomic lesions. A barium examination allows better evaluation of mild strictures or complicated diverticular disease, but the barium may be difficult to remove from a partially obstructed colon.

Once anatomic obstruction is ruled out, an attempt at treatment is made for patients with simple constipation. Most patients improve and no further diagnostic evaluation is necessary. However, a few patients with chronic refractory symptoms need further evaluation ([Fig. 100.1](#)).

FIGURE 100.1. Algorithm for the approach to the patient with constipation.
EVIDENCE LEVEL: C. Expert Opinion.

The transit of stool through different segments of the colon is evaluated by means of following the progression of swallowed radiopaque markers over several days. Colonic inertia (slow transit throughout) can be differentiated from normal transit with functional outlet obstruction. Inertia in localized regions of the colon also can be identified. Marker studies are particularly useful for objective documentation of decreased stool frequency. A surprisingly large number of patients, albeit still a minority, have completely normal colorectal transit times. Some even deny stool output, although abdominal radiographs clearly show disappearance of markers. Many of these patients have psychologic factors that influence their symptoms. The approach to further evaluation and treatment is quite different from that of patients with abnormal colorectal transit.

Anal manometry is used to assess the function of the internal and external anal sphincters. Rectal distention normally initiates a reflex that relaxes the internal anal sphincter and contracts the external anal sphincter. Loss of this reflex suggests Hirschsprung's disease, a diagnosis that must be confirmed by means of rectal biopsy. Unexplained poor relaxation of the internal sphincter and paradoxical contraction of the external sphincter during defecation have been described as causes of constipation. Severe idiopathic constipation is associated with impaired rectal sensation to balloon distention. An overly compliant rectum combined with a sensory loss may interfere with the normal urge to evacuate among these patients.

Defecography and serial specialized radiographs allow dynamic evaluation of the defecation process. The anorectal angle helps maintain fecal continence. Squatting in preparation for defecation straightens this angle to allow normal stool passage. Straining relaxes the puborectalis sling muscle to further straighten the anorectal angle. Failure to relax this muscle causes constipation among some patients. Abnormal perineal descent, obstructing enteroceles, rectoceles, and rectal prolapse also can be identified with defecography.

STRATEGIES FOR OPTIMAL CARE

Metabolic abnormalities must be corrected and constipating medications changed if possible. Daily exercise such as walking or running is encouraged. Adequate hydration and dietary fiber intake (20 to 30 g) is emphasized. The patient is encouraged to allocate a limited time for defecation after a chosen meal. This approach takes advantage of the gastrocolonic reflex and helps establish a bowel routine.

Simple constipation often responds to daily fiber supplementation. Dietary fiber and hydrophilic colloid laxatives consist of poorly absorbed plant polysaccharides. Fiber products increase fecal volume and shorten colonic transit time by increasing the colonic bacterial mass and retaining luminal water. Greater fecal bulk enlarges the colonic diameter, which decreases intraluminal pressure. This may ease the straining associated with passage of small, scybalous stools. Fiber supplements such as psyllium, methylcellulose, and polycarbophil are available in various forms. These products are taken on a daily basis as a dietary supplement, not "as needed" in the manner of a laxative. Coadministration of at least 8 ounces (240 mL) of fluid is recommended, because GI obstruction can occur with use of these agents. Fiber supplementation merits at least a 2- to 3-week trial. The patient must be warned that symptoms of flatus and bloating may transiently worsen. Fiber products must be used cautiously by patients with a dilated, atonic colon or a severe defecation disorder because of risk of fecal impaction.

If fiber supplementation alone is unsuccessful, short-term or intermittent use of laxatives may be necessary. Saline (magnesium hydroxide, magnesium citrate), lubricant (mineral oil), and hyperosmotic (lactulose, polyethylene glycol) laxatives are best suited for this use. Emollient laxatives or stool softeners are of marginal benefit. Stimulant laxatives should be used for only brief periods because they can damage myenteric neurons and cause dependency. Chronic use of stimulant laxatives is a predisposing factor for a dilated, featureless colon recognized at barium enema examination as cathartic colon. Anthraquinone laxatives often cause benign hyperpigmentation of the colorectal mucosa (melanosis coli). The changes of cathartic colon and melanosis coli may be reversible on withdrawal of the laxative.

The spastic constipation of IBS occasionally responds to smooth muscle relaxants such as nitrates, anticholinergics, and calcium channel blockers, but these medications are of unproven benefit and cause constipation among many patients. Patients with hypoperistalsis need medication to stimulate smooth-muscle activity. Although many stimulants have been tried, none has yet proved efficacious in the management of constipation.

Nonpharmacologic therapies occasionally are beneficial to certain constipated patients. Psychotherapy and relaxation techniques help some patients with depression or IBS. A specific biofeedback technique has successfully retrained persons with constipation caused by anismus.

Surgery is rarely needed and is considered only to manage long-standing intractable symptoms or serious complications. A marker transit study combined with a defecation study allows a rational physiologic approach to surgical therapy. The procedure of choice for slow transit ascertained at marker study is colectomy with ileorectal anastomosis. Although colectomy is beneficial to some patients, chronic postoperative symptoms of diarrhea, persistent constipation, and acute small-intestinal obstruction are not unusual. The possibility of a diffuse motility disorder of the GI tract must be considered before this operation is performed. Lesser resections have a lower success rate and a high incidence of anastomotic leaks but can be considered if regional motility disorders or localized segments of dilatation can be identified. Some patients with prominent rectocele who have improved defecation dynamics when digital pressure is exerted on the posterior vaginal wall may benefit from surgical repair of this lesion. Rectopexy and operations to support the pelvic floor may improve defecation for patients with rectal prolapse or abnormal perineal descent.

COMPLICATIONS

Chronic constipation may have a role in the development of rectal prolapse, hemorrhoids, and anal fissure. Severe and even life-threatening complications ([Table 100.2](#)) are most common among elderly or debilitated patients. Fecal impaction, or fecaloma, may produce local mechanical problems such as urinary tract obstruction. Stercoral ulcers due to pressure necrosis from the fecal mass can bleed or perforate. Fecal impaction and less commonly perineal nerve damage may lead to incontinence. Fecal incontinence in turn can contribute to urinary tract infection and decubitus ulcers, both common causes of sepsis among the elderly.

Hemorrhoids
Anal fissures
Rectal prolapse
Cecal perforation
Volvulus
Ischemic colitis
Fecal impaction
Colonic obstruction
Urinary tract obstruction
Stercoral ulceration
Fecal incontinence
Decubitus ulcers
Urinary tract infection
Laxative use
Cathartic colon
Melanosis coli

TABLE 100.2. COMPLICATIONS OF CONSTIPATION

Indications for HOSPITALIZATION

Hospitalization rarely is needed even for severe constipation.

Indications for REFERRAL

Referral is appropriate if an underlying metabolic, neurologic, or anorectal cause of constipation is identified that requires the expertise of a specialist or a colorectal surgeon. Refractory symptoms despite fiber and laxative trials among women with idiopathic constipation and persistent constipation or recurrent fecal impaction in the elderly are indications for referral to a gastroenterologist with expertise in physiologic testing and medication regimens.

FECAL INCONTINENCE

The unintended release of fecal contents is a socially disabling and embarrassing symptom. Direct questioning may be needed to ascertain that a patient with “loose stools” or “bowel problems” has fecal incontinence, because the presence of this symptom is not always volunteered readily. The prevalence of fecal incontinence is highest among women, the elderly, and persons in long-term care facilities. About 10% of elderly persons living in residential facilities are incontinent of stool at least once a week.

PATHOPHYSIOLOGY

Rectum and Its Contents

The contents, motility, compliance, and sensation of the rectum are important determinants of fecal continence. Nearly everyone has experienced fecal urgency during an acute diarrheal illness. Large volumes of liquid stool delivered to the rectum challenge the continence mechanisms of even healthy persons. In general, bulky solid stools are easiest to control. The ability of a normally compliant rectum to accommodate and sense material presented to it is an important determinant of continence and defecation. Neuropathic damage from long-standing diabetes and poor distensibility caused by radiation proctitis may interfere with normal rectal reservoir function and predispose to fecal incontinence.

Anal Canal and Sphincters

The anal canal is a slit 3 to 4 cm long and slightly anteroposterior that is the final barrier to fecal flow. It is normally closed by tonic contractions of the surrounding sphincter musculature. Spongy vascular anal cushions help fine-tune this closure. Prolapsing tissue or previous hemorrhoidectomy may interfere with this seal to allow minor seepage. The internal sphincter muscle is the thickened distal portion of the circular muscle layer of the rectum. It is under involuntary control and is responsible for most of the resting sphincter tone. The external sphincter is a surrounding sleeve of striated muscle that extends a small distance below the caudal margin of the internal sphincter. It helps to maintain a degree of resting tone but is predominantly responsible for the augmented tone needed to maintain continence during periods of rectal distention or sudden increases in abdominal pressure, such as during coughing or lifting. Unlike the rectum, which is sensitive only to distention, the mucosa of the anal canal can detect touch, pain, and temperature.

When material enters the distal rectum, anal sampling may occur to differentiate flatus from liquid or solid stool and allow selective passage of these materials. Traumatic childbirth injuries and damage to the sphincter muscles during operations for anal fissure or hemorrhoids may be a predisposing factor to incontinence. Neuropathic damage to the sphincters be caused by various conditions such as diabetes, spinal cord injury, or more commonly chronic constipation with straining (stretch injury to the pudendal nerve) and degenerative changes associated with aging.

Puborectalis Muscle and Defecation

The puborectalis muscle attaches to the symphysis pubis and wraps around the posterior aspect of the anorectal junction to form a sling. Tonic contraction of this muscle produces an approximate right angle between the axes of the anus and rectum to act as a barrier to passage of rectal contents. The origin and innervation (sacral branches) of the puborectalis muscle and external sphincter are similar, so these muscles act in concert. Stool entering the rectum causes reflex relaxation of the internal sphincter so that anal sampling can occur. External sphincter contraction maintains continence during rectal accommodation to the bolus. The act of voluntary withholding increases the anterior pull of the puborectalis muscle and accentuates the acuteness of the angle to better maintain continence. When the decision is made to defecate, sitting or squatting increases (straightens) the anorectal angle to facilitate stool passage. If the person is resisting strongly the call to stool, simply relaxing conscious control allows defecation. Otherwise, a Valsalva maneuver is performed to increase intra-abdominal pressure, and pushing relaxes the puborectalis muscle to further straighten the angle. The pelvic floor descends, the rectum contracts, the sphincter relaxes, and the bolus is expelled. Traumatic or

affected by diet, intestinal transit, and alterations of colonic flora produced by antibiotics or bowel cleansing.

HISTORY AND PHYSICAL EXAMINATION

Patients with gaseousness may describe bad breath, belching, chest pain, dyspepsia, excessive bloating, abdominal discomfort, loud bowel sounds, or flatulence. These symptoms often reflect a functional disorder such as aerophagia, nonulcer dyspepsia, and IBS. Symptoms among these patients typically are not nocturnal or progressive and have been present at least intermittently for months or years. The possibility of a severe organic disorder must be considered, however, especially if vomiting, weight loss, fever, bleeding, or steatorrhea is present. A careful dietary history may relate symptoms to ingestion of legumes, beans, wheat products, fruit, candy, and carbonated beverages. The consumption of milk products must be specifically addressed, because lactose intolerance can develop even later in life. Medications, especially those that slow GI motility, such as anticholinergics, antiarrhythmic agents, and narcotics may cause bloating and other symptoms.

DIFFERENTIAL DIAGNOSIS

Important disorders to consider when a patient has gaseousness include obstruction, GI dysmotility, and malabsorption or maldigestion. Partial obstruction at the pylorus or duodenal bulb may be caused by peptic ulcer disease. Hernia, Crohn's disease, or adhesions from abdominal operations may produce intestinal obstruction that if subtle, may masquerade as unexplained bloating or gaseousness. Tumors of the GI tract, particularly ovarian cancer among women, can manifest as bloating without weight loss or frank obstruction. Autonomic neuropathy from diabetes or neuromuscular dysfunction as a result of systemic sclerosis may produce bloating, early satiety, and nausea. Stasis from these or other GI motility disorders predispose a patient to bacterial overgrowth. When the normally sterile upper GI tract becomes overgrown with anaerobic bacteria, these organisms metabolize ingested foodstuffs into gas and organic acids and cause diarrhea, bloating, and flatulence. Similar symptoms may be caused by giardiasis and malabsorption (celiac sprue) or maldigestion (pancreatic insufficiency).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Extensive testing is not necessary if a patient with gaseousness has no worrisome symptoms to suggest a specific organic disorder. Simple laboratory tests, including a blood cell count, chemical screen, and stool studies, and abdominal radiography help rule out specific disorders and relevant systemic diseases. Barium examination or endoscopy may be indicated if intestinal obstruction, peptic ulcer disease, or malabsorption is an important concern. Hydrogen breath tests can be used to diagnose bacterial overgrowth, lactase insufficiency, and carbohydrate intolerance, especially if ingestion of the test food reproduces the patient's typical symptoms.

STRATEGIES FOR OPTIMAL CARE

In the absence of a specifically identified disorder, therapy for gaseousness consists of reducing swallowed air and dietary restrictions to reduce colonic production of bacterial gas. Aerophagia is reduced by means of elimination of gum chewing, eating hard candies, smoking, and chewing tobacco. For chronic belching, simply identifying the process of air swallowing for the patient might relieve symptoms. If not, anxiolytics or behavioral modification may be considered. A patient with flatus may benefit from a low-flatus diet, which restricts beans, onions, legumes, fruits, wheat products, starches, and milk. Simethicone and activated charcoal are used with occasional success, although the mechanism is uncertain and efficacy is not clearly shown. Lactase enzymes can be tried for gaseousness produced by milk products and bacterial α -galactosidase for that produced by nondigestible oligosaccharides (beans, legumes).

[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION

The signs and symptoms of an intra-abdominal or pelvic mass can be caused by the effects of the mass on surrounding structures or by the indirect, systemic effects of the underlying process, which is usually neoplastic or inflammatory. The diagnostic approach is in large part determined by the clinical presentation. With the increasing use of cross-sectional imaging, a mass may be detected incidentally in a patient, posing a different set of diagnostic questions and issues.

Pain is frequently the presenting symptom of an abdominal mass. The location of the pain often is determined by the developmental origin of the organ involved (see [Chapter 96](#)). Gastrointestinal or genitourinary bleeding, whether macroscopic or microscopic, is an important finding and always must be sought when a mass is suspected. Through disruption of mucosal integrity, blood in the stool or urine directs the investigation toward the mucosa of the respective system. If bleeding is not present, the lesion is more likely to be extrinsic to the gastrointestinal or genitourinary epithelium and may not be accessible to endoscopic investigation.

Luminal obstruction is a frequent presentation of masses that originate in the organs of the digestive tract. The nature of this presentation is related to luminal diameter and the relation of the mass to surrounding structures. Masses in the head of the pancreas frequently cause obstruction of the common bile duct, which courses through the pancreatic head, and less commonly obstruction of the duodenum, which courses adjacent to the pancreatic head. In the colon, the progressively smaller size of the lumen makes a distal mass much more likely to cause obstruction than a proximal mass. Masses arising in the small intestine are relatively rare, and do not account for most episodes of small-intestinal obstruction, which is more commonly attributable to adhesions that are sequelae of earlier surgery (often gynecologic, intestinal, or colonic, less commonly biliary or gastric), intra-abdominal infection (peritonitis), or irradiation. Impingement of a mass on surrounding blood vessels that leads to syndromes of vascular insufficiency, such as lower extremity edema or intestinal ischemia, may denote the presence of a large lesion. The presence of ascites in the setting of an abdominal mass suggests the presence of peritoneal metastasis.

The systemic constitutional effects of an abdominal mass often may be the only presentation. High fever points toward an intra-abdominal abscess. Unexpected loss of more than 5% to 10% of body weight suggests the presence of malignant disease. Paraneoplastic syndromes are a rare presentation of abdominal tumors. Cases of pseudoachalasia related to hepatoma and of dermatomyositis or polymyositis related to malignant gastrointestinal disease have been described. Gastric cancer may cause microangiopathic hemolytic anemia, chronic disseminated intravascular coagulation, membranous nephropathy, sudden appearance of seborrheic keratosis (Leser-Trélat sign), or filiform pigmented lesions in skin folds (acanthosis nigricans). Unexplained deep venous thrombosis in an elderly patient raises the possibility of an underlying adenocarcinoma (Trousseau's syndrome).

Discovery of abdominal masses among adults without symptoms is increasing in frequency as cancer screening recommendations put forth by professional societies become widely adopted. This is true of colorectal cancer, for which screening with fecal occult blood testing and sigmoidoscopy is recommended. In this era of increased availability of cross-sectional imaging techniques, it is not uncommon to find an abdominal mass during investigations for unrelated problems. More than 20% of adults have benign liver cysts or tumors, such as hemangioma or focal nodular hyperplasia, and 30% of adults older than 50 years have cystic renal lesions. Among patients with incidental masses, careful radiologic description coupled with evaluation of the clinical situation determines the need for further testing.

PATHOPHYSIOLOGY

The clinical consequences of an abdominal mass depend on its location and the underlying etiologic factors. A pancreatic mass can compromise the exocrine function of the gland. The profound weight loss associated with pancreatic cancer is initially caused by fat malabsorption due to reduced pancreatic secretion from tumor obstruction of the pancreatic duct. Lesions in the head of the pancreas obstruct a greater length of the main pancreatic duct and therefore cause a greater degree of malabsorption.

In the liver, unaffected parenchyma has great capacity to compensate functionally for the injury caused by a mass lesion. Even very large liver lesions do not manifest with hepatic failure. Because the hepatic parenchyma is enclosed within Glisson's capsule, an expanding mass frequently causes pain. If there is diffuse underlying injury due to cirrhosis, the development of a mass lesion can unmask hepatic failure; deterioration causes jaundice, coagulopathy, ascites, or encephalopathy. The same is true of the kidneys, where development of renal failure is a rare complication of a mass lesion in the absence of severe underlying renal disease.

In most hollow abdominal organs, such as the stomach, small intestine, colon, and rectum, the capacity of the organs is such that a mass can grow to great size before intestinal function is affected. Given the great surface area of these organs, a discrete mass is unlikely to manifest with maldigestion or malabsorption. The absence of afferent pain fibers from the wall of the digestive tract also renders growth of these lesions painless until local invasion into the peritoneum or adjacent structures occurs. Mass lesions in the hollow organs therefore can be clinically inapparent until they reach an advanced stage.

HISTORY AND PHYSICAL EXAMINATION

The nature of any pain symptoms must be defined carefully with respect to duration, food ingestion, and defecation. Pain that closely follows a meal suggests a lesion in the gastrointestinal tract. The location and radiation of pain can help localize the lesion, and the temporal relation to meals can help localize a proximal or distal lesion. Defecatory pain points to the anal canal as the source and suggests a rectal abscess, fissure, or anal canal tumor. Decreased frequency of defecation (constipation) or decreased caliber of the stool point to a lesion in the distal colon. Fecal incontinence, urgency, or a sensation of incomplete evacuation suggests a rectal lesion, especially if blood coats the stool. Blood also may be mixed with stool, suggesting a source in the colon. Melena generally indicates a proximal source in the stomach, small intestine, or right colon. Other causes of black stool, such as iron or bismuth ingestion, must be ruled out. The term *hematochezia*, denoting the passage of bright red blood per rectum, is an ineffective descriptor because it has been used in different contexts. It is more valuable to describe precisely the appearance of the blood-containing stool. Dysuria or hematuria may indicate that the mass either originated in or extends into the urinary tract. The latter can occur in the setting of an inflammatory mass, such as that caused by Crohn's disease, which also can cause pneumaturia if an enterovesicular fistula is present.

Important aspects of the social history include the use of alcohol, which predisposes to hepatic or pancreatic lesions, or risk factors for viral hepatitis. A family history of neoplasia, such as colorectal polyps or cancer, may suggest a genetic predilection. A history of blunt abdominal trauma is sought, because that can lead to formation of a duodenal hematoma or pancreatic pseudocyst.

Fever greater than 38° (100.4°F) in a patient with an abdominal mass suggests an intra-abdominal abscess. Neoplasms that commonly cause fever, such as renal cell carcinoma and hepatocellular carcinoma, are not associated with such severe temperature elevations.

The characteristics of an abdominal mass at palpation can be revealing. Tenderness with rebound suggests that the mass is inflammatory and associated with localized or generalized peritonitis. A firm, nontender, nonpulsatile mass is likely to be neoplastic. In most instances of intra-abdominal neoplasia, however, the mass is not detectable at physical examination before it extends regionally. Ability to palpate a neoplasm therefore usually indicates a poor prognosis. Evidence of lymphadenopathy at examination suggests metastatic disease. Gastric cancer, for example, may spread to intra-abdominal lymph nodes and supraclavicular nodes (Virchow's node) or may involve a periumbilical nodule (Sister Mary Joseph's node). Digital rectal examination allows palpation of approximately half of all rectal neoplasms. It is an important component of the physical examination because it also allows stool testing for occult blood by means of a guaiac-based test. A positive test result has a positive predictive value between 10% and 20% for colorectal cancer among persons who have no symptoms and undergo screening, but that value is substantially higher if a patient has a known abdominal mass.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory testing plays a minor role in the evaluation of a suspected abdominal or rectal mass, although a complete blood cell count is an important initial test. The leukocyte count is important if an infectious cause of the mass is being considered. The hemoglobin and red blood cell count indices allow assessment of the chronicity of gastrointestinal bleeding. In the setting of a hepatic mass, abnormalities in measurements of hepatic function, such as conjugated bilirubin, albumin, and international normalized ratio, suggest underlying cirrhosis. Use of immunologic tests for serum tumor markers has been controversial in the diagnosis of malignant abdominal tumors. Neuroendocrine tumors express synaptophysin and chromogranin A. Measurement of mucin-related carbohydrate antigens CA 19-9 and CA 242 has approximately 75% sensitivity for pancreatic adenocarcinoma but is fairly nonspecific. The test result can be positive for other cancers of the gastrointestinal tract, such as hepatobiliary or gastric cancer, among many patients with chronic pancreatitis, and among healthy persons. Measurement of carcinoembryonic antigen also is nonspecific for colorectal cancer; levels are elevated in the presence of benign liver and pancreatic disease. Carcinoembryonic antigen testing has limited use in the follow-up care of patients who have undergone surgical resection of colorectal cancer for the detection of recurrence. α -Fetoprotein, another oncofetal protein, is secreted by most but not all hepatocellular carcinomas. Overall, serum tumor markers are unreliable for diagnosis but may corroborate the diagnosis of a malignant disease under the appropriate clinical circumstances.

If a patient with an abdominal mass has ascites, it is important to perform diagnostic paracentesis for evaluation of the serum-ascites albumin gradient. A difference in serum-to-ascites albumin concentrations lower than 1.1 suggests that the ascites is not related to portal hypertension and is likely to indicate peritoneal metastasis. Cytologic examination of ascitic fluid has a sensitivity of about 50% for peritoneal carcinomatosis if adequate volume is aspirated but is highly specific. Increased levels of triglycerides in ascitic fluid (chylous ascites) strongly suggest underlying lymphoma.

In the case of masses of the stomach, small intestine, colon, or rectum, the most important diagnostic test is endoscopy coupled with endoscopic biopsy, which can be performed under sedation. A conventional upper gastrointestinal endoscope can reach lesions as far as the third portion of the duodenum. An enteroscope is needed to see jejunal lesions, and a side-viewing duodenoscope is used for better visualization of a mass in the region of the ampulla of Vater. In the lower gastrointestinal tract, anoscopy and rigid proctoscopy have limited diagnostic value when flexible fiberoptic endoscopy can be performed instead. Flexible sigmoidoscopy allows examination of the distal 60 cm of colon, which usually translates to an area around the mid descending colon. The examination can be undertaken after easy preparation with two cleansing enemas. The 180-cm colonoscope allows inspection of the entire colon and rectum (see [Chapter 127](#)).

The diagnostic use of endoscopic retrograde cholangiopancreatography (ERCP) is limited to masses of the pancreatic head or biliary tract. High-grade, abrupt obstruction of both the pancreatic duct and common bile duct (double duct sign) has high specificity for cancer of the pancreatic head. Cytologic brushings obtained at ERCP have less than 50% sensitivity for cancer of the bile duct or pancreas. A development in imaging of the biliary tree is magnetic resonance cholangiography, the clinical utility of which as an alternative, noninvasive modality remains to be fully elucidated.

Despite the great utility of endoscopic procedures in the diagnosis of an abdominal mass, these examinations should not always be undertaken if the mass is believed to be inflammatory or infectious. Inflammation of the wall may increase the risk of perforation during endoscopy, and endoscopic biopsy is not always definitive in identifying the cause of inflammation. Radiologic evaluation of the mass is a reasonable alternative.

Many cross-sectional imaging techniques are of use in evaluating abdominal masses. Ultrasonography is effective in imaging the hepatic parenchyma and the biliary system but is otherwise limited for use in the abdomen by gas in overlying intestine. In the kidneys, ultrasonography can be used reliably to diagnose most benign simple cysts. Computed tomography has emerged as the preferred technique for abdominal imaging because it allows a comprehensive evaluation of the viscera (see [Chapter 128](#)). Magnetic resonance imaging (MRI) can help define difficult to characterize lesions such as focal nodular hyperplasia and focal fatty infiltration.

CT is the standard for evaluation of renal and adrenal masses. MRI currently carries no appreciable advantage over CT in the evaluation of renal masses. CT also is widely used for imaging of the pancreas, in which contrast enhancement can be used reliably to detect masses more than 2 cm in diameter. In evaluation of pancreatic masses, however, CT is limited in defining involvement of peripancreatic vessels and peritoneal metastases, both of which are important indicators that the tumor is unresectable. These challenges have been addressed by the development of endoscopic ultrasonography (EUS), which can give greater detail about the pancreatic parenchyma and surrounding blood vessels and lymph nodes. With an endoscope fitted with an ultrasound probe, images of the pancreatic parenchyma can be obtained through adjoining parts of the stomach and duodenum. EUS is superior to other imaging modalities in the detection of small pancreatic masses. It is the most accurate method of local staging of pancreatic masses and of rectal masses. Because it also allows detailed visualization of the intestinal wall, EUS also is useful in evaluating submucosal lesions throughout the digestive tract, including the esophagus, stomach, small intestine, and rectosigmoid colon.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an abdominal mass is broad. It includes infectious, inflammatory, vascular, traumatic, and neoplastic lesions. These can be difficult to differentiate on the basis of history and physical findings alone given the nonspecific presentation. Careful radiologic characterization of the lesion is important because both the prognosis and the management decisions depend on the cause of the mass.

The importance of radiologic characterization is nowhere more important than in the liver ([Fig. 101.1](#)). With advanced imaging techniques, it is possible to diagnose most liver lesions, such as cysts, hemangioma, adenoma, focal nodular hyperplasia, focal fatty infiltration, and hepatocellular carcinoma. The presence of multiple lesions always prompts a search for an extrahepatic primary malignant tumor, usually carcinoma of the breast, colon, rectum, or lung. Even with the most advanced radiologic means, however, differentiating a liver tumor from an abscess may be difficult. Pyogenic (bacterial) liver abscesses may be single or solitary and mimic metastatic disease. They may arise from hematogenous spread of bacteria or from local spread from contiguous infections, often cholangitis. The diagnosis is considered even when patients have nonspecific symptoms such as low-grade fever and malaise, because 50% of patients with a liver abscess lack signs or symptoms referable to the right upper quadrant. Amebic abscess is a rare entity in the United States and is preceded in 90% of cases by a history of bloody diarrhea (dysentery) within the previous year. Abscess formation with an indolent presentation also can occur in the subphrenic space, arbitrarily defined as the space between the diaphragm and the transverse colon. In 90% of cases, this is a delayed complication of operations on the biliary tract, stomach, or duodenum.

FIGURE 101.1. Evaluation of a liver mass.

EVIDENCE LEVEL: B. Reference: Saim S. Imaging of the hepatobiliary tract. *N Engl J Med* 1997; 336:1889–1894.

In the evaluation of a suspected upper abdominal mass, the malignant potential of the mass is determined by its location, best defined with CT ([Fig. 101.2](#)). A mass arising in the stomach is adenocarcinoma until proved otherwise, because benign tumors of the stomach rarely grow to considerable size. Adenocarcinoma accounts for 95% of all cancers of the stomach and may defy endoscopic biopsy diagnosis if it presents in its infiltrating form, linitis plastica. Lymphoma is the second most common malignant tumor of the stomach, but it often manifests as an infiltrating, submucosal lesion rather than a single, ulcerating mass. A mass in the small intestine is less likely to be malignant than is a mass in the stomach. Benign small-intestinal tumors include adenoma, leiomyoma, lipoma, and less commonly hamartoma, fibroma, and angioma. The most common malignant tumors of the small intestine are adenocarcinoma (40% to 45%), carcinoid tumor (30%), leiomyosarcoma (10%), and lymphoma (15%). Throughout the gastrointestinal tract, the diagnosis of lymphoma is considered in the evaluation of patients with AIDS or profound

immunosuppression.

FIGURE 101.2. Evaluation of a suspected upper abdominal mass.
EVIDENCE LEVEL: C. Expert Opinion.

A solid mass in the pancreas, as in the stomach, is caused by cancer until proved otherwise (Fig. 101.3). Pancreatic cancer usually arises from the epithelium of the pancreatic duct (ductal adenocarcinoma). Other types of solid pancreatic masses are functional neuroendocrine tumors (insulinoma, gastrinoma, and VIPoma) and pancreatic lymphoma. When a pancreatic mass contains cystic components, the differential diagnosis includes inflammatory lesions such as pancreatic pseudocyst. The challenge lies in differentiating this benign lesion from a cystic pancreatic neoplasm, such as mucinous cystadenoma or cystadenocarcinoma. Mucinous cystic neoplasms occur more commonly among women (6:1 female-to-male ratio) between the ages of 40 and 60 years. Patients often have large, complex cysts that harbor foci of adenocarcinoma, which are difficult to visualize with any imaging modality. Because of that possibility, any large cystic lesion of the pancreas that is not clearly a pseudocyst complicating pancreatitis is evaluated for possible resection.

FIGURE 101.3. Evaluation of a pancreatic mass.
EVIDENCE LEVEL: C. Expert Opinion.

Neuroendocrine tumors of the gastrointestinal tract (carcinoids) arise most commonly in the appendix, followed by the ileum, rectum, and stomach. They are usually indolent with low rates of growth and therefore often have metastasized to mesenteric lymph nodes, liver, or lung by the time they come to medical attention. The symptoms of neuroendocrine tumors usually are caused by local effects of tumor growth, including obstruction and intussusception. Small-intestinal carcinoids in particular can cause obstruction due to an associated severe desmoplastic reaction in the mesentery, which is nearly pathognomonic at CT. Carcinoid syndrome, which comprises flushing, diarrhea, and valvular lesions and is attributed to secretion of serotonin, is experienced by less than 5% of all patients with carcinoids. It occurs only in the setting of hepatic metastases except for a few cases of foregut-derived carcinoids the venous drainage of which bypasses the liver.

Tumors arising from smooth muscle (leiomyoma or leiomyosarcoma) or submucosal or mesenteric fat (lipoma or liposarcoma) can occur throughout the digestive tract. Leiomyoma can arise from the muscularis mucosa or from the muscularis propria. In the stomach, leiomyoma has been known to display metastatic potential despite lacking the histologic features of leiomyosarcoma. Less common lesions of the digestive tract are spindle cell tumors, including neurofibroma, schwannoma, and leiomyoblastoma. Cystic masses based in the mesentery include mesenteric cysts (which lack smooth-muscle or lymphatic elements in their walls), cystic teratoma, and cystic mesothelioma. Because of their submucosal origins, these lesions usually do not cause bleeding until they have grown and eroded into the lumen. Symptoms may be nonspecific, including vague pain and obstruction. Perforation is rare but can occur with lymphoma or leiomyosarcoma. Metastatic lesions of the intestine are extremely rare, but can occur with melanoma, renal cell carcinoma, and breast carcinoma.

In the lower abdomen and rectum, a mass in a patient younger than 40 years is unlikely to be malignant unless the patient is part of a kindred of hereditary colorectal cancer, such as familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer syndrome. A mass in a young patient may be caused by perforation of an inflamed appendix or a segment of intestine involved with Crohn's disease. Among patients older than 50 years, a mass may be the result of the same processes or of diverticulitis or chronic intestinal ischemia. Perforated colorectal cancer also can cause abscess formation, so a thorough investigation for underlying malignant disease is recommended for this age group (Fig. 101.4).

FIGURE 101.4. Evaluation of colorectal abnormality.

If a colorectal mass is shown at colonoscopy or sigmoidoscopy to arise from the mucosa, the differential diagnosis is considerably narrowed. A polyp is a protrusion of mucosa into the intestinal lumen and is differentiated from a mass by its smaller size. Polyps are divided histologically into neoplastic (typically adenomatous) and non-neoplastic types. Nonadenomatous polyps whether hyperplastic or hamartomatous have no malignant potential but in rare instances can cause intussusception or discomfort when prolapsing through the anus. Adenomatous polyps (adenoma) are characterized by the finding of dysplasia at microscopic examination. The likelihood that an adenoma contains adenocarcinoma or will progress to adenocarcinoma is related to its size. The presence of a lesion larger than 1 cm in greatest dimension increases risk. Most colorectal cancers are adenocarcinoma, although colonic lymphoma, carcinoid tumor, and Kaposi's sarcoma also can occur. The appearance of colorectal cancer can be mimicked by colitis cystica profunda, a rare, benign disease characterized by large, submucosal, mucus-filled cysts that is

most common in the rectum. Because these distinctions can be difficult to make at endoscopy, a biopsy is performed on any polypoid or mass lesion.

A renal mass can be infectious, neoplastic, or congenital. Perinephric abscess, a complication of acute pyelonephritis, can be differentiated from a tumor at CT. Any solid renal mass that becomes enhanced with intravenous administration of contrast material during CT is presumed malignant. The most common malignant tumor is renal cell carcinoma, which often has systemic manifestations. The differential diagnosis of a solid renal mass also includes transitional cell carcinoma of the renal pelvis with parenchymal invasion, renal lymphoma, and a renal oncocytoma. Cystic renal masses most often are simple cysts, which are found at CT among 30% of patients older than 50 years. However, renal cysts also can harbor cancer. This is especially true among patients with von Hippel–Lindau disease or tuberous sclerosis (who also have renal angiomyolipoma), or among the 90% of patients undergoing long-term dialysis (more than 5 years) who have renal cysts. About 1% to 2% of these patients eventually have renal cell carcinoma.

A mass with a history of blunt trauma to the abdomen suggests the possibility of hematoma. The abdominal organs most susceptible to this type of injury are the spleen, the kidneys, and the retroperitoneal duodenum. A pulsatile mass found with abdominal palpation suggests an aortic aneurysm, although transmitted pulsation to a solid mass can be deceptive and confusing.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The discovery of an abdominal mass is a cause of great anxiety to a patient, so a physician is bound to feel urgency to arrive rapidly at a diagnosis. However, abdominal masses rarely constitute a medical emergency. It is important, therefore, to formulate a stepwise, logical approach that utilizes the strengths of the diagnostic modalities available in a cost-efficient and logical way.

The initial step is always an effort to define the characteristics and location of the mass. The information gleaned from physical examination must be complemented by appropriate radiologic evaluation. In the hepatobiliary system, CT has emerged as the optimal diagnostic test, except when gallstone disease (cholelithiasis or choledocholithiasis) is the presumptive diagnosis. Contrast-enhanced CT can be used to classify most focal liver lesions, such as a cyst, hemangioma, or metastasis. MRI is the state-of-the-art modality used in atypical cases and has largely supplanted liver biopsy in the diagnosis of liver lesions such as focal nodular hyperplasia, focal fatty infiltration, and some cases of adenoma. If the nature of a focal lesion is unclear, a directed biopsy can be undertaken under laparoscopic guidance. Patients with focal hepatocellular cancer or a solitary metastatic lesion are referred to a surgeon specialized in treatment of diseases of the hepatobiliary tract for possible resection. Resection of multifocal hepatocellular carcinoma or multiple metastatic lesions usually is not possible. The finding of metastatic liver lesions prompts a thorough, directed search for a primary source. Hepatic adenoma is resected when possible because of the risk of rupture or hemorrhage and the rare occurrence of malignant transformation. Focal nodular hyperplasia, which is more common than adenoma but less frequently symptomatic, can be followed, because it imparts no malignant risk. A patient with adenoma or focal nodular hyperplasia should stop taking oral contraceptives.

Outside the liver, CT again is an important early diagnostic tool. It offers a comprehensive analysis of the abdomen and pelvis, which includes the presence of enlarged lymph nodes. When malignant growth is suspected, CT is a diagnostic and staging study.

The need to obtain tissue for histologic diagnosis of an abdominal mass depends on the index of suspicion of malignancy and on the accessibility of the mass to biopsy techniques. For a mass in the stomach, colon, or rectum, endoscopic biopsy is easy if the mass involves the mucosa. For a mass in the pancreas, obtaining tissue for diagnosis is difficult unless the mass involves the ampulla; further evaluation with cholangiopancreatography or MRI often is necessary. In the evaluation of renal masses, percutaneous needle sampling to define the nature of a mass is not recommended. In the case of a cystic renal mass, malignancy cannot be reliably ruled out with fine-needle aspiration cytologic examination, and the therapeutic benefit of aspiration is limited, because the recurrence rate of benign cysts exceeds 90% unless sclerosis is performed. In the evaluation of solid renal masses, percutaneous biopsy is not recommended unless a diagnosis of lymphoma is suspected, because of the risk of needle track seeding.

The management of nonmalignant abdominal masses depends on the underlying cause, the presence of symptoms, and the risk of malignant transformation. Intra-abdominal abscesses are drained, and therapy is directed at the underlying disease, whether it is inflammatory bowel disease, urinary or biliary obstruction, pancreatitis, or vascular insufficiency. Pancreatic pseudocysts can be drained percutaneously, endoscopically, or surgically. Indications for drainage include symptoms (abdominal pain, nausea, continuing weight loss) or suspicion of infection. The staging and management of malignant abdominal tumors are discussed in [Chapter 115](#), [Chapter 116](#), [Chapter 118](#), and [Chapter 126](#).

COMPLICATIONS AND PITFALLS

A pitfall in the management of a mass lesion is a missed malignant tumor. A tumor can be missed because biopsy material from the lesion gave false-negative results for malignancy or the biopsy missed the target lesion. For that reason, if a biopsy result does not confirm a diagnosis or does not agree with the clinical or endoscopic impression, it is important to repeat the biopsy or proceed with an alternative sampling technique. If an abdominal mass lies outside the intestinal lumen and is therefore not accessible to endoscopic biopsy, laparoscopy is considered.

The evaluation of an abdominal mass involves procedures that in rare instances lead to serious complications. Intravenous administration of contrast material for CT exposes patients to the risk of anaphylactic reaction or acute renal failure. Endoscopic procedures are associated with a risk of hemorrhage or perforation, although these complications are rare (less than one in 500 procedures). The risk increases in the presence of active intestinal inflammation or other systemic disease. ERCP causes pancreatitis in 5% of cases. The risks of each diagnostic procedure and the comorbidity must be considered in determining how to proceed in the care of each patient.

Indications for HOSPITALIZATION

Most abdominal or rectal mass lesions can be evaluated on an outpatient basis. Endoscopic and radiologic tests are routinely performed as outpatient procedures. Patients with intestinal obstruction, intractable pain or vomiting, suggestion of an intra-abdominal abscess, or active gastrointestinal bleeding are evaluated in the hospital.

Indications for REFERRAL

If ERCP or EUS is indicated, it is preferable to refer the patient to a gastroenterologist with experience in advanced endoscopic procedures. The diagnostic accuracy of EUS in particular depends on the level of experience of the examiner. Early consultation with a surgical colleague is desirable even if surgery is not imminent to allow timely investigation of comorbid factors and discussion with the patient of the indications for surgery and its attendant risks and the alternatives. For malignant lesions, a multimodality approach with the collaboration of medical specialists, surgical specialists, oncologists, and radiation therapists is optimal management.

CHAPTER 102: APPROACH TO THE PATIENT WITH GASTROINTESTINAL BLEEDING

GRACE H. ELTA

[Presentation](#)
[Acute Upper Gastrointestinal Bleeding](#)
[Acute Lower Gastrointestinal Bleeding](#)
[Occult GI Bleeding](#)
[Gastrointestinal Bleeding from an Unknown Source](#)

Gastrointestinal (GI) bleeding is a common clinical problem that varies in severity from life-threatening hemorrhage to slow, insidious bleeding that produces only iron deficiency. The annual rate of hospitalization for upper GI bleeding has been estimated to be 36 to 102 patients per 100,000 members of the general population, and the rate is twice as common among men as among women. Lower GI bleeding is less common, requiring approximately 20 hospitalizations per 100,000 persons. The rate of both acute upper GI and acute lower GI bleeding is higher among patients who take aspirin than among those who do not, and the risk appears to be dose related. Most bleeding episodes from both upper GI and lower GI sources resolve spontaneously. However, patients with severe and persistent bleeding have high mortality rates and may need invasive interventional techniques. Early and accurate diagnosis among patients with severe bleeding facilitates therapeutic maneuvers that lower mortality. The foundation of management of GI bleeding is rapid assessment and appropriate resuscitation.

PRESENTATION

The presentation of GI bleeding depends on its acuity and the source. Chronic GI blood loss may manifest with unsuspected iron deficiency anemia or the finding of occult blood in routine screening stool examinations. More severe cases of chronic or unrecognized GI bleeding may manifest with symptoms of anemia, such as pallor, dizziness, angina, or dyspnea. Acute GI bleeding usually has a much more obvious presentation. Bleeding from the upper GI tract often manifests with hematemesis, or bloody vomitus. This may be from recent bleeding, which causes bright red vomitus, or previous bleeding, which gives vomitus a coffee grounds appearance. Melena is black, tarry, loose, malodorous stool caused by the presence of degraded blood in the intestine and generally indicates an upper GI source, although the bleeding may originate in the proximal colon or small intestine. Other causes of black stool, such as iron or bismuth ingestion, must be ruled out. Hematochezia, or bright red blood from the rectum that may be mixed with stool, generally indicates a lower GI lesion.

ASSESSMENT AND RESUSCITATION

The first step in assessment of GI bleeding is to determine the urgency of the situation. Agitation, pallor, hypotension, and tachycardia may indicate shock, which necessitates immediate volume replacement. Shock occurs when blood loss approaches 40% of blood volume. If there is no evidence of hypotension and tachycardia, the presence of orthostatic vital signs helps establish the diagnosis of lesser degrees of intravascular volume depletion. Postural hypotension of 10 mm Hg or greater usually indicates 20% or greater reduction in blood volume. If the patient has acute bleeding, intravenous access must be established. If the patient has signs of shock or continued bleeding, a large-bore central intravenous line is useful. Blood samples are obtained immediately for assessment of hematocrit, platelets, and coagulation factors and blood typing and cross-matching.

The initial hematocrit of a patient with acute bleeding poorly reflects the degree of blood loss. Because hematocrit is expressed in terms of red blood cell volume as a percentage of total blood volume, it does not drop until blood volume has been restored. This repletion of blood volume from extravascular fluid begins immediately but takes 24 to 48 hours to equilibrate completely. Therefore a patient with acute bleeding needs close attention to blood pressure and heart rate. Gross evidence of ongoing bleeding is better for evaluating blood loss than are laboratory tests. In contrast, hematocrit is an accurate reflection of the degree of anemia among patients with chronic blood loss. However, the severity of iron deficiency, reflected by microcytic indices and low serum ferritin, is a better indicator of the duration of bleeding.

Patients with severe acute GI bleeding need admission to an intensive care unit. Intravascular volume is repleted with normal saline solution to prevent the consequences of shock while blood is being cross-matched for transfusion. The specific criteria that define when a patient needs transfusions vary with the age of the patient, the presence of concomitant cardiopulmonary disease, and the presence of continued bleeding. In general, the hematocrit is maintained above 30% for elderly patients and above 20% for young, healthy patients. With continued evidence of bleeding, the decision to transfuse cannot be based on hematocrit alone. Plasma volume after acute GI bleeding also often is overexpanded by intravenous fluids; thus the hematocrit immediately after transfusion may be an underestimate of final value. In general, packed red blood cells are the primary source of blood. Transfusion of whole blood is reserved for the unusual circumstances of massive blood loss and need for coagulation factor replacement. If results of coagulation tests are abnormal, as is the case among many patients with cirrhosis, fresh frozen plasma and platelets may have to be administered. Even patients with an initially normal prothrombin time and platelet count eventually need plasma and platelet transfusions when repeated transfusions are performed. In rare instances patients who undergo massive transfusions need calcium supplementation to counter the effects of calcium-binding agents in banked blood.

Indications for HOSPITALIZATION

Patients with ongoing bleeding, a need for transfusion, or endoscopic findings that put them at risk of recurrent bleeding need to be admitted to the hospital. Changes in practice over the last 10 years show that hospitalization days have decreased considerably and that more than 90% of patients with upper GI bleeding undergo endoscopy within 24 hours of admission. Twenty-five percent of these endoscopic examinations include endoscopic hemostatic therapy. An important change in the management of nonvariceal upper GI bleeding has been the use of upper GI endoscopy to assess the risk of rebleeding and allow outpatient care of selected patients, which has led to considerable cost savings. Because most of the hospital cost of providing care for patients with upper GI hemorrhage is the hospital bed cost, shortening the length of stay or eliminating the need for hospitalization can greatly lower costs.

Indications for REFERRAL

Patients with GI bleeding need early referral for endoscopy because in most instances this examination is necessary for diagnosis. Early endoscopy also allows an accurate prognosis for the bleeding episode and allows endoscopic therapy.

LOCATION OF BLEEDING

In the case of obvious upper GI bleeding that manifests with hematemesis, a nasogastric tube is placed to further assess the rate of ongoing blood loss. When upper GI bleeding is only suspected, as when a patient has melena or a history of epigastric symptoms or disease, the presence of blood in a nasogastric tube confirms the upper GI tract as the source. Not infrequently, however, duodenal bleeding with melena may not produce blood in the nasogastric aspirate because the pylorus is competent and there is little duodenogastric reflux. Therefore a normal nasogastric aspirate does not preclude the upper GI tract as the bleeding source. Testing for occult blood in nasogastric aspirates rarely is necessary because the blood often is obvious. A simple positive test result for occult blood may merely indicate nasogastric tube trauma. The one occasion on which occult blood testing is helpful is when a coffee grounds aspirate appearance is produced by food. When occult testing of a gastric aspirate is performed, it is important not to rely on standard stool kits, which give false-negative results in acidic solutions.

Hematochezia usually indicates a lower GI source. However, a patient with rapid bleeding from an upper GI source may pass bright red blood through the rectum because of rapid GI transit. Therefore placement of a nasogastric tube and even performance of an upper endoscopic examination are considered if there is any clinical question about the bleeding location in a patient with hematochezia.

For patients with occult bleeding or iron deficiency, the history and physical examination often help localize the likely source of blood loss. However, patients may have more than one GI lesion, so a lesion in the upper GI tract may accompany a problem in the intestine. Therefore many of these patients need diagnostic evaluation of the entire GI tract.

ACUTE UPPER GASTROINTESTINAL BLEEDING

Approximately 80% of episodes of upper GI bleeding are self-limited and necessitate only supportive therapy. Recent mortality rates for upper GI hemorrhage vary from 3.5% to 7% in the United States, although a large study in the United Kingdom showed a mortality rate of 14%. Patients with continued or recurrent bleeding have mortality rates of 25% to 30%. Factors predictive of a poor prognosis for upper GI bleeding include the age of the patient (over 60), severity of the initial bleeding, concomitant illnesses, the cause of bleeding, and signs of recent hemorrhage. The most important prognostic indicator is the cause of bleeding. Variceal hemorrhage has much higher rebleeding and mortality rates than other diagnoses. Onset of bleeding during hospitalization has a mortality of 33% compared with only 7% among patients who start to bleed before admission. Patients who need emergency surgical treatment have a surgical mortality as high as 30%; those undergoing elective operations have a surgical mortality of 10%.

Endoscopic visualization of signs of recent bleeding, such as active arterial spurting, oozing of blood, visible vessel, or fresh or old blood clot, is an important predictor of outcome among patients with peptic ulcer bleeding ([Table 102.1](#)). The rebleeding rate among patients with arterial spurting from an ulcer is higher than 70%; for patients with a visible vessel, which may be hidden by an adherent clot, it is 50%. This contrasts to other less common signs such as black eschar, oozing, or clot, which are associated with rebleeding rates of 6% to 8% compared with no rebleeding of ulcers without stigmata.

Sign	Incidence (%)	Risk of Rebleeding (%)
Spurting arterial bleeding	8	85-100
Nonbleeding visible vessel	17-50	19-55 (mean, 43)
Adherent clot (no visible vessel)	18-26	24-41
Other signs	12-18	5-9
No signs	10-36	0

TABLE 102.1. SIGNS OF HEMORRHAGE AND RISK OF REBLEEDING

ETIOLOGY

The three major causes of upper GI bleeding are peptic ulcer disease, gastropathy (or gastric erosions), and varices ([Table 102.2](#)). The distribution of causes varies with the patient population studied. In all endoscopic series, 10% to 15% of patients have no diagnosis confirmed, and as many as 20% to 30% have more than one diagnosis. The patients with no endoscopic diagnosis have an excellent prognosis.

Diagnosis	Percentage of All Diagnoses
Duodenal ulcer	24.3
Gastric erosions	23.4
Gastric ulcer	21.3
Varices	10.3
Mallory-Weiss tear	7.2
Esophagitis	6.3
Erosive duodenitis	5.8
Neoplasm	2.9
Stomal ulcer	1.8
Esophageal ulcer	1.7
Miscellaneous	6.8

TABLE 102.2. FINAL DIAGNOSES OF CAUSE OF UPPER GASTROINTESTINAL BLEEDING AMONG 2,225 PATIENTS

Peptic Ulcer

Duodenal, gastric, or stomal ulcers account for 40% to 50% of upper GI bleeding. Continued bleeding or recurrent bleeding is an indication for endoscopic therapy. Multipolar electrocoagulation, heater probe, neodymium: yttrium-aluminum-garnet (Nd:YAG) laser therapy, and injection therapies all are therapeutic options through flexible endoscopy. These therapeutic endoscopic methods are accepted for cessation of bleeding. They are also used for prevention of rebleeding among patients at high risk with signs of bleeding identified at endoscopy. Early surgical therapy is considered for persistent or recurrent bleeding from ulcers not controlled with endoscopic techniques. Only when a patient has an inoperable condition would alternative treatment such as angiographic embolization with gelatin foam or autologous clot be reasonable. Intra-arterial infusion of vasopressin is relatively ineffective in the control of ulcer bleeding, presumably because the vessels that bleed tend to be large.

Gastric Erosions or Gastropathy

The term *gastritis* should be reserved for pathologists; it is defined histologically and may have no endoscopic or clinical correlate. Gastropathy can be divided into several etiologic categories. Drug-induced gastropathy due to use of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) is generally a self-limited disease that heals rapidly after discontinuation of the offending agent. The GI hemorrhage caused by drug-induced gastropathy is common because of the widespread use of these medications but is usually minor and transient.

Alcohol is also a gastric mucosal irritant, although it is uncertain whether alcohol in the doses usually consumed causes gastropathy or whether some of the damage that occurs among persons with alcoholism is related to underlying portal hypertension. Gastropathy associated with portal hypertension frequently is present in patients with cirrhosis. The GI hemorrhage from this lesion can be recurrent and difficult to manage but rarely is massive. In the unusual case of profuse chronic blood loss from portal gastropathy, portosystemic shunting and propranolol are reported to be effective.

Stress gastritis is an important type of gastropathy that causes serious hemorrhaging. It occurs among patients in intensive care units who have risk factors such as respiratory failure, hypotension, sepsis, renal failure, thermal burns, peritonitis, jaundice, and neurologic trauma. Risk of bleeding for an individual patient varies with the number of risk factors. Endoscopic evidence of stress gastropathy is found among almost all patients in intensive care units, although only 2% to 10% of these patients have serious bleeding. All therapeutic modalities for clinically significant bleeding are associated with high failure rates and high morbidity.

Endoscopic therapy usually is the first and safest choice for treatment although it has not been studied for this specific indication. The presence of multiple bleeding sites precludes use of endoscopic therapy in the care of some patients. In contrast to therapy for bleeding ulcers, angiographic control of bleeding due to stress gastropathy by means of intra-arterial administration of vasopressin reportedly has a good success rate because of the small vessel size in these superficial lesions. Operative mortality is extremely high for stress gastropathy, and rebleeding after surgery is common, so surgery is the last alternative. The main emphasis in the management of stress gastropathy is prophylaxis. Routine use of high-dose antacids, H₂ blockers, or sucralfate for patients at risk has been shown to decrease the incidence of bleeding. Use of agents that improve mucosal defense without altering intragastric pH, such as sucralfate, may lower the rate of nosocomial pneumonia

among patients breathing with respirators, although these data are controversial.

Varices

Hemorrhage from esophageal varices often is massive and has a high mortality rate. The highly specialized therapy for variceal bleeding necessitates an early and accurate diagnosis. The presence of cirrhosis does not assure that varices are the bleeding source because 30% to 60% of patients with cirrhosis who have upper GI bleeding have a nonvariceal source. In addition to standard resuscitation measures, patients with variceal hemorrhage are treated with intravenous octreotide or vasopressin plus nitroglycerin, sclerotherapy or band ligation, and occasionally balloon tamponade. When sclerotherapy or band ligation fails the patient eventually may need portosystemic shunting. This traditionally has necessitated a surgical procedure, which carries high risk among patients with advanced cirrhosis. As an alternative, transjugular intrahepatic portosystemic shunting (TIPS) achieves portal decompression and allows time for consideration of liver transplantation (see [Chapter 105](#)).

Other Causes of Upper Gastrointestinal Bleeding

Mallory–Weiss tears are retching-induced superficial tears in the gastric or esophageal mucosa close to the gastroesophageal junction. Many patients with this lesion give a history of vomiting foodstuffs before vomiting blood. However, the presence of blood with the first emesis does not rule out this diagnosis. Patients often have a history of alcohol intake. Mallory–Weiss tear usually responds to conservative management but may necessitate therapy with endoscopic hemostatic techniques or even intra-arterial vasopressin.

Gastric varices usually accompany esophageal varices and are caused by underlying liver disease. It is important, however, to consider splenic venous thrombosis as the cause of the increased venous pressure when gastric varices are associated with minimal to absent esophageal varices. This may occur as a complication of pancreatitis owing to contiguous inflammation from the body and tail of the pancreas. These patients are best treated with simple splenectomy and have an excellent prognosis because of the lack of underlying liver disease.

Esophagitis and esophageal ulcers account for approximately 8% of instances of upper GI hemorrhage. The primary cause of these lesions is peptic reflux. Other etiologic factors are irradiation, infectious esophagitis caused by pathogens such as *Candida* organisms or herpesvirus, pill-induced damage, and sclerotherapy-induced ulcers. Persistent or recurrent bleeding is managed aggressively with therapeutic endoscopic or angiographic techniques because esophageal lesions are less amenable to surgery than is peptic ulcer disease.

Hemorrhage from erosive duodenitis is closely related to duodenal ulcer bleeding but usually is less severe because the lesions are shallower and involve smaller vessels. It accounts for approximately 5% of cases of upper GI hemorrhages.

Neoplasms are an uncommon source of upper GI bleeding but do cause persistent or recurrent bleeding. Surgical removal of the neoplasm often is indicated. However, for patients at poor risk who have known metastatic disease, other means of hemostasis such as endoscopic therapy or angiographic embolization of tumor vessels is quite successful.

Vascular ectasia, or angiodysplasia, which occurs less commonly in the stomach or duodenum than in the colon, cause 5% to 7% of cases of upper GI bleeding. The lesions may be associated with hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease), chronic renal failure, aortic valve disease, or radiation therapy. They also occur sporadically among elderly persons. Therapeutic endoscopic methods of ablation have been successful in some instances, although when the lesions are multiple, recurrences are common. Because it improves platelet function, estrogen therapy is effective in decreasing blood loss from vascular ectasia among patients with renal disease. Estrogen-progesterone therapy has been shown to decrease transfusion requirements among patients with normal kidney function who have chronic bleeding from vascular ectasia. An unusual variant of gastric vascular ectasia is watermelon stomach. The endoscopic appearance is a column of vessels that run along the top of longitudinal rugal folds that traverse the antrum and resemble the stripes on a watermelon.

Aortoenteric fistula is a rare cause of bleeding, but it must be diagnosed promptly. This fistula occurs primarily among patients who have undergone insertion of a Dacron graft because of an aortic aneurysm and in whom the graft has eroded into the duodenum, usually the third portion. Most patients with aortoenteric fistulas have relatively minor bleeding one or two times (herald bleeds) before fatal exsanguinating hemorrhage occurs. A high index of suspicion in the evaluation of patients who have undergone operations on the aorta may allow early surgical intervention.

Hematemesis and hemosuccus pancreaticus, or bleeding into the GI tract through the ampulla of Vater, is rare. Causes include liver trauma or liver biopsy, cancer, hepatic arterial aneurysm, hepatic abscess, gallstones, and pancreatic pseudocyst. The diagnosis may be made endoscopically but requires angiographic confirmation. The lesions may be managed with angiographic embolization or surgery.

Dieulafoy's syndrome is protrusion of a ruptured artery into the proximal portion of the stomach with essentially no surrounding ulceration. The cause of bleeding is thought to be not a primary ulcerative process but pressure erosion of the overlying epithelium by the ectatic vessel. These lesions often respond to electrocoagulation, although surgical ligation may be needed.

DIAGNOSTIC APPROACH

Whether all patients with upper GI bleeding should undergo a diagnostic examination is controversial. Those with self-limited minor bleeding and other more serious medical problems may not need an examination, because endoscopic diagnosis has not been shown to alter prognosis. However, for most patients, even those with relatively little bleeding, an accurate diagnosis is desirable to direct further care ([Fig. 102.1](#)). For some patients with profuse bleeding, the diagnostic examination or endoscopy can be used for therapeutic maneuvers.

FIGURE 102.1. Evaluation of nonvariceal upper gastrointestinal bleeding.
EVIDENCE LEVEL: C. Expert Opinion.

History and Physical Examination

While initial resuscitation measures are being implemented, a history interview is conducted and a physical examination performed. The history often raises specific diagnostic possibilities. A history of peptic disease or dyspeptic symptoms suggests ulcer bleeding. Recent use of aspirin or NSAIDs must always be ascertained. A history of ingestion of alcohol or a caustic substance is important. A history of cirrhosis, or symptoms of cirrhosis such as ascites, may suggest the need for urgent endoscopy to diagnose variceal bleeding. Other medical conditions, such as having undergone aortic graft surgery, coagulopathy, cancer, or a recent nosebleed, may suggest diagnoses.

Physical examination of the skin may provide diagnostic clues. Signs of cirrhosis or evidence of underlying malignant disease, such as Kaposi's sarcoma, may be

present. Findings of lymphadenopathy or abdominal masses may suggest malignant disease. Abdominal tenderness in the epigastrium is a common sign of peptic disease. Hepatic or splenic enlargement may occur with liver disease or some malignant disorders. When a patient has upper GI bleeding, results of a rectal examination may indicate the magnitude of blood loss by demonstrating maroon or melanic stools in patients with severe bleeding.

Endoscopy

Barium contrast studies have been replaced by endoscopy in the diagnosis of upper GI bleeding. The much greater accuracy and therapeutic potential of endoscopy generally makes it the diagnostic procedure of choice. Diagnostic endoscopy is viewed as a safe and simple procedure by both patient and physician, although morbidity and mortality rates of 1.0% and 0.1%, respectively, have been reported. Endoscopy is contraindicated when the patient is uncooperative or is likely to have a perforated viscus. Endoscopy can be used for precise location of the bleeding when there is continued bleeding or when signs of bleeding persist. For some patients with massive hemorrhage, the source of bleeding cannot be discerned at endoscopy. For patients whose bleeding has stopped and no signs of bleeding remain, a lesion seen at endoscopy, such as a clean ulcer base, is the presumed source. Sometimes more than one lesion or no lesions are identified. Under these circumstances, no definitive diagnosis can be made, and these patients need to undergo another examination if they bleed again.

The timing of the diagnostic endoscopy depends on the severity and suspected cause of the hemorrhage. Patients who do not stop bleeding with simple supportive care need urgent endoscopy to guide further therapeutic techniques. For patients with underlying cirrhosis, endoscopy is performed as soon as possible after the bleeding episode because these patients often have more than one site of potential hemorrhage, and the diagnosis of bleeding varices alters future approaches to treatment. In most instances, when bleeding ceases, diagnostic endoscopy can be postponed for 24 hours without seriously altering diagnostic accuracy. When there are no complications and both patient and physician are comfortable without a specific diagnosis, an empiric trial of treatment may be indicated. Barium radiography may be used in this situation to rule out more serious lesions and avoid endoscopy altogether.

Radionuclide Scanning

Localization of the site of GI bleeding can be accomplished by means of scanning for extravasation of intravascular radiolabeled material. In one method technetium Tc 99m sulfur colloid is used, and scans are obtained soon after injection. Another method with technetium Tc 99m pertechnetate-labeled red blood cells allows repetition of scans for 24 to 36 hours after injection to detect intermittent bleeding. These techniques can reveal bleeding when the rate of blood loss is as low as 0.5 mL per minute and have no associated morbidity. The disadvantage of radionuclide scanning is that the bleeding merely is localized to an area of abdomen; the scans do not show the specific location or the responsible lesion. For this reason, radionuclide studies often are used as a screening tool to determine whether a patient has sufficient bleeding to warrant angiography. The value as an angiography screen has been questioned, but the scans may allow more selective angiographic studies and thereby decrease the load of contrast material.

Angiography

Angiography is used as a diagnostic examination in acute upper GI bleeding only when endoscopy has not provided enough information to establish a diagnosis. The source of blood loss must be arterial and flowing at a rate of 0.5 to 0.6 mL per minute to detect extravasation. Angiography may be chosen as a therapeutic alternative for delivery of intra-arterial vasopressin to patients with stress gastropathy or for embolization of inoperable bleeding ulcers or neoplasms. Angiography also can be used to diagnose difficult cases of recurrent GI bleeding from an unknown source. Angiographic demonstration of vascular ectasia may suggest the source of bleeding, although for patients who are not actively bleeding, the diagnosis is uncertain since these are frequent lesions. Angiography provides an accurate diagnosis in 50% to 75% of instances but is associated with a serious complication rate of about 2%. Complications of angiography are related to catheter placement (dissection, thrombosis, or false aneurysm) or the contrast material (allergic reactions, renal failure). When embolic occlusion of vessels with gelatin foam or autologous clot is performed, the complication rate increases with potential ischemic necrosis and perforation.

MANAGEMENT

Treatment of patients with upper GI bleeding always begins with resuscitation measures. Once the patient's condition is stable, two types of treatment are available, empiric and specific. Specific treatment depends on the diagnosis and the presence or absence of continued bleeding. For patients with severe bleeding, specific treatment is endoscopic or angiographic control or surgery. Empiric treatment often is initiated before diagnostic examinations are performed, especially when bleeding stops, as occurs in most instances.

Gastric Lavage

Gastric lavage with iced saline solution is a frequently used method of control of upper GI bleeding. The procedure is performed through a nasogastric tube, which has been placed to identify the location of bleeding. The theoretical advantage of use of a cold solution is that it may slow blood flow. It can be argued, however, that ice water may impair coagulation factors and that it increases patient discomfort by making them cold. Therefore room temperature tap water is used. This allows monitoring of the rapidity of bleeding, although it is unlikely that appreciable therapeutic benefit is obtained.

Drug Treatment

More than 25 randomized, controlled studies have been performed on the use of histamine type 2 (H_2) antagonists in the management of upper GI hemorrhage. An analysis of pooled results from treatment of more than 2,500 patients suggested that treatment may reduce the rate of surgical intervention 20% and of death 30%, although these reductions were only marginally significant. Because even a moderate reduction in mortality is desirable and because H_2 -blockers are without great toxicity, these agents are commonly administered to patients with ulcer bleeding despite the lack of proven efficacy. Although it has been suggested that more potent acid suppression with continuous intravenous administration of H_2 -antagonists or with high doses of omeprazole may be more effective than standard doses of H_2 -antagonists, this effect had been difficult to demonstrate. In a comparison of omeprazole and placebo in the treatment of ulcer patients at high risk with bleeding signs at endoscopy who were not treated by means of endoscopy, it was found that high-dose omeprazole (40 mg twice a day) significantly lowered the rates of further bleeding and surgical intervention. Although potent acid suppression is unlikely to replace endoscopic therapy, it appears to be the medical treatment of choice, perhaps because clotting activity is stabilized.

Several other drug treatments have been studied. Intravenous administration of somatostatin decreases acid secretion, splanchnic blood flow, and portal pressure. Evidence of the efficacy of this therapy for acute nonvariceal GI bleeding is not strong. For variceal hemorrhage, both intravenous vasopressin and somatostatin are reported to be helpful, although these data are controversial. Complications of vasopressin therapy are primarily cardiovascular and increase with higher doses. Sublingual or intravenous administration of nitroglycerin with vasopressin markedly decreases the complication rate of vasopressin therapy and improves control of bleeding, perhaps because of a reduction in portal venous resistance and portal venous pressure. For other types of bleeding lesions, the only commonly used method of delivery of vasopressin is through an angiographically placed arterial catheter. Mucosal protective agents such as sucralfate and prostaglandins have not been well studied in the control of bleeding but may be of similar benefit as acid-reducing therapy.

Endoscopic Treatment

Endoscopic methods can be divided into two types, thermal and nonthermal. Nonthermal methods include injection of sclerosing agents such as alcohol or ethanolamine, injection of vasoconstrictors such as epinephrine, or simple injection of normal saline solution. Thermal methods include the Nd:YAG laser therapy, use of a heater probe, multipolar electrocoagulation (BICAP), and argon plasma coagulation. Both the heater probe and the BICAP device are small, mobile units that can be used in the intensive care unit or emergency department. Direct probe pressure is used to tamponade the bleeding vessel, then the tissue temperature is raised to coagulate and seal the vessel. Nd:YAG laser therapy is as effective as use of a heater probe or BICAP device. However, the immobility of the Nd:YAG laser, the requirement for trained support personnel, and the high cost of the equipment reduce the attractiveness of this therapy. Because of its lower depth of injury, argon plasma coagulation has been used primarily to manage superficial lesions such as vascular ectasia. Although most studies have not shown improvement in mortality rates with endoscopic therapy, a meta-analysis of numerous trials suggested that mortality is improved, although the results reached statistical significance only for laser therapy. It is now widely accepted that in addition to controlling upper GI bleeding, therapeutic endoscopic methods can prevent rebleeding of high-risk ulcers when signs of bleeding are found. However, a lack of standardized definitions of the various signs of recent hemorrhage and sufficient knowledge of the course of development of each sign continue to be problems in deciding when this preventive therapy is warranted.

Angiographic Treatment

Intra-arterial delivery of vasopressin through angiographically placed catheters is successful in the management of upper GI bleeding when the bleeding vessel is of small caliber, as in stress gastropathy. Embolization is an effective alternative when the bleeding vessel is large, as in hemobilia or in inoperable cancer or ulcer bleeding.

Surgical Treatment

The indications for urgent surgical therapy for GI bleeding have remained essentially the same over the last 50 years except that now endoscopic therapy may be tried as a first approach. Patients who continue to bleed for more than 24 hours, need more than six to eight transfusions, or have recurrent bleeding despite endoscopic treatment need surgery. This decision may be delayed for patients who are at poor operative risk and can undergo angiographic treatment or when a specific diagnosis has a known high surgical mortality rate, such as stress gastropathy or acute variceal hemorrhage. If the patient requires surgery, decisions must be made quickly, before the patient's condition deteriorates.

ACUTE LOWER GASTROINTESTINAL BLEEDING

Lower GI bleeding is defined as bleeding that originates below the ligament of Treitz. The average patient is older than the average patient with upper GI bleeding. The mortality rate for lower GI bleeding is reported to be 3.6%, similar to that for upper GI bleeding. The mortality is markedly higher when bleeding begins after hospitalization. A decrease in mortality from acute lower GI bleeding has been witnessed in the past three decades. This decrease has been attributed to better localization and diagnosis of bleeding by means of colonoscopy and angiography, which allow more selective surgical and angiographic treatment. It also may be attributed to better resuscitation care and medical and surgical management.

ETIOLOGY

The two major causes of acute lower GI bleeding are diverticulosis and angiodysplasia ([Table 102.3](#)). As in the case of upper GI bleeding, 80% of bleeding episodes resolve spontaneously, and 20% are associated with persistent blood loss. Among patients whose bleeding ceases, about 25% have recurrent bleeding. Unlike upper GI bleeding, most lower GI bleeding is slow and intermittent and does not necessitate hospitalization. The most common causes of chronic lower GI bleeding are hemorrhoids and colonic neoplasia.

Diagnosis	Percentage of all Diagnoses
Diverticulosis	43
Angiodysplasia	20
Undetermined	12
Neoplasia	9
Colitis

TABLE 102.3. FINAL DIAGNOSES OF MAJOR LOWER GASTROINTESTINAL BLEEDING

Diverticulosis

Diverticular bleeding occurs among only about 3% of patients with diverticulosis. However, it is the most common cause of lower GI hemorrhage because of its high prevalence in the Western world. Despite the left-sided preponderance of diverticula, angiographic studies have demonstrated that 70% of bleeding diverticula occur in the right colon. In contrast, colonoscopic studies have suggested a higher incidence of bleeding diverticula in the left colon. Regardless of the most common location, better localization of the bleeding source with either angiography or colonoscopy allows directed surgical therapy and is associated with lower postsurgical rebleeding rates. When diverticular bleeding ceases spontaneously, no further therapy is indicated because most patients do not have recurrences. Approximately 20% of patients have recurrent diverticular bleeding, and they need elective surgical excision of the portion of the colon bearing the bleeding site. In the event of failure to localize the bleeding area, right hemicolectomy or subtotal colectomy is indicated when the patient's general medical condition and anticipated life span warrant such aggressive therapy. Among the 20% of patients with persistent hemorrhage from diverticulosis, angiography can be used for both diagnosis and treatment.

Bleeding from diverticula is presumed to be caused by penetration of a colonic artery into the dome of the diverticulum. The artery ruptures into the diverticular sac and causes copious bleeding, but clinical evidence of diverticulitis or inflammation usually is not present. Diverticulosis is thought not to produce occult heme-positive stool or slow bleeding.

Angiodysplasia

Vascular ectasia, or angiodysplasia, is a common cause of both lower GI hemorrhage and slow, intermittent blood loss. Most of the lesions are degenerative and are associated with aging, unlike the congenital vascular lesions that occur throughout the GI tract among various age groups. Two-thirds of patients with colonic angiodysplasia are older than 70 years. Angiodysplastic lesions usually are multiple, less than 5 mm in diameter, and primarily involve the cecum and right colon. There appears to be some clinical association with aortic valve stenosis. The diagnosis of vascular ectasia can be made with colonoscopy or angiography. Both diagnostic modalities frequently depict the lesions without demonstrating active bleeding. Despite this limitation, if no other source of GI bleeding is identified, the presence of angiodysplasia in a patient with recurrent or persistent GI bleeding is an indication for treatment. Intra-arterial administration of vasopressin has been successful for control of continued hemorrhage. When bleeding has ceased, endoscopic techniques of hemostasis may be tried. When there are too many lesions or when bleeding reoccurs despite therapeutic colonoscopy, right hemicolectomy or subtotal colectomy is indicated depending on the location of the lesions. Medical therapy with estrogen and progesterone has decreased transfusion requirements among patients with inoperable lesions or those with presumed small-intestinal angiodysplasia, which cannot be reached with colonoscopy or enteroscopy.

Neoplasms

Benign and malignant neoplasms of the colon are common lesions that like diverticulosis and angiodysplasia occur predominantly among the elderly. Neoplasms rarely cause hemorrhage but usually manifest with intermittent episodes of a small amount of bleeding or occult blood in the stools. The diagnosis is made by means of colonoscopy or barium enema radiographic examination. Treatment is by means of surgical or colonoscopic excision. Tumors of the small intestine are rare but may be diagnosed by radiography of the small intestine or enteroclysis.

Other

Hemorrhoids are probably the most common cause of minor intermittent lower GI bleeding. The characteristic clinical history is bright red blood on the toilet tissue or around the stool but not mixed in the stool. Bleeding often occurs with straining or passage of hard stool. A similar history is common among patients with anal fissures, although fissures tend to be more painful. However, rectal polyps and carcinoma may have a similar history, so patients always are evaluated with flexible sigmoidoscopy. Perianal disease is managed with sitz baths, stool softeners, avoidance of straining, and ointments or suppositories. It is unknown whether actual therapeutic benefit is obtained with local application of medications containing lubricants and hydrocortisone, but many patients report symptomatic relief. When

bleeding or other symptoms continue to be troublesome, hemorrhoidal banding or surgery may be indicated.

The amount of bleeding from inflammatory bowel disease and ischemic, infectious, or radiation-induced colitis usually is small to moderate; it rarely is massive. The blood is mixed with the stool, and often there are other symptoms of the disease, such as diarrhea, pain, and tenesmus. Diagnosis and management of these entities must be individualized according to diagnosis.

Meckel's diverticulum is the most frequent congenital anomaly of the intestinal tract. It is caused by incomplete obliteration of the vitelline duct, which leaves an ileal diverticulum that may contain gastric mucosa capable of acid secretion. Most Meckel's diverticula remain asymptomatic. The most common complication, bleeding, usually occurs in childhood, although in rare instances it occurs among adults. The diagnosis can be made by means of radiolabeled technetium scanning, but false-negative findings are not uncommon. Barium filling of the diverticulum may occur, especially with enteroclysis. Mesenteric angiography may show the site of bleeding. Surgical excision is the treatment of choice.

Intussusception may become manifest with maroon stools and is almost always accompanied by crampy abdominal pain. Uncommon among adults, intussusception usually has a leading point such as a polyp or malignant tumor. The diagnosis may be suggested by plain abdominal radiographs and the findings of a sausage-shaped mass at physical exam. Barium enema radiographic examination may be useful for diagnosis and, among children, for therapeutic reduction. Treatment of adults for intussusception usually is surgical.

Ileal or colonic varices, which have a predilection to occur around ostomies, may cause massive lower GI bleeding. The diagnosis often is made by means of angiography, and treatment is portosystemic shunting with surgery or TIPS. Multiple lesions of colonic vascular ectasia among patients with portal hypertension, called portal colopathy, can cause hematochezia or Hemoccult-positive stools. Solitary rectal ulcer, which may be caused by internal prolapse of the rectal mucosa, also causes lower GI bleeding, although bleeding rarely is massive. Colonic ulcers, especially in the cecum, may be related to use of NSAIDs. Aortoenteric fistulas not associated with prosthetic grafts have been found in the ileum and colon. The diagnosis usually is made at angiography, the treatment is surgical.

DIAGNOSTIC APPROACH

All patients with lower GI bleeding need a diagnostic examination unless the overall prognosis is too poor to warrant further testing (Fig. 102.2). For most patients whose bleeding ceases spontaneously, elective colonoscopy after routine preparation is indicated. Patients with continued bleeding need an urgent diagnosis. If a perianal or rectal source is suspected, simple proctoscopy can be performed quickly and may provide the diagnosis. For most colonic bleeding, a more thorough examination is needed. If the bleeding is slow to moderate, rapid intestinal lavage by means of nasogastric intubation allows adequate preparation for urgent colonoscopy. In the presence of rapid bleeding, the colonoscopic view may be obscured, so immediate angiography must be performed. Before angiography, upper GI endoscopy is considered to rule out an upper GI source of bleeding.

FIGURE 102.2. Evaluation of lower gastrointestinal bleeding.
EVIDENCE LEVEL: C. Expert Opinion.

History and Physical Examination

A thorough history and physical examination often point to the correct diagnosis. For example, a prior diagnosis of hemorrhoids or inflammatory bowel disease is important. Symptoms that occur in association with bleeding, such as abdominal pain or diarrhea, suggest specific diagnoses. A recent history of anorexia or weight loss may indicate malignant disease. The finding of an abdominal mass at physical examination also suggests cancer.

Colonoscopy

Colonoscopy has generally replaced barium enema radiographic examination for diagnostic evaluation of lower GI bleeding. Several series have demonstrated the superior diagnostic sensitivity of colonoscopy even over that of double-contrast barium enema examination. Ten percent to 20% of patients with lower GI bleeding and normal results of barium enema examinations have abnormal colonoscopic findings. When lower GI bleeding is the clinical indication for colonoscopy, the diagnostic yield is high (40% to 50%). If results of a barium enema examination are abnormal, colonoscopy usually is still indicated for biopsy or therapeutic maneuvers. For these reasons, most clinicians favor colonoscopy as the primary examination. In the rare instances in which full colonoscopy is not technically feasible or when the colonoscopic findings do not provide enough information for a diagnosis, a barium enema examination is helpful. Patients with rapid, ongoing blood loss need diagnostic angiography or urgent colonoscopy after purging.

Angiography

For a patient with rapid bleeding, angiography offers accurate diagnosis and therapy. Most angiographers prefer that radionuclide scans be obtained first to demonstrate active bleeding and direct the angiographic examination. When dye extravasation does not occur, angiography can lead to a presumptive diagnosis, such as angiodysplasia (Fig. 102.3). Rare small-intestinal lesions, such as arteriovenous malformations or neoplasms, may be demonstrated. Despite the diagnostic accuracy of both colonoscopy and angiography, the source of bleeding in many patients with a presumed lower GI source is not found. Most of these patients undergo repeated studies.

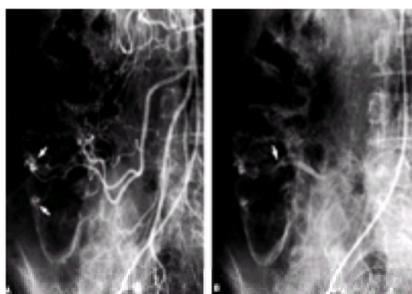

FIGURE 102.3. **A:** Angiogram shows two vascular tufts (*arrows*) that suggest cecal angiodysplasia. **B:** Venous image from the same arteriogram demonstrates early venous filling (*arrow*), reflecting arteriovenous communication through a dilated vascular ectasia.

TREATMENT

Resuscitation must be the initial step in patient care. Most patients whose bleeding stops need elective treatment of the source of bleeding depending on the diagnosis. Urgent therapeutic maneuvers are indicated when a patient needs transfusion of more than three units of red blood cells.

Intra-arterial Administration of Vasopressin

For patients with extensive bleeding, vasopressin is infused at a rate of 0.2 units per minute after selective catheterization of the bleeding vessels. Contrast injection is repeated in 30 minutes to confirm cessation of hemorrhage. If hemorrhage is controlled, the vasopressin dose is reduced to 0.1 unit per minute and maintained for about 12 hours. If the hemorrhage persists, the dose may be increased to 0.3 unit per minute. If vasopressin therapy fails, the patient needs surgery. Embolization techniques are used as a last resort in the care of patients who cannot withstand surgical treatment.

Therapeutic Colonoscopy

When bleeding has ceased or is slow, electrocoagulation techniques may be used to manage angiodysplasia. There are a few reports of this type of therapy for bleeding diverticula, although the success and complication rates are not yet known.

Surgery

Accurate localization of bleeding sites with angiography and colonoscopy has led to improved mortality and rebleeding rates among patients with lower GI bleeding. For the difficult situation of recurrent bleeding without demonstration of bleeding site, a subtotal colectomy may be indicated when the patient's overall prognosis is good.

OCCULT GI BLEEDING

Occult GI bleeding is defined as bleeding of which the patient is unaware and which is manifested by guaiac-positive stools or iron deficiency anemia. Absorption of dietary iron (average, 1 to 2 mg a day) equals or just exceeds iron loss through normal daily occult GI bleeding (average, 1 mg a day). Large amounts of blood may be lost in the GI lumen and yet remain occult. Ingestion of more than 200 mL of blood is required to produce melena, and a bolus of more than 150 mL of blood into the cecum is required to produce melena or hematochezia.

Hemoglobin components in stool depend on the bleeding site. Bleeding from the upper GI tract allows degradation of hemoglobin and conversion of heme to porphyrins, which are not detectable with conventional guaiac-based tests (can be negative with losses of 30 mL of blood per day). The hydration of stools also affects guaiac positivity; liquid or soft stools are much more likely to be positive. In addition the presence of fruits and vegetables that have peroxidase activity or of red meat can cause false-positive results. In general blood loss must exceed 10 mL a day for a Hemoccult test result to be positive half the time. Hemoquant, which is a quantitative measurement of stool heme-derived porphyrin, is much more accurate in measuring GI blood loss. However, the high cost of the Hemoquant test and the requirement of collection of a stool specimen (possibly leading to decreased compliance) has hampered widespread use.

The best discriminant of iron deficiency is serum ferritin level, which correlates better with iron stores than do either serum iron and transferrin saturation or hypochromic microcytic indices. Iron deficiency presents primarily with fatigue, which is multifactorial and not caused by anemia alone. Pica, or compulsive eating behavior for ice or soil, is associated with iron deficiency. Physical findings include koilonychia, glossitis, cheilitis, and esophageal webs.

Most of the lesions that cause gross GI bleeding can also cause chronic oozing and occult bleeding. In Western countries acid-peptic disease accounts for 30% to 70% of instances of occult bleeding. In tropical countries, hookworm infestation is the most common cause. A few specific causes of occult bleeding that were not mentioned in the discussion of gross bleeding deserve comment. Large hiatal hernias are associated with iron-deficiency anemia thought to be caused by longitudinal erosions (Cameron's erosions) in the gastric mucosa at the level of the diaphragmatic hiatus. Long distance runners may have iron deficiency caused by occult bleeding due to mesenteric ischemia or repetitive jarring. A common cause of occult GI bleeding is gastroduodenal and small-intestinal damage due to use of aspirin and other NSAIDs. If the occult bleeding is caused by use of NSAIDs and the patient needs to continue use of these drugs, switching to enteric-coated aspirin, nonacetylated salicylates, or a less damaging NSAID may decrease mucosal irritation. Another alternative is cotreatment with prostaglandins or proton pump inhibitors (PPIs), which has been shown to be effective in the prevention of gastropathy and ulcers due to NSAIDs. Prophylactic treatment with H₂-blockers appears effective against duodenal disease but not gastric disease. It remains unclear who should receive prophylaxis because most patients taking NSAIDs do not have appreciable upper GI bleeding, and routine prophylaxis with prostaglandins or PPIs is expensive and has side effects. It seems reasonable to recommend cotreatment with prostaglandins or PPIs in the care of patients who have marked upper GI bleeding but need to continue NSAID intake.

Current health care maintenance recommendations include yearly testing of three stool specimens for the presence of blood after the age of 40 to 50 years. This may allow for early detection and better cure rates for colonic carcinoma, the second most common cause of cancer deaths in the United States (see [Chapter 116](#)). Unfortunately, patients with asymptomatic colorectal cancer often have fecal blood levels below the threshold of guaiac tests and within the normal range of quantitative tests. Several studies have shown Hemoccult detection rates for asymptomatic colon cancer of 20% to 30% with compliance rates for screening programs in the range of 30% to 60%. Therefore it is not surprising that fecal blood screening confers only marginal reductions in cancer mortality.

The amount of diagnostic evaluation indicated for patients with occult bleeding depends on the severity of blood loss, age of the patient, and clinical history ([Fig. 102.4](#)). All patients who have anemia due to GI blood loss warrant evaluation. Depending on drug history, symptoms, and age, this may consist of endoscopic examination of either the upper or the lower GI tract. Many patients need study of both potential sites of blood loss, because concurrent lesions are common. In the absence of anemia or GI symptoms in a patient older than 40 years, colonoscopy or air-contrast barium enema examination plus sigmoidoscopy is adequate. For young patients without GI symptoms or anemia, simple follow-up hematocrit readings and examinations of stool samples may be sufficient because diagnostic studies are both expensive and uncomfortable.

FIGURE 102.4. Evaluation of occult gastrointestinal bleeding.
EVIDENCE LEVEL: C. Expert Opinion.

GASTROINTESTINAL BLEEDING FROM AN UNKNOWN SOURCE

A few instances of chronic bleeding or recurrent acute bleeding elude diagnosis despite upper and lower GI radiography and upper GI and lower GI endoscopy. It has been estimated that as many as 5% of patients do not have an identifiable source of bleeding despite extensive examination. The cause of most instances of GI

bleeding of obscure origin is thought to be vascular ectasia.

For young patients a radionuclide scan for Meckel's diverticulum is valuable. A useful approach toward identifying small-intestinal sources of bleeding is enteroclysis or small-intestinal infusion radiography. This necessitates oral intubation and fluoroscopic positioning of the tip of the tube at the duodenojejunal junction. Barium is then rapidly injected with methylcellulose and water to achieve a double contrast effect. If the results of the small-intestinal studies are negative among patients bleeding from an unknown source and the blood loss can be offset with iron supplementation, no further evaluation may be necessary. If transfusions are needed, however, visceral angiography or small-intestinal enteroscopy is indicated. Angiography for patients who are not actively bleeding may reveal vascular anomalies or small-intestinal tumors not identified with other studies. Small-intestinal enteroscopy has been reported successful in making a diagnosis for 30% of patients with bleeding of obscure origin that has eluded all other diagnostic tests. Intraoperative transluminal endoscopy has been useful in locating small-intestinal angiodysplastic lesions. Endoscopic thermal ablation of angiodysplasia is recommended when the lesions are accessible. If ablation is unsuccessful or not feasible because of the presence of multiple lesions, surgical resection of the involved segments may be necessary. A therapeutic trial of estrogen-progesterone therapy for the possible underlying diagnosis of vascular ectasia may be worthwhile even if there is not a definite diagnosis. Rare instances of bleeding from an unknown source defy diagnosis, or the patient is too ill for surgery and must undergo transfusions as needed.

Jaundice, or icterus, is yellow pigmentation of the skin, mucous membranes, sclerae, and body fluids. It is caused by excess accumulation in tissue of bilirubin, a distinctively colored degradative product of heme. It is a dramatic sign of liver disease or, less commonly, hemolysis, and has been recognized for centuries.

PRESENTATION

Jaundice is the clinical manifestation of hyperbilirubinemia. Yellow discoloration of the skin caused by chronic ingestion of large amounts of foods rich in carotene or lycopene, such as carrots or tomatoes, respectively, or of drugs such as quinacrine and busulfan is readily differentiated from jaundice with the documentation of normal serum bilirubin levels and the absence of scleral icterus. Jaundice usually is detectable when serum bilirubin levels are greater than 2.5 to 3 mg per deciliter (43 to 51 μmol per liter). It is more difficult to appreciate jaundice of darkly pigmented skin and under artificial light. Clinical jaundice lags the increase in serum bilirubin level by several days, reflecting the time required for bilirubin to permeate the skin and mucous membranes. As a consequence, in disorders associated with conjugated hyperbilirubinemia, darkening of the urine and light-colored (acholic) stools may precede the development of jaundice.

PATHOPHYSIOLOGY

The ability to develop a differential diagnosis of jaundice requires a familiarity with certain fundamental aspects of the normal physiologic mechanism of bilirubin production and excretion. Bilirubin is formed by the breakdown of heme ([Fig. 103.1](#)). Approximately 80% of bilirubin is derived from heme released from the breakdown of senescent erythrocytes in the reticuloendothelial system. The rest comes from the heme moieties of other heme-containing proteins, such as myoglobin and tissue cytochromes. Under normal conditions, less than 1% of bilirubin is derived from ineffective erythropoiesis in the bone marrow. The microsomal enzyme, heme oxygenase, converts heme to biliverdin, which is then converted to bilirubin by biliverdin reductase. The unconjugated bilirubin produced by these enzymatic reactions is transported in blood tightly but reversibly bound to albumin. Competition for albumin binding by certain drugs displaces unconjugated bilirubin. In neonates this may result in diffusion of bilirubin across the blood-brain barrier and bilirubin encephalopathy or kernicterus. Because of its tight albumin binding and hydrophobicity, unconjugated bilirubin is not filtered or secreted by the kidney. Instead, unconjugated bilirubin is avidly taken up by the liver.

FIGURE 103.1. Bilirubin metabolism. The conversion of heme to biliverdin by microsomal heme oxygenase occurs predominantly in the reticuloendothelial cells of the spleen. Biliverdin undergoes further oxidation by cytosolic biliverdin reductase to form bilirubin. Unconjugated bilirubin circulates in plasma largely bound to albumin. After dissociation from albumin, bilirubin is taken up by the liver, where it is bound to the cytosolic proteins, glutathione S-transferases (GST). Glucuronidation of bilirubin is catalyzed by microsomal uridine diphosphoglucuronyl transferase (UDPGT), and the reaction results in formation of bilirubin monoglucuronide (BMG) and bilirubin diglucuronide (BDG). Conjugated bilirubin is then excreted into bile.

Hepatic uptake of bilirubin across the sinusoidal membrane is mediated, in part, by a protein termed *organic anion transporting polypeptide* (OATP). Other proteins, yet to be cloned, such as bilitranslocase, also mediate the sinusoidal uptake of unconjugated bilirubin. In the hepatocyte, bilirubin is bound to cytosolic binding proteins and transported to the endoplasmic reticulum, where it is converted to a water-soluble form by means of conjugation as a diglucuronide. This process facilitates its excretion into bile and is mediated by the microsomal enzyme, bilirubin uridine diphosphoglucuronyl transferase (UDPGT).

Hepatic bilirubin uptake and conjugating activity are preserved in most forms of liver disease. Biliary excretion represents the rate-limiting step in overall bilirubin metabolism. This step is mediated by a canalicular multispecific organic anion transporter (cMOAT) that has been identified as an adenosine triphosphate (ATP)-binding cassette transporter that belongs to the family of multidrug resistance proteins (MRP2).

Jaundice can be classified pathophysiologically as the result of unconjugated or of conjugated hyperbilirubinemia. Unconjugated hyperbilirubinemia occurs when there is a defect in bilirubin metabolism before hepatic uptake. Conjugated hyperbilirubinemia results when the defect occurs after hepatic uptake. This classification scheme is artificial: even in pure hemolytic states, serum conjugated bilirubin levels are elevated somewhat, albeit to a lesser extent than the rise in unconjugated bilirubin. Likewise, liver disease, in which predominantly conjugated hyperbilirubinemia occurs, also may raise levels of serum unconjugated bilirubin. Hemolysis may accompany certain forms of liver disease, such as Wilson's disease, and intrahepatic cholestasis may be associated with hemolytic disorders, such as the jaundice associated with sickle cell anemia. Hemolytic disorders also are associated with pigment gallstone formation, which may lead to obstructive jaundice.

HISTORY AND PHYSICAL EXAMINATION

Many clues to the cause of jaundice and the presence of liver disease can be obtained from a carefully performed history interview and physical examination. These clues include the following:

- History of exposure to infectious agents, such as the hepatitis viruses, drugs, organic solvents, alcohol, or other hepatotoxins
- History of gallstones, previous operations on the biliary tract, and previous episodes of jaundice or inflammatory bowel disease
- Family history of jaundice or liver disease
- The presence of pruritus, fever, or abdominal pain
- Signs of chronic liver disease, including palmar erythema, spider angiomas, parotid gland enlargement, gynecomastia, Dupuytren's contracture, and testicular atrophy
- Physical findings of chronic cholestasis, including excoriation, xanthelasma, and xanthoma
- Physical signs of inflammation or malignant disease, including hepatomegaly, splenomegaly, palpable gallbladder, tenderness with palpation, mass lesions, and cachexia

Age and sex are important clues. Viral hepatitis occurs more commonly among younger adults; choledocholithiasis and malignant disease occur among older patients. Primary biliary cirrhosis and choledocholithiasis are more common among women; pancreatic cancer and primary sclerosing cholangitis are more common among

men.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Serum levels of total, conjugated, and unconjugated bilirubin confirm the clinical diagnosis of jaundice and direct further evaluation. A complete blood cell count, reticulocyte count, and microscopic examination of a peripheral blood smear are useful in identifying hemolysis as the predominant cause of jaundice. Serum bilirubin levels typically do not exceed 5 mg per deciliter with hemolysis. Routine liver function tests (serum albumin and prothrombin time [PT]) and liver chemical analysis (serum alanine aminotransferase [ALT], aspartate aminotransferase [AST], and alkaline phosphatase) should be performed. In the absence of hemolysis, the finding of isolated hyperbilirubinemia indicates Gilbert's syndrome or familial hyperbilirubinemia as the cause of jaundice.

Elevation of the serum alkaline phosphatase and transaminase activities of a patient with jaundice points to the presence of hepatobiliary disease. As more fully discussed in [Chapter 104](#), the pattern of liver chemistry abnormalities is helpful in differentiating hepatocellular from cholestatic liver injury. Hepatocellular injury invariably causes an increase in serum aminotransferase activity, but marked (fourfold or greater) elevations of serum alkaline phosphatase activity are typically seen among patients with cholestatic disorders. If serum alkaline phosphatase level is normal, extrahepatic obstruction is unlikely.

Imaging of the biliary tree is an early and important step in the evaluation of patients with jaundice who are thought to have cholestatic jaundice. The role of these studies is to determine whether bile duct dilatation is present and, if it is present, the site and cause of the obstruction. Ultrasonography (US) and computed tomography (CT) are the primary imaging modalities used. US is less expensive than CT and obviates use of contrast agents and ionizing radiation. Although US can readily depict cholelithiasis, it is more limited than CT in detecting the level and type of obstruction. US evaluation of the pancreas and distal common bile duct may be obscured by overlying intestinal gas. Obesity also may limit the technical quality of US. CT may be indicated as the first-line imaging study if malignant disease is suspected because it provides information about pancreatic abnormality, retroperitoneal lymph node involvement, and ability to resect the tumor.

If bile duct dilatation is found, or if bile duct dilatation is absent but clinical suspicion for bile duct obstruction is high, direct visualization of the biliary tree with either endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous cholangiography (PTC) is warranted. In certain cases, such as that of a patient who has undergone cholecystectomy and is likely to have choledocholithiasis, direct visualization of the bile duct as the initial diagnostic study may be the most appropriate and cost-effective approach. The choice between ERCP and PTC, two invasive studies, is governed by the availability of skilled personnel, the patient's clotting function, the anticipated need for therapeutic intervention (sphincterotomy, placement of biliary stents or drains), earlier operations, such as Roux-en-Y gastrojejunostomy, and the anticipated level of obstruction. ERCP is favored over PTC for distal lesions; PTC is favored over ERCP for proximal lesions.

Magnetic resonance cholangiopancreatography (MRCP) is a relatively new technique of noninvasive visualization of the bile ducts and pancreatic ducts without the use of contrast material. Early trials suggest it may be useful in the evaluation of jaundice. Endoscopic ultrasonography (EUS) is another imaging modality that has demonstrated utility and accuracy in the diagnosis of choledocholithiasis. For patients with a low to moderate likelihood of having choledocholithiasis, EUS may be a more cost-effective strategy than ERCP without the potential complication of pancreatitis. In contrast, hepatobiliary imaging with iminodiacetic acid derivatives labeled with technetium 99m, although useful in the diagnosis of acute cholecystitis, has no role. Oral cholecystography and intravenous cholangiography also should not be performed. If biliary obstruction has been excluded or hepatocellular disease is strongly suspected, liver biopsy may be warranted.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of jaundice is based on whether the disease responsible for jaundice is likely to be hemolytic, hepatocellular, or cholestatic. If the disease is cholestatic, it depends on whether the process is intrahepatic or extrahepatic. An algorithm for the diagnostic approach to jaundice is shown in [Fig. 103.2](#).

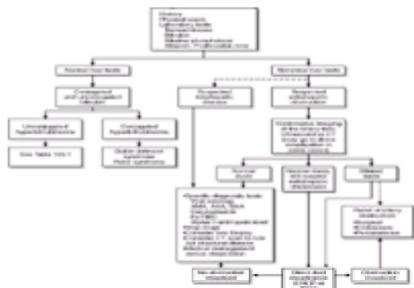

FIGURE 103.2. Evaluation for jaundice. *Dotted line*, alternative approach for certain patients. *AMA*, antimitochondrial antibody; *ANA*, antinuclear antibody; *SMA*, smooth-muscle antibody; *Fe/TIBC*, iron/total iron binding capacity. **EVIDENCE LEVEL: C. Expert Opinion.**

UNCONJUGATED HYPERBILIRUBINEMIA

Unconjugated hyperbilirubinemia is caused by an increase in bilirubin production, impaired hepatic uptake, or impaired conjugation ([Table 103.1](#)). As much as 85% of total serum bilirubin is the unconjugated form in these disease states. Increased red blood cell destruction in disorders associated with ineffective erythropoiesis and in hemolytic disorders increases bilirubin production. Examples include ineffective erythropoiesis associated with pernicious anemia, sideroblastic anemia, thalassemia, and lead poisoning and congenital and acquired hemolytic conditions, including hereditary spherocytosis, hemoglobinopathy, autoimmune hemolysis, and hemolysis associated with drug use or sepsis. Reductions in hepatic blood flow due to congestive heart failure or portosystemic shunting impair the delivery and uptake of bilirubin to hepatocytes. Impaired hepatic uptake at the sinusoidal membrane occurs in Gilbert's syndrome and after administration of certain drugs, such as sulfonamides, penicillin, salicylates, and rifampin. The hyperbilirubinemia of Gilbert's syndrome is mild (2 to 4 mg per deciliter) and is exacerbated by fasting and intercurrent viral infection. Reduced activity of UDPGT leads to impaired bilirubin conjugation and occurs among neonates and patients with Gilbert's and Crigler–Najjar type I and II syndromes. UDPGT activity can be induced by phenobarbital, effectively reducing the jaundice in Crigler–Najjar type II syndrome.

TABLE 103.1. PATHOPHYSIOLOGIC CLASSIFICATION OF JAUNDICE

Category	Subcategory	Examples
Increased bilirubin production	Hemolytic	Ineffective erythropoiesis Increased red blood cell destruction Gilbert's syndrome
	Other	Drugs (e.g., rifampin, radiographic contrast agents, Meprobamate)
Impaired hepatic uptake	Acquired	Congestive heart failure Surgical or anastomotic portosystemic shunts Hepatic jaundice
	Genetic	Crigler–Najjar syndrome Gilbert's syndrome
Impaired conjugation	Acquired	Drugs (e.g., phenobarbital, chlorzoxazone, carbamazepine)
	Genetic	Crigler–Najjar type I and II syndromes

TABLE 103.1. PATHOPHYSIOLOGIC CLASSIFICATION OF JAUNDICE

CONJUGATED HYPERBILIRUBINEMIA

Conjugated hyperbilirubinemia can occur in a wide spectrum of hepatobiliary diseases, including disorders associated with acute or chronic liver injury, extrahepatic biliary obstruction, and the familial abnormalities of bilirubin excretion—Dubin–Johnson and Rotor’s syndromes. Cholestasis, or impaired bile formation, is the most common cause of jaundice. Cholestasis can be categorized further as a functional defect in bile formation at the level of the hepatocyte (intrahepatic cholestasis) or obstruction of bile flow within the biliary tract (extrahepatic cholestasis). The most common causes of intrahepatic and extrahepatic cholestasis are listed in [Table 103.2](#). Hepatobiliary disorders associated with a cholestatic pattern of jaundice often are accompanied by pruritus. Extrahepatic biliary obstruction may manifest with signs of cholangitis, such as fever, right upper quadrant abdominal pain, leukocytosis, and hypotension. Serum alkaline phosphatase levels are disproportionately elevated relative to serum aminotransferase levels, and serum cholesterol levels may be elevated. A prolonged PT, reflecting malabsorption of fat-soluble vitamin K, is corrected by means of parenteral administration of vitamin K.

Intrahepatic	Extrahepatic
Acute hepatocellular disorders	Cholelithiasis
Viral hepatitis	Biliary strictures
Alcoholic hepatitis	Cholangiocarcinoma
Drugs	Pancreatic carcinoma
Chronic hepatocellular injury	Pancreatitis
Primary biliary cirrhosis	Periampullary carcinoma
Sclerosing cholangitis	Biliary atresia
Chronic active hepatitis	Choledochal cysts
Drugs	Miscellaneous disorders
Total parenteral nutrition	
Systemic infection	
Postoperative state	
Benign recurrent causes	
Miscellaneous conditions	

TABLE 103.2. DIFFERENTIAL DIAGNOSIS OF CHOLESTATIC SYNDROMES

Jaundice produced by disorders associated predominantly with hepatocyte necrosis or dysfunction has a hepatocellular pattern. Examples of such disorders include acute viral hepatitis, autoimmune hepatitis, and most forms of drug-induced hepatotoxicity. Malaise, anorexia, nausea, and vomiting may dominate the clinical signs and symptoms of these disorders. Disproportionate elevations in serum aminotransferase levels relative to serum alkaline phosphatase levels reflect the underlying hepatocellular damage and necrosis. In complete biliary obstruction, serum bilirubin level tends to plateau over time between 10 and 30 mg per deciliter. Levels greater than 30 mg per deciliter are more likely to occur among patients with hepatocellular disease. Additional factors, such as renal failure, excessive hemolysis, and sepsis, are present among patients with severe hyperbilirubinemia. Prolongation of PT in these disorders points to the presence of impaired hepatocellular synthetic function and, in contrast to cholestatic forms of jaundice, is typically not corrected by means of administration of vitamin K. The importance of differentiating intrahepatic from extrahepatic causes of cholestatic jaundice and cholestatic from hepatocellular jaundice is reflected in the divergent approaches to the diagnosis of the disorder and treatment of patients with these different processes.

INTRAHEPATIC CAUSES OF CHOLESTASIS

HEPATOCELLULAR DISORDERS

Although hepatocellular forms of liver injury characteristically cause a disproportionate increase in serum aminotransferase levels relative to serum alkaline phosphatase levels, several hepatocellular disorders may have patterns more consistent with cholestatic injury. An atypical variant of acute hepatitis A viral infection characterized by prolonged intrahepatic cholestasis has been described. Usual features of the clinical illness include pruritus, fever, diarrhea, weight loss, pronounced jaundice, and serum bilirubin levels greater than 10 mg per deciliter followed by complete recovery after 12 weeks or more. The importance of this syndrome lies in differentiating this relatively benign disorder from extrahepatic obstruction. Acute hepatitis B virus infection, particularly among the elderly, may manifest with a cholestatic pattern. Cholestatic hepatitis with atypical histologic features, such as ductular proliferation and acute pericholangitis, has been reported among liver transplant recipients with hepatitis C virus infection. Cholestasis also is a characteristic of epidemic, or waterborne, non-A, non-B hepatitis, or hepatitis E viral infection.

A predominant cholestatic picture, with striking elevations in serum alkaline phosphatase levels, occasionally occurs with acute alcoholic hepatitis. In these cases, liver biopsy specimens typically contain signs of cholangitis that involves intralobular bile ducts in the absence of extrahepatic obstruction. The degree of cholestasis found at liver biopsy is a highly significant indicator of poor outcome among patients with alcoholic hepatitis.

PRIMARY BILIARY CIRRHOSIS

Chronic nonsuppurative destructive cholangitis, commonly known as primary biliary cirrhosis (PBC), is a chronic, progressive cholestatic syndrome of unknown causation that is most common among women in the sixth or seventh decade of life. The most common symptoms of PBC are pruritus and fatigue of insidious onset. Jaundice is present among about one-fourth of patients when they come to medical attention. Physical findings among patients with PBC can be variable. For patients with symptoms, examination is more likely to reveal hepatomegaly, splenomegaly, hyperpigmentation, excoriation, and signs of chronic liver disease, such as spider angioma and palmar erythema. The physical finding of xanthelasma correlates with moderate elevations in serum lipid levels, whereas xanthoma usually are a reflection of severe hyperlipemia.

More than 80% of patients with PBC have at least one associated autoimmune disease and nearly 50% have two or more such disorders, often manifesting themselves after the diagnosis is made. Keratoconjunctivitis sicca is the most commonly reported association.

The triad of an elevated serum alkaline phosphatase level (corroborated by similar elevations in 5 α -nucleotidase, g-glutamyl transpeptidase [GGTP], or leucine aminopeptidase level), detectable titers of antimitochondrial antibody, and an elevated serum IgM level is of considerable discriminatory value in the diagnosis of PBC. Percutaneous liver biopsy with special stains for copper is critical in the diagnostic approach when PBC is suspected.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a chronic, progressive inflammatory disorder that primarily affects the extrahepatic and intrahepatic bile ducts and leads to fibrosis and stricture of the biliary tract (see [Chapter 125](#)). Obstruction of the biliary tree is manifested as chronic cholestasis that results in secondary biliary cirrhosis, portal hypertension, and hepatic failure.

Physical findings of PSC may include jaundice, hepatomegaly, and splenomegaly. Early in the development of PSC, however, the physical findings may be entirely normal. Later stages of the disease are characterized by the signs of chronic liver disease and of portal hypertension common to other forms of cirrhosis. The development of cholangiocarcinoma is another late complication of PSC. The hallmark of PSC is the presence of multiple areas of stenosis of bile ducts (see [Chapter 125](#)).

Biliary tract abnormalities resembling PSC have been described as a complication of AIDS. Clinical manifestations include fever, right upper quadrant pain, nausea, and vomiting. Marked elevations of serum alkaline phosphatase levels and lesser changes in serum aminotransferase and bilirubin levels are found. Cholangiography reveals intrahepatic and extrahepatic ductal dilatation with focal stricture formation or beading and decreased arborization and terminal pruning of secondary and tertiary intrahepatic biliary radicles. Endoscopic sphincterotomy results in symptomatic and biochemical improvement among some patients with concomitant stenosis of the papilla of Vater. Opportunistic infection of the biliary tract with cytomegalovirus or *Cryptosporidium* species and resultant cholangitis have been proposed as a pathogenic mechanism for this cholestatic syndrome.

Histiocytosis X, cystic fibrosis, and hepatic metastases from adenocarcinoma of the pancreas and colon may manifest with cholangiographic findings identical to those

of PSC. A caustic form of sclerosing cholangitis has been found after injection of a scolical solution for the management of hepatic *Echinococcus* cysts. This form of sclerosing cholangitis affected only the parts of the biliary tract that came in contact with this agent. Progressive cholestasis associated with diffuse intrahepatic duct involvement that mimics PSC has been found after bone marrow transplantation.

DRUG-INDUCED INTRAHEPATIC CHOLESTASIS

Cholestasis is a common feature of drug-induced liver injury and typically is manifested as bland cholestasis (e.g., estrogenic steroids) with minimal biochemical or histologic evidence of hepatic inflammation or as an inflammatory cholestasis (e.g., phenothiazines), which often is accompanied by systemic features of a hypersensitivity reaction, such as fever, rash, arthralgia, and eosinophilia, and histologic features of hepatocellular necrosis. A wide spectrum of drugs have been implicated (Table 103.3).

Amoxicillin ^a	Ketoconazole
Amoxicillin/clavulanic acid	Neritizimazole
Atenolol	Methyltestosterone
Azathioprine	Nitrofurantoin ^b
Captopril	Phenybutazone
Chlorpromazine ^a	Procainamide
Chlorpropamide	Propofolperazine
Cyclosporine	Propafenone
Danazol	Sulfonamides
Erythromycin	Sulfindac
Estrogens	Thiabendazole
Flouridone	Tolazamide
Flurazepam	Tolbutamide
Flutamide	Trazodone
Gold salts	Trimethoprim-sulfamethoxazole
Griseofulvin	Valproic acid ^b
Haloperidol	Warfarin
Imipramine	

^a Reports of vanishing bile duct syndrome have been described.
^b Typically cause hepatocellular injury, although cholestasis has been described.

TABLE 103.3. DRUGS ASSOCIATED WITH INTRAHEPATIC CHOLESTASIS

CHOLESTASIS ASSOCIATED WITH TOTAL PARENTERAL NUTRITION

Several different biochemical and histologic patterns of hepatic dysfunction have been recognized during administration of total parenteral nutrition (TPN). Steatosis appears to be related to TPN formulas containing large amounts of carbohydrates as the only caloric source. Intrahepatic cholestasis, although more common among newborn premature infants, also occurs among adults during hyperalimentation, particularly patients with inflammatory bowel disease. Twofold elevations in serum alkaline phosphatase and total bilirubin levels are encountered and abnormalities in ALT levels characteristically are more pronounced than elevation in AST levels. GGTP level appears to be the most sensitive indicator of TPN cholestasis in the pediatric population. Several mechanisms have been proposed, including direct effects of constituents of TPN solutions and intraluminal effects resulting from the interruption of oral intake or loss of intestinal surface area. Elevated biliary levels of the cholestatic bile acid lithocholate, which normally is formed by bacterial degradation of chenodeoxycholate, have been described among patients with abnormalities in liver chemical values during TPN. Antibiotic suppression of putative intestinal bacterial overgrowth among patients receiving TPN may be effective in preventing cholestasis.

Extrahepatic forms of cholestasis must be considered in the differential diagnosis of jaundice among patients receiving long-term hyperalimentation. Several factors that work in concert to promote bile stasis during TPN are thought to be responsible for the increased incidence of gallbladder sludge, cholelithiasis, and acalculous cholecystitis among these patients.

JAUNDICE IN BACTERIAL INFECTIONS

Cholestatic jaundice among patients with bacterial infections is a well-recognized clinical syndrome. The pathogenic mechanism is thought to involve circulating bacterial endotoxin, because cholestasis is associated with infection with a variety of gram-negative bacteria and is found in the absence of documented bacteremia. Sepsis-associated cholestasis is not restricted to gram-negative bacteria. Clinical hepatic dysfunction usually is overshadowed by the symptoms and signs of the underlying disease, although the sudden appearance of jaundice with a high fever may herald the systemic infection. Conjugated hyperbilirubinemia occurs and levels typically are within the range of 5 to 10 mg per deciliter. Twofold to threefold elevations in serum alkaline phosphatase levels occur among about one-half of all patients, but serum aminotransferase levels usually are normal.

POSTOPERATIVE JAUNDICE

Postoperative jaundice is a commonly encountered cholestatic syndrome. The importance lies in determining the cause among the various etiologic or contributory factors. Increased bilirubin production may be the result of transfusions, particularly of stored blood; resorption of blood from hematomas and other extravascular spaces; or hemolysis, which is encountered often among patients undergoing cardiac surgery. Careful review of the anesthesia record may point to hepatocellular dysfunction from anesthetics, such as halothane and other haloalkanes, and to periods of relative hypotension or hypoxemia. The perioperative use of potentially hepatotoxic drugs and the presence of occult infection should be considered. The transfusion requirement should be documented; as many as 90% of cases of transfusion-transmitted hepatitis occur within 5 to 12 weeks after transfusion. Concurrent renal impairment may decrease the clearance of conjugated bilirubin. After biliary tract surgery, biliary strictures or retained common bile duct stones may be present. When all causative factors have been addressed and excluded, the impairment in bile secretion that leads to the development of jaundice by the second or third postoperative day is referred to as *benign postoperative intrahepatic cholestasis*. Early postoperative jaundice among patients undergoing cardiopulmonary bypass surgery (so-called *pump jaundice*) may have poor prognostic implications independent of the underlying mechanism of hyperbilirubinemia.

BENIGN RECURRENT INTRAHEPATIC CHOLESTASIS

The clinical features of benign recurrent intrahepatic cholestasis, a relatively uncommon familial syndrome, are characterized by recurrent episodes, lasting an average of 3 to 4 months, of pruritus, anorexia, weight loss, and jaundice. During attacks, serum bilirubin levels range from 10 to 20 mg per deciliter with a predominant increase in the conjugated fraction; serum alkaline phosphatase levels are increased; and liver biopsy samples exhibit striking central-zone bile stasis and a mild portal inflammatory infiltrate. Findings at ERCP performed to rule out extrahepatic obstruction in such patients routinely are normal. Liver chemistries and histologic features return to normal between episodes, and progression to chronic liver disease does not occur.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy is differentiated from other liver diseases occasionally encountered during pregnancy by its relative benignity. Familial studies support an autosomal dominant mode of inheritance with variable expression. Epidemiologic studies have shown a high frequency of this disorder among Scandinavians and Chilean Indians. Although the pathogenesis is not completely understood, abnormal sensitivity to endogenous estrogens appears to play a primary role. Women with a history of intrahepatic cholestasis of pregnancy have clinical and laboratory abnormalities of the syndrome when challenged with oral contraceptives when they are not pregnant.

Pruritus is the principal symptom of intrahepatic cholestasis of pregnancy. The onset most often occurs during the third trimester. Jaundice, reflecting underlying conjugated hyperbilirubinemia, typically is mild. Twofold to fivefold elevations of AST and ALT levels may occur, and serum alkaline phosphatase and cholesterol levels are increased. Percutaneous liver biopsy, rarely necessary in the diagnosis, reveals varying degrees of cholestasis with minimal or no inflammatory reaction. Pruritus and laboratory abnormalities resolve promptly after delivery, underscoring the self-limited nature of this disorder. However, increased risk of fetal distress, prematurity, and stillbirths has been demonstrated.

FAMILIAL FORMS OF INTRAHEPATIC CHOLESTASIS

Arteriohepatic dysplasia (Allagille's syndrome) is an autosomal dominant form of infantile cholestasis characterized by survival into adulthood. Well-defined clinical

features include hepatic ductular hypoplasia, abnormal facies, peripheral pulmonic stenosis, and vertebral anomalies. A nonsyndromic form of paucity of interlobular bile ducts resembling that described among infants and children has been reported among adults. This disorder, possibly familial, may progress rapidly to end-stage biliary cirrhosis.

MISCELLANEOUS DISORDERS

A syndrome of chronic intrahepatic cholestasis resembling PBC has been described among patients with sarcoidosis. Clinical and biochemical features include insidious onset of pruritus, jaundice, hepatomegaly, marked elevations in serum alkaline phosphatase level, and hypercholesterolemia. Mitochondrial antibodies typically are absent. The pathogenesis of this disorder is thought to involve progressive destruction of bile ducts by portal and periportal granulomas that leads to a biliary form of cirrhosis.

Hepatic involvement is common among patients with both the primary and secondary forms of amyloidosis. Mild hepatic dysfunction occurs even with extensive hepatic infiltration, manifesting primarily as hepatomegaly and moderate elevations in serum alkaline phosphatase levels. Severe intrahepatic cholestasis, however, has been reported among a small percentage of patients with systemic amyloidosis. Hepatomegaly, ascites, and pruritus often are present, and striking elevations in serum bilirubin, alkaline phosphatase, and cholesterol levels occur. Liver biopsy demonstrates prominent amyloid deposition in periportal regions with relative sparing of central-zone hepatocytes. Interference of the movement of bile into septal bile ducts by amyloid deposits is thought to be the mechanism of cholestasis.

The cause and pathophysiologic mechanism of intrahepatic cholestasis associated with extrabiliary Hodgkin's disease and other lymphomas are poorly understood. Attempts to relate the cholestasis to abnormal hormones elaborated by the tumor have been unsuccessful. Intrahepatic cholestasis may occur with thyrotoxicosis, even in the absence of congestive heart failure.

EXTRAHEPATIC CHOLESTASIS

Structural or mechanical obstruction of the bile ducts most often is caused by choledocholithiasis, pancreatic and periampullary cancer, or biliary strictures. Biochemical features are similar to those of intrahepatic cholestasis; they include striking elevations in serum bilirubin and alkaline phosphatase levels. Symptoms such as abdominal pain, fever, and chills may assist in the diagnosis, but extrahepatic obstruction can occur in the absence of such symptoms. Initial evaluation may be aided by abdominal US and, in certain clinical settings, such as suspected retained common bile duct stones, by direct visualization of the biliary tree and anatomic definition of the level of obstruction with ERCP or PTC.

CHOLEDOCHOLITHIASIS

Stones in the bile ducts figure prominently in the differential diagnosis of cholestasis and are classified as primary (arising de novo), secondary (originating and migrating from the gallbladder), recurrent (re-forming after biliary tract surgery), or retained (overlooked at surgery). Primary bile duct stones often are associated with biliary infections and intrahepatic stones. Among Asians they may be part of the syndrome referred to as *recurrent pyogenic cholangitis*. Differentiation between retained and recurrent stones is hampered by the absence of reliable information regarding the time required for a ductal stone to re-form. Recurrent stones are more likely to be composed of bile pigments, whereas retained stones contain primarily cholesterol.

Clinical features include epigastric pain that radiates to either right or left upper quadrant, nausea, vomiting, and jaundice due to ductal obstruction. Acute pancreatitis or angina pectoris caused by a reflex decrease in coronary blood flow also may be a part of the presentation. Fever and rigor signify the development of obstructive cholangitis.

BILIARY STRICTURES

The cause of more than 90% of all benign strictures involving the major bile ducts is iatrogenic injury, which occurs mainly during operations on the biliary tract. An ischemic basis of this type of stricture has been postulated. Postoperative pain, fever, jaundice, and excessive discharge through drains or the abdominal incision should alert the physician to the possibility of bile duct injury. The critical aspect of the management of biliary strictures is prevention.

CHOLANGIOMATOSIS

Biliary cancer, despite its relative rarity, should be considered in the differential diagnosis of extrahepatic cholestasis. Sixty percent of patients are men, in contrast to the female preponderance for primary carcinoma of the gallbladder, and the presentation typically is in the sixth or seventh decade of life. Infestation with liver flukes (*Clonorchis sinensis*, *Opisthorchis felinus*, and *O. viverrini*), ulcerative colitis, and congenital choledochal cysts all appear to be associated with bile duct carcinoma. The clinical features are similar to those of other forms of extrahepatic obstruction, and the disorder commonly mimics benign biliary stricture or sclerosing cholangitis.

PANCREATIC CAUSES

Pancreatic carcinoma and periampullary carcinoma often have features of extrahepatic obstruction. Benign disorders occur less often, but stenosis of the distal segment of the common bile duct has been recognized increasingly as a common complication of chronic alcoholic pancreatitis. Partial obstruction may be manifested as anicteric elevation in serum alkaline phosphatase level; episodic or persistent jaundice; secondary biliary cirrhosis; and less commonly, suppurative cholangitis with microabscesses or macroabscesses in the liver. Histologic findings of alcohol-induced liver injury are notably absent among such patients. Surgical biliary decompression is recommended in the treatment of patients with persistent stenosis of the intrapancreatic portion of the common bile duct. Strictures of the distal common bile duct also have been described among patients with cystic fibrosis.

MISCELLANEOUS DISORDERS

Although choledochal cysts are congenital malformations, as many as one-half of patients with cysts do not come to medical attention until adulthood. Symptoms at presentation are those of acute cholangitis: right upper quadrant abdominal pain, fever, and jaundice. Diagnosis is accomplished best with abdominal US and ERCP. Surgical therapy consists of resection of the abnormal duct in view of the malignant potential of congenital choledochal cysts. Caroli's disease is an intrahepatic variant of cystic disease of the biliary tract. Periampullary duodenal diverticula, usually incidental findings at endoscopy or barium radiographic studies, rarely may cause structural extrahepatic obstruction.

Hemobilia caused by hepatic trauma, rupture of an aneurysm of the hepatic artery, biliary ascariasis, hepatobiliary neoplasms, choledocholithiasis, or a ruptured liver abscess may cause extrahepatic obstruction and gross or occult gastrointestinal blood loss. Extrahepatic biliary obstruction also can be caused by metastatic disease, most commonly tumors of gastrointestinal origin. Patients often are assumed to have hepatic metastasis, and response to chemotherapy differentiates certain neoplasms, notably lymphoma and small-cell lung cancer. Nonneoplastic disease, specifically tuberculous adenitis, has been reported to cause extrinsic extrahepatic obstruction in rare instances. Other unusual infectious causes of bile duct obstruction are ascariasis and candidiasis.

STRATEGIES FOR OPTIMAL CARE

Management of most of the diseases that cause jaundice is discussed in the disease-specific chapters. Management of extrahepatic biliary obstruction is discussed briefly here. The two goals of such management are, first, to drain bile above the obstruction, thereby relieving pruritus and reducing the risks of secondary biliary cirrhosis, cholangitis, and hepatic abscesses and, second, to remove or bypass the cause of obstruction.

Temporary drainage of obstructed ducts can be achieved for almost all patients by means of placement of percutaneous or nasobiliary catheters above the level of obstruction at the time of diagnostic PTC or ERCP, respectively. In cases of inoperable malignant obstruction, internal biliary stents are preferred over percutaneous transhepatic stenting or surgical bypass because of lower short-term morbidity and cost. Plastic biliary stents offer the advantage of low cost and ease of placement, but a short patency period necessitates replacement. Self-expanding metallic stents, on the other hand, remain patent for longer periods but are expensive and cannot be exchanged. Membrane-covered stents that have the combined attributes of metal and plastic stents are under development.

Although patients with jaundice and biliary obstruction have increased postoperative morbidity and mortality, principally because of sepsis and renal failure, elective

preoperative percutaneous biliary drainage does not appear to reduce operative risk but increases hospital stay and cost.

The management of choledocholithiasis has been dramatically altered by the advent of laparoscopic cholecystectomy. The main indication for ERCP and endoscopic sphincterotomy (ES) once was choledocholithiasis among patients who had undergone cholecystectomy or patients with choledocholithiasis and an intact gallbladder considered to be at high surgical risk or those suffering from complications, such as cholangitis or severe acute pancreatitis, which carry a high surgical mortality rate. Four strategies currently are followed in the care of a patient scheduled to undergo laparoscopic cholecystectomy: (a) preoperative ERCP and ES if common bile duct stones are present; (b) intraoperative cholangiography with postoperative ERCP and ES if common bile duct stones are present; (c) intraoperative cholangiography with laparoscopic common bile duct exploration if common bile duct stones are present; and (d) postoperative ERCP only for patients with recurrent symptoms that suggest biliary obstruction from retained common bile duct stones. The optimal strategy has not been defined but requires that the likelihood of a common bile duct stone be balanced against the rate of technical failure and the risk of complications from any given intervention. The risk of pancreatitis from ERCP is approximately 5% and is nearly doubled if ES is performed. Laparoscopic common bile duct exploration is technically difficult, is not performed at most centers, and frequently necessitates postoperative ERCP. Nevertheless, there is a growing trend away from preoperative ERCP with greater experience in laparoscopic common bile duct exploration.

Despite advances in the endoscopic management of choledocholithiasis, 2% to 5% of stones are resistant to conventional endoscopic techniques. Extracorporeal shock wave lithotripsy may be effective but is limited by availability and cost. Intracorporeal laser-induced shock wave lithotripsy involves positioning with a conventional duodenoscope and use of a laser fiber close to the stone in the common bile duct for the delivery of laser pulses. This may become, in combination with conventional endoscopic extraction, the preferred management of complicated common bile duct stones.

COMPLICATIONS AND PITFALLS

Although bile duct dilatation found at US or CT has a high predictive value for obstruction, this finding may be absent in certain settings in which extrahepatic obstruction is present. Intermittent or partial obstruction, as is the case among as many as one-third of patients with choledocholithiasis, may not cause detectable bile duct dilatation. Encasement of the bile ducts by cholangiocarcinoma or diffuse fibrosis from PSC may prevent dilatation even if a dominant stricture is present. For the same reason, intrahepatic ductal dilatation may be limited in the presence of cirrhosis. Therefore, if on the basis of clinical evaluation, extrahepatic obstruction is suspected, direct visualization of the bile ducts with either PTC or ERCP should be pursued.

Acute biliary obstruction may cause serum transaminase elevations disproportionate to serum bilirubin and alkaline phosphatase elevations, often more than 2,000 U per liter. The levels rapidly decline to near normal within 72 hours, unlike serum transaminase levels in disorders associated with hepatocellular jaundice, which typically remain elevated for longer periods (ischemic hepatitis is a notable exception).

Indications for HOSPITALIZATION

Symptoms and signs of cholangitis (abdominal pain, fever, leukocytosis, and hypotension) necessitate immediate hospitalization. Among elderly patients with suspected biliary obstruction, hospitalization may be warranted, even in the absence of these symptoms and signs. For disorders associated with hepatocellular jaundice, a decision regarding hospitalization is based on factors other than the mere finding of jaundice, including the presence of coagulopathy, the need for intravenous therapy and parenteral nutrition, and the need for inpatient therapy for the underlying disorder.

Indications for REFERRAL

Acute viral hepatitis is the most common cause of jaundice among young adults. If uncomplicated, it may not necessitate referral. For other disorders associated with hepatocellular jaundice or intrahepatic cholestasis a likely diagnosis may be rendered by the referring physician, and the need to refer depends substantially on the clinical setting and the degree of reassurance needed by the patient. The need for liver biopsy among such patients may lead to a referral. Biliary obstruction from either choledocholithiasis or a malignant tumor is more likely among older patients, and in most cases the expertise of a gastroenterologist is needed.

CHAPTER 104: APPROACH TO THE PATIENT WITH ABNORMAL LIVER CHEMISTRIES

RICHARD H. MOSELEY

[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Serum Markers of Hepatobiliary Dysfunction](#)
[Disease-Specific Markers](#)

The approach to the patient with abnormal liver chemistries is not governed by any well-defined diagnostic algorithms. Instead, a systematic approach to patients with suspected liver disease involves, first, an understanding of the diverse panel of available measurements of liver function and serum markers of hepatobiliary disease. From this panel, a group of indices most appropriate to the particular clinical problem is selected. A single test is rarely sufficient in the analysis of most clinical problems, but the selection process is facilitated by several distinct patterns of liver injury.

HISTORY AND PHYSICAL EXAMINATION

As in most disease states, an accurate history is critical. Systemic symptoms of liver disease (e.g., anorexia, weight loss, chills and fever, nausea, and vomiting) are nonspecific and typically of little help in the differential diagnosis. Valuable information can be elicited by questions regarding family history, drug use (prescription and over-the-counter medications), alcohol consumption, illicit substance use/abuse, exposure history, sexual and menstrual history, occupational or environmental history, travel history, past surgery (including anesthesia records, if available), and transfusion history.

Familial forms of intrahepatic cholestasis such as arteriohepatic dysplasia (Alagille's syndrome) are well described. Hemochromatosis, Wilson's disease, and α_1 -antitrypsin deficiency are examples of liver diseases transmitted by an autosomal recessive mode of inheritance, and genetic factors may play a role in other hepatobiliary disorders, such as primary sclerosing cholangitis and autoimmune hepatitis.

Given the relatively nonspecific presentation of drug-induced liver disease, drug-related hepatic injury may not be suspected initially in a patient with abnormal liver chemistries. Difficulties in diagnosis are compounded by the unknown hepatotoxicity of newly introduced agents. Nevertheless, the possibility of drug-induced liver injury should be considered in all patients with a seemingly nonspecific change or worsening in liver chemistries; such considerations are aided by a complete drug history. Alcohol and nonprescription medication use is an important part of this inquiry. Alcoholic patients should always be questioned about acetaminophen use because of its propensity to cause hepatotoxicity at even therapeutic doses.

Viral hepatitis should be investigated in patients with abnormal liver chemistries and a history of exposure to or contact with jaundiced persons, syringes or needles (including tattoo paraphernalia), or blood and blood products. A history of recent ingestion of raw oysters or steamed clams should suggest hepatitis A infection. Additional risk factors associated with hepatitis A in the United States include homosexual contact and contact with children attending day care centers. The patient's source of water is occasionally relevant, because private water supplies are often implicated in hepatitis A outbreaks. The development of abnormal liver chemistries in the "healthy" hepatitis B carrier warrants strong consideration of hepatitis D virus superinfection. Recent travel to areas endemic for viral hepatitis should be noted; water-borne outbreaks of hepatitis E most commonly occur in Southeast Asia and the Indian subcontinent. Abnormalities in smell (dysosmia) and taste (dysgeusia) may be noted by patients with viral hepatitis. Arthritis, abrupt in onset, with a strong predilection for proximal interphalangeal joints and often accompanied by an interstitial rash, occurs during the prodromal phase in 20% of patients with hepatitis B.

Sexually transmitted diseases are an important cause of abnormal liver chemistries; therefore, a sexual history should be included in the evaluation. The number of sexual partners that the patient has had in the preceding 6 months should be determined, considering that the average incubation period of hepatitis B is from 6 to 12 weeks. A sexual history in the female patient should always include information on contraceptive use. A menstrual history may reveal the presence of secondary amenorrhea, a common complication of chronic liver disease.

Although the use of hepatotoxins such as carbon tetrachloride, chloroform, and trinitrotoluene has diminished, liver injury associated with accidental or occupational exposure to workplace chemicals remains a significant problem. Although an itemized list is beyond the scope of this chapter, exposure to industrial and environmental hepatotoxins should be elicited by a thorough occupational history.

The nature of and indications for previous abdominal surgery should be ascertained. Information concerning the gross appearance of the liver at the time of surgery may prove valuable. In the postoperative patient, surgical and anesthesia records should be reviewed for the inhalational agent administered, the presence and duration of intraoperative hypotension, and the amount of blood product support required. Chronic liver disease is a late complication of jejunoileal bypass surgery; biliary strictures, retained and recurrent stones, or papillary stenosis should be considered in the postcholecystectomy patient with abnormal liver chemistries.

Generalized pruritus may be a presenting symptom in patients with liver disease, particularly cholestatic syndromes. Pruritus in the jaundiced patient is frequently nocturnal and is most pronounced on the palms and soles. The presence or absence and character of abdominal pain may provide some clues toward establishing a cause of abnormal liver chemistries. In contrast to the intense and rapidly developing right upper quadrant abdominal pain of acute extrahepatic obstruction as in choledocholithiasis, the pain associated with acute viral hepatitis is a heavy or dragging sensation. Pain from primary and metastatic tumors of the liver may be distinguished by its dull or boring character, although hemorrhage into the tumor may result in the sudden appearance of severe pain.

Physical findings of some discriminative value in the patient with abnormal liver chemistries include stigmata of chronic liver disease (e.g., spider angiomas, palmar erythema, parotid gland enlargement, gynecomastia, Dupuytren's contracture, and testicular atrophy), hepatomegaly and liver consistency, splenomegaly, gallbladder distention, and abdominal tenderness. Although the degree of hepatomegaly can vary in all forms of hepatobiliary disease, a liver span of more than 15 cm is more often associated with passive congestion from right-sided heart failure or neoplastic and infiltrative processes (e.g., amyloidosis, myeloproliferative disorders, and glycogen and lipid storage disorders). A pulsatile liver may be encountered in tricuspid insufficiency. A hepatic bruit or friction rub should alert the examiner to the possibility of an underlying hepatocellular carcinoma. Murphy's sign (inspiratory arrest during deep palpation of the right upper quadrant) can be elicited in those with acute cholecystitis. Punch or fist tenderness may help to differentiate hepatobiliary from pleural-based pain. Jaundice manifested by yellow pigmentation of the skin, mucous membranes, and sclerae typically requires a serum bilirubin concentration higher than 3 mg per deciliter for detection; artificial light makes detection at low levels more difficult. Sunflower cataracts and Kayser–Fleischer rings are highly suggestive of Wilson's disease.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

TESTS OF LIVER FUNCTION

Laboratory determinations that reflect hepatic disease are often called liver function tests, although only some are true measurements of hepatic function. Therefore, the use of this term should be discouraged. Tests that examine the liver's ability to excrete substances into bile, particularly organic anions, fall within this strict definition, as do laboratory assessments of the liver's synthetic and metabolic capacity.

BILIRUBIN

Tests of bilirubin metabolism are important in the assessment of hepatic function because bilirubin is an endogenous organic anion, derived primarily from the degradation of hemoglobin from senescent erythroid cells. Total serum bilirubin is separated into two fractions, a water-soluble, direct-reacting conjugated form and a lipid-soluble, indirect-reacting form representing unconjugated bilirubin. Almost all the bilirubin normally present in serum is the unconjugated fraction. Hyperbilirubinemia, clinically manifested as jaundice, is accordingly classified as either predominantly unconjugated or predominantly conjugated, simply by subtracting direct from total serum bilirubin to estimate the indirect, or unconjugated, bilirubin. Increased production of bilirubin, impaired transport into hepatocytes, or defective bilirubin conjugation within the hepatocyte are disorders associated with unconjugated hyperbilirubinemia. Up to 85% of total serum bilirubin is the unconjugated form in these disease states. Besides the rate of hemolysis, the liver's ability to conjugate bilirubin determines the degree of unconjugated hyperbilirubinemia observed. Even in severe hemolytic disorders, total serum bilirubin rarely exceeds 5 mg per deciliter in the presence of normal hepatic function. In

contrast, in hepatocellular disorders with impaired intrahepatic excretion of bilirubin and in extrahepatic obstruction, a conjugated hyperbilirubinemia is observed. In these settings, typically more than 50% of the serum bilirubin is in the direct-reacting form.

Urine bilirubin is invariably conjugated bilirubin and thus is encountered only in conditions in which serum levels of direct or conjugated bilirubin are elevated. The tea-colored appearance of urine caused by the presence of bilirubin must be differentiated from similar discoloration by hemoglobinuria and myoglobinuria. Bilirubinuria may precede the clinical appearance of jaundice, largely because of the low (less than 1 mg per deciliter) renal threshold for excretion of conjugated bilirubin.

SERUM BILE ACIDS

Two primary bile acids (cholic and chenodeoxycholic acid) are synthesized in the liver from cholesterol and converted by intestinal bacteria to the secondary bile acids (deoxycholic, ursodeoxycholic, and lithocholic acid). Although serum bile acids are almost always elevated in moderate to severe liver disease, poor diagnostic sensitivity in patients with mild liver disease has prevented the widespread application of serum bile acid determination. The finding of normal fasting levels of cholic acid conjugates, however, may be helpful in supporting a diagnosis of Gilbert's syndrome in patients with unconjugated hyperbilirubinemia.

CLOTTING FACTORS

Liver disease is a common cause of impaired coagulation. Normal serum activities of the vitamin K-dependent coagulation factor proenzymes (factors II, VII, IX, and X), as assessed by the one-stage prothrombin time (PT), require intact hepatic synthesis and adequate intestinal absorption of lipid-soluble vitamin K. A prolonged PT can therefore be seen in patients with hepatocellular disorders that impair hepatic synthetic function (e.g., hepatitis, cirrhosis) and in those with cholestatic syndromes that interfere with lipid absorption. Hepatocellular injury can be differentiated from cholestatic causes of PT prolongation by the parenteral administration of vitamin K; intact hepatic function is established by an improvement in the PT of more than 30% within 24 hours. A prolonged PT in acute viral hepatitis signifies severe hepatocellular necrosis, may antedate other manifestations of hepatic failure, and is associated with a worse prognosis. Plasma concentrations of individual proteins may be useful clinical guides; in view of its short half-life, factor VII is the best index of the severity of liver disease and of prognosis.

ALBUMIN

Albumin is quantitatively the most important of several plasma proteins formed in the liver. Accordingly, the measurement of total concentration of serum albumin is a useful test of hepatic synthetic function. The relatively long half-life of serum albumin (20 days) makes the serum albumin level a better index of severity and prognosis in patients with chronic liver disease than in patients with acute hepatic injury in whom levels are usually normal or only minimally depressed. Nutritional factors (i.e., the availability of amino acids) are critical determinants of the rate of albumin synthesis. Moreover, alterations in serum albumin levels may reflect disturbances in synthesis and changes in the rate of catabolism, dilution by expanded plasma volume (as seen in cirrhosis), or enhanced loss through the gastrointestinal tract or kidneys.

IMMUNOGLOBULINS

Although measurement of serum globulins does not fulfill the operational definition of a liver function test, the hypergamma-globulinemia commonly observed in patients with liver disease indirectly represents functional impairment of the reticuloendothelial cells of the hepatic sinusoids. Hypergammaglobulinemia higher than 3.0 g per deciliter in a patient with chronic hepatitis is more consistent with autoimmune liver disease than viral hepatitis. A predominant rise in the immunoglobulin A (IgA) fraction is observed in hypergammaglobulinemia associated with alcoholic cirrhosis. A disproportionate elevation of IgM is a feature that differentiates primary biliary cirrhosis from other liver diseases, specifically autoimmune hepatitis, which are associated with prominent hypergammaglobulinemia. A specific diagnosis, however, is rarely established by quantitative determinations of immunoglobulins. Instead, hyperglobulinemia demonstrated on serum protein electrophoresis is a clue to the presence of chronic liver disease.

TESTS OF HEPATIC METABOLISM

Drug metabolism is another critical hepatic function, and liver disease is often associated with impaired drug metabolism. The most widely performed tests of hepatic metabolic capacity are the antipyrine clearance determination and the aminopyrine demethylation breath test. Although these quantitative tests may be noninvasive predictors of hepatic histology, difficulties with interindividual differences in the metabolism of a single drug and intraindividual differences in the metabolism of different drugs make interpretation difficult.

SERUM MARKERS OF HEPATOBILIARY DYSFUNCTION

Routine biochemical laboratory tests are not true indices of hepatic function. Instead, they serve as markers of hepatobiliary dysfunction—specifically, hepatocellular necrosis, cholestasis, or infiltrative processes.

AMINOTRANSFERASES (TRANSAMINASES)

Aspartate aminotransferase (AST; serum glutamic-oxaloacetic transaminase [SGOT]) and alanine aminotransferase (ALT; serum glutamic-pyruvic transaminase [SGPT]) are important markers of hepatocellular injury. AST is found in various tissues (notably cardiac and skeletal muscle, kidney, and brain), but ALT is limited primarily to the liver. Given the tissue distribution of the two enzymes, elevations of serum ALT are a more specific reflection of hepatocellular disease than serum AST levels. Within the liver cell, AST is present in mitochondria and the cytosol, and ALT is localized to the cytosol. The highest serum elevation of both enzymes is seen in patients with viral, toxin-induced, and ischemic hepatitis; smaller elevations (less than 300 units) relative to the degree of histologic necrosis are usually seen in cases of alcoholic hepatitis. The AST/ALT ratio in serum is a useful indicator of alcoholic liver disease: a ratio above 2 is highly suggestive of alcohol-induced hepatic injury. In contrast, in patients with acute and chronic viral hepatitis (and extrahepatic biliary obstruction), an AST/ALT ratio of less than 1 is typical, although an AST/ALT ratio above 1 has been associated with cirrhosis in patients with chronic hepatitis B infection. Thus, an AST/ALT ratio above 1 in the setting of nonalcoholic chronic liver disease may signify underlying cirrhosis. In the presence of cirrhosis, however, this ratio may be less useful in differentiating alcoholic from nonalcoholic forms of liver disease.

Although these indices of hepatocellular injury do not predict histologic findings, serial determinations of serum AST and ALT levels may reflect the extent of hepatocellular injury and are useful in following the progression of liver disease. Decreases in AST and ALT levels in serum, however, may be either a sign of recovery from an acute injury or, particularly in the case of fulminant hepatic failure, an indication of limited hepatic reserve after overwhelming hepatocyte necrosis.

ALKALINE PHOSPHATASE

In the liver, alkaline phosphatase appears to be an integral enzyme of the exterior surface of the bile canalicular membrane. Hepatocellular injury invariably results in increases in serum aminotransferase activity, but significant (fourfold or greater) elevations of serum alkaline phosphatase activity are typically seen in patients with cholestatic syndromes. Lesser increases in levels lack specificity and may be present in all forms of liver disease. Alkaline phosphatase activity can also be demonstrated in bone, placenta, intestine, kidney, and leukocytes. Liver and bone are the predominant sources of serum alkaline phosphatase activity in normal persons, with less than 20% derived from the intestine. In pregnancy, a substantial fraction may be derived from the placenta. Ectopic production of an alkaline phosphatase isoenzyme occurs in patients with cancer, and elevations may therefore be observed in the absence of bony or hepatic metastases. Low levels of serum alkaline phosphatase have been reported in acute hemolytic anemia complicating Wilson's disease, hypothyroidism, pernicious anemia, zinc deficiency, and congenital hypophosphatasia.

OTHER ENZYME MARKERS OF CHOLESTASIS

Although the alkaline phosphatase isoenzymes can be separated electrophoretically, alternative approaches are used in clinical practice. Serum γ -glutamyl transferase or transpeptidase (GGTP) determination establishes the hepatic origin of an elevated alkaline phosphatase by virtue of its localization within the hepatobiliary tree. Alcohol consumption, presumably through enzyme induction, raises serum enzyme levels, and this finding has been invoked as a sensitive marker of chronic alcohol consumption that occurs independently of any liver damage. Serum GGTP levels are also elevated in patients with pancreatic disorders, myocardial

infarction, uremia, chronic obstructive pulmonary disease, rheumatoid arthritis, and diabetes mellitus and in those using microsomal enzyme-inducing drugs such as anticonvulsants and warfarin.

Determination of serum 5 α -nucleotidase (5 α -NT) or serum leucine aminopeptidase (SLAP) levels plays a role similar to that of serum GGTP determination. Despite their presence in a wide variety of other body tissues, elevated enzyme levels in the nonpregnant patient are specific for hepatobiliary disease and correlate well with elevated alkaline phosphatase levels of hepatic origin. SLAP levels are elevated in pregnancy, and conflicting data exist concerning 5 α -NT levels in pregnancy. In patients with cancer, elevated 5 α -NT levels are a sensitive marker in the diagnosis of metastatic disease to the liver. A normal 5 α -NT level does not necessarily exclude liver disease in the setting of an elevated alkaline phosphatase, because these markers may not increase parallel with early or mild hepatic injury.

LACTATE DEHYDROGENASE

Although commonly available, measurement of total serum lactate dehydrogenase (LDH) has limited diagnostic specificity for hepatocellular disease, and fractionation of LDH to determine levels of the isoenzyme of hepatic origin (LDH-5) is rarely indicated. Moderate elevations of LDH are often seen in hepatocellular disorders such as viral hepatitis and cirrhosis and are less common in cholestatic disorders.

DISEASE-SPECIFIC MARKERS

The laboratory tests previously outlined alert the physician to the presence of hepatobiliary disease. Additional markers of specific disorders are discussed in the following section.

VIRAL SEROLOGY

Diagnosis of acute hepatitis A is based on the serologic detection of hepatitis A virus-specific IgM antibody (IgM anti-HAV; [Chapter 119](#)) ([Table 104.1](#)). Seropositivity first becomes detectable at the onset of clinical illness and is invariably present at the onset of jaundice. This serologic marker typically persists for 120 days, far exceeding both clinical and biochemical resolution of illness. Prolonged periods of seropositivity of more than 200 days have been observed. Nevertheless, it is best regarded as a marker of acute or recent hepatitis A viral infection. In contrast, IgG anti-HAV is present primarily in convalescent sera and persists for long periods after infection, perhaps for life.

Disease	Serologic Test
Hepatitis A	IgM anti-HAV
Hepatitis B	HBsAg, IgM anti-HBc
Hepatitis C	Anti-HCV, HCV RNA
Hepatitis D	HBsAg, anti-HDV

HBc, hepatitis B core; HBsAg, hepatitis B surface antigen.

TABLE 104.1. SEROLOGIC DIAGNOSIS OF ACUTE VIRAL HEPATITIS

Several serologic tests are available to establish hepatitis B viral infection ([Chapter 119](#)). Hepatitis B surface antigen (HBsAg) is the first marker detectable in serum, preceding elevations in serum aminotransferases and the onset of symptoms. HBs antigenemia typically lasts for 1 to 2 months in self-limited infections. Antibody to core antigen (anti-HBc) is detected in serum about 2 weeks after the appearance of HBsAg; typically, a window or lag period then occurs before specific antibody to HBsAg (anti-HBs) appears. During this period and in the 10% of patients who do not manifest detectable levels of HBsAg, anti-HBc may be the only detectable serologic marker of recent infection with hepatitis B virus. HBeAg is considered to be a marker of hepatitis B virus (HBV) replication and infectivity. During the recovery phase of acute HBV infection, HBeAg-to-anti-HBe seroconversion precedes HBsAg-to-anti-HBs seroconversion. In patients with chronic hepatitis B, seroconversion from HBeAg to anti-HBe is usually associated with loss of HBV DNA in serum and remission of liver disease. Tests for HBV DNA should be reserved for patients with chronic HBV infection to assess HBV replication and candidacy and response to antiviral therapy.

Infection with the hepatitis C virus (HCV) is identified using an enzyme-linked immunosorbent assay (ELISA) to detect circulating antiviral antibodies ([Chapter 119](#)). Because increased serum γ -globulins or other serum components may produce false-positive results by ELISA, a recombinant immunoblot has been used to supplement the ELISA in the diagnosis of HCV. Nevertheless, determining whether viremia underlies the finding of antibody to HCV by any method requires the demonstration of HCV RNA by the polymerase chain reaction. The appearance of antibody to HCV may be delayed up to 6 months after acute infection.

Infection with hepatitis D virus should be considered in any HBsAg-positive patient with acute or chronic hepatitis, especially if the disease is severe or the patient is in a high-risk group. Serologic confirmation of hepatitis D coinfection or superinfection is accomplished by testing for hepatitis D antigen and anti-hepatitis D antibodies. At least one acute and one convalescent serum sample should be assayed for anti-hepatitis D, because this antibody can be transient, at low titer, and appear late in infection. Total (predominantly IgG) antibodies to hepatitis D virus are usually detectable in high titer in superinfections. Persistence of IgM anti-hepatitis D typically predicts progression to chronic hepatitis D infection.

IMMUNOLOGIC TESTS

Immunologic abnormalities occur in a wide spectrum of liver diseases. The antinuclear antibody reaction in autoimmune hepatitis is of the homogeneous pattern by immunofluorescence, and a titer of 1:160 or more is usually required. Antimitochondrial antibodies are present in over 90% of patients with primary biliary cirrhosis and in about 25% of patients with autoimmune hepatitis and drug-induced liver injury. In fact, an antimitochondrial antibody titer higher than 1:40, even in the absence of serum alkaline phosphatase elevation, strongly suggests primary biliary cirrhosis. Smooth muscle antibodies, reactive to S actin, may be detected in up to 70% of patients with autoimmune hepatitis, in about 50% of patients with primary biliary cirrhosis, and in occasional patients with acute viral hepatitis. A circulating antineutrophil cytoplasmic antibody (ANCA) has been reported in up to 87% of patients with primary sclerosing cholangitis.

Human leukocyte antigens (HLA) have also been associated with a wide spectrum of liver diseases; specifically, HLA-B8 and -DRw3 have been associated with autoimmune hepatitis, and HLA-A3 and -B14 have been linked to hemochromatosis. The increased incidences of these HLA haplotypes, however, are neither absolute nor diagnostic. Thus, although HLA typing provides information on gene frequencies, it is not routinely recommended.

CERULOPLASMIN

Determination of the serum concentration of ceruloplasmin, a copper transport protein in plasma, is particularly useful in the diagnosis of Wilson's disease. Although not directly involved in the pathogenesis of this autosomal recessive copper storage disorder, low levels of ceruloplasmin (less than 20 mg per deciliter) are found in about 90% of homozygotes and about 10% of heterozygotes. In contrast to Wilson's disease, serum ceruloplasmin is typically elevated in primary biliary cirrhosis, another disorder associated with increased hepatic copper concentrations. Increased serum levels in this disorder and other forms of liver disease reflect the role of ceruloplasmin as a nonspecific acute-phase reactant. Accordingly, normal values are sometimes seen during the chronic active hepatitis phase of Wilson's disease. Pregnancy and exogenous estrogen administration may also lead to elevated values for this protein. Likewise, hypoceruloplasminemia may result from the drop in hepatic synthetic function observed in non-wilsonian fulminant hepatic injury, and less commonly in severe malnutrition, other protein-losing states, and Menkes' syndrome.

IRON STORAGE PARAMETERS

Measurements of serum iron level and total iron-binding capacity (or transferrin) are useful in the diagnosis of the hepatic iron overload state, hemochromatosis (Chapter 123). Transferrin is normally 20% to 45% saturated, and the serum iron level and percent saturation of transferrin are elevated early in the course of this disorder. However, these tests have a relatively low degree of specificity in patients with liver disease; increased serum iron levels, with normal transferrin saturation, are common in patients with alcohol-induced liver injury. Acute elevations in serum iron levels have also been observed in acute viral hepatitis. Assays of serum ferritin may more closely estimate total body iron stores, and elevated serum ferritin levels are common early in the course of hemochromatosis before any histologic evidence of liver injury. Other forms of hepatocellular necrosis and systemic infection are associated with elevated serum ferritin levels disproportionate to body iron stores. For this reason, quantitative determination of tissue iron concentration on liver biopsy remains the definitive test for the diagnosis of hemochromatosis. Representative iron storage parameters in symptomatic hemo-chromatosis are shown in Table 104.2, compared with parameters encountered in alcoholic liver disease.

Marker	Normal Range	Alcoholic Liver Disease	Hemochromatosis
Transferrin-iron saturation (%)	20-50	50-60	>62
Serum ferritin (ng/mL)	15-200	300-1,000	500-4,000
Hepatic iron concentration (μ g/g dry weight)	300-1,000	1,000-5,000	10,000-30,000
Iron index (liver iron in μ g/g dry weight divided by [patient's age \times 55.8])	<1.1	<1.6	>1.9

TABLE 104.2. COMPARISON OF MARKERS IN HEMOCHROMATOSIS AND ALCOHOLIC LIVER DISEASE

A genetic test for hemochromatosis is now available. Approximately 85% of patients with hemochromatosis are homozygous for a C282Y mutation in a gene referred to as *HFE*. A second mutation, H63D, is associated with hemochromatosis when it occurs in C282Y/H63D compound heterozygotes. At present, the cost of this molecular diagnostic test limits its use as a screening tool, although it has great applicability in studies of family members. Genetic testing should be performed in all first-degree relatives of the affected patient, known as the *proband*, and in the spouse of the proband. If the spouse does not carry one of the mutations, the biologic children would not need to be tested because they would be heterozygotes. Because cirrhosis is rarely observed in patients with hemochromatosis who are younger than 40 years old, treatment most likely can be started and liver biopsy avoided in C282Y homozygotes, unless patients are 40 years and older or unless they exhibit abnormal serum aminotransferases.

α -FETOPROTEIN

A sensitive radioimmunoassay for α -fetoprotein, a major serum protein during fetal life, has been used to screen for primary hepatocellular carcinoma. Whereas 70% to 90% of patients with hepatocellular carcinoma have elevated serum α -fetoprotein, significant elevations also occur in patients with germ cell tumors, other gastrointestinal malignancies, and such nonneoplastic hepatic disorders as autoimmune hepatitis, viral and alcoholic hepatitis, and primary biliary cirrhosis. To enhance the specificity of this test in the diagnosis of hepatocellular carcinoma, concentrations exceeding 400 ng per milliliter have been generally cited, although this arbitrary cutoff may exclude up to one-third of patients with biopsy-proven hepatocellular carcinoma. A monoclonal radioimmunoassay may improve the specificity of α -fetoprotein screening.

α_1 -ANTITRYPSIN

α_1 -Antitrypsin is a 52-kd glycoprotein synthesized in the liver (and to a lesser extent in monocytes and macrophages) that migrates in the α_1 -globulin fraction on serum protein electrophoresis. Normal serum levels (150 to 350 mg per deciliter) may increase postoperatively and in association with inflammation, malignancy, pregnancy, and estrogen therapy. Persons homozygous for the electrophoretically slowest of the genetic variants of this protein (Pi ZZ [Pi, protease inhibitor]) have markedly decreased serum α_1 -antitrypsin levels and are predisposed to the early onset of chronic active hepatitis and cryptogenic cirrhosis and hepatocellular carcinoma. Heterozygotes (Pi MZ) have serum levels 50% to 60% of normal. The inability of the hepatocyte to process and secrete the Z protein, which differs from the normal M protein by a single amino acid substitution, results in the characteristic presence of periodic acid-Schiff (PAS)-positive, diastase-resistant globules in periportal hepatocytes on percutaneous liver biopsy. The diagnosis of a α_1 -antitrypsin deficiency should be entertained in a patient with liver chemistry abnormalities showing a hepatocellular injury pattern when an absent α_1 -globulin peak is observed on serum electrophoresis. It should be confirmed by serum α_1 -antitrypsin activity determination and genetic Pi typing.

SERUM AMMONIA

Urea formation in the liver via the Krebs-Henseleit cycle is required for the disposal of ammonia, the toxic product of nitrogen metabolism. Thus, elevated serum ammonia levels are common in acute and chronic forms of liver disease. Striking elevations in fulminant hepatic failure result from the impaired conversion of ammonia to urea in the setting of severe hepatocellular necrosis, whereas the hyperammonemia present in patients with cirrhosis and portal hypertension primarily reflects the portosystemic shunting of ammonia derived from colonic bacteria. The serum ammonia determination, most accurately measured on arterial blood, is best regarded merely as an aid in the differential diagnosis of encephalopathy; serial determinations have little role in clinical practice.

PERCUTANEOUS LIVER BIOPSY

Unlike most of the laboratory tests previously discussed, no predictive value can be assigned to a specific morphologic feature observed with a percutaneous liver biopsy. For proper biopsy interpretation, all clinical, biochemical, immunologic, and radiographic data should be correlated with the histologic features. The positive predictive value of a prebiopsy diagnosis ranges from 88% for alcoholic liver disease to 56% for fatty liver. Elevations of serum transaminases more than three times normal also correlate positively with enhanced prebiopsy diagnostic accuracy. Other major applications of liver biopsy include determining the indication for antiviral therapy in chronic viral hepatitis and establishing the diagnosis in patients with unexplained hepatomegaly, suspected systemic disease (e.g., tuberculosis, sarcoidosis, or fever of unknown origin), and suspected primary or metastatic carcinoma.

DIFFERENTIAL DIAGNOSIS

Initially, nonhepatic causes must be considered (Table 104.3). Then, a proper diagnostic approach must be selected for the patient with suspected liver disease. Liver disease can be classified into four major types: cholestatic, hepatocellular, infiltrative, and immunologic. Depending on the target of the immune response, immunologic injury results in either a cholestatic picture (when the bile ducts are involved preferentially, as in primary biliary cirrhosis) or a hepatocellular form of injury (when the primary insult is to the hepatocyte membrane, as in viral and autoimmune hepatitis). Cholestasis can be categorized further as either a functional defect in bile formation at the level of the hepatocyte (intrahepatic cholestasis) or a structural impairment in bile secretion and flow (extrahepatic cholestasis). Evaluation is aided by the presence of these relatively discrete patterns of liver injury and tests of discriminative value in the detection of these patterns. Routinely, serum aminotransferase activity, serum alkaline phosphatase, serum total and direct bilirubin, serum total protein, with albumin and globulin fractionation, and PT should be determined in all patients with suspected liver disease before disease-specific markers are sought.

pattern of abnormalities suggesting HBsAg- and HCV-negative chronic hepatitis, autoimmune hepatitis, or cryptogenic cirrhosis. Ingestion of nutritional supplements (e.g., vitamin A) and herbal products and the use of unconventional forms of therapy should also be considered in the setting of hepatocellular injury of unknown origin.

INFILTRATIVE DISORDERS

Isolated elevation of serum alkaline phosphatase, confirmed by SLAP, 5 ϕ -NT, or GGTP to be of hepatic origin, strongly suggests an infiltrative process, whether a localized (primary biliary cirrhosis) or systemic granulomatous disease, such as sarcoidosis, miliary tuberculosis, coccidiomycosis, histoplasmosis, brucellosis, Q fever, or a drug reaction (e.g., allopurinol, quinidine), or, alternatively, the first indication of metastatic carcinoma to the liver. Serum alkaline phosphatase levels elevated more than three times in patients with cirrhosis should raise concern of the development of hepatocellular carcinoma. The triad of an elevated serum alkaline phosphatase level, detectable titers of antimicrobial antibody, and an elevated serum IgM level in a middle-aged woman is of considerable discriminative value in the diagnosis of primary biliary cirrhosis. Alternatively, in a patient with a history of malignancy, the presence of an elevated serum alkaline phosphatase warrants an evaluation for metastases.

The absence of diagnostic findings on abdominal ultrasonography, computed tomography of the abdomen, technetium sulfur colloid nuclear imaging, and invasive tests such as endoscopic retrograde cholangiopancreatography (ERCP) is a major indication for performing a percutaneous or laparoscopic liver biopsy. A decision tree that can be used in the approach to the patient with an elevated alkaline phosphatase is shown in [Figure 104.1](#).

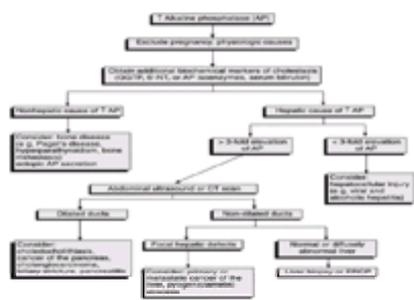

FIGURE 104.1. Diagnosing the patient with elevated serum alkaline phosphatase levels. *CT*, computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography; *GGTP*, serum g-glutamyl transpeptidase; 5 ϕ -NT, 5 ϕ -nucleotidase.

EVIDENCE LEVEL: C. Expert Opinion.

THE LIVER IN SYSTEMIC DISORDERS

The liver may be a target organ in a vast array of systemic disorders. In particular, but by no means exclusively, the presence of coexistent cardiac, pancreatic, and inflammatory bowel disease should be considered in the approach to any patient with abnormal liver chemistries. A prolonged PT, often disproportionate to other signs of liver dysfunction, is the most common abnormality in patients with congestive heart failure. Patients with clinically inapparent left-sided heart failure may present with a picture like that of acute or chronic hepatitis. Hemochromatosis, in turn, may present as a congestive cardiomyopathy. Distal common bile duct stenosis is a well-described complication of chronic alcoholic pancreatitis to be considered in the setting of persistent anicteric alkaline phosphatase elevations. Hepatobiliary manifestations of clinical importance occur in up to 10% of patients with inflammatory bowel disease. Membranoproliferative glomerulonephritis and essential mixed cryoglobulinemia have been associated with chronic HCV infection. Hematologic disorders, such as polycythemia rubra vera, myeloproliferative disorders, and paroxysmal nocturnal hemoglobinuria may predispose to hepatic vein thrombosis. Patients with renal cell carcinoma may present with liver chemistry abnormalities, primarily elevated alkaline phosphatase levels, in the absence of hepatic metastases. Bacteremia, particularly with gram-negative organisms, should be considered in any ill person with disproportionate elevations of serum bilirubin compared with levels of alkaline phosphatase and aminotransferases.

Liver diseases peculiar to the gravid female include intrahepatic cholestasis of pregnancy, toxemia, and acute fatty liver of pregnancy, although viral hepatitis is the most common cause of jaundice during pregnancy. Fatty liver should be considered in the obese patient presenting with mildly elevated levels of serum transaminases and alkaline phosphatase. A form of nonalcoholic liver disease resembling alcoholic hepatitis and cirrhosis has been described. Previously considered to be a disorder predominantly seen in middle-aged, obese women with hyperglycemia or hyperlipidemia, nonalcoholic steatohepatitis (NASH) is now recognized to exhibit a broader clinical profile. Diagnosis relies on the presence of macrovesicular steatosis and parenchymal inflammation with or without Mallory bodies, fibrosis, and cirrhosis in liver biopsy specimens in the absence of a history of excessive alcohol consumption. Abnormal serum aminotransferases are the most common biochemical abnormality in this disorder, although there is a lack of association between biochemical abnormalities and the degree of steatosis. In general, serum aminotransferases are only mildly to moderately elevated; less than one-third of patients have serum AST or ALT levels more than threefold elevated. Weight reduction in obese patients may lead to improvement in serum aminotransferase abnormalities.

Multitransfused hemophiliacs have a high incidence of asymptomatic abnormalities in liver chemistries, and liver biopsies demonstrate a wide histologic spectrum of liver disease, ranging from mild chronic persistent hepatitis to chronic active hepatitis and cirrhosis. The prevalence of HCV seropositivity in these patients is very high.

In AIDS patients, mild to moderate increases in serum aminotransferase activities are common. Increases in alkaline phosphatase levels and jaundice are less common. Macrosteatosis and nonspecific portal inflammation are the most common histologic abnormalities on liver biopsy; in the past, information provided by liver biopsy had little effect on therapy or survival. Liver biopsy is more sensitive than bone marrow aspiration and biopsy at detecting mycobacterial infection.

ELEVATED AMINOTRANSFERASES IN ASYMPTOMATIC PERSONS

Several studies, performed before HCV antibody testing, addressed the issue of evaluating asymptomatic patients with moderately elevated serum aminotransferase levels. Apart from determinations of ferritin, ceruloplasmin, a₁-antitrypsin, and markers for hepatitis B virus, blood tests have little discriminative value. A high incidence of obesity and regular alcohol use has been demonstrated in these patients. Fatty infiltration consequently is the most common finding on liver biopsy; however, histologic findings of chronic persistent or active hepatitis in many patients support the use of percutaneous liver biopsy in the diagnostic approach to patients with persistently elevated levels of serum aminotransferases. In studies performed since the advent of serologic tests for HCV, some patients with asymptomatic elevations in serum ALT have evidence of HCV infection. Therefore, antibody to HCV should be routinely determined. Asymptomatic anti-HCV-positive patients often are found to have chronic liver disease on liver biopsy even with no serum ALT elevations. This has led some authors to recommend that all anti-HCV-positive patients (confirmed by recombinant immunoblot) should undergo liver biopsy, regardless of serum ALT levels. However, liver biopsy may be avoided in anti-HCV-positive patients with normal ALT levels whose serum HCV-RNA is also negative.

Indications for HOSPITALIZATION AND REFERRAL

Because abnormalities in liver chemistries are merely markers of hepatocellular injury, decisions regarding hospitalization should not be made on the basis of the degree of abnormality. Even tests of liver function, serum albumin, serum bilirubin, and PT cannot be used as the sole criteria for admission, with the exception of a prolonged PT in acute viral hepatitis.

The diagnostic tests previously discussed suggest but rarely provide a specific diagnosis in a patient with suspected liver disease. Nevertheless, information obtained from these tests should facilitate the efficient use of other noninvasive and invasive tests such as ultrasonography, computed tomography, radionuclide hepatobiliary scanning, percutaneous transhepatic cholangiography, endoscopic retrograde cholangiopancreatography, and laparoscopy. Liver biopsy has a key role in the evaluation of patients with abnormal liver chemistries, and referral is usually on this basis. However, a likely diagnosis can be rendered by the referring physician, and the need to refer may depend substantially on the clinical setting and the degree of reassurance required by the patient.

[Fulminant Hepatic Failure](#)

Cirrhosis is a diffuse pathologic process in which the normal structure of the liver is replaced by regenerative nodules of hepatocytes separated by bands of fibrosis. Cirrhosis may result from various forms of chronic hepatic insult ([Table 105.1](#)). It is often associated with three sets of clinical phenomena: hepatocellular insufficiency, portal hypertension, and cholestasis. Although these syndromes usually coexist in a cirrhotic patient, they are separated here for purposes of description.

Chronic Toxic Insults
Alcohol
Chronic Viral Infection
Hepatitis B = hepatitis D
Hepatitis C
Inherited Metabolic Disease
Wilson's disease
Hemochromatosis
= = Antitrypsin deficiency
Secondary Metabolic Disease
Secondary hemochromatosis
Autoimmune Disorders
Chronic autoimmune hepatitis (autoimmune chronic active hepatitis)
Chronic Biliary Disorders
Primary biliary cirrhosis
Secondary biliary cirrhosis
Primary sclerosing cholangitis
Biliary atresia
Alagille's syndrome
Caroli's syndrome
Cystic fibrosis
No Apparent Cause/Miscellaneous
Cryptogenic cirrhosis
Congenital hepatic fibrosis

TABLE 105.1. CAUSES OF CIRRHOSIS

PORTAL HYPERTENSION

PATHOPHYSIOLOGY

The portal vasculature is normally a high-flow, low-pressure, low-resistance system. The normal portal pressure is 5 to 10 mm Hg (7 to 14 cm H₂O). Portal hypertension occurs when resistance to flow causes an increase in blood pressure within the portal vein. *Portal hypertension* is defined as a portal blood pressure of 5 mm Hg greater than the pressure in the inferior vena cava (IVC) or as a direct measurement of a portal pressure of 30 cm H₂O or more. Although cirrhosis is the most common cause in the developed world of an increase in resistance to portal flow, not all portal hypertension is due to cirrhosis. The origin of portal hypertension may be subdivided into presinusoidal, sinusoidal, and postsinusoidal causes ([Fig. 105.1](#)). Portal hypertension is usually a feature of chronic liver injury, but it may be seen clinically in some acute circumstances, including the more protracted forms of acute hepatic failure, such as submassive hepatic failure and acute forms of Budd–Chiari syndrome or veno-occlusive disease of the liver.

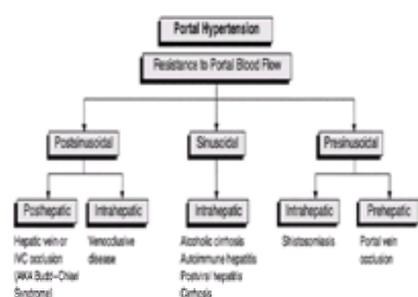

FIGURE 105.1. Theoretical subclassification of portal hypertension according to the locus of obstruction to portosystemic communication.

Portal pressure may be measured by direct placement of a catheter in the portal vein, either by a puncture from the skin through the liver (percutaneous transhepatic portal pressure) or by a transjugular route. Today, the latter is often a prelude to placing a transjugular intrahepatic portosystemic shunt (TIPS). This approach also allows measurement of the IVC or free hepatic vein pressure and calculation of the transsinusoidal pressure gradient. A transjugular approach can be used to measure the wedged hepatic vein pressure, an indirect measure of the portal vein pressure when a transhepatic incursion into the portal vein is ill advised. Wedged hepatic venous pressures have been validated as an estimate of portal pressure in alcoholic cirrhosis only.

CLINICAL FEATURES OF PORTAL HYPERTENSION

PORTOSYSTEMIC COLLATERALS

The portal and systemic systems are connected through many collateral vessels. When portal pressure is increased, these collaterals dilate and are called *varices*. The most common site of variceal development is the lower esophagus, followed by the stomach and rectum. Mesenteric varices or stomal varices are less common. When the portal pressure rises higher than 12 mm Hg, esophageal varices are likely to bleed. Endoscopic studies have shown that variceal size, the presence of red marks on the variceal surface (red wale marks), and decompensated cirrhosis (Child–Pugh class C) are predictors of future hemorrhage ([Table 105.2](#)). Varices at other sites such as the stomach may also bleed.

Factor	Points		
	1	2	3
Encephalopathy	None	1, 2	3, 4
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	1-2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds prolonged)	1-4	4-6	>6
Bilirubin (mg/dL)	1-4	4-10	>10

Grading (total score): 1-6, class A; 7-9, class B; 10-15, class C.

TABLE 105.2. CHILD-TURCOTTE-PUGH SCORE

Portal hypertensive gastropathy, another important clinical manifestation of portal hypertension, is present in at least 50% of patients with cirrhosis who have varices that have bled. Endoscopically, “lizard skin” mosaic pattern with diffuse erythema with or without cherry-red spots (submucosal hemorrhage) or a hemorrhagic appearance. Histology reveals diffusely dilated, tortuous mucosal and submucosal arteries, capillaries, and veins. Portal gastropathy leads to oozing, which can become a source of significant blood loss, even requiring transfusion.

SPLENOMEGALY

Portal hypertension commonly results in splenomegaly, although the correlation between splenic size and portal pressure measurements is poor. Splenomegaly leads to hypersplenism, which causes consumption and sequestration of white cells and platelets and results in leukopenia and thrombocytopenia, respectively. Another cause of thrombocytopenia in affected patients is relatively low levels of thrombopoietin, a growth factor that is produced by the liver and stimulates platelet production.

ASCITES

Ascites is the accumulation of serous fluid in the peritoneal cavity. It is often associated with fluid collection in a hemithorax, termed *cirrhotic hydrothorax*. Cirrhotic hydrothorax usually occurs on the right side and occasionally is found without overt ascites. The mechanisms underlying ascites formation in portal hypertension include altered Starling forces in the portal circulation as a result of increased portal pressure and reduced portal venous oncotic pressure as a result of hypoalbuminemia, altered renal sodium handling, increased hepatic, and possibly splanchnic lymph formation. Peripheral arterial vasodilatation theory was recently proposed as the initial defect, resulting in increased vascular capacity and relative hypovolemia. Transient sodium and water retention occurs as a compensatory mechanism to refill the intravascular circulation. These mechanisms eventually fail, and, in conjunction with hypoalbuminemia, from liver failure, ascites develop. This is further contributed to by the inability of the kidneys to handle sodium and water loads, followed by sodium retention and increased peripheral blood volume with a concomitant reduction in central blood volume.

Increasing abdominal girth and rapid weight gain are the most common symptoms associated with new-onset ascites. Ascites is detected clinically by dullness on percussion of the abdominal flanks that moves as the patient changes position (“shifting dullness”) and by a fluid wave. Small volumes of ascites (less than 1500 mL) are often clinically undetectable and require an imaging study such as computed tomography (CT) scanning or sonography for confirmation.

Investigation of new-onset ascites that is unexplained by standard clinical investigations should always include diagnostic paracentesis. In addition to examination of the fluid for culture and cytology, diagnostic paracentesis allows calculation of the serum/ascites albumin gradient (serum albumin [grams per deciliter] minus ascites albumin [per deciliter]). This is the most reliable method of distinguishing ascites due to portal hypertension from all other forms of ascites and has replaced the use of the exudate–transudate paradigm (Table 105.3). Portal hypertensive ascites has a serum/ascites albumin gradient of 1.1 g per deciliter or more; ascites not associated with portal hypertension has a value of less than 1.1 g per deciliter. Similarly, analysis of portal hypertension-induced hydrothorax yields the same results.

High Gradient (>1.1 g/dL)
Cirrhosis
Alcoholic hepatitis
Congestive/restrictive heart failure
Massive hepatic metastases
Fulminant hepatic failure
Budd–Chiari syndrome
Veno–occlusive disease
Portal vein occlusion
Acute fatty liver of pregnancy
Myxedema
Low Gradient (<1.1 g/dL)
Peritoneal carcinomatosis
Tuberculous peritonitis (without cirrhosis)
Pancreatic ascites (without cirrhosis)
Bile leak
Nephrotic syndrome
Systemic lupus erythematosus
Bowel obstruction or infarction

TABLE 105.3. CLASSIFICATIONS OF A ASCITES BY SERUM/ASCITES ALBUMIN CONCENTRATION GRADIENT

Patients with ascites are best managed with a combination of loop diuretic, such as furosemide, and a distal-acting aldosterone-inhibiting diuretic, such as spironolactone. Both drugs achieve synergy in producing diuresis and saluresis.

Refractory ascites is ascites that does not respond to maximal diuretic therapy or results in diuretic-related side effect, such as renal insufficiency or hyponatremia. At the end of the spectrum of refractory ascites is hepatorenal syndrome (HRS).

HEPATORENAL SYNDROME

Hepatorenal syndrome is defined as renal insufficiency in the presence of liver failure and the absence of parenchymal or obstructive renal disease that does not respond to volume expansion. In HRS, the kidney responds to reduced effective circulating volume with intense vasoconstriction of the renal circulation. Reduced renal blood flow and glomerular filtration rate ensue.

All cirrhotic patients who develop new-onset renal failure should undergo renal sonography to exclude intrarenal and postrenal structural lesions. Doppler sonograms allow assessment of renal vasoconstriction. The diagnosis of HRS should be suspected in any patient with advanced hepatic failure and portal hypertension who has developed renal insufficiency without response to plasma volume expansion. Renal insufficiency is progressive over weeks or days in the presence of severe liver disease without intrinsic renal disease, ongoing infection, hypovolemia, or nephrotoxic agents such as nonsteroidal anti-inflammatory agents.

Laboratory evidence of HRS includes low glomerular filtration rate, as indicated by serum creatinine greater than 1.5 or 24-hour creatinine clearance less than 40 mL per minute, absence of proteinuria, and lack of ultrasonographic evidence of obstructive uropathy or parenchymal kidney disease. Other laboratory evidence that supports this diagnosis is urine volume less than 500 mL per day; urine sodium less than 10 mEq per liter; urine osmolality greater than plasma osmolality; urine red blood cell count less than 50 per high-power field; and serum sodium less than 130 mEq per liter. There are two forms of HRS. Type I is rapidly progressive and associated with early mortality, whereas type II is more chronic and lasts from weeks to months.

HRS often overlaps other forms of acute renal insufficiency, particularly prerenal uremia and acute tubular necrosis. The patient often has a history of one or more precipitating factors, including hypovolemia from blood loss, diuretics, paracentesis, or lactulose; use of cyclooxygenase inhibitors, which precipitate HRS on account

of the role of intrarenal prostaglandins in the maintenance of renovascular tone; or exposure to other hepatotoxins, including intravenous dye or aminoglycosides. The serum creatinine level underestimates glomerular filtration in patients with cirrhosis and ascites.

The prognosis of patients with HRS is grave. Renal failure is an independent poor prognostic indicator of survival from liver transplantation. The role of liver transplantation, with or without renal grafting, in patients with HRS remains controversial.

HEPATIC ENCEPHALOPATHY

The principal mechanism for the development of hepatic encephalopathy in cirrhotic patients is the transmission of portal blood to the right heart through intrahepatic or extrahepatic shunts, thereby bypassing the hepatic mass. This tendency is exacerbated by surgically created portosystemic shunts or TIPS. Although chronic hepatic encephalopathy is caused by nitrogenous substances arising from the gut, it is still uncertain which substances are the actual mediators of the syndrome. Candidates include ammonia, either directly or through a disturbance in the balance of excitatory/inhibitory neurotransmitters; aromatic amino acids enhancing either “false neurotransmitters” or synergistic neurotoxins including mercaptans, fatty acids, and phenols; g-aminobutyric acid (GABA); and endogenous or exogenous benzodiazepine ligands.

Clinically, chronic hepatic encephalopathy varies from a subtle alteration in higher cerebral function detectable only on neuropsychometric testing to a broad range of neuropsychological syndromes up to and including coma. Among its characteristic features are variability in severity with rapid reversibility, especially in patients using lactulose.

As shown in [Figure 105.2](#), the new onset of a change in mental status in a patient with cirrhosis can have a bewildering variety of precipitating causes. It may be the mode of presentation of infections, electrolyte abnormalities or covert gastrointestinal bleeding that might otherwise go unnoticed. If, despite a thorough investigation, no precipitating cause is found for apparent hepatic encephalopathy that fails to resolve with standard measures, one should consider other progressive neurologic disorders. Wilson’s disease is an important diagnosis not to miss. Occasionally, patients with portosystemic shunts develop an idiopathic syndrome of cerebrosplinal demyelination.

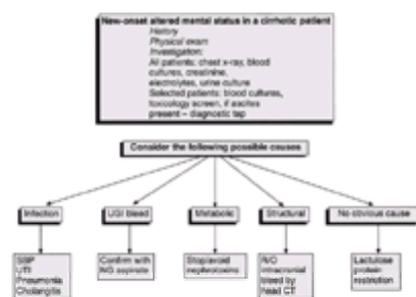

FIGURE 105.2. New-onset altered mental status in a cirrhotic patient.

PULMONARY MANIFESTATIONS OF CHRONIC LIVER DISEASE

Two distinct pulmonary disorders are associated with portal hypertension and result from right-to-left intrapulmonary shunting. The first is called the *hepatopulmonary syndrome*, characterized by pulmonary capillary vasodilatation and hypoxemia without associated pulmonary hypertension. This phenomenon is mediated by nitric oxide. The other disorder is the *portopulmonary syndrome*, characterized by portopulmonary hypertension as the primary feature, which may preclude liver transplantation.

CHOLESTASIS

PATHOPHYSIOLOGY

Cholestasis is characterized by pruritus, jaundice, and elevated alkaline phosphatase; it results from impairment of bile secretion and specific defects in the secretion of anions ([Chapter 103](#)). Jaundice often is a feature of cholestasis, but it may precede the onset of pruritus and elevated alkaline phosphatase by several weeks to years. Approximately 20% to 50% of jaundiced patients experience pruritus. The cause of this symptom is unknown but has been attributed to the poor excretion of pruritogenic agents in bile. Cholestyramine, a bile acid chelating agent, may be used as first-line therapy. In refractory cases, the opiate antagonist, naltrexone, which works by inhibiting endogenous opiate-like agents has proved effective. Also, rifampin, which inhibits bile acid uptake into hepatocytes, may also be used. Phenobarbital and ursodeoxycholic acid are also efficacious in the management of pruritus.

CLINICAL FEATURES OF CHOLESTASIS

Hyperlipidemia occurs in patients with chronic cholestasis owing to impaired excretion of cholesterol and phospholipids into bile. It has been traditionally thought that the hyperlipidemia of cholestasis does not lead to atherosclerotic disease, but this is controversial.

Fat malabsorption and steatorrhea may result from impaired bile acid delivery and poor micelle formation. Reduced absorption of the fat-soluble vitamins, A, D, E, and K is a consequence of fat malabsorption; therefore, replacement of these vitamins is recommended. Also, calcium–fatty acid complexes may form, and this impairs calcium absorption. The bone disease that is prevalent in chronic cholestasis is osteoporosis, although osteomalacia may also be found. These patients are best evaluated with bone densitometric studies. If osteopenia is diagnosed, an oral diphosphonate is indicated.

HEPATOCELLULAR INSUFFICIENCY

PATHOPHYSIOLOGY

Hepatocellular insufficiency is a pathologic deficiency of one or more of the paradigmatic hepatocellular activities: protein synthesis, metabolism and excretion of bilirubin and bile salts, and metabolism of endogenous proteins and xenobiotics. When hepatocellular insufficiency is life-threatening, with or without portal hypertension, it is called *end-stage liver failure*. Because estimates of prognosis in chronic liver failure are inaccurate, end-stage liver failure remains an imprecise concept. Hepatocellular insufficiency may arise acutely in response to a sudden massive destruction of liver, but it more commonly occurs in patients with chronically diseased livers, in whom much of the functioning hepatic mass has been lost because of cirrhosis. Liver failure resulting from cirrhosis is usually more gradual in onset and less uniform in presentation than that in acute liver injury. Coagulopathy and hypoproteinemia may predominate in one patient, whereas encephalopathy may be more prominent in another. In addition, other factors such as vitamin K deficiency or the presence of a portosystemic stent may affect the clinical features at a particular time.

CLINICAL FEATURES OF HEPATOCELLULAR INSUFFICIENCY

Coagulopathy

The liver is the site of synthesis of many protein factors involved in the regulation of hemostasis, including factor I (fibrinogen), factor II (prothrombin), and factors V, VII, IX, X, XII, and XIII, high-molecular-weight kallikrein, protein S, protein C, and antithrombin III.

Inadequate hemostasis accompanies liver failure both because of impaired synthesis of clotting factors as a result of a substantial reduction in functioning hepatic mass and because of vitamin K deficiency in cholestatic disorders. Hepatic synthesis of clotting factors II, VII, IX, and X requires vitamin K. Occasionally, patients with liver failure and autoanticoagulation develop clinical evidence of a hypercoagulable state, such as deep venous thrombosis or pulmonary embolus. This is explained, presumably, by a relatively greater perturbation to the synthesis of anticoagulant factors, such as protein S, protein C, and antithrombin III, than to the procoagulant factors.

The clinical manifestations of coagulopathy include easy bruising, bleeding from the gums and nose, and minor degrees of anorectal bleeding. Hemorrhage from varices is multifactorial in origin, and coagulopathy is one contributing factor ([Fig. 105.3](#)).

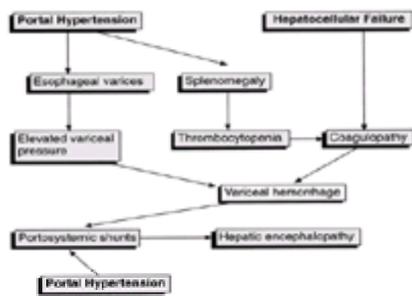

FIGURE 105.3. Interaction of portal hypertension and hepatocellular failure, leading to variceal hemorrhage and hepatic encephalopathy.

Hypoalbuminemia

Hypoalbuminemia in chronic liver disease has a complex pathogenesis. In some patients with cirrhosis and ascites, a reduced serum albumin concentration is the result of dilution rather than reduced synthesis. Indeed, given that its half-life in serum is 20 days, albumin is a poor indicator of “acute” hepatic injury. The reduction in serum albumin in many cirrhotics also depends on nutritional status.

Endocrine Effects

Male patients with cirrhosis display a combination of androgenic failure and feminization, whereas cirrhosis in females is complicated by amenorrhea and anovulation ([Table 105.4](#)). Spider angiomas and palmar erythema are thought to be endocrine features of hepatocellular insufficiency. Spiders are found in the distribution of the superior vena cava (upper torso, face, arms, and hands) and are not pathognomonic of liver injury: they may also occur in healthy adults (in whom they usually number less than six), during pregnancy, and in healthy children (in whom they may resolve with maturity). The mechanisms underlying these endocrine phenomena are complex and confounded in many studies by the direct effect of alcohol on the hypothalamus–pituitary–gonadal axis.

Men
Hypoandrogenic/feminization
Loss of libido
Impotence
Testicular atrophy
Gynecomastia
Loss of body hair
Spiders
Palmar erythema
Women
Loss of libido
Anovulation

TABLE 105.4. ENDOCRINE EFFECTS OF CIRRHOSIS

MISCELLANEOUS COMPLICATIONS/ASSOCIATIONS OF CIRRHOSIS AND END-STAGE LIVER DISEASE

ENDOCRINE DISORDERS

The presence of diabetes mellitus accompanying cirrhosis should prompt investigation for hereditary hemochromatosis. Disorders of thyroid function, particularly hypothyroidism, are common in primary biliary cirrhosis and to a lesser extent in chronic autoimmune hepatitis. Unrecognized hypothyroidism may be the cause of clinical deterioration in a previously stable cirrhotic.

BONE DISEASE

Many forms of chronic liver disease are complicated by disorders of bone metabolism (hepatic osteopenia). The causes are multifactorial, including immobility leading to lack of sunlight, disordered hepatic metabolism of vitamin D, and the effect of ethanol on bone. Hepatic osteodystrophy is particularly common in chronic cholestatic disorders, especially primary biliary cirrhosis. Clinically, it produces vertebral collapse and pathologic fractures of the long bones.

INFECTION

Cirrhosis is a state of relative immunosuppression, with a higher incidence of infection. Pneumonia or urosepsis may present as worsening hepatic failure or hepatic encephalopathy. Tuberculosis is more common in cirrhotic patients, especially those with alcoholic cirrhosis.

The most important locus of infection in cirrhotics with ascites is the peritoneum (spontaneous bacterial peritonitis [SBP]; [Table 105.5](#)). SBP is a monomicrobial bacterial infection of ascites fluid in a patient with portal hypertension in whom there is no precipitating cause of peritonitis. A similar syndrome may complicate cirrhotic hydrothorax. SBP occurs almost exclusively in cirrhotic patients but occasionally complicates acute hepatic failure. The most important predictor of a first episode is a low total ascites protein content (less than 1 g per deciliter). A previous episode of SBP is predictive of future episodes. Inadequate opsonic and chemotactic activity in the ascites and overall reduced systemic clearance of bacteria are the putative mechanisms in the pathogenesis of SBP. Gram-negative aerobes such as *Escherichia coli* and *Klebsiella pneumoniae* or gram-positive aerobes such as *Streptococcus pneumoniae*, and rarely anaerobes, are most commonly responsible for SBP.

Occurs with cirrhosis and ascites
 Total ascites protein <1 g/dL
 Previous episodes of SBP are predictive
 Low ascitic opsonic activity
 Presentation protean, subtle: requires high index of suspicion
 Diagnosis by paracentesis: >250 polymorphonuclear leukocytes/
 mm³ diagnostic
 No organism found in 30–50% of cases
Escherichia coli, *Klebsiella pneumoniae*, *Streptococcus pneu-*
moniae found rarely anaerobes
 3–5 days intravenous cephalosporin may be sufficient; oral quin-
 olones, or co-trimoxazole reduces incidence of recurrence

TABLE 105.5. SPONTANEOUS BACTERIAL PERITONITIS (SBP): KEY CHARACTERISTICS

SBP often has a subtle presentation lacking characteristic signs or symptoms of peritonitis. Consequently, SBP must be suspected whenever a cirrhotic patient with ascites develops a sudden deterioration in hepatic or renal function, worsening malaise, encephalopathy, or an unexplained leukocytosis. SPB should also be sought when a cirrhotic patient develops fever and abdominal pain more typical of acute peritonitis. Small pockets of infected ascites may be present that are detectable only by sonography or CT scanning and are hazardous to aspirate. In such cases, it is often wise to presume SBP and institute appropriate antibiotics rather than to attempt a difficult aspiration.

The key to recognizing SBP is diagnostic paracentesis. The diagnosis of SBP is made by finding more than 250 polymorphonuclear cells (PMN)/mm³. A very elevated PMN count in ascites (e.g., more than 5,000/mm³) suggests an intra-abdominal abscess or a secondary cause of peritonitis. Demonstration of an organism is not required for the diagnosis; in fact, no organism is identified in 30% to 50% of cases of SBP. A culture of multiple organisms from ascites suggests a perforated viscus.

All patients in whom SBP is suspected should receive blood cultures, a chest radiograph, and urine microscopy and culture in pursuit of blood-borne sepsis and other sites of infection.

MALIGNANCY

Hepatoma may manifest as right upper quadrant pain, weight loss, and deteriorating hepatic function. Alternatively, hepatoma is increasingly being recognized as an asymptomatic phenomenon in at-risk persons, especially during evaluation for liver transplantation. Maleness, cirrhosis, chronic hepatitis B (HBV) infection, or chronic hepatitis C (HCV) infection, and hemo- chromatosis are risk factors for hepatoma. A very high incidence of hepatoma occurs in children with tyrosinemia. Serum a-fetoprotein and either liver ultrasonography or magnetic resonance imaging (MRI) of the abdomen are appropriate screening tools for patients who are at risk for hepatoma.

Cholangiocarcinoma may arise de novo, or it may complicate primary sclerosing cholangitis and occasionally other cystic disorders such as Caroli's disease. It is often difficult to make a definitive diagnosis of cholangiocarcinoma ([Fig. 105.4](#)).

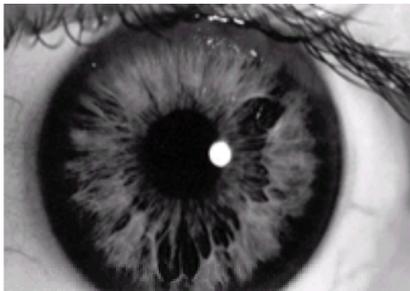

FIGURE 105.4. Kayser-Fleischer ring. See [color figure 105.4](#).

APPROACH TO THE PATIENT WITH LIVER DISEASE

When a physician encounters a patient with newly recognized liver disease for the first time, he or she should consider whether it represents an acute injury to a previously healthy liver or the first presentation of a previously unrecognized chronic liver disease. Many of the clinical features of liver injury, such as jaundice and encephalopathy, are common to the acute or chronic state. A careful history and physical examination are of fundamental importance in distinguishing acute and chronic liver disease ([Table 105.6](#)). For example, a history of subtle features of chronic liver injury, such as pruritus or amenorrhea, which predate the presentation of overt liver disease may provide important clues. Patients may not recognize the significance of previous illnesses such as jaundice or hepatitis unless asked specifically. Similarly, careful attention should be paid to a history of exposure to sources of liver injury, such as alcohol, blood transfusions, intravenous drug use, and sexual history. The history and physical examination allow the formulation of a differential diagnosis and selection of investigations.

Duration of symptoms
 Previous similar episodes
 Current or past history of jaundice, pruritus, ascites, hemor-
 rhage, confusion or altered mental state; men: impotence,
 painful gynecomastia; women: amenorrhea
 Past medical history: operations, blood transfusions, hepatitis,
 hemorrhage
 Review of symptoms: alcoholism (CAGE questions), hypothyroid-
 ism, diabetes mellitus heart failure, prostatic disease, emphy-
 sema, sexual/lifestyle history
 Social history: IV drug use, occupation, marital/social status
 Family history: liver disease, death from cirrhosis, gastrointesti-
 nal hemorrhage, alcoholism
 Current medications
Important Observations on Clinical Exam
 Neurologic: mental status, asterix, gait
 Hands: palmar erythema, spider nevi, Dupuytren's contracture,
 finger clubbing, muscle wasting
 Eyes: scleral icterus, xanthomata, Kayser-Fleischer rings
 Skin: spider nevi, jaundice, excoriations, easy bruising, purpura
 Head/neck: muscle wasting
 Abdomen: distended vessels, ascites, hepatomegaly, splenomeg-
 ally, rectal examination
 CAGE, questionnaire for alcoholism evaluation

TABLE 105.6. IMPORTANT DATA IN ANY PATIENT PRESENTING WITH PUTATIVE LIVER DISEASE

The same approach applies to new-onset deterioration in a patient with established cirrhosis. Usually, acute deterioration occurs because of a precipitating event, which may be ameliorated even when the underlying liver disease is intractable other than by liver transplantation. The precipitating events include infection, variceal hemorrhage, and the ill-advised use of toxins such as intravenous dye or medicines.

INVESTIGATION OF PATIENTS WITH CIRRHOSIS

LIVER TESTS

Profiles of serum transaminases, bilirubin, albumin, and alkaline phosphatase are not specific for diagnosis of cirrhosis but indicate broader categories of liver injury such as hepatocellular injury or cholestasis, which often coexist in an individual patient ([Chapter 104](#)). The best measures of hepatic synthetic function are the prothrombin time and the serum albumin level. The long half-life of albumin makes it a suitable measure of synthesis in chronic liver injury only. The measurement of specific clotting factors is of little practical usefulness, although factor V has the theoretical advantage of being vitamin K-independent and synthesized exclusively in the liver.

The totals of these measures of synthetic and excretory function are included in the empirically derived global measure of hepatic function, the Child–Pugh score ([Table 105.2](#)).

NONSPECIFIC TESTS

Many commonly measured laboratory parameters may be deranged in end-stage liver disease. For example, the impact of cirrhosis and ascites on renal function was described in the section on HRS. Cirrhosis and ascites are often accompanied by hyponatremia. This is dilutional in origin and is contributed to by marked hyperaldosteronism and exacerbated by diuretics. It is a grave prognostic sign when hyponatremia persists despite withholding diuretics and restricting intake of fluids and salt. Hematologic abnormalities common in end-stage liver disease include leukopenia and thrombocytopenia due to hypersplenism, iron-deficiency anemia, and macrocytosis due to target cells. Disease-specific noninvasive tests are discussed in detail in [Chapter 104](#).

LIVER IMAGING STUDIES

Liver imaging studies include sonography with Doppler imaging, CT scanning, MRI, angiography, and CT angiography. All patients with putative chronic liver disease who are undergoing investigation should have at least one baseline structural imaging study, the choice of which depends on local expertise and resources. Many patients with chronic cholestatic liver disease receive a cholangiogram, either endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography, or more recently, magnetic resonance cholangiography. Endoscopic retrograde cholangiopancreatography remains the method of choice for distinguishing primary sclerosing cholangitis from other chronic cholestatic processes.

LIVER BIOPSY

Histopathologic examination of liver tissue may be helpful in confirming the presence of cirrhosis or in estimating the degree of activity of chronic hepatitis. It may assist making the diagnosis of specific conditions including hemochromatosis, Wilson's disease, α_1 -antitrypsin deficiency, autoimmune chronic hepatitis, chronic cholestatic disorders such as primary biliary cirrhosis, and congenital hepatic fibrosis, among others. Liver biopsy is the only unequivocal way of diagnosing acute cellular rejection in a liver allograft. Guided biopsies may be useful for diagnosing hepatic malignancy. Liver biopsy is sometimes eschewed in patients with hepatic masses who are being considered for liver transplantation, to avoid spreading malignant cells outside the hepatic capsule. On the other hand, liver biopsy has little clinical usefulness in diagnosis or management of acute hepatic injury and often yields relatively nonspecific findings in chronic liver diseases.

Percutaneous liver biopsy is the most common method of obtaining liver tissue. It is usually carried out as a day-case outpatient procedure. Outpatient liver biopsy should be limited to patients with preserved hematology and coagulation parameters: hemoglobin greater than 10 g, platelet counts $\geq 70,000$ and prothrombin time ≤ 1.5 seconds or international normalized ratio up to 1.3. Patients with renal failure may have platelet dysfunction, and a platelet count of 100,000 is required for an outpatient procedure. Patients whose measures fall outside these parameters may still be suitable for percutaneous liver biopsy after replenishment of platelets, clotting factors, or fresh frozen plasma. However, our policy is to observe for at least 16 hours all patients who require blood products to have a percutaneous liver biopsy. Transjugular liver biopsy is an alternative for these patients. It is often wise to have had an imaging procedure (CT, sonogram, or MRI) before proceeding to biopsy to identify mass lesions or unusual structural anomalies, such as atrophic right hepatic lobe.

Minor complications of percutaneous liver biopsy include vasovagal reaction with hypotension, bradycardia, and nausea; pain at the site of insertion; or shoulder tip pain. Pain usually resolves within 2 to 4 hours upon administration of simple analgesia. Percutaneous liver biopsy may be followed by a dull ache in the right upper quadrant for 24 hours. More significant complications include perforation of a viscus, pneumothorax, or hemorrhage. Puncture of the gallbladder is followed by intense abdominal pain and is not likely to go unrecognized. Similarly, pneumothorax, leading to pain and difficulty in breathing, is readily diagnosed. Significant hemorrhage may manifest as a subtle onset of hypotension and dizziness hours after the procedure. For this reason, our policy is to keep outpatients for 4 hours after the procedure while their blood pressure and heart rate are monitored. Patients are advised to go to an emergency room if they experience severe pain, difficulty in breathing, or dizziness after discharge home. Significant hemorrhage may require ablation of a bleeding vessel by angiography or ultimately laparotomy. Hemorrhage is the cause of occasional mortalities after liver biopsy. The presence of cancer in the liver and coagulation defects are the principal risk factors for postprocedure bleeding.

Alternatives to percutaneous liver biopsy include transjugular biopsy, laparoscopic guided biopsy, and open liver biopsy. The main advantage of transjugular biopsy is that bleeding from the liver should remain within the vascular space. Laparoscopic liver biopsy has its devotees, but, except for occasional patients with anomalous atrophy of the right hepatic lobe, it has no advantages over percutaneous liver biopsy. There are few indications if any for open liver biopsy.

WHY DO PATIENTS WITH END-STAGE LIVER DISEASE DIE?

Acute gastrointestinal hemorrhage, bacterial infection, and multisystem failure, particularly the combination of hepatic and renal failure, are the most common modes of death in patients with cirrhosis. Bacterial infection may present as SBP, pneumonia, urinary tract infection, cholangitis, or occasionally meningitis. A few patients, less than 5% in the United States, die of hepatocellular carcinoma, although this percentage is higher in areas of greater prevalence for hepatitis B and C. As shown in [Figure 105.2](#) and [Figure 105.3](#), hemorrhage, infection, and multisystem failure often interact in the same patient and carry a high mortality. Thus, 20% to 25% of patients with cirrhosis die during hospitalization for their initial variceal bleed. Similarly, in one large series, 50% of cirrhotic patients died within 1 year of their initial episode of SBP. Ninety percent of patients who develop renal failure in addition to acute alcoholic hepatitis (usually an event within chronic alcoholic liver disease) die in the same hospital admission.

END-STAGE LIVER FAILURE

Although therapy may control the initial decompensating event (e.g., acute sclerotherapy for bleeding esophageal varices or antibiotics for SBP), these measures do not change the long-term mortality unless liver failure is corrected. Therapies that reverse liver failure include abstinence from alcohol in patients with end-stage alcoholic cirrhosis, corticosteroids for autoimmune chronic hepatitis, specific therapies for metabolic disorders such as hemochromatosis and Wilson's disease, and liver transplantation for many forms of cirrhosis. Patients with alcoholic liver disease, especially acute alcoholic hepatitis, can make substantial recoveries after withdrawal from alcohol.

Liver transplantation has become the treatment of choice in the developed world for end-stage liver disease ([Chapter 132](#)). Its wider application is limited by an inadequate supply of donor organs and its cost.

MANAGING THE COMPLICATIONS OF CIRRHOSIS, PORTAL HYPERTENSION, AND HEPATOCELLULAR FAILURE

BLEEDING ESOPHAGEAL VARICES

A minority of esophageal varices bleed. Variceal hemorrhage is most likely in patients with large varices, varices with longitudinal red marks on their surface, and decompensated cirrhosis as shown by Child–Pugh class ([Table 105.2](#)). Elevation of portal pressure higher than a threshold of 12 mm Hg is critical to the initiation of variceal bleeding. Prophylactic therapy with noncardioselective β -blockade such as propranolol reduces the portal pressure and the incidence of first or recurrent variceal bleeding in high-risk patients, but it remains controversial whether this translates into a survival benefit. Patients with cirrhosis and features of portal hypertension should undergo endoscopy to assess the presence, size, and surface markings of esophageal varices to determine whether prophylactic β -blockade is

appropriate. Prophylactic variceal injection sclerotherapy is not recommended in cirrhotic patients with varices who are found to have a high risk for an initial bleed.

Variceal hemorrhage—whether a first or a subsequent bleed—is always an emergency. Once an upper gastrointestinal bleeding source has been confirmed, either by presentation of hematemesis or by gastric aspiration in those who present with melena or subtle signs of decompensation, the patient should be managed with supportive and specific therapy ([Chapter 107](#)). Upper gastrointestinal endoscopy rarely reveals blood issuing from an esophageal varix; more commonly, blood is present in the esophagus and stomach in the presence of esophageal varices. Unless another source of bleeding is identified, such as an actively bleeding gastric varix or a gastric or duodenal ulcer, the esophageal varices are the presumed source of hemorrhage and should be treated accordingly. It is often impossible to get an adequate view of all the stomach owing to adherent clot, and this must be reviewed at a later date to rule out gastric varices or other pathology. Injection sclerotherapy direct into the varix using sodium tetradecyl sulfate, ethanolamine, or 5% morrhuate sodium is the standard approach for varices that have recently bled. Ligation banding per endoscopy is an alternative to sclerotherapy but can be technically difficult during vigorous hemorrhage.

Balloon compression using a Sengstaken–Blakemore tube is a complementary approach often used to control persistent bleeding. Endotracheal intubation and mechanical ventilation to protect the airway are standard procedures in the United States before placing the tube. Balloon tamponade is effective in controlling bleeding in 80% of cases, but rebleeding occurs in the same hospital admission in at least 50% of these cases. Prolonged use (more than 12 hours) of the inflated esophageal balloon increases the risk of esophageal perforation, especially if the patient has received extensive recent sclerotherapy.

Intravenous octreotide (50 µg bolus followed by 50 µg per hour for 48 hours) appears to be as effective as vasopressin and has considerably fewer side effects. It acts by producing splanchnic vasoconstriction. Intravenous vasopressin (0.2 to 0.4 units per minute) is the longest-established pharmacologic agent for controlling variceal hemorrhage, although studies of its efficacy are equivocal. Vasopressin is usually administered with glyceryl trinitrate to limit cardiac side effects. Terlipressin, an analogue of vasopressin without cardiac effects, has been promoted as an alternative. If bleeding persists or recurs, TIPS is the treatment of choice. When performed by an experienced interventional radiologist, TIPS is a very effective method for controlling acute or recent variceal bleeding. It is also the best method to control bleeding gastric varices. Emergency operative portosystemic shunting carries a high mortality and has been replaced by TIPS.

Serial sclerotherapy or band ligation until variceal obliteration is the standard of care for longer-term management. Patients should also receive b-adrenergic blockade using a nonselective adrenergic b-antagonist.

Late recurrent bleeding is common despite sclerotherapy or banding. Each episode should be managed as for an initial bleed. When Child–Pugh class A patients rebleed despite appropriate sclerotherapy or banding, an operative portosystemic shunt can be considered. Child–Pugh class B and C patients need evaluation for liver transplantation.

ASCITES

Management of ascites due to portal hypertension is directed at controlling fluid overload, avoiding precipitating renal failure, and, in selected patients, providing prophylaxis against SBP. The key to ascites control is dietary restriction of sodium and judicious use of diuretics. Limiting sodium chloride intake to 2 g per day is not excessive and is compatible with a palatable diet. Furosemide and spironolactone are the most widely used diuretics; careful monitoring of serum sodium and potassium levels is required when these agents are used. Painful gynecomastia is a common and troublesome side effect of spironolactone in men with cirrhosis who have ascites. In these patients, amiloride should be substituted for spironolactone. Whenever the serum creatinine level exceeds 2.0 mg per deciliter (an arbitrary figure) or the serum sodium level is below 125 mEq per liter, the diuretic regimen must be reviewed. Hyponatremia of ≤ 125 mEq per liter demands withholding all diuretics and restricting fluid intake to initially 1.5 L per day in addition to sodium restriction. There is no need to restrict fluid when the serum sodium concentration exceeds 125 mEq per liter.

In patients with advanced disease, in those whose sodium restriction and diuretics are inadequate, or in those whose complications such as renal failure or electrolyte imbalance limit their use, ascites can become very difficult to control (intractable ascites). Intractable ascites is managed by intermittent large-volume paracentesis, usually performed as an outpatient procedure. Ten or more liters of ascitic fluid can be removed at one time. The role of albumin replacement (12.5 g of albumin for each liter of ascites removed) is controversial. Limiting removal to 2 L and using intravenous albumin is a reasonable, although unproven, precaution in patients with an elevated serum creatinine level. Recently, it has been shown that a functioning TIPS improves ascites control, reducing or eliminating the need for diuretics in some patients with large-volume ascites. A functioning TIPS increases urinary sodium clearance while correcting the increased serum levels of renin, aldosterone, and norepinephrine. TIPS should be considered for any patient who requires paracentesis on a weekly basis.

Cirrhotic hydrothorax, occurring with ascites or as an isolated phenomenon, is sometimes a difficult clinical problem causing dyspnea. It is managed using the same approach as for ascites alone. However, cirrhotic patients with hydrothorax are especially suitable for TIPS. Any patient with intractable ascites or troublesome cirrhotic hydrothorax should be considered for liver transplantation.

Prophylactic therapy against SBP has been studied with quinolones or trimethoprim-sulfamethoxazole, which significantly reduces the incidence of SBP in patients who are at risk. A reasonable plan is to limit prophylaxis to patients who are awaiting liver transplantation, who are considered to be at high risk for a first episode of SBP, or who have had a previous episode of SBP.

CHRONIC HEPATIC ENCEPHALOPATHY

Acute exacerbations of hepatic encephalopathy in cirrhotic patients should always prompt a search for a precipitating cause: gastrointestinal bleeding, new-onset renal failure or electrolyte disturbance, infection (especially SBP), or intracranial hemorrhage ([Fig. 105.3](#)). Medication should be reviewed, particularly among hospital inpatients, to check for inadvertent administration of benzodiazepines or other central nervous system depressants.

Lactulose is the mainstay of management of chronic hepatic encephalopathy. The dosage should be titrated to produce two or three soft bowel movements daily. The value of antibiotics in the management of chronic hepatic encephalopathy is less certain. The theoretical risk of ototoxicity, particularly if the patient develops renal failure, has led some experts to eschew the use of neomycin. Metronidazole is a safer alternative if lactulose is insufficient. Restriction of dietary protein intake is a time-hallowed response to chronic hepatic encephalopathy. Recent studies suggest that modest protein replenishment is safe in most cirrhotic patients. Protein restriction should be reserved for acute management of episodes of severe encephalopathy and for patients with disabling chronic encephalopathy.

HEPATOMA

Small localized unilocular hepatomas, discovered when screening with α -fetoprotein measurements or imaging studies, may be resectable, even from a cirrhotic liver. Alternatively, it is appropriate to consider these patients for liver transplantation. A full discussion of hepatoma can be found in [Chapter 126](#).

FULMINANT HEPATIC FAILURE

Acute hepatic injury presents as a sudden increase in previously normal liver transaminases. Fulminant hepatic failure refers to a specific subgroup of patients with severe acute hepatic injury, defined as the development of acute hepatic encephalopathy within 8 weeks of the onset of symptomatic hepatocellular disease in a previously healthy person. Submassive hepatic necrosis is similar to fulminant hepatic failure except that it is slower in onset. Submassive hepatic necrosis (synonyms: subfulminant hepatic failure, subacute hepatic failure) is defined by the development of acute hepatic encephalopathy within 9 to 24 weeks of onset of symptomatic hepatocellular disease in a previously healthy person.

CLINICAL FEATURES

Acute hepatic injury with no hepatic encephalopathy always resolves, except when it is due to other ongoing systemic disease or when the elevated transaminases represent the first recognition of previously covert chronic liver disease. The incidence of acute hepatic injury is unknown. An estimated 2,000 cases of fulminant hepatic failure and subacute hepatic necrosis occur in the United States annually and 80% of these patients die. Outcome is determined by the course of encephalopathy, which is measured on a four-grade scale ([Table 105.7](#)). Cerebral edema, leading to increased intracranial pressure (ICP), is a common feature of severe fulminant hepatic failure and may cause permanent cerebral injury and death. Fulminant hepatic failure and submassive hepatic necrosis are always

whenever there is evidence of hemorrhage (intracranial hemorrhage, gastrointestinal bleeding). In most circumstances, it is not necessary to give fresh frozen plasma simply to correct a prolonged prothrombin time of up to 30 seconds.

Hypotension is common in fulminant hepatic failure, despite high cardiac output, because of associated low systemic vascular resistance. Hypotension may exacerbate low cerebral perfusion pressure (CPP) consequent to raised ICP. Assisted ventilation should be undertaken in patients with grade IV coma or in patients with evidence of hypoxia or respiratory distress, because pulmonary edema and adult respiratory distress syndrome are features of deteriorating hepatic failure. Ventilation also maintains hypocapnea as an adjunct to controlling elevated ICP.

Patients with fulminant hepatic failure or subacute hepatic necrosis have a high risk for sepsis. Daily cultures of blood, urine, and other body fluids are advisable. This is particularly important because sepsis may prevent liver transplantation. The syndrome of high-output hypotension mimics septicemia. Unexplained fever despite broad-spectrum antibiotic coverage warrants consideration of an antifungal prophylaxis.

Cerebral edema is the single most dangerous complication of fulminant hepatic failure. Patients with hepatic failure may have rapid and extreme changes in cerebral perfusion pressure precipitated by positional changes and movement. Acute elevation in ICP may manifest as seizures, changes in pupillary responses, and cerebral posturing. The immediate response to clinical signs of increased ICP should also exclude hypoglycemia, because it may mimic acute changes in mental status. Hypoglycemia is a particular risk for patients with acetaminophen-related fulminant hepatic failure or patients with the microvesicular fat deposition disorders (e.g., Reye's syndrome, acute fatty liver of pregnancy, valproate poisoning). Only mannitol has been shown to offer a therapeutic benefit to the elevated ICP/reduced CPP syndrome of hepatic failure. Dexamethasone is of no value. The ability of barbiturate coma and ventilator-driven hypocapnea to reverse ICP elevations associated with hepatic failure is unknown, but often tried on an empiric basis.

Because ICP is subject to rapid changes, ICP monitoring in the treatment of severely ill patients with fulminant hepatic failure has received much attention. However, it is associated with side effects and uncertain clinical usefulness.

Liver transplantation is a life-saving procedure for patients with hepatic failure or submassive hepatic necrosis that does not respond to medical management. The most important indicators of the need for liver transplantation are the level of encephalopathy and the trend of change in encephalopathy. Unfortunately, because acute hepatic encephalopathy can vary between grades II and III in a matter of minutes, making a decision based on these factors remains difficult. Even when listed as a highest emergency status, it is not unusual for a patient in North America to wait 72 hours or longer for a suitable donor. During this time, further deterioration, especially worsening cerebral edema, may make transplantation impossible. For this reason, human heterotopic auxiliary transplants, live-donor segmental liver transplantation, extracorporeal perfusion through human or pig livers or artificial hepatocyte perfusion devices, and xenografts have been attempted to sustain the patient until spontaneous recovery develops or a suitable organ is found. The outcome of liver transplantation in patients with fulminant hepatic failure is somewhat worse than that for transplantation performed for other causes. One-year survival rates of 50% to 60% are common.

CHAPTER 106: DISEASES OF THE ESOPHAGUS

JOEL E. RICHTER

[Anatomy and Physiology](#)
[Diagnostic Procedures](#)
[Gastroesophageal Reflux Disease](#)
[Other Inflammatory Disorders of the Esophagus](#)
[Esophageal Motility Disorders](#)
[Miscellaneous Esophageal Disorders](#)

The esophagus is a relatively simple tubular organ connecting the oropharynx to the stomach. The pleasures of eating and maintaining adequate nutrition require a normal, healthy esophagus. The three major functions of the esophagus are to transport ingested material from the oropharynx to the stomach, to prevent regurgitation of food and gastric contents from the stomach into the esophagus, and to allow venting of ingested air to reduce abdominal bloating.

ANATOMY AND PHYSIOLOGY

The esophagus can be divided functionally into three regions: the upper esophageal sphincter (UES), the esophageal body, and the lower esophageal sphincter (LES).

UPPER ESOPHAGEAL SPHINCTER

The UES consists of striated muscle formed primarily by the horizontal fibers of the cricopharyngeus muscle, located at the level of the C5-6 vertebrae. The UES, like the striated muscles of the oropharynx and upper portion of the esophagus, is innervated like skeletal muscle, receiving motor input directly from the brain stem (nucleus ambiguus) to the motor end plates in the muscle. The UES is tonically closed and opens momentarily in response to a swallow. The UES also serves as a secondary barrier preventing aspiration of gastroesophageal contents.

BODY OF THE ESOPHAGUS

The esophageal body consists of an empty tube lined by squamous mucosa. It has a submucosal layer and two layers of muscles: inner circular and outer longitudinal muscles. No serosa overlies the muscle layers. The upper portion of the esophagus is primarily striated muscle; the lower two-thirds is predominantly smooth muscle. The nerve network for the esophageal body lies between the muscle layers. Meissner's (submucosa) plexus is between the muscularis mucosa and the circular muscle layer. Auerbach's (myenteric) plexus is between the circular and longitudinal muscle. Similar to the LES, innervation of the smooth muscle portion of the esophageal body is primarily through the vagus nerve from neurons arising in the dorsal motor nucleus of the brain stem and nerve endings in the myenteric plexus.

At rest, the esophageal body is quiet without motor activity. Normal esophageal motor activity is characterized by the orderly progression (peristalsis) of a contraction along the esophagus in coordination with relaxation and contraction of the UES and LES ([Fig. 106.1](#)). These activities are initiated by the voluntary act of swallowing, but perpetuation through the distal esophagus is under the control of the enteric nervous system.

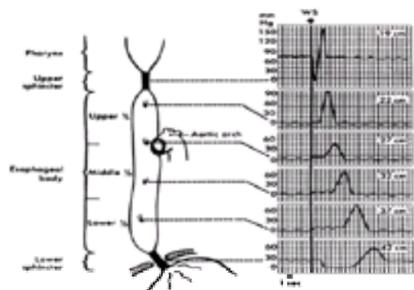

FIGURE 106.1. Manometric pressure changes with a swallow of an 8-mL bolus (WS). Distance (cm) from nares is shown on tracings. Proximal and distal tracings are from the upper (UES) and lower (LES) esophageal sphincters, respectively. Immediately after a swallow, UES pressure falls transiently. Shortly thereafter, LES pressure falls and remains low until the peristaltic contraction passing aborally through the UES and then through the esophageal body closes the LES. (From Dodds WJ. Examination of the Esophagus. In: Margulis AR, Burhenne HJ, eds. *Alimentary tract radiology*, fourth ed. St. Louis: CV Mosby, 1989:529, with permission.)

LOWER ESOPHAGEAL SPHINCTER

The LES is a high-pressure zone of smooth muscle that straddles the diaphragm and is the major component of the antireflux barrier. At rest, the sphincter is tonically contracted, preventing the reflux of gastric contents. On swallowing, the LES relaxes and stays relaxed until the peristaltic wave reaches the end of the esophagus and produces sphincter closure. LES relaxation is vagally mediated by preganglionic cholinergic nerves and postganglionic noncholinergic, nonadrenergic nerves. The candidates for inhibitory neurotransmitters include vasoactive intestinal polypeptide (VIP) or nitric oxide.

The tonic contractions of the LES are predominantly due to intrinsic muscle activity. LES pressure fluctuates greatly over time, even from minute to minute. Much of this is due to various extraesophageal factors that modulate LES pressure, including the foods ingested (proteins increase and fats decrease LES pressure) and other factors such as cigarette smoking and gastric distention, both of which decrease LES pressure. The latter factor is a critical trigger for transient LES relaxation, which is important in the venting of ingested gases. In response to transient increases in intra-abdominal pressure, LES pressure increases to a greater degree than the pressure increases in the abdomen below, thus preventing gastroesophageal reflux (GER). In addition, many hormones and peptides affect LES pressure. For example, gastrin, motilin, substance P, and pancreatic polypeptide increase LES pressure, whereas secretin, cholecystokinin, glucagon, and VIP decrease LES pressure.

DIAGNOSTIC PROCEDURES

A thorough history and physical examination are critical in evaluating patients with esophageal disorders and often identify the diagnosis and direct further testing. The barium esophagogram is the most important test for the diagnosis of structural and motor abnormalities of the esophagus ([Chapter 94](#)). A proper examination should include videotaping of the oropharyngeal and esophagus portions of swallowing, as well as full-column and air-contrast views of the distended esophagus to identify mucosal irregularities, masses, and regions of luminal narrowing. Endoscopic ultrasonography is useful in diagnosing and staging benign and malignant esophageal neoplasms ([Chapter 127](#)). Endoscopic ultrasonography is superior to computed tomography in evaluating the depth of tumor infiltration and assessing regional lymph node metastases. Manometry is the definitive test for diagnosing esophageal motility disorders because it allows accurate measurements of sphincter pressures and esophageal pressure waves and more completely evaluates abnormalities of esophageal peristalsis ([Chapter 129](#)). Fiberoptic endoscopy with biopsy and brush cytology is the best way to identify mucosal abnormalities of the esophagus ([Chapter 127](#)). Prolonged ambulatory monitoring of the esophagus (up to 24

hours) is the most reliable way to diagnose GER disease ([Chapter 129](#)).

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD), with its major symptom heartburn, is the most common disorder of the esophagus. It is the major indication for antacid consumption and probably the most prevalent condition originating from the gastrointestinal tract. In a recent Gallup survey, 44% of adult Americans experienced heartburn at least once every month, and 10% complained of weekly symptoms. Over 40% of the subjects took antacids for their heartburn, but only one in four discussed this complaint with a physician. Pregnant women have the highest prevalence of heartburn: at least 25% have daily symptoms, usually in the third trimester.

GERD is defined as the sequelae, both clinical and histopathologic, of the movement of gastroduodenal contents into the esophagus. GERD, however, represents a spectrum of disease and occurs in many healthy persons without adverse consequences. Episodes of "physiologic reflux" are typically postprandial, short-lived, and asymptomatic and almost never occur at night. Pathologic reflux leads to inflammatory changes and mucosal injury (reflux esophagitis) and usually symptoms.

PATHOPHYSIOLOGY

The pathophysiology of GERD results from the complex interplay of multiple factors ([Fig. 106.2](#)). The common denominator for acid reflux is the creation of a common cavity representing equilibration of intragastric and intraesophageal pressures. The LES is the major barrier against GER, with a secondary component from the crural diaphragm during inspiration, but the measurement of a single LES pressure is not very discriminatory. Rather, transient LES relaxation, occurring with either normal or low LES pressure, is the major mechanism that promotes free reflux of gastric contents. Transient relaxation accounts for nearly all episodes of reflux in normal subjects and 65% of episodes in patients with GERD. Other patients have reflux because of very low baseline LES pressures with either transient increases in intra-abdominal pressure (stress reflux) or spontaneous reflux across an atonic sphincter.

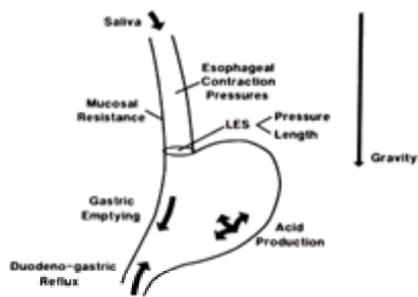

FIGURE 106.2. Major factors in the pathophysiology of gastroesophageal reflux disease.

Esophageal acid clearance normally occurs as a two-step process. First, swallow-induced peristaltic esophageal contractions rapidly clear fluid volume from the esophagus. Next, the small amount of residual acid is neutralized by saliva, which has a pH of 6.4 to 7.8. Dysfunction of the esophageal clearance mechanisms contributes to esophagitis, particularly in patients with severe motility disorders such as scleroderma or in patients with sicca complex.

The nature and volume of gastric contents are important. The primary role of acid is indisputable, but its mechanism of mucosal damage involves the action of coexisting pepsin more than direct damage from acid alone. In animal models, bile salts and pancreatic enzymes can produce esophagitis, but their importance in human disease is unknown. Acid hypersecretory states, such as the Zollinger–Ellison syndrome, are associated with a high prevalence of esophagitis. Delayed gastric emptying promotes GER, but this is an important factor in only 10% to 15% of patients with GERD.

The same degree of acid exposure may lead to variable degrees of mucosal damage, probably related to individual variations in esophageal mucosal resistance. Factors contributing to mucosal resistance include mucus, bicarbonate ions secreted by submucosal glands, stratified squamous cells and their tight junctions, and mucosal blood flow.

The relation between a sliding hiatal hernia and the development of GERD remains controversial. Most patients with esophagitis have a sliding hiatal hernia, but many persons with hiatal hernias do not have GERD. A large irreducible hernia may interfere with normal esophageal clearance by acting as a fluid trap, promoting acid reflux during swallow-induced LES relaxation, particularly in the supine position.

CLINICAL PRESENTATIONS

Heartburn is the classic symptom of GERD, but associated symptoms include dysphagia, odynophagia, regurgitation, water brash, and belching. Patients describe their heartburn as a retrosternal burning pain that also may be noted in the epigastrium, neck, throat, and occasionally the back. It often occurs postprandially and is exacerbated by recumbency or bending over. In the patient with heartburn, dysphagia should suggest the presence of a peptic stricture. Alternative diagnoses include severe inflammation without stricture, peristaltic dysfunction, and an esophageal cancer arising in Barrett's esophagus. The presence of odynophagia usually represents ulcerative esophagitis. The effortless regurgitation of acid fluid, especially postprandially and at night, is highly suggestive of GERD. Water brash is the sudden appearance in the mouth of a slightly sour or salty fluid from the salivary glands in response to intraesophageal acid exposure.

Patients with GERD may present with extraesophageal symptoms, including chest pain ([Chapter 94](#)) and respiratory and ear, nose, and throat problems. In these patients, the clinical symptoms of heartburn or regurgitation may be mild or even absent. Chronic cough, recurrent aspiration pneumonia, and pulmonary fibrosis may be related to GERD. Some studies suggest a close association between asthma and GERD: up to 80% of asthmatics have evidence of excessive acid reflux by pH testing. Hoarseness, sore throat, halitosis, vocal cord granuloma, and even laryngeal cancer may be caused by intermittent aspiration of gastric contents.

DIAGNOSIS

In most patients with classic symptoms of heartburn or regurgitation, the history is sufficiently typical to permit a trial of therapy without the need for diagnostic tests. The following situations should lead to early investigation: esophageal symptoms not responding to medical therapy, dysphagia and atypical presentations of suspected GERD, possible complications of reflux disease, and before consideration of antireflux surgery. Tests for GERD evaluate different variables in the disease spectrum ([Table 106.1](#)). There is no single best selection of tests; these tests must be applied selectively based on the information desired.

Potential for Reflux	Acid Sensitivity
Hiatal hernia	Acid perfusion Bernstein test
Manometry	24-h pH test with symptom correlation
Esophageal Damage	Presence of Abnormal Reflux
Barium esophagogram	Barium esophagogram
Endoscopy	24-h pH test
Mucosal biopsies	

TABLE 106.1. CATEGORIES OF DIAGNOSTIC TESTS FOR GASTROESOPHAGEAL REFLUX DISEASE

All patients with persistent reflux symptoms or frequent relapses after histamine receptor antagonist therapy should have endoscopy to identify the possible presence of esophagitis or other complications of GERD. Patients with esophagitis and complications need biopsies to exclude associated malignancies and Barrett's esophagus. However, most patients with GERD have no evidence of esophagitis at the time of endoscopy.

The barium esophagogram should be the first diagnostic procedure in most patients with dysphagia. An optimal double-contrast barium esophagogram detects erosive and ulcerative esophagitis in about 90% of cases. However, the radiologic detection of mild (nonerosive) esophagitis is unreliable. The barium esophagogram is also the preferred method for identifying a hiatal hernia and is good for identifying GER fluoroscopically, particularly with provocative maneuvers.

Prolonged esophageal pH monitoring is helpful in patients with atypical presentations or difficult management problems. It has essentially replaced the acid perfusion Bernstein test. The most common indications include noncardiac chest pain, suspected pulmonary or ear, nose, and throat presentations of GERD, and intractable reflux symptoms associated with a negative workup. Prolonged pH monitoring also should be conducted before antireflux surgery if there is any question about the diagnosis. It is the best test for diagnosing GERD, with a sensitivity of 85% and a specificity above 95%.

Manometry of LES pressure is not a sensitive diagnostic test: less than 25% to 50% of patients with GERD have a low resting LES pressure (less than 10 mm Hg). Manometry is reserved for patients in whom another diagnosis is suspected (e.g., achalasia), and it is mandatory before antireflux surgery to ensure adequate esophageal pump function.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

The rationale for GERD therapy depends on a careful definition of specific aims ([Table 106.2](#)). In patients without esophagitis, the therapeutic goal is simply to relieve the acid-related symptoms. In patients with esophagitis, the ultimate goal also is to heal esophagitis while attempting to prevent further complications such as strictures and Barrett's metaplasia. These goals are set against a complex background, since GERD is a chronic condition and patients with esophagitis generally experience relapse when medical therapy is stopped.

	Symptoms without Esophagitis	Mild Esophagitis	Severe Esophagitis or Intractable Symptoms
Acute	Lifestyle changes PPI medication H ₂ antagonists Antacids Alginic acid Prokinetics	Lifestyle changes Daily medications H ₂ antagonists Cisapride	Lifestyle changes Daily medications Proton pump inhibitor
Maintenance	PPI medications as above	H ₂ antagonists Cisapride	Proton pump inhibitor Antireflux surgery

PPI, as need arises.

TABLE 106.2. GENERAL APPROACH TO THE MANAGEMENT OF GASTROESOPHAGEAL REFLUX DISEASE

Lifestyle Modifications

Lifestyle changes, which form the cornerstone of effective reflux treatment for all patients, are summarized in [Table 106.3](#).

Decreases LES Pressure	Improves Acid Clearance	Direct Esophageal Irritants	Decreases Gastric Distention
Avoid certain foods (fat, chocolate, coffee, carbonated) Avoid certain medications (theophylline, progesterone, antidepressants, nitrates, calcium channel blockers)	Elevate head of bed Upright position after meals	Avoid citrus, spicy, or tomato-based products Avoid medications causing pill-induced esophagitis	Avoid large meals Take evening meals several hours before retiring Lose weight

LES, lower esophageal sphincter.

TABLE 106.3. LIFESTYLE MODIFICATIONS FOR GASTROESOPHAGEAL REFLUX DISEASE AND THEIR MECHANISMS OF ACTION

Antacids and Alginic Acid

Antacids and alginic acid are useful for treating mild, infrequent reflux symptoms, especially those brought on by lifestyle indiscretions. They are ineffective in healing esophagitis. Antacids work primarily by neutralizing acid, although for relatively short periods. Therefore, patients need to take these agents frequently, usually 20 to 30 minutes after meals and at bedtime. Aluminum hydroxide antacids containing alginic acid form a highly viscous solution that floats on the surface of the gastric pool and acts as a mechanical barrier. Alginic acid tablets (Gaviscon) effectively prevent episodes of upright acid reflux.

Prokinetic Drugs

Bethanechol and metoclopramide are prokinetic drugs that effectively relieve heartburn symptoms, but their efficacy in treating esophagitis is equivocal. Bethanechol (25 mg) and metoclopramide (10 mg) are given 30 minutes before meals and at bedtime. Side effects are common in both young and elderly patients. The prokinetic drug cisapride is more effective than placebo and equal to H₂ antagonists in controlling reflux symptoms and healing mild esophagitis. Cisapride promotes the release of acetylcholine at the myenteric plexus, thereby increasing LES pressure, improving peristalsis amplitude, and accelerating gastric emptying. At a dose of 10 mg 30 minutes before meals and bedtime, cisapride has minimal side effects; the most common are abdominal cramps, borborygmi, and diarrhea. However, recent concerns have been raised about serious cardiac arrhythmias (ventricular fibrillation, torsades de pointes, QT prolongation) and death associated with drug interactions with cisapride. These drugs include common antibiotics (e.g., clarithromycin, erythromycin), antifungal agents (e.g., fluconazole, ketoconazole), and antiviral agents (e.g., indinavir, ritonavir). When taken with cisapride, these drugs inhibit the cytochrome P450 enzyme that metabolizes cisapride, thereby potentially increasing cisapride blood level to dangerous levels. Cisapride also may be useful in maintenance therapy of patients with reflux symptoms and mild esophagitis.

H₂ Antagonists

H₂ antagonists is a family of drugs that achieved the first real breakthrough in the treatment of GERD and continues to be the backbone of therapy for mild reflux esophagitis. Despite advertising to the contrary, all H₂ antagonists (cimetidine, ranitidine, famotidine, nizatidine) are equally effective in improving reflux symptoms and healing mild to moderate esophagitis, when properly dosed. H₂ antagonists are usually given once or preferably twice a day. Recent data on patterns of acid exposure show that the bulk of acid reflux occurs during the early evening hours after dinner and decreases markedly during the sleeping hours. Therefore, it may be preferable to take an H₂ antagonist 30 minutes after dinner rather than at bedtime. Heartburn can be decreased significantly by H₂ antagonists, and esophagitis is healed in about 60% of patients after up to 12 weeks of treatment. Healing rates differ, depending primarily on the degree of esophagitis before therapy. Mild esophagitis heals in 75% to 90% of patients; moderate and severe esophagitis heals in only 40% to 50% of patients. H₂ antagonists may also be effective in preventing the relapse of GERD in patients with reflux symptoms and mild esophagitis. Recently, these drugs at lower doses are available over the counter for intermittent relief of heartburn and the prevention of episodic heartburn events.

Proton Pump Inhibitors

Omeprazole and lansoprazole are potent, long-acting inhibitors of both basal and stimulated acid secretion. They act by selective, noncompetitive inhibition of the H⁺/K⁺-ATPase pump on the parietal cell. Proton pump inhibitors completely abolish reflux symptoms in most patients with severe GERD, usually within 1 to 2 weeks. Complete healing of esophagitis occurs after 8 weeks in 80% of patients. Omeprazole and lansoprazole are superior to H₂ blockers in relieving symptoms and healing esophagitis, particularly in patients with severe reflux symptoms and severe esophagitis, as well as maintenance therapy to prevent relapse of esophagitis for up to a year.

Side effects are minimal with both short- and long-term use. One concern with long-term use of proton pump inhibitors is that profound hypoacidity stimulates gastrin release, promoting the proliferation of enterochromaffin-like cells in the gastric fundus. In the rat model, prolonged use of omeprazole causes gastric carcinoids. However, in extensive human studies in which patients on continuous omeprazole were followed for up to 7 years, no cases of gastric carcinoids or even dysplasia were observed.

Antireflux Surgery

Antireflux surgery, done openly or by laparoscopic techniques, attempts to maintain a segment of the tubular esophagus below the diaphragm and usually includes wrapping the stomach around the distal esophagus to produce increased LES pressure. Long-term relief of symptoms occurs in about 80% of patients followed up for up to 20 years. Critical for successful antireflux surgery are the preservation of esophageal function, confirmed by esophageal testing before surgery, and an experienced surgeon. Indications for antireflux surgery include younger patients with severe GERD who otherwise would require lifelong medical therapy, recurrent difficult-to-dilate strictures, nonhealing ulcers, severe bleeding from esophagitis, and aspiration symptoms from related reflux disease.

COMPLICATIONS

Peptic strictures represent the end stage of ongoing reflux, mucosal damage, healing, and secondary fibrosis. Patients with strictures present with slowly progressive dysphagia for solids, usually without much weight loss. Radiographically, peptic strictures are commonly found in the lower esophagus and are characterized by smooth-walled, tapered, circumferential narrowings. The benign nature of the stricture must be confirmed by endoscopy and biopsies. Therapy of peptic strictures consist of a careful review of dietary and medication habits, aggressive antireflux therapy, and bougienage. Patients should chew their food well while taking fluids liberally and avoid potentially damaging pills, such as aspirin, nonsteroidal anti-inflammatory drugs, or potassium chloride. Aggressive acid suppression, particularly with proton pump inhibitors, may reduce the need for subsequent dilations. Dilating (stretching) the narrowed distal esophagus with blunt bougies, either passed freely or over a guide wire, can markedly relieve the symptoms of dysphagia.

Barrett's esophagus is secondary to severe esophagitis and produces a unique reparative process in which the original squamous epithelium lining is replaced by metaplastic columnar epithelium. The prevalence of Barrett's esophagus varies, depending on the population being studied. Patients with symptomatic GERD have a prevalence rate of 5% to 12%; those with esophagitis, scleroderma, and peptic strictures can have higher rates (11% to 44%). The diagnosis of Barrett's esophagus is best made by endoscopy and confirmed by biopsy. Although Barrett's epithelium may comprise three types of mucosa, only the specialized columnar epithelium has malignant potential.

Therapy for Barrett's esophagus is no different from that for any other form of esophagitis. The major concern is the increased prevalence and incidence of adenocarcinoma of the esophagus. The prevalence is an estimated 10%, a 30- to 40-fold increase over the general population, whereas incidence varies, ranging from 1 case in 46 to 441 patient-years of follow-up. The columnar lining of the esophagus may evolve over time through increasing degrees of dysplasia to cancer. For this reason, endoscopic surveillance is recommended in patients with Barrett's esophagus to detect high-grade dysplasia or early cancer, thereby permitting curative surgical resection.

OTHER INFLAMMATORY DISORDERS OF THE ESOPHAGUS

Inflammatory disorders of the esophagus are usually acute in onset and characterized clinically by odynophagia and dysphagia. An algorithm for evaluating patients with odynophagia is shown in [Figure 106.3](#).

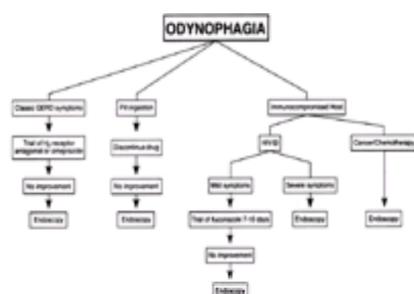

FIGURE 106.3. Approach to the patient with odynophagia. (Modified from Wilcox CM. Esophageal disease in the acquired immunodeficiency syndrome: etiology, diagnosis and management. *Am J Med* 1992;92:412–421.)

EVIDENCE LEVEL: B. Reference: Speckler SJ. AGA Technical review of treatments of patients with dysphagia. *Gastroenterology* 1999;17:233–254.

INFECTIOUS ESOPHAGITIS

Infections of the esophagus are rare in the general population, but, when present, should prompt a search for an immunodeficiency. Esophageal infection is seen primarily in three groups of immunocompromised patients: HIV-positive patients, cancer patients with granulocytopenia after chemotherapy, and organ transplant recipients receiving immunosuppressive therapy. Other predisposing conditions include malignancy, alcoholism, diabetes mellitus, and therapy with corticosteroids or other immunosuppressive agents.

The most common causes of infectious esophagitis are *Candida*, herpes simplex virus, and cytomegalovirus. Candidal esophagitis is most common in HIV-infected

patients and in granulocytopenic cancer patients; viral esophagitis predominates in bone marrow transplant recipients. Both candidal esophagitis and viral esophagitis are seen after solid organ transplantation. Less common causes of infectious esophagitis include histoplasmosis, *Mycobacterium tuberculosis*, *Mycobacterium avium* complex, *Cryptosporidium*, *Pneumocystis carinii*, Epstein–Barr virus, HIV, and gram-negative and gram-positive bacteria. Mixed infections are present in about 30% of patients.

Esophageal infections should be suspected in the immunocompromised patient presenting with odynophagia, dysphagia, or chest pain. Oral thrush is commonly sought, but its presence does not preclude the possibility of infections with other organisms besides *Candida*, and its absence does not exclude the presence of *Candida*. Endoscopy with brush cytology, biopsy, and culture is the best initial diagnostic test.

Patients with candidiasis present with discrete, 3- to 5-mm, raised yellowish plaques or confluent cheeselike exudates. The diagnosis is most easily established by brushing the plaques and smearing the material on a clear glass slide, allowing it to dry, applying 10% potassium hydroxide, and examining the slide for the appearance of typical branch hyphae and budding yeast. Fungal cultures and histologic examination of biopsy specimens are also helpful. Treatment for candidal esophagitis depends on the severity of the infection and the nature of the underlying immune defect ([Table 106.4](#)).

Infection	Treatment	
Candida	Mild to moderate (i.e., diabetes, steroids)	Nystatin 1–2 million U q.i.d. Clotrimazole 100 mg t.i.d. Itraconazole 200–400 mg/d
	AIDS patients	Fluconazole 100 mg/d
Herpes simplex virus	Failure of above	Amphotericin B 0.3 mg/kg/d
	Immunocompetent patient	Supportive care Analgesics Topical anesthetics
Cytomegalovirus	Immunocompromised patients	Acyclovir 200–400 mg 5–10 orally
	Mild cases	Acyclovir 15 mg/kg/d
HIV	More severe cases	Ganciclovir 5 mg/kg b.i.d. or 12 hr Foscarnet 60 mg/kg b.i.d. or 8 hr Prednisone 40 mg/d

Modified from Weiss CS, Kasper DL: Esophageal infections: etiology, diagnosis, and management. *Gastroenterology* 1994;106:1188.

TABLE 106.4. TREATMENT REGIMENS FOR COMMON ESOPHAGEAL INFECTIONS

Herpetic esophagitis is characterized early in its course by clear vesicles. Because the vesicles are short-lived, the usual finding is that of discrete, small, superficial ulcers with a punched-out appearance and raised yellow edges. The intervening mucosa often appears normal. Brushing and biopsies show cytologic changes that may suggest herpetic infection (Cowdry type A inclusions).

Cytomegalovirus esophagitis appears as an extensive area of mucosal injury with inflammatory exudate and ulcerations. The ulcers are deep, progress in size, and occasionally perforate. Biopsy specimens, brush cytology, or viral cultures may show evidence of this virus.

Esophageal ulcerations have been described in patients with seroconversion to HIV. These patients present with a syndrome characterized by fever, myalgia, maculopapular rash, and odynophagia. Endoscopy shows multiple discrete esophageal ulcerations; electron microscopic examination of tissue shows retroviral organisms, indicating HIV as the direct cause.

Treatment of these viral esophagitides is summarized in [Table 106.4](#).

PILL-INDUCED ESOPHAGITIS

More than 50% of the cases of pill-induced esophagitis result from tetracycline and its derivatives, particularly doxycycline. Other commonly prescribed medications causing esophageal injury include slow-release potassium chloride, iron sulfate, quinidine, corticosteroids, and nonsteroidal anti-inflammatory drugs. A common factor is a history of improper ingestion. Nearly 50% of the reported patients took little or no fluid while swallowing the pills or took them just before bedtime. Patients with pill-induced esophageal injury generally complain of odynophagia and retrosternal burning; only a few report that the pills get stuck in their chest. Endoscopy, the first investigative study, usually reveals discrete ulcers at the level of the aortic arch or distal esophagus. Patients with pill-induced esophagitis improve with withdrawal of the offending medication. Symptomatic resolution and endoscopic healing is usually evident in 3 days to 6 weeks. In addition to drug discontinuation, other therapies include palliation of odynophagia with viscous lidocaine, prevention of acid reflux, and assurance of adequate nutrition. Rarely, patients develop strictures requiring dilation. To prevent further pill-induced esophageal injuries, patients should be encouraged to ingest all pills with 8 ounces of water while standing or sitting upright and should be discouraged from taking pills just before bedtime.

ESOPHAGEAL MOTILITY DISORDERS

Functional disturbances of the esophagus, from either neurologic or muscular disorders, may involve the striated or smooth muscle segments of the esophagus. The skeletal muscle causes of oropharyngeal dysphagia are discussed in [Chapter 94](#); the common smooth muscle esophageal disorders are discussed in the text that follows.

ACHALASIA

Achalasia is characterized by a double defect in esophageal function. The LES does not appropriately relax, offering resistance to the flow of liquids and solids from the esophagus into the stomach. In addition, there is loss of peristalsis in the lower two-thirds (smooth muscle portion) of the esophagus. Achalasia usually manifests between the ages of 25 and 60 years; men and women are affected equally. Its cause is unknown. The two most popular theories suggest that achalasia is secondary to a viral infection or a degenerative disease of the neurons. In South America, infection with the protozoan *Trypanosoma cruzi* produces ganglion damage and an achalasia-like syndrome with megaesophagus.

Pathophysiology

Abnormalities in muscle and nerves can be detected in achalasia, although a neural lesion is thought to be of primary importance. Three major neural anatomical changes are described: loss of ganglion cells within Auerbach's plexus, degeneration of the vagus nerve, and qualitative and quantitative changes in the dorsal motor nucleus of the vagus. There is selective damage to inhibitory neurons with marked reduction of VIP and nitric oxide receptors, which may account for the observed motility disturbances. Further evidence of denervation is the exaggerated contractions in the LES and esophageal body observed when these patients are given methacholine. This response indicates denervation hypersensitivity.

Clinical Presentation

Nearly all patients with achalasia have dysphagia for solids; most also have dysphagia for liquids. The onset is gradual, and most patients have symptoms for an average of 2 years before the diagnosis is made. Postural changes, such as throwing the shoulders back, lifting the neck, and performing a rapid Valsalva maneuver, help improve esophageal emptying. Fullness in the chest and regurgitation of undigested nonacidic food are seen in many patients. Undigested food may be regurgitated postprandially or at night, causing choking, cough, and aspiration pneumonia. Chest pain occurs in some patients and is more common in younger patients with earlier disease. It is surprising that heartburn is described by some achalasia patients, presumably because of the fermentation of intraesophageal contents. Weight loss is very common and usually progresses with the duration of the disease.

Diagnosis

With suspected achalasia, the first test is a barium esophagogram. Early in the course, the esophagus may appear normal in diameter but with a loss of normal peristalsis. As the disease progresses, the esophagus becomes more dilated and tortuous with retained food and air–fluid levels (Fig. 106.4A). The distal esophagus is characterized by a smooth, symmetric, tapering “bird beak” appearance. Clues to the diagnosis may also be found on chest radiographs, which demonstrate a widened mediastinum, thoracic air–fluid level, and absence of the gastric air bubble. Diagnosis of achalasia is confirmed by esophageal manometry, which reveals such characteristic features as absence of peristalsis in the distal smooth muscle esophagus, incomplete or abnormal LES relaxation, elevated LES pressures, and elevated intraesophageal pressures relative to gastric pressures (Table 106.5). All achalasia patients should undergo upper gastrointestinal endoscopy to differentiate primary achalasia from pseudoachalasia, usually secondary to an adenocarcinoma.

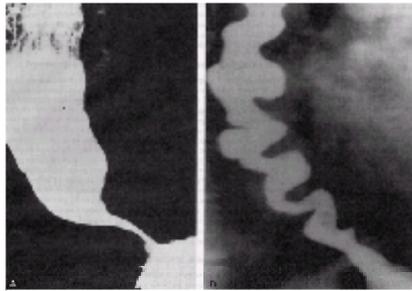

FIGURE 106.4. A: Achalasia characterized by a moderately dilated esophagus with lack of peristalsis and retention of barium and secretions, forming an air–fluid level in the proximal esophagus. Spastic LES relaxes incompletely, causing a bird-beak appearance of the distal esophagus with poor emptying. **B:** Diffuse esophageal spasm characterized by a nondilated esophagus and multiple spastic contractions, causing the barium to move to and fro and the esophageal lumen to have a segmented appearance.

	Spastic Motor Disorders				
	Achalasia	DES	Nutcracker	Hypertensive LES	Scleroderma
Striated muscle/LES	Normal	Normal	Normal	Normal	Normal
Smooth muscle	Aperistalsis	Intermittent peristalsis	Normal peristalsis	Normal peristalsis	Low-amplitude peristalsis or Aperistalsis
		Simultaneous, repetitive High amplitude Long duration Spontaneous	High amplitude		
LES	Incomplete relaxation High pressure	Occasional LES dysfunction	Normal	High pressure Normal relaxation	Low or no pressure

DES: diffuse esophageal spasm; LES: lower esophageal sphincter; UES: upper esophageal sphincter.

TABLE 106.5. MANOMETRIC CHARACTERISTICS OF THE ESOPHAGEAL MOTILITY DISORDERS

Strategies for Optimal Care Management

The goal of therapy in achalasia is to diminish the high residual LES pressure after swallowing. If esophageal emptying is improved, esophagus stasis and its consequences are reduced. Although peristalsis rarely returns, the patient feels as if swallowing is nearly normal. Three treatments are available: pharmacologic therapy, pneumatic dilation, and surgical myotomy.

Smooth muscle relaxants, including sublingual isosorbide dinitrate or calcium antagonists such as nifedipine, can be used prophylactically with meals or as necessary for pain or dysphagia. These medications provide variable relief of symptoms, and their effectiveness tends to decrease with time. Recent studies suggest that botulinum toxin injections via endoscopy directly into the lower sphincter may relieve symptoms for 3 to 12 months. The toxin inhibits the release of acetylcholine, which overcomes the unopposed excitation of the smooth muscle esophagus resulting from selective loss of inhibitory neurons in the myenteric plexus.

Pneumatic dilation involves placing a balloon across the LES; it is then inflated to a pressure adequate to tear the muscle fibers of the sphincter. Good to excellent results occur in 50% to 90% of patients. The procedure can be done on an outpatient basis, recovery is rapid, and discomfort is short-lived. About 30% of patients require subsequent dilations. Perforation, a major complication, is reported in about 5% of patients and usually requires surgical repair.

Heller myotomy involves incising the circular muscle of the LES and more distal esophagus down to the mucosa and allowing the muscle to protrude through. Myotomy produces good to excellent results in 60% to 90% of cases, and the operative mortality is low. Disadvantages of surgery are the morbidity associated with the operation, a long hospital stay, increased costs compared with pneumatic dilation, and an increased risk of postoperative GER. To prevent the latter problem, many surgeons now add a loose antireflux operation to the myotomy. Laparoscopic and thoroscopic techniques for esophageal myotomy are under investigation (Chapter 131).

SPASTIC MOTILITY DISORDERS

Spastic motility disorders produce manometric patterns different from those of achalasia. They are characterized by normal peristalsis intermittently interrupted by simultaneous contractions, high-amplitude or long-duration waves, or dysfunction of the LES. Confusion has arisen as to whether these manometric abnormalities are separate, distinct entities or are variations of diffuse esophageal spasm (Table 106.5). However, the similarities among these disorders in presentation, natural history, and treatment suggest that they often overlap and should be best designated as spastic motility disorders of the esophagus.

Pathophysiology

The cause of spastic motility disorders is unknown, and no specific characteristic pathologic lesion is present. Spastic motility abnormalities are commonly associated with other medical conditions, particularly GER. Central nervous system processing could produce some of these manometric abnormalities. Psychologically stressful interviews, loud noises, or difficult mental tasks can produce simultaneous waves and increase contraction amplitudes in the distal esophagus of normal persons and patients with spastic motility disorders. These patients also appear to have both a motor and sensory component to their spastic disorder. Acid instillation may stimulate sensitive neural receptors, producing discomfort independent of motility changes. Esophageal balloon distention can reproduce esophageal pain at low distending volumes without noticeable motor changes.

Clinical Presentation

Spastic disorders of the esophagus generally present during middle age and are more common in women. Dysphagia and chest pain are the cardinal symptoms, and most patients present with both. Dysphagia for liquids and solids is present in 30% to 60% of patients. This symptom is intermittent and varies daily from mild to very severe, but usually it is not progressive or severe enough to interfere with eating or to cause weight loss. Intermittent anterior chest pain, sometimes mimicking angina pectoris, is reported by most patients. Pain episodes last from minutes to hours and may require narcotics or nitroglycerin, further confusing the distinction between

esophageal and cardiac pain. Many patients also have symptoms compatible with the irritable bowel syndrome, as well as urinary and sexual dysfunction in women.

Diagnosis

Spastic motility disorders are best defined by esophageal manometry (Table 106.5). The patient's chief symptom is an important factor in the prevalence and type of motility disorder identified (Fig. 106.5). In patients with diffuse esophageal spasm, the barium esophagogram may reveal severe lumen-obliterating tertiary contractions that trap barium and delay transit, producing a to-and-fro movement of the bolus (Fig. 106.4B). Patients with other spastic motility disorders often have a normal barium esophagogram. Endoscopy may be done, but its major role is to identify possible structural lesions or to rule out reflux esophagitis. Provocative tests, such as edrophonium chloride (Tensilon) and balloon distention, may be able to provoke the chest pain. Ambulatory 24-hour pH monitoring is useful to identify associated GERD, which is present in 20% to 50% of these patients.

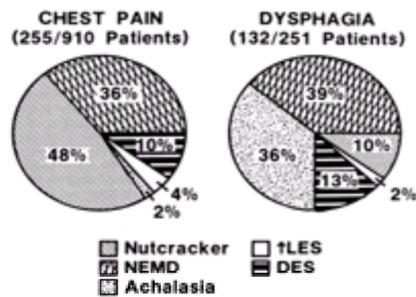

FIGURE 106.5. Incidence of esophageal motility disorders in patients with noncardiac chest pain (left) and dysphagia (right) in a 3-year experience with nearly 1,200 consecutive patients undergoing esophageal manometry. The chief complaint is an important factor in the prevalence and type of motility disorders identified. NEMD, nonspecific esophageal motor disorder; tLES, hypertensive lower esophageal sphincter; DES, diffuse esophageal spasm. (From Katz PO, Dalton CB, Richter JE, et al. Esophageal testing of patients with noncardiac chest pain or dysphagia. *Ann Intern Med* 1987;106:593–597, with permission.)

Strategies for Optimal Care Management

Many patients respond favorably to confident reassurance that their chest pain is not coming from their heart and has an esophageal origin. GER should be identified and aggressively treated. Otherwise, no single drug has proven efficacy in the treatment of spastic esophageal motility disorders. Smooth muscle relaxants, such as long-acting nitrates, calcium channel blockers, and anticholinergic agents, may decrease high-amplitude contractions but have not relieved chest pain consistently. Antidepressant medications may reduce the amount of discomfort experienced as well as the patient's reaction to pain, although the esophageal motility abnormality does not change. Passive dilation of the esophagus is of no value, but pneumatic dilation helps some patients with diffuse esophageal spasm or hypertensive LES who complain of severe dysphagia with documented delays in esophageal emptying. Rarely, a long surgical myotomy helps some patients, but aggressive interventions must be used cautiously because symptoms may not be relieved.

SCLERODERMA ESOPHAGUS

Esophageal involvement is seen in 70% to 80% of patients with scleroderma. It is seen in both progressive systemic sclerosis and the CREST syndrome (calcinosis, Raynaud's, esophageal involvement, sclerodactyly, and telangiectasias). The pathophysiology involves an abnormality in muscle excitation and responsiveness owing to muscle atrophy and decreased cholinergic excitation. The classic manometric features of advanced scleroderma include low LES pressure, peristaltic dysfunction of the smooth muscle portion of the esophagus characterized by low-amplitude contractions or aperistalsis, and preserved function of the striated esophagus and oropharynx (Table 106.5). As a result of these manometric abnormalities, patients may have dysphagia and severe GERD. It is surprising that dysphagia for solids and liquids is reported by less than 50% of patients with scleroderma. More severe dysphagia suggests esophagitis, often with an associated stricture. Esophagitis is present in most patients.

Management of scleroderma centers on the treatment of GER and its complications. Patients should chew their food well and drink plenty of fluids. GERD should be identified and aggressively treated using H₂ antagonists or proton pump inhibitors. Strictures respond to frequent dilations. In severe cases, antireflux surgery may be warranted.

Benign and malignant tumors of the esophagus are discussed in Chapter 115.

MISCELLANEOUS ESOPHAGEAL DISORDERS

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are outpouchings of one or more layers of the esophageal wall. They occur in three main areas: immediately above the UES (Zenker's diverticulum), near the midpoint of the esophagus (traction diverticulum), and immediately above the LES (epiphrenic diverticulum). Zenker's diverticulum is seen in older patients, who complain of cervical dysphagia, gurgling in the throat, halitosis, regurgitation of foul food, and sometimes a neck mass (Fig. 106.6A). It was originally thought to be related to discoordination of UES relaxation, but recent studies show that the sphincter opens incompletely because of reduced muscle compliance. To compensate for this decreased cross-sectional area, the hypopharyngeal bolus pressure increases, leading to dysphagia and diverticula formation. Traction diverticula are usually asymptomatic. They are thought to be secondary to external inflammatory processes such as tuberculosis or to a localized segmental motility disorder. Epiphrenic diverticula are invariably associated with esophageal motility disorders, especially achalasia. Diverticula are best diagnosed by a barium esophagogram; endoscopy is rarely required. Symptomatic diverticula require surgery.

FIGURE 106.6. A: Small Zenker's diverticulum, representing an outpouching immediately above the incompletely opened and noncompliant upper esophageal sphincter (arrow). B: Lower esophageal (Schatzki's) ring characterized by a smooth, thin (less than 4 mm) symmetric narrowing at the level of the squamocolumnar junction above a small hiatal hernia.

RINGS AND WEBS

The lower esophageal (Schatzki's) ring at the squamocolumnar junction is the most common cause of intermittent dysphagia for solids ([Fig. 106.6B](#)). Rings are usually found in patients over age 50 and are rarely seen before age 30. The origin of the lower esophageal ring is unknown, but it may be a complication of GERD. The diagnosis is made with the barium swallow using the prone position, having the patient perform the Valsalva maneuver, or having the patient swallow a marshmallow or tablet to bring out the ring. Treatment includes reassurance, adjustments in eating habits, dilation of the ring with a blunt bougie, and treatment of associated GERD.

Webs are membranous narrowings covered entirely by squamous mucosa, which can occur anywhere along the esophagus but are found primarily in the upper 2 to 4 cm of the esophagus. Some webs are congenital; others are associated with iron-deficiency anemia (Paterson–Kelly or Plummer–Vinson syndrome). Most webs are asymptomatic and are incidental radiologic findings. Symptomatic patients are usually women who report dysphagia for solids rather than liquids. Diagnosis is made by the lateral view on the barium esophagogram. Treatment with bougienage is often successful.

[Mucosal Cytoprotection](#)
[Gastritis](#)
[Effects of *Helicobacter Pylori* Gastritis on Normal Gastric Physiology](#)
[Ulcer Pathophysiology](#)
[Peptic Ulcer](#)

Peptic ulcers are defects in the gastrointestinal mucosal lining that extend through the submucosa into the muscle layer. They require the presence of aggressive noxious substances including acid and pepsin for their formation and therefore are classified as an acid-peptic disorder. Peptic ulcers are rarely due simply to excessive secretion of acid. Most cases represent an imbalance between aggressive factors and factors that undermine mucosal integrity, especially the presence of gastric inflammation (gastritis). Chronic gastric infection with the gram-negative bacterium, *Helicobacter pylori* (*H. pylori*), is the most important factor that predisposes to peptic ulceration. *H. pylori* gastritis causes peptic ulceration by having an indirect effect on gastric acid secretion (especially with regard to duodenal ulcers) and by causing gastritis, thereby undermining gastric mucosal integrity (especially with regard to gastric ulcers). Gastropathy due to the ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs) is the second most common cause of ulcers. Although NSAIDs do not cause gastritis per se, they undermine mucosal integrity by depleting gastric mucosal prostaglandins. Rarer causes of gastritis are not generally associated with the presence of peptic ulceration.

EPIDEMIOLOGY OF PEPTIC ULCER DISEASE

Duodenal ulcers are common. Although their incidence and prevalence appear to be decreasing, approximately one in ten persons are affected during their lifetime ([Fig. 107.1](#)). The illness is often considered to be a disease of young and middle-aged adults, but the incidence of first-time ulcers peaks after age 50. The incidence of duodenal ulcer in men has been decreasing during the past 30 years, but no decrease has been found in women. Therefore, the male-to-female ratio has dropped from 4 to 1 to almost 1 to 1 in the United States.

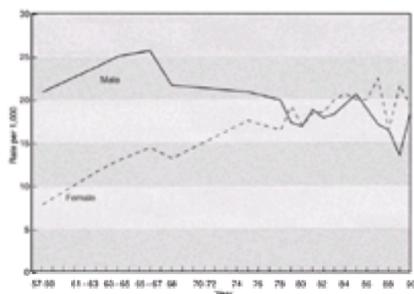

FIGURE 107.1. One-year period prevalence by sex for peptic ulcer disease. Data from the National Center for Health Statistics. (From Kurata JH. Epidemiology: peptic ulcer risk factors. *Semin Gastroenterol Dis* 1993;4:2–12, updated since 1990 by personal communication, with permission.)

Hospitalizations for gastric ulcer have not decreased during the past 20 years. In the United States and Western Europe, however, there has been a large drop in duodenal ulcer disease hospital admissions in men during the latter part of this century. The most dramatic decrease has been in elective hospitalizations, but ulcer-related mortality also has decreased. The age-adjusted mortality rates for duodenal ulcer have decreased during the past 20 years from about 4 in 100,000 in men and 0.8 in 100,000 in women to about 1 in 100,000 in men and 0.5 in 100,000 in women. Age-adjusted mortality rates for gastric ulcer in men have fallen from about 4 per 100,000 to 1.5 per 100,000; in women they have remained between 1.1 and 1.2 per 100,000. On the other hand, rates of ulcer complications such as bleeding, perforation, gastric outlet obstruction, and penetration into the pancreas have shown much less change ([Fig. 107.2](#)).

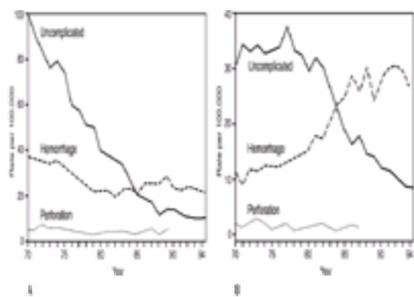

FIGURE 107.2. Hospitalization rates for uncomplicated or bleeding duodenal (**A**) and gastric ulcers (**B**). Data from the National Center for Health Statistics. (From Kurata JH. Epidemiology: peptic ulcer risk factors. *Semin Gastroenterol Dis* 1993;4:2–12, updated since 1990 by personal communication.)

Bleeding is the most common complication and is the most common cause of death from peptic ulcer. Mortality from bleeding occurs almost exclusively in older patients who have at least one additional major disease. Some evidence suggests that the rates of duodenal ulcer are beginning to stabilize in the United States ([Fig. 107.1](#)).

Major factors associated with ulcers are chronic *H. pylori* infection, smoking, and the use of NSAIDs ([Fig. 107.3](#)). About 15% to 20% of *H. pylori*-infected subjects develop ulcers during their lifetime. Eradication of this infection markedly decreases the recurrence of peptic ulcers. Much of the decrease in ulcer incidence observed in recent years may be due to the decrease in *H. pylori* gastritis in developed countries such as the United States. The overall association between cigarette smoking and duodenal ulcer is strong. Smokers have a higher incidence of duodenal ulcer, and after treatment their ulcers heal more slowly and recur more rapidly than do ulcers of nonsmokers. Death rates from ulcer in smokers also are higher; however, this finding may reflect a higher frequency of other smoking-related diseases. NSAIDs are implicated in the formation of gastric and duodenal ulcers, and bleeding from gastric and duodenal ulcers is increased in patients taking aspirin or other nonsteroidal agents.

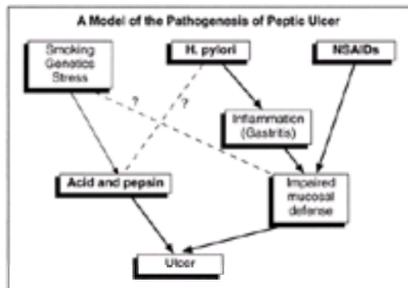

FIGURE 107.3. Pathogenesis of peptic ulcer. (Modified from Soll AH. Pathogenesis of peptic ulcer and implications for therapy. *N Engl J Med* 1990; 322:909–916.)

DISEASES WITH INCREASED ULCER RISK

Two conditions have a clear association with peptic ulceration. *H. pylori* gastritis is associated with both duodenal and gastric ulcers. Multiple endocrine neoplasia syndrome type I (MEN-I) is a rare, dominantly inherited disorder characterized by enteropancreatic neuroendocrine tumors (especially nonfunctional tumors, gastrinomas, and insulinomas), parathyroid hyperplasia, and pituitary tumors (especially prolactinomas and adrenocorticotropic hormone [ACTH]-secreting tumors). Zollinger–Ellison syndrome characterized by the triad of an enteropancreatic neuroendocrine tumor, gastric acid hypersecretion, and peptic ulceration (almost exclusively of the duodenum) develops in more than 50% of MEN-I patients. This accounts for about 25% of all patients with gastrinoma—itsself a rare disorder with an annual incidence of approximately 0.5 per million. Familial hyperpepsinogenemia, C1-esterase deficiency, and Neuhauser's syndrome are rare disorders associated with peptic ulcer.

Peptic ulcer is common in patients with chronic obstructive pulmonary disease. The risk is not explained simply by the association of both diseases with smoking. Duodenal ulcers are common in cirrhosis, regardless of the underlying cause. Several series have found that patients with cirrhosis and esophageal varices are as likely or more likely to bleed from duodenal ulcer as from the varices. Alcohol abuse without cirrhosis is not associated with an increased ulcer risk. Some patients with renal failure have unexplained acid hypersecretion, which frequently is associated with duodenal ulcer. A larger percentage of these patients experience decreased acid secretion associated with hypergastrinemia but no ulcer disease. After renal transplantation, complications of peptic ulcer disease are common. Weak associations with duodenal ulcer have been found in coronary heart disease, polycythemia vera, Crohn's disease, the carcinoid syndrome, and myasthenia gravis.

DISEASES WITH DECREASED ULCER RISK

Gastric atrophy leads to decreased acid secretory capacity and decreases the risk of duodenal ulcer. The most extreme example is pernicious anemia in which achlorhydria results from autoimmune destruction of parietal cells (type A gastritis). Many persons with chronic *H. pylori* infection have pangastritis (type B gastritis) in which progressively lower acid secretory capacity develops with time. The risk of duodenal ulcer decreases in proportion to acid secretion, but the risk for gastric ulcer is maintained in these patients until acid secretion is quite low.

NORMAL PHYSIOLOGY OF GASTRIC SECRETION

The epithelial lining of the stomach secretes acid, pepsin, intrinsic factor, mucus, and bicarbonate into its lumen. These substances participate in the early phases of digestion of protein, permit efficient absorption of dietary vitamin B₁₂ and iron in the intestine, and help protect the gastric mucosa from injury. The presence of an acid environment in the stomach helps prevent access of ingested organisms to the intestine. However, *H. pylori* organisms are specifically adapted to survival in the acidified gastric mucus layer.

The stomach is divided functionally into two secretory components. The proximal oxyntic gland region includes the anatomical corpus (body) and fundus. The distal pyloric gland region comprises the antrum. The major secretory cells in the oxyntic gland region are the parietal cells that secrete acid and intrinsic factor, the enterochromaffin-like (ECL) cells that secrete histamine, and the chief cells that secrete group I pepsinogen. The G and D cells in the pyloric gland region secrete the hormones gastrin and somatostatin, respectively. Throughout the stomach, mucous neck cells and surface epithelial cells secrete group II pepsinogen, mucus, and bicarbonate.

Gastric secretion varies according to the time of day, the time and types of food intake, psychological states, and other metabolic activities of the body. Secretion is highest in the evening and lowest in the early morning. The thought of food or the process of eating stimulates the cephalic phase of gastric secretion, causing a modest increase in secretory rate above basal levels. Cephalic stimulation is largely cholinergic via the vagus nerve and is strongly antagonized by muscarinic cholinergic antagonists, such as atropine. Gastrin is the major mediator of the gastric phase of acid secretion. Antral distention and exposure to protein and certain other food constituents stimulate the gastric phase of gastric secretion, leading to a significant further increases in secretory rate. Release of gastrin by food is caused by direct interaction between food components and the gastrin-secreting G cells that line antral glands.

Gastrin release also is mediated by receptors on G cells for gastrin-releasing peptide, a neuropeptide found in nerve fibers that innervate antral glands. Lowering the pH of the gastric contents from 4 to 1 results in a progressive decrease in gastrin release and acid secretory responses to food. Regulation of gastrin release by gastric pH is the major autoregulatory mechanism of the gastric phase (feedback inhibition). As food leaves the stomach and is digested and absorbed in the intestine, additional endocrine pathways are activated, which further modulate gastric secretion (the intestinal phase of gastric acid secretion).

Parietal cells are located in the middle and lower parts of oxyntic glands. In the unstimulated basal state, tubulovesicles are present in the cytoplasm. When the parietal cell is stimulated, the tubulovesicles fuse with one another and with the apical membrane to form the secretory canalicular complex. Secretory canaliculi are lined with proton pumps (H⁺, K⁺-ATPase enzymes), which traverse the apical cellular membrane and are responsible for acid secretion. Energy derived from the hydrolysis of adenosine triphosphate (ATP) is used to pump hydrogen ions into the secretory canaliculi in exchange for potassium ions. Equimolar amounts of chloride enter the canaliculi through nearby chloride channels, producing hydrochloric acid. Other channels permit efflux of potassium ions, making them available to be exchanged again for more hydrogen ions. The secretory canaliculi are directly connected to the lumen of the stomach by way of the orifices of the oxyntic glands. Oxyntic glands secrete hydrochloric acid at concentrations greater than 100 mmol per liter (pH ~1) without autodigestion occurring. The linings of the secretory canaliculi and other epithelial surfaces of the stomach are highly impermeable to back-diffusion of hydrogen ions. Tight junctional complexes between cells creates an additional barrier, and parietal cell generation of bicarbonate in a 1 to 1 ratio with hydrochloric acid production (the alkaline tide) also serves to protect the stomach from acid-induced injury.

Partial cell activity is regulated by receptors located on the parietal cell and on adjacent regulatory cells. The major regulatory cells include the histamine-secreting ECL cells located in the basal and midportions of oxyntic glands, the somatostatin-releasing D cells located throughout the gastric mucosa and the gastrin-releasing G cells located primarily in the antrum. The three principal parietal cell receptors are the histamine H₂ receptor, which responds to histamine released from ECL cells; the muscarinic cholinergic receptor, which responds to acetylcholine released from vagal nerve fibers; and the cholecystikinin (CCK)-B/gastrin receptor, which responds to circulating gastrin released from antral G cells. CCK/gastrin receptors are also found on ECL cells, where activation leads to the release of histamine and D cells that release somatostatin. Somatostatin acts as a master feedback regulator that inhibits ECL and G cells by binding to type 2 somatostatin receptors on these cells. Mucosal nerves contain other inhibitory peptides such as galanin and neuropeptide Y, which may mediate neural inhibition of ECL and G cells as well.

ACID SECRETORY CAPACITY

The ability to secrete acid is determined by the number of functional parietal cells. Basal acid output rates in normal subjects after an overnight fast are 0 to 10 mmol per hour in men and 0 to 8 mmol per hour in women. The rate of acid secretion at any given time is the fraction of the maximal acid secretory capacity that is stimulated by endogenous regulators of parietal cell activity. Parietal cell mass is estimated by measurement of acid secretion rates during maximal stimulation with histamine, gastrin, or a synthetic analogue of one of these agents such as pentagastrin. The normal rate of maximal acid output (MAO) ranges from 10 to 48 mmol per hour in men. Normal MAO levels are about 25% lower in women. Peak acid output is somewhat higher than MAO. Basal acid output averages about 10% of MAO and

rarely exceeds 20%.

Increased MAO is often found in duodenal ulcer patients, especially patients with Zollinger–Ellison syndrome. About 25% of idiopathic duodenal ulcer patients have MAO rates higher than the upper limit of normal. Parietal cell hyperplasia in these patients is probably explained by the trophic effect of gastrin on the acid-secreting gastric mucosa. Decreased MAO (hypochlorhydria) is found in many patients with chronic gastritis. Total absence of gastric acid secretion during maximal stimulation is known as achlorhydria. Patients with pernicious anemia have achlorhydria combined with insufficient intrinsic factor secretion. Many other patients with chronic atrophic gastritis have achlorhydria but retain the ability to secrete enough intrinsic factor to permit intestinal absorption of cobalamin sufficient to prevent development of pernicious anemia.

Operations used to treat peptic ulcer disease also decrease MAO. Vagotomy decreases gastric responsiveness to stimuli but has little effect on parietal cell mass. Subtotal gastric resection, surgical removal of part of the parietal cell region along with antrectomy, decreases acid secretion out of proportion to the number of parietal cells removed. Resection strictly limited to the antrum also leads to decreased acid secretion, possibly by removing the trophic effect of gastrin. Antisecretory drugs cause temporary, reversible decreases in MAO.

MUCOSAL CYTOPROTECTION
