If angina persists despite intensive medical management, coronary revascularization with either coronary angioplasty or coronary artery bypass surgery should be considered.[16,17] The use of other approaches to manage angina that persists despite anti-anginal drugs and coronary revascularization is discussed elsewhere.[14]

Acute coronary syndromes

Unstable angina pectoris is a transitory syndrome that results from disruption of a coronary atherosclerotic plaque that critically decreases coronary blood flow causing new onset angina pectoris or exacerbation of angina pectoris. Transient episodes of coronary artery occlusion or near occlusion by thrombus at the site of plaque injury may

occur and cause angina pectoris at rest. The thrombus may be labile and cause temporary obstruction to flow. Release of vasoconstriction substances by platelets and vasoconstriction due to endothelial vasodilator dysfunction contribute to a further reduction in coronary blood flow, and in some patients, myocardial necrosis with non-ST-elevation myocardial infarction (NSTEMI) occurs. Elevation of serum cardiospecific troponin I or T or creatine kinase-MB levels occur in patients with NSTEMI but not in patients with unstable angina.

Older patients with unstable angina pectoris should be hospitalized, and depending on their risk stratification, may need monitoring in an intensive care unit. In a prospective study of 177 consecutive unselected patients hospitalized for an acute coronary syndrome (91 women and 86 men) aged 70–94 years, unstable angina was diagnosed in 54%, NSTEMI in 34%, and ST-segment elevation myocardial infarction (STEMI) in 12%.[18] Obstructive IHD was diagnosed by coronary angiography in 94% of elderly men and in 80% of elderly women.

Therapy

Treatment of patients with unstable angina pectoris/NSTEMI should be initiated in the emergency department.[14] Reversible factors precipitating unstable angina pectoris should be identified and corrected. Oxygen should be administered to patients who have cyanosis, respiratory distress, congestive heart failure, or high-risk features. Oxygen therapy should be guided by arterial oxygen saturation and should not be given if the arterial oxygen saturation is more than 94%. Morphine sulfate should be administered intravenously when anginal chest pain is not immediately relieved with nitroglycerin or when acute pulmonary congestion and/or severe agitation is present.

Aspirin should be administered to all patients with unstable angina pectoris/NSTEMI unless contraindicated and continued indefinitely. The first dose of aspirin should be chewed rather than swallowed to ensure rapid absorption.

The American College of Cardiology (ACC)/American Heart Association (AHA) 2002 guidelines update state that clopidogrel should be administered for up to nine months in addition to indefinite use of aspirin in hospitalized patients with unstable angina pectoris/NSTEMI in whom an early non-interventional approach is planned or in whom a percutaneous coronary intervention (PCI) is planned and clopidogrel should be withheld for 5 to 7 days in patients in whom elective coronary artery surgery is planned.[19] On the basis of data from the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial and from the Clopidogrel for the Reduction of Events During Observation (CREDO) trial, aspirin 80 mg daily plus clopidogrel 75 mg daily should be administered to patients with unstable angina/NSTEMI for at least one year.[14]

Nitrates should be administered immediately in the emergency department to patients with unstable angina/NSTEMI.[14] Patients whose symptoms are not fully relieved with three 0.4 mg sublingual nitroglycerin tablets or spray taken five minutes apart and the initiation of an intravenous beta-blocker should be treated with continuous intravenous nitroglycerin. Topical or oral nitrates are alternatives for patients without ongoing refractory symptoms.

Beta-blockers should be administered intravenously in the emergency department unless there are contraindications to their use followed by oral administration and continued indefinitely.[14,19] Metoprolol may be given intravenously in 5 mg increments over 1 to 2 minutes and repeated every 5 minutes until 15 mg has been given followed by oral metoprolol 100 mg twice daily. The target resting heart rate is 50 to 60 beats per minute.

An oral ACE inhibitor should also be given unless there are contraindications to its use and continued indefinitely.[19] In patients with continuing or frequently recurring myocardial ischaemia despite nitrates and beta-blockers, verapamil or diltiazem should be added to their therapeutic regimen in the absence of LV systolic dysfunction (class IIa indication). The benefit of calcium-channel blockers in the treatment of unstable angina pectoris is limited to symptom control. Intra-aortic balloon pump counterpulsation should be used for severe myocardial ischaemia that is continuing or occurs frequently despite intensive medical therapy or for haemodynamic instability in patients before or after coronary angiography.[19]

A platelet glycoprotein IIb/IIIa inhibitor should also be administered in addition to aspirin and clopidogrel and heparin in patients in whom coronary angioplasty is planned.[14] Abciximab can be used for 12 to 24 hours in patients with unstable angina/NSTEMI in whom coronary angioplasty is planned within the next 24 hours. Eptifibatide or tirofiban should be administered in addition to aspirin and low-molecular-weight heparin or unfractionated heparin to patients with continuing myocardial ischaemia, an elevated cardiospecific troponin I or T, or with other high-risk features in whom an invasive management is not planned.

Intravenous thrombolytic therapy is not recommended for the treatment of unstable angina/NSTEMI.[19] Prompt coronary angiography should be performed without non-invasive risk stratification in patients who fail to stabilize with intensive medical treatment. Coronary revascularization should be performed in patients with high-risk features to reduce coronary events and mortality.[14,19]

On the basis of the available data, the ACC/AHA 2002 guidelines recommend the use of statins in patients with acute coronary syndromes and a serum LDL cholesterol of 100 mg dl^{-1} or higher 24 to 96 hours after hospitalization.[19] Statins should be continued indefinitely after hospital discharge. The ACC/AHA 2002 guidelines also recommend

use of a fibrate or nicotinic acid if the serum HDL cholesterol is less than 40 mg dl^{-1}, occurring as an isolated finding or in combination with other lipid abnormalities.

Patients should be discharged on aspirin plus clopidogrel, beta-blockers, and on ACE inhibitors in the absence of contraindications. Nitrates should be given for ischaemic symptoms. A long-acting non-dihydropyridine calcium-channel blocker may be given for ischaemic symptoms that occur despite treatment with nitrates plus beta-blockers. Hormonal therapy should not be administered to postmenopausal women.

Therapy of STEMI

Chest pain due to acute MI should be treated with morphine, nitroglycerin and beta-blockers.[20] If arterial saturation is lower than 94%, oxygen should be administered. Aspirin should be given on day 1 of an acute MI and continued indefinitely to reduce coronary events and mortality. The first dose of aspirin should be chewed rather than swallowed. Early intravenous beta-blockade should be used during acute MI and oral beta-blockers continued indefinitely to reduce coronary events and mortality. ACE inhibitors should be given within 24 hours of acute MI and continued indefinitely to reduce coronary events and mortality. Statins should be given to patients with acute MI.[9] Statins should be continued indefinitely after hospital discharge to reduce coronary events and mortality.[9]

The ACC/AHA guidelines state there are no class I indications for the use of calcium-channel blockers during or after acute MI.[21] However, if older persons have persistent angina after MI despite treatment with beta-blockers and nitrates and are not suitable candidates for coronary revascularization, or if they have hypertension inadequately controlled by other drugs, a non-dihydropyridine calcium-channel blocker such as verapamil or diltiazem should be added to the therapeutic regimen if the LVEF is normal. If the LVEF is abnormal, amlodipine or felodipine should be added to the therapeutic regimen.

The ACC/AHA guidelines recommend using intravenous heparin in persons with acute MI undergoing primary coronary angioplasty or surgical coronary revascularization and in persons with acute MI at high risk for systemic embolization such as persons with a large or anterior MI, atrial fibrillation, history of pulmonary or systemic embolus, or LV thrombus.[21] In persons with acute MI not receiving intravenous heparin, the ACC/AHA guidelines recommend using subcutaneous heparin 7500 U twice daily for 24 to 48 hours to decrease the incidence of deep venous thrombosis.[21]

Thrombolytic therapy is beneficial in the treatment of STEMI in patients younger than 75 years of age.[20,21] From the available data, one cannot conclude whether thrombolytic therapy is beneficial or harmful in patients older than 75 years with acute MI.[22] However, the data favour the use of primary coronary angioplasty in eligible patients younger and older than 75 years with acute MI to reduce coronary events and mortality.[23]

Therapy after MI

Elderly persons after MI should have their modifiable coronary risk factors intensively treated as discussed previously in this chapter. Aspirin or clopidogrel should be given indefinitely to reduce new coronary events and mortality.[12,15,24] The ACC/AHA guidelines recommend as class I indications for long-term oral anticoagulant therapy after MI: (1) secondary prevention of MI in post-MI patients unable to tolerate daily aspirin or clopidogrel; (2) post-MI patients with persistent atrial fibrillation; and (3) post-MI patients with LV thrombus.[21] Long-term warfarin should be given in a dose to achieve an INR between 2.0 and 3.0.

Beta-blockers (Table 37.2) and ACE inhibitors (Table 37.3) should be given indefinitely unless contraindications exist to the use of these drugs to reduce new coronary events and mortality.[12,24] Long-acting-nitrates are effective anti-anginal and anti-ischaemic drugs.[24]

There are no class I indications for the use of calcium-channel blockers after MI.[21] Teo *et al*. analyzed randomized controlled trials comprising 20 342 persons that investigated the use of calcium-channel blockers after MI.[24,25] Mortality was 4% insignificantly higher in persons treated with calcium-channel blockers. In this study, beta-blockers significantly reduced mortality by 19% in 53 268 persons. In another study, elderly persons who were treated with beta-blockers after MI had a 43% decrease in two-year mortality and a 22% decrease in two-year cardiac hospital readmissions than elderly persons who were not treated with beta-blockers.[24] Use of a calcium-channel blocker instead of a beta-blocker after MI doubled the risk of mortality.[24]

Anti-arrhythmic therapy after MI

A meta-analysis of 59 randomized controlled trials comprising 23 229 persons that investigated the use of class I anti-arrhythmic drugs after MI showed that mortality was 14% significantly higher in persons receiving class I anti-arrhythmic drugs than in persons receiving no anti-arrhythmic drugs.[25] None of the 59 studies showed a reduction in mortality by class I anti-arrhythmic drugs.

In the Cardiac Arrhythmia Suppression Trials I and II, older age also increased the likelihood of adverse effects including death in persons after MI receiving encainide, flecainide, or moricizine.[24,26] Compared with no anti-arrhythmic drug, quinidine or procainamide did not reduce mortality in elderly persons with CAD, normal or abnormal LVEF, and presence versus absence of ventricular tachycardia.[26]

Table 37.2 Effect of beta-blockers on mortality in older patients after myocardial infarction.

Study	Follow-up	Results
Goteborg Trial	90 days	Compared with placebo, metoprolol caused a 45% significant decrease in mortality in patients aged 65–74 years
Norwegian Multicentre Study	17 months (up to 33 months)	Compared with placebo, timolol caused a 43% significant reduction in mortality in patients aged 65–74 years
Norwegian Multicentre Study	61 months (up to 72 months)	Compared with placebo, timolol caused a 19% significant decrease in mortality in patients aged 65–74 years
Beta-Blocker Heart Attack Trial	25 months (up to 36 months)	Compared with placebo, propranolol caused a 33% significant reduction in mortality in patients aged 60–69 years
Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction Trial	1.3 years	Compared with placebo, carvedilol caused a 23% significant reduction in mortality, a 24% significant reduction in cardiovascular mortality, a 40% significant reduction in non-fatal myocardial infarction, and a 30% significant reduction in all-cause mortality or non-fatal myocardial infarction in patients, mean age 63 years

Source: The studies are discussed in Aronow, 2008.[24]

Table 37.3 Effect of angiotensin-converting-enzyme inhibitors on mortality in older patients after myocardial infarction.

Study	Follow-up	Results
Survival and Ventricular Enlargement Trial	42 months (up to 60 months)	In patients with MI and LVEF $\leq$40%, compared with placebo, captopril reduced mortality 25% in patients aged $\geq$65 years
Acute Infarction Ramipril Efficacy Study	15 months	In patients with MI and clinical evidence of CHF, compared with placebo, ramipril decreased mortality 36% in patients aged $\geq$65 years
Survival of Myocardial Infarction Long-Term Evaluation Trial	1 year	In patients with anterior MI, compared with placebo, zofenopril reduced mortality or severe CHF 39% in patients aged $\geq$65 years
Trandolapril Cardiac Evaluation Study	24 to 50 months	In patients, mean age 68 years, with LVEF $\leq$35%, compared with placebo, trandolapril reduced mortality 33% in patients with anterior MI and 14% in patients without anterior MI
Heart Outcomes Prevention Evaluation Study	4.5 years (up to 6 years)	In patients aged $\geq$55 years with MI (53%), cardiovascular disease (88%), or diabetes (38%) but no CHF or abnormal LVEF, ramipril reduced MI, stroke, and cardiovascular death 22%
European trial on reduction of cardiac events with perindopril in patients with stable coronary artery disease	4.2 years	In patients, mean age 60 years, with coronary artery disease and no CHF, compared with placebo, perindopril reduced cardiovascular death, MI, or cardiac arrest 20%

CHF, congestive heart failure; LVEF, left ventricular ejection fraction; MI, myocardial infarction
Source: The studies are discussed in Aronow, 2008.[24]

Compared with placebo, d,l-sotalol did not reduce mortality in post-MI persons followed for one year.[26] Mortality was also significantly higher at 148-day follow-up in persons treated with d-sotalol (5.0%) than in persons treated with placebo. On the basis of the available data, persons after MI should not receive class I anti-arrhythmic drugs or sotalol.

In the European Myocardial Infarction Amiodarone Trial, 1486 survivors of MI with a LV ejection fraction of 40% or less were randomized to amiodarone (743 patients) or to placebo (743 patients).[24] At two-year follow-up, 103 patients treated with amiodarone and 102 patients treated with placebo had died. In the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial, 1202 survivors of MI with non-sustained ventricular tachycardia or complex ventricular arrhythmias were randomized to amiodarone or to placebo.[24,26] Amiodarone was very effective in suppressing ventricular tachycardia and complex ventricular arrhythmias. However, the mortality rate at 1.8-year follow-up was not significantly different in the persons treated with amiodarone or placebo. In addition, early permanent discontinuation of drug for reasons other than outcome events occurred in 36% of persons taking amiodarone.

In the Cardiac Arrest in Seattle: Conventional Versus Amiodarone Drug Evaluation Study, the incidence of pulmonary toxicity was 10% at two years in persons receiving

amiodarone in a mean dose of 158 mg daily.[24,26] The incidence of adverse effects for amiodarone also approaches 90% after five years of treatment. On the basis of the available data, amiodarone should not be used in the treatment of persons after MI.

However, beta-blockers have been shown to reduce mortality in persons with non-sustained ventricular tachycardia or complex ventricular arrhythmias after MI in patients with normal or abnormal LV ejection fraction.[24,26] On the basis of the available data, beta-blockers should be used in the treatment of elderly persons after MI, especially if non-sustained ventricular tachycardia or complex ventricular arrhythmias are present, unless there are specific contraindications to their use.

In the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, 1016 persons, mean age 65 years, with a history of ventricular fibrillation or serious sustained ventricular tachycardia were randomized to an automatic implantable cardioverter defibrillator (AICD) or to drug therapy with amiodarone or d,l-sotalol.[26] Persons treated with an AICD had a 39% reduction in mortality at one year, a 27% reduction in mortality at two years, and a 31% reduction in mortality at three years. If persons after MI have life-threatening ventricular tachycardia or ventricular fibrillation, an AICD should be inserted.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT) II randomized 1232 persons, mean age 64 years, with a prior MI and a LVEF of 30% or less to an AICD or to conventional medical therapy.[27] At 20-month follow-up, compared with conventional medical therapy, the AICD significantly decreased all-cause mortality 31% from 19.8% to 14.2%. The effect of AICD therapy in improving survival was similar in persons stratified according to age, sex, LV ejection fraction, New York Heart Association class, and QRS interval. These data favour considering the prophylactic implantation of an AICD in post-MI persons with a LVEF of 30% or lower.

Hormone replacement therapy

The Heart Estrogen/Progestin Replacement Study (HERS) investigated in 2763 women with documented IHD the effect of hormonal therapy versus double-blind placebo on coronary events.[28] At 4.1-year follow-up, there were no significant differences between hormonal therapy and placebo in the primary outcome (non-fatal MI or IHD death) or in any of the secondary cardiovascular outcomes. However, there was a 52% significantly higher incidence of non-fatal MI or death from IHD in the first year in persons treated with hormonal therapy than in persons treated with placebo. Women on hormonal therapy had a 289% significantly higher incidence of venous thromboembolic events and a 38% significantly higher incidence of gallbladder disease requiring surgery than women on placebo.

At 6.8-year follow-up in the HERS trial, hormonal therapy did not reduce the risk of cardiovascular events in women with IHD.[29] The investigators concluded that hormonal therapy should not be used to decrease the risk of coronary events in women with IHD. At 6.8-year follow-up in the HERS trial, all-cause mortality was insignificantly increased 10% by hormonal therapy. The overall incidence of venous thromboembolism at 6.8-year follow-up was significantly increased 208% by hormonal therapy. At 6.8-year follow-up, the overall incidence of biliary tract surgery was significantly increased 48%, the overall incidence for any cancer was insignificantly increased 19%, and the overall incidence for any fracture was insignificantly increased 4%.

Revascularization

Medical therapy alone is the preferred treatment in elderly persons after MI (Table 37.4). The two indications for revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management. In a prospective study of 305

Table 37.4 Overall medical approach to older patients after myocardial infarction.

Stop cigarette smoking and refer to smoking cessation programme.
Treat hypertension with beta-blockers and angiotensin-converting enzyme (ACE) inhibitors; the blood pressure should be reduced to $<$140/85 mmHg and to $\leq$130/80 mmHg in persons with diabetes mellitus or renal insufficiency.
The serum low-density lipoprotein cholesterol should be reduced to $<$70 mg dl^{-1} with statins if necessary and at least 30–40%.
Diabetes, obesity, and physical inactivity should be treated.
Aspirin or clopidogrel, beta-blockers, and ACE inhibitors should be given indefinitely unless contraindications exist to the use of these drugs.
Long-acting nitrates are effective anti-anginal and anti-ischaemic drugs.
There are no class I indications for the use of calcium-channel blockers after myocardial infarction (MI).
Post-infarction patients should not receive class I anti-arrhythmic drugs, sotalol, or amiodarone.
An automatic implantable cardioverter-defibrillator should be implanted in post-infarction patients at very high risk for sudden cardiac death.
Hormone replacement therapy should not be administered to postmenopausal women after MI.
The two indications for coronary revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management.

patients aged 75 years and older with chest pain refractory to at least two anti-anginal drugs, 150 patients were randomized to optimal medical therapy and 155 patients to invasive therapy.[30] In the invasive group, 74% had coronary revascularization (54% coronary angioplasty and 20% coronary artery bypass surgery). During the six-month follow-up, one-third of the medically treated group needed coronary revascularization for uncontrollable symptoms. At six-month follow-up, death, non-fatal MI, or hospital admission for an acute coronary syndrome was significantly higher in the medically treated group (49%) than in the invasive group (19%). Revascularization by coronary angioplasty[16] or by coronary artery bypass surgery[17] in elderly persons is extensively discussed elsewhere. If coronary revascularization is performed, aggressive medical therapy must be continued.

Key points

- Coronary risk factors should be intensively treated in elderly persons with IHD.
- Elderly persons with IHD should be treated indefinitely with antiplatelet drugs, beta-blockers, ACE inhibitors, and statins unless contraindications to the use of these drugs exist.
- The data favour the use of primary angioplasty in eligible patients younger and older than 75 years with acute MI to reduce coronary events and mortality.
- Hormone replacement therapy should not be administered to elderly women with IHD.
- The two indications for revascularization in elderly persons with IHD are prolongation of life and relief of unacceptable symptoms despite optimal medical management.

CHAPTER 38

Lipid management

Adie Viljoen[1] and Anthony S. Wierzbicki[2]

[1]Lister Hospital, Stevenage, Hertfordshire, and Bedfordshire and Hertfordshire Postgraduate Medical School, Luton, Hertfordshire, UK
[2]Guy's & St Thomas' Hospitals, London, UK

Introduction

Atherosclerosis is a disease of ageing. Cardiovascular event rates increase in a curvilinear fashion after age 65 years in men and 75 years in women.[1–2] The decline in age-standardized cardiovascular disease (CVD)-associated death rates has shifted mortality to increasingly advanced age, with the number of cardiovascular events in those aged >80 years having increased by 60% since 1970.[3] Numerous epidemiological studies have shown that age is the principal unmodifiable risk factor for events.[4–6] Both diabetes and hypertension are strongly age-related risk factors.[7] In parallel with these risk factors levels of total cholesterol rise with age especially after middle age or the menopause. The increasing incidence of metabolic syndrome and obesity with age means that high density lipoprotein cholesterol (HDL-C) levels tend to fall and triglyceride levels rise.[8] Thus hyperlipidaemia is an increasing risk factor for coronary events, aortic valve disease, stroke, peripheral vascular disease including abdominal aortic aneurysm and possibly dementia (multi-infarct type). As many elderly patients have suffered one cardiovascular event they are at high risk of another, often in a different vascular bed. Thus patients with strokes more often have coronary events than second strokes.

As life expectancy increases, preventive efforts will become increasingly important for preventing morbidity, improving quality of life (QOL), and reducing healthcare expenditures for older persons. Clinicians need to consider additional factors in the elderly which most often are not applicable in younger individuals when faced with treatment decisions. These include co-morbid conditions, polypharmacy, drug–drug interactions and differential safety and tolerability profiles; all of which could lead to alterations in the benefit-harm balance. This highlights the importance of considering both the treatment options and the evidence for their use in the elderly population.

Cholesterol in the elderly

Ageing is associated with a progressive increase in cholesterol levels in men and in many women profound changes in lipids follow the menopause with substantial increases in low density lipoprotein cholesterol (LDL-C) secondary to possibly changes in proprotein convertase subtilisin kexin-9 (PCSK-9) levels which are under the control of sex steroids and a reduction in HDL-C most probably caused by changes in sex steroids.[9] However, most hyperlipidaemia in the elderly is still caused by dietary and lifestyle choices. The slowly declining metabolic rate of the elderly, associated with reduced levels of activity due to concurrent ageing or osteological problems means that many show features of the metabolic syndrome. Dietary conservatism also tends to mean that currently the elderly are less likely to consume a diet rich in fruit and vegetables and are more likely to eat a diet rich in saturated fat.

Secondary causes of hyperlipidaemia are more common in the elderly. The most common cause of mixed hyperlipidaemia is insulin resistance and/or type 2 diabetes. Rates of chronic renal disease also increase in the elderly, which allied to greater arterial stiffness, result in increases in pulse pressure, isolated systolic hypertension and secondary cardiovascular risk. Other causes that tend to be associated with ageing include alcohol-induced hyperlipidaemia which is more commonly due to a reduction in liver-related detoxification in the elderly and its frequent association with depression, especially in single men. Alcohol-induced hyperlipidaemia may show a profile varying between mixed hyperlipidaemia to pure hypercholesterolaemia depending on the frequency of alcohol intake. Non-alcoholic steatitic hepatitis, which is often associated with a mixed hyperlipidaemia, is more common in the centrally obese elderly.

The most common cause of pure secondary hypercholesterolaemia is hypothyroidism. The significance of this is that prescription of a lipid-lowering drug to a grossly

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

hypothyroid patient massively increases their risk of drug-associated rhabdomyolysis.

However, despite these factors the positive association between total and LDL-C and cardiovascular risk attenuates with advancing age.[10] In epidemiological studies a 1 mmol l^{-1} lower total cholesterol (TC) is associated with approximately 50% reduction in coronary heart disease (CHD) mortality in patients aged 40–49 years, 33% in those aged 50–69 and 15% in those aged 70–89 years.[11] Yet, though the relative risk reduction associated with lower cholesterol decreases with age, the absolute effects of lower cholesterol on annual ischaemic heart disease mortality rates are greater in the elderly given the higher prevalence of atheroma. Also cholesterol levels decline in acute and chronic disease states, inflammation, malnutrition and cancer, all of which are more common in the elderly and thus this attenuated association may be partly due to confounding.[12]

Clinical signs

Clinical signs present differently in the elderly. Arcus senilis is associated with familial hypercholesterolaemia in the young but not in the elderly. Xanthelasma are associated with mixed dyslipidaemia and reduced skin thickness and elasticity and thus are more common in older individuals. Tendon xanthomata may be confused with gout tophi or Heberden's nodes which are common in the elderly but may be clinically distinguished by their movement with the underlying tendon.

Lipoproteins and their measurement

Blood lipids are transported in macromolecular complexes called lipoproteins. Figure 38.1 shows a schematic representation of these complex molecules. Their function is to transport triglycerides (energy) and fat soluble vitamins to sites of storage or metabolism, the principal function of the apolipoprotein B group (chylomicrons, very low density lipoprotein, low density lipoprotein (LDL)). They also function to detoxify lipopolysaccharide toxins and remove potentially toxic fatty acid metabolites – principally through reverse transport by apolipoprotein A-1 containing high density lipoproteins (HDLs). Blood lipids are most often measured either as TC, LDL, HDL as well as plasma total triglyceride (TG) components. Only the cholesterol fraction (-C) of the major lipoprotein fractions is measured routinely and the concentrations of the cholesterol subfractions do not necessarily reflect the activity of these dynamic pathways – as is most true of HDL. LDL-C is generally not measured by laboratories but calculated instead, using the Friedewald equation [LDL-C (mmol l^{-1}) = TC – (HDL-C + TG/2.20)].[13] This approximation becomes less reliable

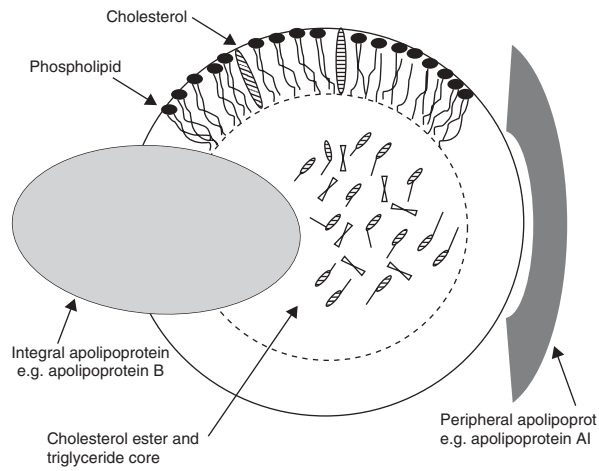

Figure 38.1 Schematic representation of a lipoprotein molecule.

at higher triglyceride concentrations (TG > 4.5 mmol l^{-1}) and cannot be used in non-fasting samples.[14]

Alternatively the concentrations of the principal proteins – apolipoproteins (apo) B and A1 can be measured and can be better measures of total CVD risk[12] analogous to the use of non-HDL cholesterol and HDL-C.[14]

Diagnosis

Lipid screening in the elderly should comprise a full profile of TC, TG and HDL-C with a calculated LDL-C. At lower levels of TC, current recommendations from the UK National Institute of Health and Clinical Excellence[15] and the Joint British Societies guidelines[16] recommend risk assessment using the Framingham (1991) equation. Treatment is recommended for any cardiovascular risk factor at 20%/future decade risk of CVD (15%/future decade risk of CHD). This approach differs from European[17] and US guidelines[18] where risk is assessed at the chronological age and treatment instituted at 20% CHD risk. It should be noted that risk assessment is an imprecise art with any estimate having a wide confidence interval.[19] The UK guidelines also adjust the risk assessment to age 70 to reduce prescribing in the otherwise fit elderly given the strong association of risk with age whereby almost any 75-year-old would require lipid-lowering. This statement is controversial and many would recommend direct assessment of plaque burdens using non-invasive techniques, for example carotid intima media thickness or coronary calcium scores.[20,21]

The risk assessment biochemical profile should include measurement of transaminases (AST/ALT), thyroid function tests and a baseline creatine kinase (CK). Lipid-lowering therapy with a statin or fibrate is contraindicated if AST/ALT exceeds 3 × upper reference limit of normal (ULN) (usually >150 IU l^{-1}). The actual contraindication is to persistent elevations in transaminases as many elevations

turn out to be transient and caused by either infections or are secondary to other drug therapies (e.g. heavy paracetamol or opiate-containing analgesic use). If gamma-glutamyl transferase is measured its level is irrelevant to starting or continuing lipid-lowering therapies.

Thyroid function tests should be measured. Gross hypothyroidism (TSH > 20 mU l^{-1}) is associated with a hypercholesterolaemia and this should be treated prior to re-measurement of the lipid profile due to the risk of lipid-lowering therapy-associated rhabdomyolysis. The risk factors for rhabdomyolysis are age, creatinine, reduced muscle mass, female sex and hypothyroidism. Mild hypothyroidism is common in the elderly and not a contraindication to lipid-lowering therapies though some reports suggest that reports of myalgia may be more common in patients with borderline hypothyroidism.

The significance of CK measurement in the elderly is debated. Lipid-lowering therapies are contraindicated in patients with CK > × 10 ULN though most clinicians are reluctant to prescribe if 5 × ULN. Some elevated CK measurements, for example in Africans or Afro-Caribbeans, represent normal variants. In other patients a mildly elevated CK allied with a mild adverse reaction to lipid-lowering therapies should prompt investigation for rheumatological causes of disease as the lipid-lowering therapy may have uncovered this predisposition.

LDL-C as a target of therapy with statins

Epidemiological studies incriminate high levels of LDL-C as being atherogenic with the serum TC as a good correlate for LDL-C levels.[18] However, the definitive proof has come from clinical trial work of lipid-lowering interventions which has been hailed as one of the major advances in clinical medicine. Whether cholesterol is lowered by diet, drugs, or other means, CVD risk decreases.[22] Comparing earlier trials of statins, and other treatment modalities such as bile acid sequestrant resins and ileal bypass surgery with more recent statin trials, the benefit of absolute LDL-C reduction is present across a wide range of baseline concentrations.

Statins

Statins form the cornerstone of pharmaceutical CVD prevention. These agents have shown to reduce the risk of both CHD and stroke in clinical trials enrolling persons aged up to age 80 years (Table 38.1). A meta-analysis of 90 056 patients which included 14 randomized trials showed that those aged >65 years (n = 6446) had 19% reduction in the risk of major cardiovascular events, a benefit similar to the 22% reduction in risk experienced by those aged <65 years (n = 7902).[23] Earlier secondary prevention statin trials, such as the Scandinavian Simvastatin Survival Study (4S),[24] Cholesterol and Recurrent Events (CARE),[25] and Long-term Intervention with Pravastatin in Ischemic Disease (LIPID),[26] support a benefit of lipid lowering after MI. Although these trials excluded patients >75 years of age (4S upper age limit, 69 years), subgroup analysis demonstrated a benefit of statins among younger elderly.[27,28] More data on statin therapy in the elderly became available following the Heart Protection Study which randomized more than 20 000 participants with known CVD or diabetes to either simvastatin 40 mg or placebo in the age range 40–80 (85 by trial end).[29] Simvastatin reduced the risk of cardiovascular events by 18% in those aged 70 to 80 years (n = 5806) compared with 24% in those aged <65 years. The apparent attenuated impact of simvastatin in the older age group was not statistically significant. As the elderly have a higher absolute risk of events the number of events prevented in those aged >70 years and in those aged <70 years were similar. More evidence on the benefits of statin intervention in the elderly accumulated following the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER), which was specifically aimed at evaluating the efficacy of statin use in the elderly.[30] In this study 5804 subjects between the ages 70–82 years with pre-existing CHD or at high risk for CHD were randomized to 40 mg of pravastatin or placebo. Over an average of more than three years follow-up, the pravastatin group had significantly fewer combined cardiovascular outcomes (CHD death or non-fatal or fatal myocardial infarction, fatal or non-fatal stroke). The question as to whether older individuals without evidence of CVD will benefit from statin treatment (i.e. in the primary prevention setting)[31] was answered by the recent Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial.[32] This study compared rosuvastatin 20 mg to placebo in 17 802 apparently healthy participants with relatively low LDL-C levels of <3.4 mmol l^{-1} and high sensitivity C-reactive greater than 2 mg l^{-1}. The composite primary cardiovascular endpoint showed a relative risk reduction of 44% [hazard ratio 0.56 (95% CI, 0.46–0.69)]. 5644 (32%) of participants were older than 70 years making this by far the most representative primary prevention data of the benefits of statin treatment in the elderly.

Heart failure is common in the elderly secondary to ischaemia, hypertension and cardiomyopathy. A number of statin trials have been conducted in populations with grade 2–3 heart failure after post hoc analyses of general CHD prevention trials suggested benefits in grade 1–2 disease.[33] The Controlled Rosuvastatin Multinational Study in Heart Failure CORONA[34] and GISSI-Heart Failure (GISSI-HF)[35] studies showed no benefits of adding statin therapy in advanced heart failure but also that these drugs were not toxic in these populations.

Specific prescribing points in the elderly

Data from the large trials shows little difference in side-effect rates between statin and placebo arms.[36,37] However, many patients recruited to the trials have previous experience of statins and the designs of many trials incorporate an active run-in period in which those who suffer side effects are identified early. Thus side-effect rates may be underestimated especially in elderly populations. No specific dose reduction is advised or necessary for the elderly with statins though many general practitioners worldwide initiate therapy at low doses but unfortunately do not titrate the dose to efficacious levels resulting in a persistent under-treatment of lipids in the elderly. Drug interactions vary between compounds in the statin class. The most significant interaction is of cytochrome P450 3A4 metabolized statins (lovastatin, simvastatin, atorvastatin) with other drugs metabolized by this pathway – conazole antifungals, erythromycin, and in specialist practice, cyclosporine and HIV protease inhibitors (Table 38.2). Simvastatin interacts with amiodarone at doses >20 mg and other statins should be used if amiodarone therapy is necessary (e.g. for atrial fibrillation). A weaker interaction 3A4 can occur with diltiazem through this pathway but is not usually clinically significant. Drug interactions of this type are less significant for the other statins.

All statins frequently cause gastrointestinal disturbance by a transient dysregulation of bile acid metabolism through the farnesoid-X receptor pathway. This problem may be exacerbated in patients with diverticulosis or irritable bowel disease. Gastrointestinal side effects may be accompanied by a transient increase in bilirubin and transaminases. This problem is usually self-limiting within 2–3 weeks and on repeat measurement liver profiles have usually normalized.

Myalgia occurs in 5% of patients with statin therapy and is not associated with any change in CK.[37] Again often it is self-limiting but if symptoms persist than the statin therapy should be changed to the weaker agents that show predictably better side-effect profiles (pravastatin, fluvastatin). Myositis (raised CK, muscle pain) and rhabdomyolysis (CK > 20 × ULN; muscle pain; myoglobinuria) are rare side effects of statin therapy. The risk factors for rhabdomyolysis are age, creatinine, muscle mass, female sex, hypothyroidism and concomitant therapy with drugs interacting through the relevant cytochrome pathway (usually 3A4); likely to displace statins from plasma proteins; or sharing a myopathic tendency (e.g. other lipid-lowering drugs).

Ezetimibe

The cholesterol absorption inhibitor, ezetimibe, works by reducing the upper intestinal cholesterol absorption to produce in monotherapy around 20% reduction in LDL-C. This drug has proven to be very successful in the market due to its low side-effect profile with its main benefit being add-on therapy to statins to achieve targets.[38] Currently no CVD outcomes data is available on ezetimibe and the importance of this has recently been highlighted.[39] The Simvastatin-Ezetimibe in Aortic Stenosis trial[40] investigated the efficacy of a simvastatin–ezetimibe combination in 1873 patients with aortic stenosis – a common disease in the elderly. No benefit was shown on the combined valve disease-CVD events primary outcome or on valve progression-related endpoints, though a 20% reduction was seen in cardiovascular events. The data in advanced aortic stenosis from SEAS parallels that from other surrogate outcome trials. The Study of Heart And Renal Protection (SHARP) trial investigated the efficacy of simvastatin 20 mg and ezetimibe in 9270 patients with chronic renal failure including those on dialysis and showed a 17% reduction in cardiovascular events.[41]

An ongoing trial namely, IMPROVE-IT (the Improved Reduction of Outcomes: Vytorin Efficacy International Trial), in which simvastatin plus ezetimibe is compared with simvastatin plus placebo, is underway in a middle-aged population with acute coronary syndromes. This study will hopefully provide answers with respect to the benefits of ezetimibe monotherapy on CVD outcomes.

Bile acid sequestrants

Bile acid sequestrants reduce cholesterol absorption and reduce LDL-C by 15–20%. They can be used in monotherapy or combination therapy with any lipid-lowering drug except ezetimibe. They may raise TG levels and have modest positive effects on levels of HDL-C. They are not often used in the elderly as gastrointestinal side effects are common and interact with irritable bowel syndrome and diverticulitis to cause bloating, diarrhoea and constipation. Endpoint evidence exists for bile acid sequestrants from the Lipid Research Clinics trial where they reduced coronary events by 15%.[42]

Bile acid sequestrants have multiple drug interactions as they interfere with the absorption of all lipid-soluble drugs. A four-hour clear interval is recommended between taking these drugs and taking any other medication. Bile acid sequestrants cause gastrointestinal disturbance in 40% of patients. This may be accompanied by a liver-X-receptor (LXR)-induced hypertriglyceridaemia. Myalgia, myositis (raised CK, muscle pain) and rhabdomyolysis (CK > 20 × ULN; muscle pain; myoglobinuria) are rare side effects of bile acid sequestrant therapy and usually occur when it is prescribed with a concomitant statin.

Intervention on triglycerides

Several meta-analyses have found that TGs are an independent risk factor for CHD.[43,44] Raised serum TG levels (>1.7 mmol l^{-1}) are associated with abnormal

lipoprotein metabolism giving rise to increased atherogenicity. The lipid triad of high TG, low HDL-C and increased atherogenic particle numbers (high apo B, low apo A-1 concentrations) is associated with the metabolic syndrome found in many patients with obesity, insulin resistance, or diabetes mellitus. Highly elevated TG levels (>9–10 mmol l^{-1}) are a risk factor for pancreatitis.[45]

No specific trials have addressed hypertriglyceridaemia and most exclude patients with this condition. Thus there is no clear consensus on the benefits of directly targeting hypertriglyceridaemia in order to reduce CVD risk. Three drug classes are commonly prescribed for hypertriglyceridaemia namely: fibrates, niacin and omega-3 fatty acids. Statin therapy is still recommended first line for TGs <4.6 mmol l^{-1} as statins reduce TGs in direct proportion to their efficacy on LDL-C and the baseline TG level.[46] At higher TG levels fibrates and niacin are more efficacious and are recommended first-line therapies.[18,47] Guidelines suggest TGs are viewed as risk indicators for intensifying LDL-C-reducing therapy commonly stating an indication with a residual TG >2.3 mmol l^{-1} after initial statin therapy.

Fibrates

Fibrates are used to lower TG and raise HDL-C though their principal action is to increase lipoprotein particle sizes (which is well marked by TG). They reduce TG by 30–50%, raise HDL-C by 2–15% and reduce LDL-C by 0–10% depending on the drug and dose. Four drugs are available (Table 38.1). The evidence base for fibrates is contradictory.[48] The World Health Organization clofibrate trial[49,50] showed decreased cardiovascular events but an increase in total mortality due mostly to an excess of pancreatitis/cholecystitis. Later fibrate trials with gemfibrozil in primary prevention (Helsinki Heart Study)[51] and in secondary prevention patients with low HDL-C (<0.95 mmol l^{-1}) (Veterans Administration-HDL Intervention Trial)[52] showed reductions in cardiovascular events. Data with bezafibrate in the Bezafibrate Infarct Prevention (BIP) study[53] showed a non-significant slight reduction in events concentrated in a high triglyceride group (>2.3 mmol l^{-1}) though this was not reproduced in the patients with peripheral vascular disease in the Northwick Park Study. Fenofibrate reduced CHD events non-significantly and CVD significantly by 11% in patients with type 2 diabetes in the Fenofibrate Intervention in Event Lowering in Diabetes (FIELD) study.[54] The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study also in 5518 patients with type 2 diabetes of fenofibrate added to baseline statin therapy showed a non-significant 8% reduction in CHD events with combination therapy which was, however, safe.[55] A subgroup hinted at a benefit in patients with TG >2.3 mmol l^{-1} and HDL-C <0.88 mmol l^{-1}. Meta-analyses of fibrate trials tend to suggest they are beneficial delivering a 11% reduction in CVD events mostly in smaller non-fatal events in all age groups but at the price of increases in cholecystititis, deep venous thrombosis and pulmonary embolism.[56,57]

Specific prescribing points

No specific dose reduction is advised or necessary for the elderly with fibrates. Fibrate therapy needs to be used with caution in patients with creatinine >150 μmol l^{-1}

(eGFR $< 30\,ml\,min^{-1}$) as these drugs are renally cleared. Atrial fibrillation is common in elderly patients and guidelines recommend the use of warfarin for stroke prevention. Fibrates show a significant interaction with warfarin such that warfarin doses need to be decreased by 33%. Fibrates can interact with other lipid-lowering therapies to increase the risk of rhabdomyolysis. This is a particular problem with gemfibrozil which has a unique mechanism of glucuronidation and this causes increases in free statin acid concentrations (lovastatin, simvastatin) as well as causing problems with other drugs (e.g. pioglitazone). Gemfibrozil is not recommended to be used in combination therapy (especially statins) for any lipid disorder.[58,59]

Omega-3 fatty acids

Omega-3 fatty acids reduce TG by 20–25% at high doses.[60] The active components are docosahexaenoic acid (DHA) and eicosapentenoic acid (EPA). Epidemiological studies show a progressive reduction in events with fish intake, the greatest effects being seen with minimal intake as opposed to none.[61,62] At moderate doses omega-3 fatty acids have proportionally lesser effects but seem to reduce cardiovascular events especially sudden cardiac death. They can be used in monotherapy or combination therapy with any lipid-lowering drug. The endpoint evidence with omega-3 fatty acids is controversial. In the GISSI-Prevention study (DHA/EPA)[63] and DART-1 (fish oil capsules) studies they reduced CHD events by 13–25% but in the DART-2 study an increase in CVD events was seen. More recently in the Japanese Eicosapentaenoic Lipid Intervention Study (JELIS)[64] 1 g EPA reduced CVD events by 22% in a predominantly female, mostly primary prevention Japanese population with raised LDL-C and a high fish intake. The benefits, however, were concentrated in men and those with prior CHD. The second arm of the GISSI heart failure trial (GISSI-HF)[65] in grade 2–3 heart failure showed that 1 g EPA reduced cardiovascular events and death or heart failure admission by 9% with a number need to treat of 44.

Specific prescribing points

Omega-3 fatty acids have few significant drug interactions but can cause gastrointestinal disturbance and bloating. They may be associated with weight gain if given in preparations that require taking multiple capsules – usually less pure forms of DHA-EPA.

HDL-cholesterol

The inverse relationship between HDL-C levels and atherosclerotic CVD provides the epidemiological basis for the widely accepted hypothesis that HDL is atheroprotective. Based on this epidemiological data, HDL-C measurement forms part of routine CVD risk prediction tools. However, the biology of HDL is more complex than LDL and a single measurement is not necessarily a guide to HDL fluxes. Thus some HDL-raising therapies such as hormone replacement therapy or with a specific cholesterol ester transfer protein inhibitor (CETPi) (torcetrapib) have not reduced CVD events but showed increases while others associated with reduced HDL levels (e.g. apo A1 Milano infusion) show decreases in atheroma burden. The meta-analyses of HDL do show some benefits but rely heavily on the niacin trials as other agents have modest effects.[66] Guidelines are disparate when it comes to treatment targets for HDL-C. An international consensus exists that HDL-C should be $>1\,mmol\,l^{-1}$.[67] International guidelines state that low HDL-C is in indicator of increased CVD risk but argue that there is no specific treatment for HDL-C as it is only altered modestly, and not independently of changes in other lipid parameters, in the clinical trials.

Niacin

Nicotinic acid (niacin) is used to raise HDL-C and reduce TG. It raises HDL-C by 10–25%, reduces TG by 20–40%, and reduces LDL-C by 10–20% depending on the dose. It can also reduce lipoprotein (a) levels by 10–25%.[68] There is endpoint evidence when the immediate release formulation used a 3 g/day in the Coronary Drug Project where it reduced CHD events by 22%.[69] In subsequent studies niacin added to statins reduced rates of atherosclerosis progression in coronary (HDL Atherosclerosis Treatment Study; HATS)[70] and carotid arteries (Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol; ARBITER-2)[71] even compared to ezetimibe (ARBITER-6).[72] Endpoint studies of niacin added to optimized LDL-C-lowering therapies are underway in patients with dyslipidaemia and CHD (AIM-HIGH)[73] or mixed secondary prevention and diabetes population (Heart Protection Study-2; treatment of HDL to reduce the incidence of cardiovascular events; HPS2-THRIVE[74]). In the underpowered AIM-HIGH study no benefit was seen with adding niacin to statin on CVD events in patients optimized to LDL-C $< 2\,mmol\,L^{-1}$ both prior to and post-randomization.[73] Given the problems with flushing with the immediate release form a modified release formulation (up to 2 g per day) or one co-formulated with the prostaglandin D2 type 1 receptor antagonist flush suppressant (laropiprant) are commonly used these days. These have similar lipid-lowering efficacy but lesser rates of flushing compared to immediate release niacin.

Specific prescribing points

No specific dose reduction is advised or necessary for the elderly with niacin. Niacin needs to be used with caution in

Y, Young; E, Elderly

patients with creatinine >150 μmol l^{-1} (eGFR<30 ml min^{-1}) as this drug is renally cleared. Niacin interacts with warfarin such that warfarin doses need to be decreased by 20%. It can interact with other lipid-lowering therapies to increase the risk of rhabdomyolysis but the effect is less than with statin or fibrate monotherapy. The principal side effect of nicotinic acid is facial flushing. This can extend beyond erythema to a burning sensation. Though spectacular this is not a serious side effect. It occurs in 80% of patients commencing niacin therapy and the frequency and intensity of flushes habituate with time. Flushing can be decreased by slow dose titration, concurrent aspirin therapy (150 mg) or by indomethacin (200 mg) except if laropiprant is used and by slowing absorption using a snack.

Niacin has variable effects on glycaemic control in diabetes.[75] In most patients it has no or a transient effect though in some patients increases of up to 1 mmol l^{-1} in glucose (0.5% in HbA1c) are seen. Transient increases in bilirubin and transaminases are rarer with nicotinic acid than with other lipid-lowering agents. Myalgia occurs in 0.1% of patients on niacin and is not associated with any change in CK. Again often it is self-limiting but if symptoms persist than the therapy should be changed to another drug class. Myositis (raised CK, muscle pain) and rhabdomyolysis (CK > × 20 ULN; muscle pain; myoglobinuria) are very rare side effects of niacin therapy. The risk factors for rhabdomyolysis are similar to those described for statins.

Patients older than 80 years

Very little trial evidence exists for individuals older than 80 years. Ever since the early landmark statin trials such as 4S, CARE and LIPID excluded patients older than 75 years (<70 years for 4S) there has been a paucity of data on the older elderly. The PROSPER trial, which was specifically designed to evaluate statin therapy in the elderly, included patients aged 70–82 years and the mean age was 75 years.[30] The majority of patients were, however, younger than 80 years. This randomized placebo-controlled trial extended the treatment strategy already employed to younger individuals at the time to older individuals and confirmed the suggested benefits from subgroup analysis of the earlier studies. The question of whether the elderly will benefit from primary statin intervention was answered by the recent JUPITER study where 5644 patients were aged >70 years.[32] These two recent studies confirm the benefit of statins in older individuals and suggest the benefit to those older than 80 years. A recent meta-analysis of 10 randomized controlled trials which assessed the benefits of statins in people without established cardiovascular disease but with cardiovascular risk factors found that the benefits were similar irrespective of age group (younger vs. individuals older than 65 years).[23] Little compelling trial evidence for lipid lowering in individuals older than 80 years is therefore available. However, the data available in the elderly suggests that the benefit demonstrated should extend to those older than 80 years.

Conclusion

Any clinical treatment decision requires consideration of the benefit to risk ratio. As is the case with cardiovascular risk estimation, this remains an inexact science. Statins have revolutionized preventative cardiovascular medicine and their benefits are undisputed following primary and secondary intervention trials which have now included a significant proportion of older individuals. The initiation of lipid-lowering therapy needs to be considered in the context of other CVD risk factors as CVD is multifactorial in origin with clustering of risk factors that have a multiplicative effect on CVD risk. Therefore, total cardiovascular risk management which includes factors such as lifestyle modification and blood pressure management are required in order to maximize cardiovascular risk reduction. Modifying lipids is only one of the essential components of this approach. When deciding on a therapeutic treatment option, clinicians have to weigh up the envisaged benefits against the potential detriment. Clinical acumen is therefore paramount when making a treatment decision in the elderly as these factors need to be considered.

CHAPTER 39

Hypotension

Suraj Alakkassery
Saint Louis University Medical Center, St Louis, MO, USA

Hypotension is classically defined as drop in systolic blood pressure (BP) below 90 mmHg, producing symptoms of hypoperfusion to various organs. Although generally accepted, this number is arbitrary and many people with sustained hypertension or the elderly may become symptomatic at higher BPs. The body's autoregulatory mechanism prevents a significant fall in BP so as to maintain adequate perfusion of vital organs and their proper functioning. Such compensations are very fast and individuals are generally asymptomatic. Symptoms may develop if the BP drops below the range of autoregulation or if there is a delay in initiation or disruption of the regulatory mechanism. Hypotension is significant only if associated with symptoms or in the presence of a secondary condition that, if not controlled, will worsen hypotension and produce symptoms.

Hypotension when symptomatic is never physiological and is always secondary to an underlying cause. Hypotension is associated with many conditions, such as hypovolaemia (secondary to haemorrhage, severe diarrhoea, etc.), sepsis, anaphylaxis, tachycardia, bradycardia, valvular abnormality, tamponade, myocardial ischaemia, cardiomyopathy, pulmonary embolism, pneumothorax, adrenal insufficiency or side effects/toxicity of drugs. Symptoms are related to reduced perfusion to various organs – brain (dizziness, lightheadedness, blurry vision, syncope); skin (cold extremities); heart (tachycardia, palpitations, angina); kidneys (low urine output, renal failure); or gut (nausea, vomiting) – in addition to a general feeling of lethargy and generalized weakness. Symptoms persist until the underlying causes are corrected. Although these causes can affect any age group, outcome is poorer in the elderly.

There are two conditions that classically affect the elderly population – post-prandial hypotension (PPH) and orthostatic hypotension (OH) – producing a symptomatic fall in BP after eating and standing, respectively. These are transient in nature, typically producing symptoms due to reduced cerebral perfusion – dizziness, lightheadedness, blurry vision, syncope. They rarely last long enough to produce angina or renal failure.

Post-exercise hypotension (PEH) is a transient condition usually seen in hypertensive patients after a bout of exercise.

Orthostatic hypotension

Definition

Orthostatic or postural hypotension (OH) was first described by Bradbury and Eggleston in 1925.[1] OH is diagnosed when there is a reduction of $\geq$20 mmHg in SBP or $\geq$10 mmHg in DBP within 3 min of standing or using an upright tilt table at an angle of at least 60° with or without symptoms.[2] Although the definition is based on a consensus statement and the figures are arbitrary, a more modest drop in BP associated with symptoms is equally important. Delayed orthostatic hypotension (DOH), seen in 54% of patients with OH, is defined as a sustained fall in BP occurring beyond 3 min of standing or an upright tilt table test.[3] Initial orthostatic hypotension (IOH) is defined as a transient decrease of $\geq$40 mmHg SBP and/or $\geq$20 mmHg DBP within 15 s after standing and is associated with symptoms of cerebral hypoperfusion.[4]

OH represents one end of the spectrum of disorders of cardiovascular dysregulation. The spectrum (Figure 39.1) extends from very low to very high BP. The majority of individuals with normal BP are in the middle. At the right end are hypertensive individuals who have elevated BP all the time. Labile hypertensive individuals with BP ranging from 120/80 to 140/90 occupy the borderland between hypertensive and normal population. Individuals on the right side are asymptomatic and are treated to prevent complications in the future. At the left extreme are the individuals with OH. Individuals with 'mild dysautonomias' span the region between the OH and normotensive groups and include people with postural tachycardia syndrome (POTS) and neurally mediated syncope (NMS). Individuals

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

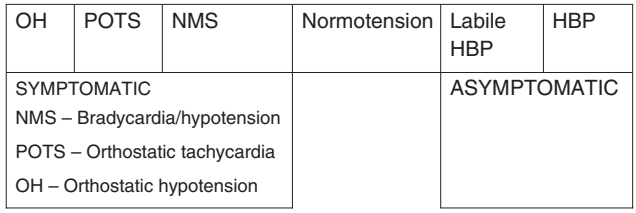

Figure 39.1 Cardiovascular dysregulation. HBP, high blood pressure; NMS, neurally mediated syncope; OH, orthostatic hypotension; POTS, postural tachycardia syndrome. Reproduced with permission from Robertson.[5]

with POTS have orthostatic tachycardia whereas those with NMS have normal pressures in all postures but occasionally have 'fainting' associated with a brief period (usually less than 1 min) of hypotension and/or bradycardia. Individuals on the left side have symptoms that affect quality of life and could be dangerous.[5]

Epidemiology

OH is a transient phenomenon with a high degree of intra-individual and intra-observer variability. OH is common among elderly populations with a varied prevalence of 6–34 % in community-dwelling people over 65 years of age[6–9] and around 20% among ambulatory nursing home residents.[10] Difference in measurement techniques of BP and timing of the measurement after change in position may contribute to the wide variations noted. The prevalence of OH increases with age from 14.8% in subjects aged 65–69 years to 26% in those 85 years and older. Differences in racial distribution have been documented by some, with predominance among whites,[11] whereas others documented no such difference.[12] The incidence of hospitalization secondary to OH increases with age and peaks over the age of 75 years at 233 per 100 000 patients. The median hospital stay is 3 days and the mortality rate is 0.9%.[13] OH is an independent predictor of 4 year all-cause mortality, with an age-adjusted relative risk of 1.8 [95% confidence interval (CI), 1.22–2.65].[14]

Many drugs have been implicated in either inducing or worsening of OH. These include antidepressants (tricyclic antidepressants, older monoamine oxidase inhibitors, serotonin–norepinephrine reuptake inhibitors), antipsychotics (phenothiazines), antihypertensives including diuretics,[15] narcotics and alcohol. Many factors have been linked with increased risk of OH (Table 39.1).

OH is highly prevalent in patients with Parkinson's disease (47%; range, 16–58%). Other neurological diseases with a high prevalence are pure autonomic failure (PAF) (33%), multiple system atrophy (MSA) (26%), idiopathic (autoimmune autonomic neuropathy) (17%) and diabetic autonomic neuropathy (14%). Among the diabetics, although the incidence of autonomic dysfunction is high (54% in type 1 and 73% in type 2), the prevalence of OH is not proportionate (8.4% in type 1 and 7.4% in type 2). OH increases the risk for coronary artery disease and all-cause mortality[17] and is associated with systolic hypertension and low body mass index,[18] stroke[19] and chronic kidney disease.[20]

Mechanism

The adoption of an upright posture by humans posed challenges for the BP regulatory system and through evolution the body developed mechanisms to accommodate the effects of gravity- and activity-mediated fluid shifts. Hormonal factors such as the renin–angiotensin–aldosterone system regulate BP over long periods. Cardiovascular regulation by the autonomic nervous system (ANS) prevents more than a 5–10 mmHg drop in SBP, increases DBP and increases the pulse rate by 10–25 beats per minute (bpm). Sympathetic autonomic dysfunction can result in the development of OH.

In normal individuals, upon standing, roughly 500–800 ml of blood is displaced from the upper part of body to the lower part, primarily to the abdomen and lower extremities. The drop in volume (~30%) reduces the venous return to the heart, leading to a drop in stroke volume and arterial pressure. This causes activation of two sets of pressure receptors: (a) high-pressure centres in the aortic arch and carotid sinuses and (b) low-pressure

Table 39.1 Factors linked with increased risk of orthostatic hypotension. Reproduced with permission from Hajjar.[16]

Physical and behavioural	Biochemical and humoral	Cardiovascular	Medications
Age	Hypokalaemia	Non-dipper status	Psychoactive medications
Low body mass index	Hyponatraemia	Postprandial hypotension	Vasodilators
Smoking	Changes in RAS	Supine elevated BP	Antiparkinsonians
Bed rest		Increased vascular stiffness	
		Decreased baroreceptor sensitivity	

receptors in the heart and lungs. These receptors, present in both the atrium and the ventricles of the heart, produce a tonic inhibitory effect on the sympathoexcitary neurons in cardiovascular areas of the medulla. A fall in venous return diminishes the stretch, decreasing their firing rates, thus resulting in increased sympathetic outflow. This causes a rise in BP by increasing systemic vascular resistance and constriction of splanchnic capacitance vessels. The baroreceptors located in the carotid sinus at the origin of the internal carotid artery transmit the local stretch signals to the nucleus tractus solitarius along the glossopharyngeal nerve. These receptors are responsible for an immediate increase in heart rate in response to the drop in carotid arterial pressure that occurs during an upright tilt test.[5] With ageing, the baroreceptor sensitivity and cardiovascular response to sympathetic stimulation are reduced, predisposing to OH.[14]

Prolonged orthostatic stress (20–30 min of standing) causes a substantial (20% in healthy adults) transcapillary filtration of the fluid shift from the blood into the interstitial space and causes additional peripheral pooling, thus decreasing venous return to the heart with a subsequent decline in BP and cardiac output. A progressive and sustained increase in muscle sympathetic nerve activity in response to prolonged orthostatic stress, together with the renin–angiotensin–aldosterone system, release of vasopressin and attenuation of atrial natriuretic factor, maintain cardiovascular homeostasis in the upright posture. This delayed OH is a consequence of one or more of the following: (a) increased peripheral venous pooling, (b) increased fluid transudation or (c) failure of the neural and humoral mechanisms.

Initial orthostatic hypotension (IOH) differs from typical OH in being transient, occurring immediately (within 15 s) upon standing, and is associated with a much greater fall in BP ($\geq$40 mmHg SBP and/or $\geq$20 mmHg DBP). This can be documented only by continuous beat-to-beat BP monitoring during active standing, hence passive tilt is of no diagnostic value. IOH is thought to be due to a mismatch between cardiac output and vascular resistance. The sudden contraction of the muscles in both the legs and the abdomen produces a compression of resistance and capacitance vessels and together with the local venoarteriolar axon reflex that constricts flow to skin muscle and adipose tissue increases the peripheral vascular resistance, thus causing an initial increase in venous return. The increase in right atrial pressure produces reflex-mediated lowering of the BP. Overcompensation drops BP to the orthostatic range. IOH explains the transient symptoms of cerebral hypoperfusion that develops after waking from an overnight sleep.[4]

Symptoms of OH occur more commonly in the mornings and after meals and is worsened by a hot bath or shower; sudden postural change, fever and alcohol consumption. It may be provoked by exercise, coughing, straining to defecate and hyperventilation. Symptoms are dependent not only on the absolute fall in BP but also on the rate of change and the ability of the cardiovasculature to autoregulate. Symptoms range from light headedness to syncope and include dizziness, weakness, blurry vision, neck pain, headache, angina, disturbed speech, confusion, impaired cognition, fall and syncope. OH is often one aspect of a more generalized disturbance in cardiovascular regulation. In the initial phase, patients tolerate the symptoms as the BP rises during the day. With progression of dysregulation, patients exhibit erratic swings of BP in response to various physiological and pharmacological stresses and develop supine hypertension by the end of the day which can cause nocturnal polyuria by pressure natriuresis.[21,22]

Causes of OH are broadly classified into acute and chronic (Table 39.2). Acute OH develops over a short duration, is more symptomatic and results from acute processes such as sepsis, dehydration or myocardial ischaemia. Chronic OH develops over a longer duration, is usually asymptomatic initially and is mostly secondary to central or peripheral nervous system diseases.[22]

Evaluation and diagnosis

A detailed history and physical examination can identify the cause in about 45% of patients with OH. One must include a comprehensive neurological assessment and look for the signs of other systemic disorders causing OH. To establish the diagnosis of OH, the first step is to determine BP and heart rate after the patient has been quietly supine for at least 5 min and again after 1 and 3 min of standing. If ambulatory BP monitoring is required, measurements before breakfast, after medication, after meals and before bed are most useful. Variations in heart rate in response to OH can provide clues to aetiology: absent or minimal cardio-acceleration (<10 bpm) suggest baroreflex impairment or defect in the autonomic nervous system, tachycardia (>20 bpm) indicates volume depletion and a drop in heart rate suggest vasovagal response.[22]

When symptoms are suggestive of OH but no obvious cause is identified, the patient's medications should be reviewed before other aetiologies are considered and potentially any causative medications should be discontinued if possible. If discontinuation of medication is not possible, consider treating OH pharmacologically. If the medication does not appear to be fully responsible for OH, check the volume status. If dehydrated, hydration may improve symptoms; if euvolumic, look for other non-neurogenic causes. Angina, dyspnoea and oedema suggest cardiac aetiology; vomiting, diarrhoea, burns and diuretic use suggest dehydration; fever may indicate sepsis or other infections. Once medication and non-neurogenic aetiologies have been ruled out, consider neurogenic causes of OH. They are difficult to diagnose and treat and a neurology

Table 39.2 Classification of orthostatic hypotension.

Acute		Chronic
Neurogenic		*Non-neurogenic*
Acute pandysautonomia		Ageing
Acute paraneoplastic autonomic neuropathy		Hypertension
Autoimmune autonomic ganglionopathy (AAG)		
Bezold–Jarisch reflex activation		*Central nervous system*
Botulism		Lewy body dementia
Carotid sinus syncope		Multiple sclerosis
Drug induced/toxic acute autonomic neuropathy		Multiple system atrophy (MSA)
Guillain–Barré syndrome		Myelopathy
Micturition syncope		Olivo-ponto-cerebellar atrophy
Porphyria		Parkinson's disease
		Posterior fossa tumours
Non-neurogenic		Spinal cord tumours
Adrenal crisis	Diarrhoea	Strokes
Anaemia	Haemorrhage	Subacute combined degeneration
Arrhythmias	Mastocytosis	Syringomyelia
Arteriovenous malformation	Myocardial infarction	Transverse myelitis
	Pheochromocytoma	
Burns	Pregnancy	*Peripheral nervous system*
Carcinoid	Sepsis	Alcoholic polyneuropathy
Carditis	Vomiting	Amyloidosis
Congestive heart failure		Autoimmune autonomic neuropathy
Dialysis		Diabetes mellitus
		Dopamine-b-hydroxylase deficiency
Drugs		Familial dysautonomia (Riley–Day syndrome)
ACE inhibitors	Insulin	HIV/AIDS
Alpha receptor blockers	Marijuana	
Barbiturates	Monoamine oxidase inhibitors	Nutritional deficiency (vitamin B_{12}, folate)
Beta-blockers	Nitrates	Paraneoplastic syndrome
Bromocriptine	Opiates	Pure autonomic failure (PAF)
Calcium-channel blockers	Phenothiazines	Tabes dorsalis
Diuretics	Sildenafil	Uraemia
Ethanol	Tricyclic antidepressants	Wernicke–Korsakoff syndrome
Hydralazine	Tizanidine	
	Vincristine	

consultation may be helpful. Laboratory tests should be directed to assist clinical diagnosis and may include haemoglobin, blood urea nitrogen and a creatinine level.[23]

Anhidrosis, miosis and reduced sphincter tone point to autonomic failure. Autonomic function tests are useful to evaluate autonomic disorder and response to therapy. Heart rate variations during deep breathing accesses the function of parasympathetic effect on the heart. Arrhythmia is measured by electrocardiograph with the patient lying supine during 1 min of slow and deep breathing with 5 s inspiration and 7 s expiration. Normally the ratio of the longest expiratory to shortest inspiratory R–R interval is >1.15. The cold pressor test assesses the function of sympathetic effects on BP in response to immersion of the hands in ice-cold water (4° C) for 1 min (Normal: rise of ≥15 mmHg in SBP or ≥10 mmHg in DBP). Age and medications may affect the response to these bedside tests. Other autonomic testing that can be performed includes the quantitative Valsalva manoeuvre, carotid sinus massage and cardiovascular sensitivity to tyramine, phenylephrine or isoproterenol. Measurement of supine and upright plasma levels of norepinephrine and vasopressin can distinguish central from peripheral causes of autonomic failure. In

central causes, the supine norepinephrine level is normal but fails to increase when posture becomes upright and vasopressin is low, whereas in peripheral causes the supine norepinephrine is low and vasopressin is normal.[21,22]

Severe OH with marked supine hypertension, modest gastrointestinal impairment, very low plasma norepinephrine level and no other neurological system involvement suggests pure autonomic failure (PAF). Some, but not all, patients with Parkinson's disease and autonomic failure have OH. Patients with dementia with Lewy bodies have visual hallucinations. Multiple system atrophy (MSA), the severest of dysautonomias, involves not only the autonomic but also the cerebellar and extrapyramidal systems. Magnetic resonance imaging (MRI) shows degenerative changes in putamen. Dopamine b-hydroxylase (DBH) converts dopamine to norepinephrine and the gene is located on chromosome 9q34. DBH deficiency is an extremely rare disorder. These patients have severe OH, exercise intolerance, ptosis and retrograde ejaculation. These patients lack norepinephrine in their neurons and instead have dopamine. They respond very well to droxidopa.[5]

Orthostatic hypertension

Some individuals have orthostatic hypertension, that is, an increase rather than a decrease in BP upon standing. More severely affected individuals have rare disorders such as baroreflex failure, mastocytosis, hyperadrenergic POTS or pheochromocytoma.[5]

Prevention and treatment of OH

The first step in the treatment of OH is diagnosis and management of underlying reversible causes such as anaemia and hypovolaemia. Non-pharmacological intervention is attempted before pharmacological treatment.

Non-pharmacological intervention[21,24]

1 Educating patient and family to avoid any potential aggravating factors such as heat and dehydration.

2 Increase intake of salt (10–20 g daily) and fluid (1.25–2.5 l daily) if there are no contraindications such as CHF.

3 Eat smaller and more frequent meals.

4 Avoid alcohol, prolonged standing, large meals, strenuous exercise, hyperventilation and straining during urination or defecation.

5 If possible, avoid medications known to cause OH.

6 Elevate the head end of bed while sleeping to reduce nocturia, supine hypertension and sudden pooling of blood when rising in the morning.

7 Rise slowly from supine to sitting to standing position.

8 Drinking two cups (500 ml) of water 30 min before rising will raise SBP >20 mmHg for 2 h.

9 Use compression stockings and an abdominal binder to minimize venous pooling.

10 Dorsiflex feet several times before standing.

11 For deconditioning – utilize exercise such as swimming or recumbent biking.

12 Physical counter-manoeuvres involve isometric contraction of muscles below the waist for 30 s at a time. Specific manoeuvres include toe raising, leg crossing and contraction, bending at the waist, leg elevation and slow marching in place.

Pharmacological treatment

When non-pharmacological interventions fail, medications should be tried to control the symptoms. The available medications are summarized below.

Fludrocortisone is a mineralocorticoid with minimal glucocorticoid effect. It expands blood volume by salt retention. The starting dose is 0.1 mg per day with increments of 0.1 mg every week until a maximum dose of 1 mg is reached or trace pedal oedema develops. Common side effects are headache, hypokalaemia, heart failure and supine hypertension.[22]

Midodrine (α_1-agonist), a prodrug, is converted into active desglymidodrine. It is well tolerated and increases the SBP by an average of 22 mmHg. It stimulates both arterial and venous systems without direct CNS or cardiac effects and does not increase heart rate. It is useful in PAF and diabetic neuropathy. The starting dose is 2.5 mg three times per day with increments of 2.5 mg weekly to a maximum dose of 10 mg three times per day. Side effects are piloerection, pruritus, urinary hesitancy and retention in males. This medication is contraindicated in patients with coronary heart disease, heart failure, urinary retention, thyrotoxicosis and acute renal failure[21]

DL- and L-dihydroxyphenylserine (DOPS) are synthetic, non-physiological, norepinephrine precursors that are decarboxylated by the ubiquitous L-amino acid decarboxylase to norepinephrine. Of the four stereoisomers, only L-*threo*-DOPS is pharmacologically active. Since the conversion of DOPS to norepinephrine bypasses the dopamine b-hydroxylation step of catecholamine synthesis, DOPS is the ideal therapeutic agent for patients with dopamine b-hydroxylase deficiency since such individuals are unable to synthesize norepinephrine and epinephrine in the central and peripheral nervous system. This agent may also be of benefit in patients with familial amyloid polyneuropathy, Parkinson's disease, multiple system atrophy and pure autonomic failure.[25]

Pyridostigmine is a cholinesterase inhibitor. As it improves ganglionic neurotransmission in the sympathetic baroreflex pathway that is activated during standing, it improves OH without worsening supine hypertension. The starting dose is 30 mg two or three times per day and the maximum dose is 60 mg three times per day. Common side effects are abdominal colic and diarrhoea.[24]

Recombinant human erythropoietin increases BP by 10 mmHg and improves orthostatic tolerance, especially dizziness in patients with anaemia that often occurs in autonomic failure. The mechanism of increase in BP, although unknown, is not believed to be due to an increase in blood volume or viscosity. The dose is 25–75 U kg^{-1} subcutaneously three times per week. It is well tolerated.[21]

NSAIDs (non-steroidal anti-inflammatory drugs) are added to fludrocortisones to control smooth muscle relaxation and to increase peripheral resistance. They possibly work by inhibiting prostaglandin synthesis, particularly prostaglandin E. The indomethacin dose is 75–100 mg per day. Side effects include gastrointestinal toxicity, renal toxicity and worsening of heart failure.[26]

Indications for referral to a specialist

Geriatric consultation should be sought for frail elderly patients and those with multiple comorbid conditions. A cardiology referral is indicated for uncontrolled supine hypertension, severe heart failure and recent arrhythmia. A neurologist can be consulted for specialized autonomic testing or progressive autonomic failure.[22]

Postprandial hypotension

Definition

A postprandial fall in BP was first observed and reported in 1935 by Gladstone in a hypertensive patient and in 1953 by Smirk in patients with autonomic failure. Kjartan Seyer-Hansen in 1977 recognized postprandial hypotension as a clinical problem in a patient with Parkinson's disease.[27,28]

Epidemiology

Postprandial hypotension (PPH) is defined as a drop in systolic BP of ≥20 mmHg within 2 h after a meal or a drop of SBP from ≥100 mmHg pre-meal to below 90 mmHg within 2 h after a meal.[28]

PPH is common in elderly individuals. The prevalence of PPH varies depending on the risk group: 24–36% among nursing home residents, 50% in elderly patients with syncope and 67% in hospitalized geriatric patients. The prevalence is higher in elderly patients with autonomic failure, diabetes mellitus, hypertension, Parkinson's disease and end-stage renal disease on dialysis.[29] Hypertensive patients with PPH have a higher prevalence of asymptomatic cerebrovascular damage than those without PPH (83 versus 44%), as evidenced by a higher number of lacunae and leukoaraiosis on MRI of the brain.[30] PPH is associated with a higher incidence of falls, syncope, new coronary events, new stroke and total mortality in the elderly population.[31] PPH is not associated with OH but the two can be additive.[32]

Risk factors

Although the aetiology of PPH is poorly defined, various risk factors have been identified that influence the magnitude of a postprandial fall in BP. These include meal composition, temperature, volume and time of meal ingestion, medications and illnesses affecting autonomic nerve function.

In healthy elders, isocaloric and isovolaemic intraduodenal infusion of glucose, fat and protein reduce SBP and increase heart rate and splanchnic blood flow by similar magnitudes but the onset is earlier with glucose. The slowing of gastric emptying and the stimulation of gastrointestinal hormone release by oral fat and protein are mediated by fatty acids and amino acids, respectively. This could be the possible reason for the relative latency in the response. A warm (50° C) meal but not cold (5° C) reduces postprandial BP. Medications, especially psychotropic, cardiovascular and diuretic drugs, when administered with a meal can potentiate PPH.[31,33–35]

Pathophysiology

Age-related illness and unhealthy ageing cause PPH. The pathophysiology of PPH is poorly understood and is multifactorial. Factors include splanchnic blood flow, gastric distension, small intestinal nutrient delivery and neural and hormonal mechanisms.

PPH appears to be secondary to inadequate cardiovascular adjustment for the normal postprandial reduction in BP. Following a meal there is a doubling of superior mesenteric arterial flow. In healthy adults, BP is maintained by an increase in heart rate, forearm vascular resistance, cardiac index and sympathetic activity. Patients with PPH develop a postprandial decline in BP and systemic vascular resistance without a change in forearm vascular resistance, reduction in left ventricular end diastolic volume and poor sympathetic response.[36] Also, in healthy adults, gastric distension attenuates PPH by increasing BP and heart rate – 'gastrovascular reflex'. This reflex is reduced in elderly people with PPH. Muscle nerve sympathetic activity response to an oral glucose load and heart rate spectral analysis showed a blunted increase in sympathetic activity associated with the intake of a meal in elderly patients with PPH compared with young adults. A 200% increase in sympathetic activity would be needed to prevent PPH.[29]

The nitric oxide (NO) synthase inhibitor N^G-nitro-L-arginine methyl ester (L-NAME) attenuated PPH with

minimal effect on gastric emptying, suggesting the role of NO in development of PPH.[37]

Various vasoactive peptides released from the small intestine in response to the ingestion of food have been implicated in PPH and include calcitonin gene-related peptide (CGRP) and glucagon-like peptide-1 (GLP-1). CGRP levels increase following a meal and this increase is associated with the reduction of BP and pathogenesis of postprandial hypotension.[38] GLP-1 released from 'L-cells' in the small intestine is associated with acarbose in attenuation of hypotensive response to sucrose and slows gastric emptying.[39] Failure of intravenous glucose, a potent stimulus to insulin secretion, to affect BP in the elderly and that PPH occurs in patients with type 1 diabetes, who are by definition insulin deficient; argue against the major role of insulin in PPH. Plasma levels of VIP and substance-P, known vasodilators, are not affected by oral glucose.

Clinical features and diagnosis

Symptoms of PPH are due to cerebral hypoperfusion and manifest as dizziness, light-headedness, weakness, fall or syncope after a meal. Patients may sometimes present with chest pain or dyspnoea. PPH is suspected in any elderly person presenting with the above complaints especially in patients with autonomic failure, diabetes mellitus, Parkinson's disease or end-stage renal disease. Ambulatory BP can be monitored to include a major meal along with continued BP monitoring for at least 2 h after the meal. In admitted patients, measuring BP every 10 min starting 15 min before until 60 min after finishing breakfast utilizing a sphygmomanometer can detect about 70% of patients with PPH. This has been suggested by some as a practical and patient-friendly way to diagnose PPH.[40]

Treatment

Non-pharmacological interventions

1 Education of patients about the risk of falling after meals.
2 Lie recumbent and avoid a prolonged sitting or standing posture after meals.
3 Discontinue potential medication.
4 Drink water before meals.
5 Reduce carbohydrate consumption.
6 Eat smaller, more frequent meals.
7 Liberal salt and water intake.
8 Avoid alcoholic beverages.

Pharmacological treatment[28,29,39,41]

Acarbose, caffeine, guar and octreotide are the most frequently used medications for PPH.

Caffeine, an adenosine receptor antagonist, may ameliorate PPH. Dosage is individualized and can be titrated from 60 to 200 mg orally before meals.

Guar gum is derived from the guar bean and acts as a bulking agent. It prevents PPH by slowing glucose absorption. The dose is 4 g orally before meals. Side effects include abdominal pain, diarrhoea and flatulence.

Octreotide, a somatostatin analogue, reduces PPH most likely by increasing splanchnic and peripheral vascular resistance. The dose is a 50μg subcutaneous injection 30 min before meals. Side effects include abdominal pain, QT prolongation and pain at injection site.

Other medications that have been evaluated for treatment include the combination of denopamine (a β_1-agonist) and midodrine (but not as monotherapy); vasopressin and indomethacin for attenuation of PPH. Cimetidine, dihydroergotamine and diphenhydramine failed to show an effect on PPH.

α-Glucosidase inhibitors such as acarbose, voglibose and miglitol act by inhibiting carbohydrate digestion at the level of the brush border in the small intestine. Their effect is secondary to alterations in circulating vasodilators and gut peptides secretion. Specifically, an increase in glucagon-like peptide I is thought to slow gastric emptying, thus inhibiting PPH. The dose is 100 mg of acarbose or 200μg of voglibose orally before meals. Miglitol can be used at 25 mg with the first bite of the meal. Side effects include diarrhoea and flatulence.

Post-exercise hypotension (PEH)

In 1897, Hill documented PEH during the 90 min following a 400 yard dash.[42] In 1971, Groom reported a consistent decrease in systolic and diastolic BP in runners immediately after running at an estimated speed of 6 mph for more than 4 h.[43] It was only after Fitzgerald's report in 1981 of a personal observation that jogging for 25 min decreased labile pressure to near normal levels that lasted for several hours[44] that the phenomenon of PEH gained importance as a clinical entity.

Definition

Post-exercise hypotension (PEH) is a term used to describe the transient reduction in BP following an acute bout of exercise. There are no defined criteria for the magnitude and duration of this decrease in BP post-exercise to diagnose PEH. Eliciting the phenomenon of PEH by electrical stimulation of muscles instead of actual exercise is called post-stimulation hypotension (PSH).[45]

Epidemiology

PEH has been observed in young and middle-aged normotensive people and with patients with borderline and established essential hypertension. PEH lacks gender specificity and occurs in both men and women. PEH does not appear to be correlated with exercise intensity or duration or the amount of exercising muscle mass. The nadir of the PEH response generally occurs within the first 60–70 min of recovery. The average drop in BP in patients with essential hypertension varied from (systolic/diastolic) 11/4 mmHg in 30–90 min post-exercise to 9/4 mmHg between 2 and 3 h to an average of 2.8/1.7 mmHg over 24 h. The average drop in borderline hypertensive patients was 14/9 mmHg and in normotensive patients it was 8/9 mmHg.[45–47] Diurnal variations have been observed in PEH, which is less marked in the morning, probably because the exercise-mediated decrease in peripheral resistance is not as apparent at this time of day.[48]

Although PEH occurs in both normotensive and hypertensive individuals after either resistance or endurance exercise, it is more predictive in hypertensive individuals.[46] In the healthy normotensive population, chronic exercise leads to structural vascular changes that include increased arterial luminal diameter and compliance. Older hypertensive individuals are resistant to alteration due to replacement of elastic fibres by collagen and calcium. PEH also occurs in endurance-trained individuals, probably due to reduced cardiac output. In sedentary men PEH is secondary to vasodilatation, suggesting that exercise training may alter the mechanism but not the magnitude of PEH. As PEH is a function of baseline BP, the magnitude of the fall is expected to be more in hypertensive individuals. The magnitude diminishes with exercise-induced reduction in baseline BP. About 25% of hypertensive individuals called 'non-responders' do not appear to sustain BP reductions after endurance training, suggesting a genetic role in PEH. Meta-analysis of longitudinal studies showed no influence of frequency or intensity of exercise training programmes on the BP-lowering effect.[49]

PEH and initial OH are not predictors of syncope post-exercise even though the inability to maintain BP is a crucial factor.

Syncope post-exercise is a phenomenon seen exclusively after prolonged exercise (~4 h). PEH is seen even after short bouts of exercise and the magnitude is unrelated to the duration of exercise, thus indicating the role of other factors involved in post-exercise syncope.[50]

Clinical implications

If PEH is of sufficient magnitude, it could be sustained and evoked under conditions of normal daily living. Then regular periodic exercise can potentially become a non-pharmacological tool in the management of hypertension. Although some studies have shown a sufficient drop in BP and sustained effect, many others are contradictory. Further studies are needed to determine the dose, timing and type of exercise required for a sustained hypertensive effect.

Key points

- Hypotension is a major problem in older persons, leading to dizziness, falls, syncope, stroke, myocardial infarction and death.
- Orthostatic hypotension can occur immediately on standing or after a few minutes.
- Postprandial hypotension is due to an increase in the vasodilatory peptide calcitonin gene-related peptide.
- Postprandial hypotension can be treated with α_1-glucosidase inhibitors, which increase glucagon-like peptide-1.

Definition and prevalence

Hypertension is a very prevalent disorder affecting about 1 billion people worldwide[1] and, as such, it is the most common modifiable risk factor for conditions such as atherosclerosis, stroke, heart failure, atrial fibrillation, diabetes mellitus, sudden cardiac death, acute aortic syndromes and chronic kidney failure and may cause death and disability in patients of all ages.[2]

It is thought to affect up to 70% of individuals over the age of 65 years. The exact prevalence of hypertension varies with the age, race and the overall health status of the population studied, and also the blood pressure cut-offs points used to define hypertension. Hypertension in elderly patients is a complex cardiovascular disorder that affects women more than men and occurs in essentially all races, ethnic groups and countries. Although it appears to be underdiagnosed in general and particularly among women, minorities and underserved populations, clearly it is also undertreated. Elderly persons are more likely to have hypertension and isolated systolic hypertension (ISH), target organ damage (left ventricular hypertrophy, renal impairment and albuminuria, hypertensive retinopathy) and clinical cardiovascular disease (CVD), to develop new cardiovascular (CV) events and are less likely to have hypertension controlled.

An international consensus exists about the limits of normal values for brachial blood pressure at 140/90 mmHg.[3] All define a blood pressure of 160/100 mmHg as requiring therapeutic intervention and 200/120 mmHg as very high risk requiring immediate management. There is less consensus on the cut-offs for blood pressure measured by other techniques. Many groups are now beginning to recommend the use of ambulatory blood pressure monitoring (ABPM) and the recent UK NICE guidelines have suggested that it has a primary role in the diagnosis of hypertension given its superior predictive value for CVD events compared with rather variable brachial measurements and its ability to counter stress-induced or 'white coat' hypertension.[4]

The US guidelines[5] introduced the concept of pre-hypertension, representing a systolic blood pressure (SBP) of 120–139 mmHg or diastolic blood pressure (DBP)of 80–89 mmHg, previously classified as 'normal' or 'high normal' blood pressure. Other guidelines recognize pre-hypertension as a potential risk factor but stress the role of CVD risk assessment and risk calculation as the primary guide to a requirement for any intervention – lifestyle or therapeutic. Pre-hypertension was introduced, in part, on findings of the Framingham Heart Study (FHS) suggesting that normotensive individuals at age 55 years have a 90% lifetime risk of developing hypertension.[6]

The recommendation was based on the results of 30 worldwide clinical trials conducted in 1997 and a report estimating that the risk of cardiovascular mortality doubles with each 20/10 mmHg rise in blood pressure, starting at levels as low as 115/75 mmHg.[7] In addition, evidence has accumulated which classifies individuals with comorbidities and an SBP >130–139 mmHg as suboptimal. These conditions include heart failure and left ventricular dysfunction, diabetes mellitus, chronic kidney disease and established CVD conditions such as coronary artery disease (CAD), peripheral arterial disease (PAD) and carotid artery disease.

A long standing controversy exists about hypertension in the elderly and some argue that usual definitions of hypertension and target BP levels might not be applicable to the elderly hypertensive population. The higher prevalence of hypertension in the elderly partially reflects the increase in the prevalence of arterial stiffening and thus changes in reflection pressure wave timing. The new generation of hypertension diagnostic devices specifically measure pulse wave reflection, velocity and pulse amplification parameters. There is no consensus on target values or optimal measures for pulse wave diagnostics as yet although all

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

studies show that either directly measured or inferred central blood pressures (ascending aortic arch) are better predictors of outcomes than brachial measurements. As this technology is not widely available, older measures of specific subtypes of hypertension are useful.

Pathophysiology

Blood pressure regulation is a complex process, subject to multiple interacting physiological systems, and also lifestyle and genetic factors. In its simplest conceptualization, the cardiovascular system is governed by Ohm's law, which, when adapted to a haemodynamic system, states that flow (Q) is proportional to the pressure gradient (ΔP) and inversely proportional to the resistance (R) across a conduit.

In terms of the cardiovascular system, BP is the product of cardiac output and vascular resistance. Since cardiac output does not increase with age, hypertension in the elderly is, to a large extent, a result of increased vascular resistance. In combined systolic and diastolic hypertension (SDH), the problem arises at the site of the resistance arterioles, the smaller muscular vessels where 80–90% of arterial resistance occurs. Increased constriction at this level affects both SBP and DBP. In contrast, ISH develops as a result of large arteries that have become less compliant and therefore less able to accommodate volume changes. In young normotensive individuals, large elastic vessels contribute little resistance to blood flow. During systole, the aorta and other large arteries expand to accommodate the stroke volume, which attenuates the rise in intra-arterial pressure. During early diastole, elastic recoil of large arteries sustains forward flow, augmenting the DBP despite runoff into arterial branches. Age-related loss of elasticity increases vascular impedance, resulting in a more rapid rise in blood pressure during systole and to a higher level. The higher peak pressure, coupled with diminished elastic recoil, results in rapid runoff to the periphery, resulting in lower DBP (Figure 40.1). A low DBP is not entirely benign. Since myocardial perfusion occurs during diastole, diastolic hypotension may result in subendocardial ischaemia. While other constituents no doubt factor into the pathogenesis of hypertension, age-related loss of arterial elasticity successfully predicts widening of the pulse pressure (PP), ISH and the plateau in DBP that develop with ageing. Figure 40.1 depicts these changes over the course of a single cardiac cycle. Ageing blood vessels undergo a host of structural and functional changes, resulting in decreased compliance and increased resistance to flow. These changes particularly affect the intima and media of large arteries. With age, elastic fibres progressively decrease in number and elasticity and the collagen matrix increases. This fibrous transformation results in arteriosclerosis and is compounded by calcification and an increase in the number and size of

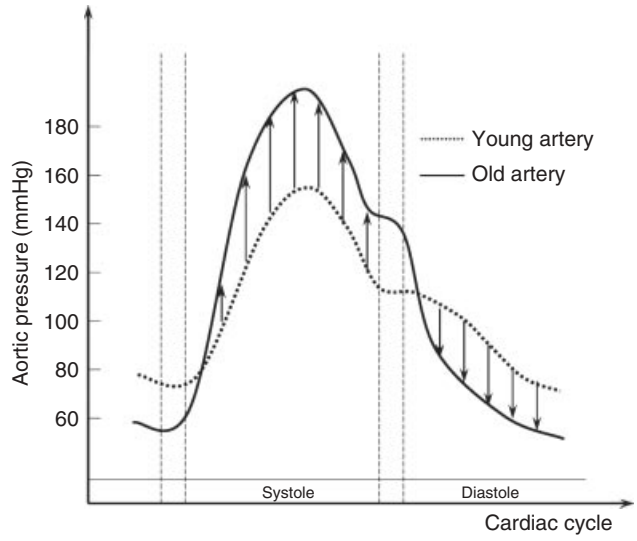

Figure 40.1 Blood pressure changes in an old versus a young artery during a cardiac cycle. The arrows indicate increased pressure during systole and decreased pressure during diastole that older arteries experience due to arteriosclerosis.

vascular smooth muscle cell. The combined effect is a fall in the total cross-sectional area of peripheral vasculature. Furthermore, the dynamic nature of endothelial-derived vasoactive substances that control vascular tone is also affected by age. The delicate balance between vasoconstricting agents (such as endothelin and angiotensin II) and vasodilating agents (such as prostacyclin and nitric oxide) is offset. Nitric oxide (NO), previously termed endothelial-derived relaxing factor (EDRF), is a potent vasodilator that has been extensively studied. An age-associated decline in NO-mediated vasodilatation has been demonstrated.[8] A decreased secretion of NO and also a blunted response to NO have further been documented. Endothelial dysfunction, possibly as a direct effect of elevated peak pressure, inhibits secretion of these compounds.[9] It remains unclear to what extent the imbalance of endothelial-derived vasoactive compounds is a cause or effect of high blood pressure, but impairment of effective vasodilator agents, in the absence of appropriate compensatory mechanisms, will result in increased vascular resistance. The endothelium also secretes a number of factors that act on smooth muscles in an autocrine manner. These include interleukin-1 and insulin-like growth factor. *In vitro*, these influence the migration and proliferation of smooth muscle cells, which in turn increase vascular rigidity and decrease lumen size.

Despite increased levels of serum norepinephrine that occur in the elderly, the role of the sympathetic nervous system in the pathogenesis of hypertension appears to be more complex than mere overstimulation. The sympathetic nervous system has little clinical impact on older normotensive subjects, even with increased levels of

serum norepinephrine. This is due to decreased adrenergic receptor function. Downregulation of β-adrenergic inotropic, chronotropic and vasodilatory response, and also α-adrenergic vasoconstrictor response, has been documented in the elderly. With receptor downregulation in the face of increased norepinephrine release, α_1-adrenergic vascular tone is comparable in old and young normotensive subjects. It has been proposed by some experts that older hypertensive subjects have a relatively less degree of suppression of α_1-adrenergic relative to β_2-adrenergic activity[10] and age-related hypertension is in part due to diminishing β-mediated vasodilatation whereas α-mediated vasoconstriction continues relatively unabated. Similar findings have been observed in animal studies. Decreased carotid baroreceptor sensitivity and responsiveness occur with age. Consequently, a larger change in blood pressure is needed to trigger the appropriate compensatory response. The impaired reflex is manifested clinically as wide blood pressure fluctuations in the elderly compared with the young, and also increased susceptibility to clinically significant orthostatic hypotension and postprandial hypotension. The age-related baroreceptor reflex dysfunction is not necessarily limited to hypertensive persons alone, but decreased vascular distensibility at the carotid sinus, as seen in hypertensive subjects, is likely to play a central role in the process and many antihypertensive medications will further exacerbate the condition.

Ageing kidneys undergo multiple changes, which may affect blood pressure regulation. A sodium load is secreted less rapidly and less completely as renal function declines. Similarly, the elderly are more sensitive to free water depletion or repletion than the young. Angiotensin II promotes sodium reabsorption from the distal tubules directly and indirectly through aldosterone release and stimulation of the autonomic nervous system. The renin–aldosterone–angiotensin axis, however, is less responsive with age. There is a decrease in serum renin levels and activity, which may be the result of decreased functional glomeruli and a decrease in serum angiotensin II and aldosterone levels. The net effect of these changes is towards sodium retention. Free water retention ensues to maintain sodium homeostasis. It has been suggested that chronic extracellular volume expansion due to sodium and water retention leads to increased vascular resistance through the mechanism of autoregulation of organ blood flow. These observations are consistent with the high prevalence of salt sensitivity among older hypertensive individuals. Atrial natriuretic peptide (ANP) is released primarily from the atria in response to stretch due to volume overload. ANP acts both as a peripheral vasodilator and as a natriuretic/diuretic hormone. Brain natriuretic peptide (BNP) was initially identified in the brain but is also present in the ventricles. It is homologous to ANP and its serum concentration is normally approximately one-fifth that of ANP. In heart failure, levels of BNP can increase dramatically. A simple serum assay has been devised for the measurement of BNP and is now commonly used in the management of heart failure.

Several variants of ANP and related hormones have been identified. Of note is a hormone with a digitalis-like effect. This putative hormone appears to be ouabain or an isomer of ouabain and binds the digitalis receptor on the sodium potassium adenosine triphosphatase pump (Na-K-ATPase) in an inhibitory manner. This hormone differs from ANP in that it increases vascular resistance. A proposed mechanism is that the Na-K-ATPase inhibitor facilitates renal sodium excretion but also diminishes intracellular sodium release, resulting in increased concentrations of sodium in smooth muscle cells. Passive sodium–calcium exchange subsequently results in increased intracellular calcium and, therefore, vascular tone.[11,12] These mechanisms may explain the high incidence of salt sensitivity in subjects with essential hypertension, but more investigation is needed to determine fully the role that this mechanism plays in the pathogenesis of hypertension. Not all the aforementioned mechanisms have conclusively been shown to be age-related changes, independent of disease and lifestyle influences. In some populations, the incidence of hypertension changes little with age and the overall prevalence is low. To some extent, hypertension is an affliction of modern society. Until very recent history, humans employed the hunter–gatherer lifestyle for survival. Such 'primitive' peoples experienced vigorous daily physical activity and a diet rich in potassium and fibre and low in fat and sodium. Patterns of Nature led to periods of diminished food intake and obesity was virtually unheard of in these communities. Modern-day populations who enjoy relatively low incidences of hypertension tend to practice daily routines that more closely resemble the primitive lifestyle of old, particularly with regard to nutrition and physical activity. The blood pressure profiles of immigrants from such regions, however, may change over the course of a few generations to resemble that of the host community. The overabundance of foods rich in sodium, calories and fat in westernized societies, coupled with sedentary levels of activity, without doubt contributes to the epidemic of obesity and hypertension. With the abundance of effective medications available for the treatment of hypertension, these potentially modifiable risk factors receive far less attention than they deserve. Finally, there is a clear genetic role in the development of hypertension in some families. Such individuals are likely to develop hypertension early in life. The genetic contribution is complex, involves multiple interacting genes and is not fully understood at this time. Genetic factors are perhaps the strongest non-modifiable risk factor for hypertension.

Related clinical entities

Isolated systolic hypertension (ISH)

SBP rises gradually throughout adult life, whereas DBP peaks and plateaus in late middle-age, declining slightly thereafter. Therefore, the proportion of hypertensive patients with ISH increases with age, from 65% of patients with hypertension older than 60 years of age and over 90% in patients older than 70 years of age. The prevalence of ISH is higher in women than in men, whereas the proportion of hypertension attributable to ISH in older adults is similar across racial and ethnic groups. Of note, in decades past, the apparently inexorable rise in SBP with increasing age fostered the view that this was an adaptive response essential to support organ perfusion and an empirical formula '100 + age' was often used to estimate the 'appropriate' SBP. However, data from the FHS and other epidemiological investigations provide compelling evidence that SBP is a strong independent risk factor for incident CV events in all decades of life.[13] Hence the above formula should be discarded. ISH actually represents the outcome of hyaline change and increased arteriolar tone in the microvasculature with increased collagen deposition, loss of elastin and changes in endothelial function. Changes in endothelial function are driven by classical CV risk factors and some advocate its measurement as a surrogate for atherosclerotic disease burden. ISH also closely corresponds to increased wave reflection and studies of pulse wave parameters including differences between central and peripheral blood pressure may have prognostic and therapeutic consequences.[14]

Pulse pressure

After age 70 years, diastolic hypertension accounts for less than 10% of all patients with hypertension. In addition, the relationship between DBP and CV risk is bimodal in older individuals, with DBPs of greater than 90 mmHg associated with similar increased risk as that associated with DBPs lower than about 70 mmHg.[15] As a result, at any given level of SBP, CAD risk increases as DBP decreases.[16,17] An important implication of this observation is that pulse pressure (i.e. difference between SBP and DBP), which increases with age and is a measure of the degree of age-related vascular stiffness, emerges as a potent risk factor for CAD events in older individuals. Pulse pressure has been identified as a stronger risk factor than SBP, DBP or mean pressure in older adults in some studies.[16,17] In the FHS, with increasing age, there was a gradual shift from DBP to SBP and then to PP as the strongest predictor of CAD risk. In patients younger than 50 years of age, DBP was the strongest predictor. Age 50–59 years was a transition period when all three BP indexes were comparable predictors, and from 60 to 79 years of age, DBP was negatively related to CAD risk so that PP became superior to SBP.[18] However, a falling DBP in the elderly correlating to an increase in PP is a bad prognostic sign.

Special populations

From the standpoint of epidemiology, pathophysiology and treatment, there are important subgroups with distinctive characteristics, including elderly women, blacks, Hispanics and Asians, that require additional focus. Hypertension prevalence is less in women than in men until 45 years of age, is similar in both genders from 45 to 64 years of age and is much higher in women than men older the 65 years of age.[19] Age-adjusted hypertension prevalence, both diagnosed and undiagnosed, from 1999 to 2002 was 78% for older women and only 64% for older men.[20]

Secondary hypertension

Although most hypertension (80–90%) is essential, that is, its pathophysiological cause is unknown, secondary causes of hypertension are being increasingly recognized as contributing to morbidity. Renal artery stenosis (RAS) is more common than is usually thought and is often associated with PAD, especially if associated with a reduction in estimated glomerular filtration rate (eGFR), signs of (micro)albuminuria. Although not contributing directly to hypertension as is the case in severe stenotic disease (>85%), it is a risk factor for angiotensin-converting enzyme inhibitor (ACE-I)/angiotensin-II receptor blocker (ARB)-induced nephrotoxicity. Any patient with these risk factors should have renal function assessed two weeks after starting an ACE-I/ARB or clinicians should be wary of slow progressive decreases in eGFR as a manifestation of RAS. Most endocrine causes of hypertension are rare (phaeochromocytoma, Cushing's disease or Conn's syndrome) but adrenal mineralocorticoid hyperplasia is common.[21] This manifests as aldosteronaemia allied with low renin and its prevalence varies in surveys from 5 to 10% of patients with hypertension. An increased prevalence of low-renin hypertension is found in the elderly, patients with diabetes and West African-derived populations. Most is not caused by adenomas but by generalized adrenal hypertrophy and can be diagnosed by finding a moderately raised aldosterone:renin ratio in a random sample taken in patients not receiving beta-blockade It often responds well to treatment with an aldosterone antagonist.

Resistant hypertension

Most hypertension is treated with polypharmacy as each individual agent reduces blood pressure by about 10%. Resistant hypertension is formally defined as a BP >140/90 mmHg after treatment with three

antihypertensive drugs.[5] Most commonly it is caused by poor compliance with polypharmacy, but other causes include ISH and contributory comorbidities including secondary hypertension and neurological hypertension. This can include anxiety states (see white coat hypertension in the section Clinical assessment and diagnosis, below), but also includes dysregulation of central mechanisms of BP regulation. The commonest cause of central dysregulation is sleep apnoea syndrome, which is often associated with obesity and can be diagnosed by oximetry studies and treated with continuous positive airways pressure maintenance (CPAP) allied commonly with weight loss.[22]

The effect of treating hypertension in the elderly – an overview of clinical trials

Salient features of the pivotal clinical trials discussed below and a summary of their findings are given in Tables 40.1 and 40.2.

The benefit of treating hypertension in the elderly was evident as early as 1967. The Veterans Administration Cooperative study, which was published in three parts between 1967 and 1972, documented the benefit of treating severe[23] and mild[24] diastolic hypertension. In subjects over the age of 60 years, a 70% reduction in the incidence of stroke and 52% reduction in cardiovascular events were observed in the treatment group.[25] Similar favourable outcomes were documented in the Australian Therapeutic Trial in Hypertension, where a 33% reduction in stroke and 18% reduction in CAD were noted in the treated subgroup age 60–69 years, compared with the placebo group.[26] In the Hypertension Detection and Follow-up Program, there was a 17% reduction in all-cause mortality after a 5 year follow-up period of patients aged 60–69 years, treated for mild diastolic hypertension.[27] These and other early studies, however, primarily treated diastolic hypertension and had relatively few participants in the geriatric age group. The subgroup 60–75 years of age in the Veterans Administration Cooperative Study represented only 20% of total enrolment. Treatment of hypertension in the elderly remained tentative and debatable until the mid-1980s, when multiple randomized trials gave credence to the benefits and safety of aggressive BP management even in advanced age. The SHEP trial addressed ISH in subjects ≥60 years of age.[28] The treatment group received chlorthalidone, with the addition of atenolol if needed, to achieve the target BP. The impact of treatment was greatest in reducing the incident of stroke by 36% and CV events by 32%. The reduction in coronary events was 27%, but not statistically significant. Comparable results were noted in the Systolic Hypertension in Europe (Syst-Eur) trial, which also studied subjects aged 60 years or older with primarily ISH.[29] Treatment was initiated with nitrendipine, with the addition of enalapril and hydrochlorothiazide if necessary. Reductions in stroke by 42%, CV events by 31% and coronary events by 26% were noted in the treatment group compared with placebo, all of which were significant. In both studies, the reductions in CV mortality (SHEP 20%, Syst-Eur 27%) and total mortality (SHEP 13%, Syst-Eur 14%) were similar and non-significant. The Systolic Hypertension in China (Syst-China) trial[30] paralleled the Syst-Eur trial and had similar enrolment criteria, but used captopril as a second-line intervention. Treatment outcome results were in line with the previous two studies, with the exception of larger and statistically significant decreases in total and CV mortality (39% in both cases), possibly due to the slightly younger age of the participants. Similarities in trial design and enrolment criteria of these three studies lend themselves to pooling analysis. When combined, reductions in strokes

Table 40.1 Characteristics of treatment trials that predominantly involved older hypertensive individuals. Trial acronyms and references are found in the body of the text.

[a] Statistically significant ($p < 0.05$).

(37%), coronary vascular disease (25%), CV events (32%), CV mortality (25%) and total mortality (17%) were noted in the treatment group compared with placebo, all of which were statistically significant.[31]

Other studies addressed systolic–diastolic hypertension. The Swedish Trial in Older Patients with Hypertension (STOP-Hypertension) compared beta-blockers and thiazide diuretics with placebo, in patients 70–84 years of age (average 76 years) with a mean BP of 195/102 mmHg.[32] In the treatment group, significant reductions in the incidence of stroke (45%), CV events (40%) and total mortality (43%) were documented after an average 25 month follow-up period. Myocardial infarctions were reduced by only 12%, which was not statistically significant. These findings were somewhat at odds with those of the European Working Party on High Blood Pressure in the Elderly (EWPHE) trial. The baseline SBP and DBP in the EWPHE trial ranged between 160–239 and 90–119 mmHg, respectively (average 182/101 mmHg) and treatment was with hydrochlorothiazide–triamterene for an average follow-up period of 4.6 years.[33] Unlike the STOP-Hypertension trial, the 9% decrease in total mortality and 32% decrease in stroke were not statistically significant, whereas the 47% decline in myocardial infarctions was. The significant 38% decrease in CV events was similar to that found in the STOP-Hypertension trial (40%). The Medical Research Council (MRC) Working Party trial studied both systolic and diastolic hypertension and randomized participants aged 65–74 years to a diuretic or beta-blocker treatment group or to placebo.[34] After an average follow-up period of 5.8 years, the mean BPs in the two treatment groups were similar and significantly lower than in the placebo group. The combined treatment group had a statistically significant 25% reduction in stroke and 17% reduction in CV events. The 19% reduction in coronary events, 9% reduction in CV mortality and 3% reduction in total mortality were not significant. However, when treatment groups were analysed separately, stroke and cardiac events were significantly lower in the diuretic group by 31 and 44%, respectively. The beta-blocker treatment group showed no such reduction in these endpoints. It is not surprising that outcome is related not only to risk stratification but also to the choice of antihypertensive agent. From the above trials, however, it appears that treatment of hypertension in the elderly generally has a greater impact on stroke reduction than coronary and CV event reduction and that this effect is independent of drug choice. This pattern is seen in other trials. Both the Shanghai Trial of Nifedipine in the Elderly (STONE)[35] and the Coope and Warrender Trial[35] showed a statistically significant reduction in stroke (57 and 42%, respectively) and a non-significant reduction in coronary heart disease (CHD) (6 and 3%, respectively). Neither demonstrated a sizable change in CV mortality, but the STONE trial revealed a significant 45% decrease in total mortality compared with a non-significant 3% in the Coope and Warrender trial. Variability in treatment outcome among studies is partly due to study design, but the importance of selection criteria in treatment risk/benefit determination, independent of other study parameters, must also be stressed. Subjects with higher initial SBP and wider PP are likely to experience greater treatment benefit, as are those in a higher risk stratum. It is estimated that the reduction in all-cause mortality in the highest risk group is nine times that in the lowest risk group,[37] emphasizing the importance of establishing an individualized treatment plan based on risk stratification, rather than on generalized guidelines *per se*. The above reasoning also introduces the concept of treatment risk, a principle that until recently has largely been overlooked and will be discussed shortly.

Other endpoints have been investigated in more recent studies, notably the relationship between hypertension and cognitive decline or dementia. Data from the dementia project of the Syst-Eur trial show a significantly lower rate of development of dementia in the treatment group,[38] but

the analysis was underpowered and the conclusion difficult to generalize with authority. The Study on Cognition and Prognosis in the Elderly (SCOPE) showed a non-significant 11% reduction in the incidence of cognitive decline in the group treated with candesartan compared with placebo.[39] The investigators concluded that at the very least, there is no evidence supporting a *negative* effect of treating hypertension on cognition in the elderly. The first credible evidence supporting the potential benefit of treating hypertension on dementia came from the Protection Against Recurrent Stroke Study (PROGRESS), whose primary outcome was assessing risk for recurrent stroke.[40] During a 4 year follow-up period, a 12% overall reduction in the risk of dementia was observed with treatment. This finding was not statistically significant. However, when analysed separately, the subgroup with prior stroke at baseline showed a 34% ($p = 0.3$) reduction in dementia risk, whereas the subgroup without prior stroke showed only a 1% change.

For cognitive impairment, a similar pattern was noted, with slightly more favourable results. Severe cognitive decline was defined as a drop of three or more points on the Mini Mental Status Examination (MMSE). The overall risk reduction with treatment was 19% ($p = 0.01$). In the subgroup with prior stroke at baseline, the reduction in the risk of developing severe cognitive decline was 45% ($p > 0.001$), but only 9% (not significant) in the subgroup without prior stroke.

Various meta-analysis reviews have been designed for the purpose of accommodating variability among individual trials or examining smaller subgroups within larger trials. A meta-analysis of nine trials[41] confirmed treatment benefit in the elderly. Reductions in stroke morbidity [odds ratio (RR) = 0.65; 95% CI, 0.55–0.76)], cardiac morbidity (RR = 0.85; 95% CI, 0.73–0.99) and total mortality (RR = 0.88; 95% CI, 0.80–0.97) were noted. Stroke and cardiac mortality individually were also significantly reduced in the treatment group. Another meta-analysis of eight ISH trials included 15 693 subjects.[42] There was a 30% reduction in combined fatal and non-fatal stroke events ($p > 0.0001$), a 26% reduction in combined CV events ($p > 0.0001$) and a 13% reduction in total mortality ($p = 0.02$). In untreated patients, after correcting for regression dilution bias and DBP, the relative hazard rates associated with a 10 mmHg higher baseline SBP were 1.26 ($p = 0.0001$) for total mortality, 1.22 ($p = 0.02$) for stroke, but only 1.07 ($p = 0.37$) for coronary events. Treatment benefit was greatest in men, patients with previous CV complications and those who had larger PPs. DBP was inversely correlated with total mortality, independently of SBP. Treatment effect was also largest in subjects over the age of 70 years, a topic of contention, which will be discussed next.

Despite compelling evidence supporting the benefit of treating hypertension in older persons,[43] the evidence for very old subjects is much less clear.[44–47] 'Very old' is arbitrarily defined as >80 years of age, since at that age the risk/benefit advantage begins to waver. Subjects over the age of 80 years are absent or under-represented in most clinical trials, even though this segment of the population is the fastest growing in the westernized world. The very old also tend to be lumped in the 65-and-over age group, whereas they clearly have diverse and distinct characteristics and data obtained in younger adults cannot instinctively be extrapolated to the very old. As early as 1986, trend analysis of EWPHE data suggested that treatment of hypertension is less effective, or even harmful, above the age of 80 years.[48] Other studies have shown mixed results. The SHEP trial found treatment benefit, particularly in stroke prevention, extending beyond the age of 80 years. In the Syst-Eur analysis, total and CV mortality were significantly lower for the treatment group under the age of 80 years, but not for those aged 80 years or older. The overall RR for CV events in the treatment group from the STOP-Hypertension trial was 0.60, but the benefit decreased with increasing age subgroups and crossed the unity point between the ages of 80 and 85 years. These trials enrolled relatively few very old subjects. A meta-analysis of randomized controlled studies that enrolled subjects older than 80 years of age included 1670 subjects followed for a mean period of 3.5 years.[49] A significant reduction in stroke (34%), CV events (22%) and heart failure (39%) occurred in the treatment group compared with the control group. No benefit in CV death and a non-significant 6% *increase* in all-cause deaths were observed in the treatment group. The trend became stronger when the analysis was limited to five double-blind trials – an 11% ($p = 0.41$) increase in CV mortality in the treatment group and a 14% ($p = 0.05$) increase in total mortality were observed.

Several population-based observational studies have demonstrated an inverse relationship between BP and mortality in the very old. One study[50] enrolled 83% of the population of Temper, Finland, aged 85 years or older ($n = 561$), and a similar study[51] enrolled 94% of the residents of Leiden, The Netherlands, aged 85 years or older ($n = 833$). In both studies, the chance of being alive after 5 years was greatest in those with the highest BP at enrolment. In the Temper study, subjects with SBP ≥200 mmHg at entry had a threefold higher survival rate than those whose SBP was 120–140 mmHg. Similar results were reported in the Helsinki Ageing Study,[52] where it was estimated that the 5 year mortality declined by 10% for every 10 mmHg increase in SBP at enrolment. These and earlier observational studies are limited to correlations and constrained by confounding variables in selection criteria. In the Leiden study, for example, low BP was associated with poor health. After adjusting for health status, the inverse relationship disappeared.

The HYVET study[53]

In the majority of studies to date, benefits in stroke reduction appear related to BP reduction, as a 10 mmHg reduction in SBP was associated with a 20–30% lower risk of stroke in individuals over 70 years of age. Furthermore, there is greater benefit with a greater reduction in BP. It is unclear whether the benefits are related solely to BP reduction or whether there are additional benefits conferred by class of BP medication. Although there was consistent benefit in stroke reduction when drugs were compared with placebo, there was little difference between drug classes.[54] The Hypertension in the Very Elderly Trial (HYVET) was the first interventional controlled trial designed to assess the risk and benefit of treating hypertension specifically in subjects older than 80 years of age.[53] Patients in the aforementioned studies consisted predominantly of the 'early elderly'. In HYVET, patients in the 'late elderly' group (>80 years of age with elevated SBP) were randomized to indapamide, with addition of perindopril if needed or placebo and followed over 2 years. This study showed major benefit in CVD events and a large reduction in new cardiac failure in those older than 80 years of age when treated with an ACE-I–indapamide combination to a target BP of 150/80 mmHg.[53] Patients in the indapamide arm had a 30% risk reduction in fatal or non-fatal stroke ($p = 0.06$). Although there have been consistent benefits in reduction of stroke with antihypertensive therapy in elderly patients, some reports have suggested that these benefits may be offset by an increase in death in treated patients).[49] The HYVET, however, found benefits consistent with a 21% risk reduction (95% CI, 4–35%; $p = 0.02$) of all-cause death in the indapamide arm.[53]

Evidence after HYVET[2]

The results of HYVET[53] modify previous recommendations for patients >80 years of age. In HYVET, 3845 patients >80 years of age with SBP >160 mmHg were randomly assigned to placebo or drug therapy. The latter included a non-thiazide sulfonamide diuretic (indapamide) supplemented by an ACE-I (perindopril) when needed for a target SBP of 150 mmHg. After 2 years, with about one-quarter of the patients using monotherapy and three-quarters combination therapy, the trial was stopped because drug treatment, although decreasing BP compared with the placebo group (144/78 versus 161/84 mmHg), reduced adverse outcomes. This consisted of reductions in the incidence of stroke (~30%), congestive heart failure (~64%) and CV morbid and fatal events (~23%). Most impressively, there was a significant reduction (~21%) in the incidence of all-cause death. Of importance, drug treatment was well tolerated. The reduction in BP in the standing position was similar to that in the sitting position. Furthermore, serum electrolyte and biochemical values were similar in drug- and placebo-treated groups. In fact, fewer serious adverse events were reported in the drug-treated than in placebo-treated patients.

The HYVET results provide clear evidence that BP lowering by drugs is associated with definite CV benefits in patients >80 years of age. They not only refute concern that this may lead to an increase, rather than a decrease, in mortality, but also show that in this stratum of the population, there is a prolongation of life. This finding is highly relevant for public health because subjects >80 years of age represent the fastest growing fraction of the population; the prediction is that by 2050, they will account for more than one-fifth of all elderly individuals.

However, HYVET has some limitations that should be taken into account when considering antihypertensive treatment in very elderly patients. Patients with stage 1 hypertension were not included. The patients on whom HYVET results are based are not representative of the general very elderly population. First, to limit dropouts, recruitment focused on patients in relatively good physical and mental condition and with a low rate of previous CVD. This is at variance from the high rate of frail and medically compromised patients typical in this very old age range. Second, because identifying appropriate subjects was difficult, recruitment required about six years and was only possible through participation of Eastern European countries and China, which together accounted for 98% of the patients. Furthermore, premature interruption of the trial (because of mortality benefit) made the average follow-up relatively short (median 1.8 years). It remains unknown whether benefits of antihypertensive treatment persist or diminish after two or three years. Also, the mean age was 83 years and only a small fraction was >85 years of age, which leaves open the question of whether the benefit extends to ages much older than those investigated in previous trials. Compared with placebo, drug treatment was not accompanied by significant improvement in the incidence of dementia or cognitive dysfunction. The HYVET-COG, a HYVET substudy, found a non-significant 14% decrease in dementia with active treatment versus placebo.[55] Although no specific class of antihypertensive drugs has been definitively linked with cognitive decline in the elderly, inadequate BP reduction is associated with cognitive decline. Although benefits in HYVET-COG were limited to CV outcomes, hypertension treatment was not associated with negative effects on cognition. Although there is clear evidence of the benefits of hypertension treatment in the reduction of both ischaemic and haemorrhagic stroke, the benefits in reducing cognitive impairment and dementia have only been demonstrated in the early elderly. In the patients, mean age 64 years, in PROGRESS, a perindopril-based BP-lowering regimen among patients with previous ischaemic stroke or transient ischaemic attack significantly reduced stroke-related dementia (34%) and severe cognitive decline

(19%).[56] Finally, the optimal BP goal for reducing CV events and mortality was not investigated.

Clinical assessment and diagnosis[2]

Diagnosis of hypertension should be based on at least three different BP measurements, taken on two or more separate office visits. At least two measurements should be obtained once the patient has been seated comfortably for at least five minutes with the back supported, feet on the floor, arm supported in the horizontal position and the BP cuff at heart level. With the switch from mercury to aneroid sphygmomanometers, adjustment is required to cut-offs and many societies now validate individual instruments to ensure accurate reporting.[57] All societies recommended measurement on at least three occasions as biological variation in BP is extensive and stress or exercise effects can be substantial.

Pseudohypertension is a falsely increased SBP that results from markedly sclerotic arteries that do not collapse during cuff inflation (e.g. 'non-compressible'). Although this occurs more commonly in the elderly, the actual prevalence is unclear. Identification of pseudohypertension is necessary to avoid overtreating high BP and should be suspected in elders with refractory hypertension, no organ damage and/or symptoms of overmedication and in patients with chronic renal disease with secondary hyperparathyroidism with marked arterial classification as defined by much raised ankle-brachial BP or extreme pulse wave velocities.

White coat hypertension is more common in the elderly and frequent among centenarians. The white coat effect is directly related to the seniority of the measurer, with greater effects shown for consultants (SBP +6 mmHg) than primary care practitioners (+4 mmHg) or nurses (reference group).

Ambulatory BP monitoring is recommended to confirm a diagnosis of white coat hypertension in patients with persistent office hypertension but no organ damage. Ambulatory BP monitoring (ABPM) is indicated when hypertension diagnosis or response to therapy is unclear from office visits, when syncope or hypotensive disorders are suspected and for evaluation of vertigo and dizziness and as the primary diagnostic assessment in the UK.[4] The optimum ABPM technique uses both day and night values,[58] but a 12 h day BP may be sufficient for diagnostic purposes. The equivalence points for ambulatory compared with brachial measurements are more controversial, ranging from 5/5 mmHg correction[4] to 10/5 mmHg (ISH[5]) or 12/6 mmHg depending on the studies. Some patients cannot tolerate the BP cuff used in ABPM nor have significant white coat effects in any clinical setting, and in these subjects home BP measurement can be useful even using wrist BP monitors, which are less accurate than brachial measures.

The case for using out-of-office BP readings in the elderly, particularly home BP measurements, is strong owing to potential hazards of excessive BP reduction in older people and better prognostic accuracy versus office BP. It is recommended that 12–14 measurements of BP are gathered at different times over 5–7 days to determine average home blood pressure.[59]

All patients should undergo a CVD risk assessment, including ascertainment of a family history of hypertension, diabetes or CVD, smoking status and history, measurement of weight and ideally waist circumference and measurement of lipids (total cholesterol; HDL-cholesterol), glucose (or HbA1c) and creatinine for determination of an estimated GFR using the Modified Diet in Renal Disease (MDRD) equation. If eGFR is significantly reduced ($<45\,ml\,min^{-1}$ per $1.73\,m^2$) in a hypertensive patient then a formal measurement should be made of urine albumin concentration to allow subclassification of the degree of renal impairment present. CVD risk should be calculated in all cases and total appropriate risk factor treatment instituted if the CVD risk exceeds 20%[4] or if the CHD risk exceeds 20% for the next decade.[3] In some groups, it may be appropriate to calculate lifetime CHD/CVD risk.

Management

Differences exist between guidelines about the optimal therapeutic strategies for hypertension. All antihypertensive drugs deliver ~5–10% reduction of initial BP. The only comparative trial of different major drug classes, the ALLHAT study, showed equivalence of a thiazide diuretic (chlorthalidone), an ACE-I and a calcium-channel blocker (CCB). Alpha-blockade was not recommended given its worse prognostic outcome.[60] Meta-analyses of BP trials have suggested that all classes are equivalent provided that BP reduction is achieved.[7] Guidelines have diverged in their recommendations, with an emphasis on diuretics and beta-blockers by some (JNC−7[5]), and an age-differentiated strategy recommending the use of CCBs and diuretics in the elderly. This has recently been revised following the results of the CAFE sub-study of ASCOT[61] and the results of the ACCOMPLISH study.[62] CAFE showed that, as previously suspected, beta-blockers were less effective at reducing central BP and thus stroke than other agents, and these drugs have been demoted to second-line status.[4] In ACCOMPLISH, an ACE-I–CCB combination was compared with an ACE-I–thiazide combination therapy, with superior results for the ACE-I–CCB on CVD events. Hence ACE-I and CCBs are the preferred initial antihypertensive drugs. Controversy exists about thiazide diuretics as they may not be therapeutically equivalent. Recent guidelines have suggested that chlorthalidone (not bendroflumethiazide or hydrochlorothiazide) should be the preferred thiazide and that an independent evidence base exists for indapamide (a non-thiazide diuretic).[4] There is no benefit to combining

ACE-Is with ARBs and this combination causes excess hypotension.[63]

Evidence for individual SBP targets remains poor and is derived from meta-analyses and indirectly from the DBPs achieved in the HOT study. Evidence suggests that populations at higher CVD risk should be targeted to lower BP levels, but clinicians need to remain mindful that that BP targets are based primarily on observational data in middle-aged patients and optimal targets for elderly patients, especially those with systolic hypertension and normal or low DBP (e.g. ISH), remain to be defined from randomized trial data.

The mantra of 'lower is better' suggested by the epidemiology of BP has been investigated in some high-risk groups. Both the ADVANCE and ACCORD BP trials found that among patients with type 2 diabetes mellitus at high risk for CV events, targeting SBP below 120 mmHg, as compared with below 140 mmHg, did not reduce the rate of fatal and non-fatal major CVD events and resulted in an increase in adverse experiences attributed to BP medications.[64,65]

Because hypertension increases with ageing and is also associated with longevity, there is often uncertainty about its management in very elderly patients. Until very recently, this was a particular dilemma for the very elderly because most hypertension management trials had upper age thresholds for enrolment (<70 years) and/or did not present age-specific results. However, the HYVET showed major benefit in CVD events and a large reduction in new cardiac failure in those older than 80 years of age when treated with an ACE-I–indapamide combination to a target BP of 150/80 mmHg.[53] No difference was found in outcomes between those with generalized hypertension and ISH, despite a greater therapeutic efficacy of the combination in ISH.[66]

Conclusion

Hypertension in the elderly is a major and increasing problem that should be assessed in parallel with other comorbidities and should be managed in the context of total CVD risk with no special allowance being made for chronological age.

Key points

- The prevalence of hypertension and wide PP increases with age.
- Treatment of high BP can significantly reduce the risk of CV mortality and morbidity in older persons, and the evidence for this is now also available for treating the very old.
- On the basis of current interventional trials, significant cardiovascular benefit may result from relatively small improvements in BP and the optimal SBP in the elderly may be 140–160 mmHg.
- The results from HYVET provide clear evidence that BP lowering by drugs is associated with definite CV benefits in patients >80 years of age.
- The benefits of treatment of hypertension need to be weighed against the hypotensive conditions commonly seen in the elderly, such as postprandial hypotension and postural hypotension, which can lead to syncope and falls.

CHAPTER 41

Heart failure

Michael W. Rich
Washington University School of Medicine, St Louis, MO, USA

Introduction

The combination of age-related changes in the cardiovascular system and the increasing prevalence of cardiovascular disease at older age predispose the older individual to the development of heart failure (HF). As a result, HF is predominantly a disorder of older adults, with persons over age 75 accounting for more than 50% of the over 1 million hospitalizations for HF each year in the United States, and over 60% of all HF-related deaths.[1] In addition, both the incidence and prevalence of HF are increasing, primarily due to the ageing of the population, and it is anticipated that the number of older adults with clinical HF will double over the next 25 years.

In addition to its effects on hospitalizations and mortality, HF is an important cause of chronic disability in older adults, and the functional limitations imposed by HF are often a key factor contributing to entry into a long-term care facility. HF is also one of the most common comorbid conditions in hospitalized older adults who develop delirium, and HF interacts detrimentally with every major geriatric syndrome. Thus, the societal burden attributable to HF in the ageing population is extremely high, as a consequence of which HF is one of the most costly medical illnesses in the United States today, with estimated annual expenditures in excess of $39 billion, representing approximately 5% of the total healthcare budget.[1]

Pathophysiology

Cardiovascular ageing

As discussed in Chapter 35, normal ageing is associated with extensive changes in cardiovascular structure and function. Taken together, these changes result in a marked reduction in cardiovascular reserve, so that older adults are less able to maintain normal cardiac output and intracardiac pressures in response to stress, whether that stress is physiologic (e.g. exercise) or pathologic (e.g. ischaemia, anaemia, infection). Figure 41.1 illustrates the striking effect of normal ageing on maximum oxygen consumption (VO_2 max) in healthy men and women carefully screened to exclude occult cardiovascular disease. Note that the decline in VO_2 max with age is not simply linear, but that it actually accelerates after age 60. Moreover, normal octogenarians often have VO_2 max levels of less than 20 ml $O_2 min^{-1} kg^{-1}$, which are similar to those typically observed in middle-aged persons with moderate HF (New York Heart Association class II). Given the normal decline in cardiovascular reserve with increasing age, it is not difficult to understand why an 85-year-old who suffers an acute myocardial infarction (MI) is substantially more prone to develop HF and cardiogenic shock than a 65-year-old who suffers an MI of equivalent size. Similarly, older patients are more likely to develop HF in response to numerous other cardiac and non-cardiac stressors, such as atrial fibrillation (AF), pneumonia, intravenous fluid administration, or any type of major surgery.

Table 41.1 summarizes the principal effects of normal ageing on cardiovascular structure and function.[2,3] Increased vascular stiffness contributes to the progressive rise in systolic blood pressure at older age, and increases impedance to left ventricular (LV) ejection (afterload). Impaired LV relaxation during early diastole (an active, energy-requiring process) and increased myocardial stiffness markedly alter the pattern of LV diastolic filling (preload) and result in a shift in the LV pressure-volume relationship upwards and to the left (Figure 41.2). These changes result in an increased reliance on atrial contraction (the 'atrial kick') to optimize LV filling, and predispose the older individual to the development of HF with preserved LV ejection fraction (HFPEF) and AF. Diminished responsiveness to β-adrenergic stimulation attenuates the heart rate response to stress and also reduces peak contractility, both of which are dependent on activation of the cardiac β_1-receptors. In addition, peripheral vasodilation is impaired due to reduced responsiveness of arteriolar β_2-receptors, further increasing afterload and limiting skeletal muscle blood

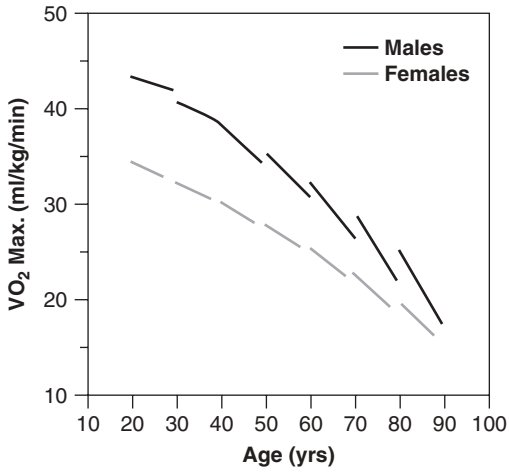

Figure 41.1 Age and VO_2max in healthy subjects: the Baltimore Longitudinal Study on Aging. Reproduced from Fleg JL *et al*. Longitudinal decline of aerobic capacity accelerates with age. *Circulation* 2000;**102**(Suppl II):II–602 [abstract], by permission of Lippincott Williams & Wilkins.

Table 41.1 Principal effects of ageing on cardiovascular structure and function.

- Increased vascular 'stiffness', impedance to left ventricular ejection, and pulse wave velocity
- Impaired left ventricular early diastolic relaxation and mid-to-late diastolic compliance
- Diminished responsiveness to neurohumoral stimuli, especially β_1 and β_2 adrenergic stimulation
- Altered myocardial energy metabolism and reduced mitochondrial ATP-production capacity
- Reduced number of sinus node pacemaker cells and impaired sinoatrial function
- Endothelial dysfunction and vasomotor dysregulation

ATP, adenosine triphosphate

flow during exercise. In healthy older adults, mitochondria in the cardiac myocytes are capable of generating sufficient ATP to meet the resting energy needs of the myocardium, but they have reduced capacity to increase ATP production in response to stress, thus further limiting peak cardiac performance. There is also a reduction in the number of functioning sinus node pacemaker cells with age, giving rise to the 'sick sinus syndrome' and contributing to chronotropic incompetence; that is, the inability to increase heart rate commensurate with demands. Finally, age-related endothelial dysfunction and vasomotor dysregulation, while not affecting cardiac performance directly, limit peak coronary blood flow and contribute to the development and progression of atherosclerosis and coronary artery disease (CAD). In summary, normal cardiovascular ageing exerts deleterious effects on all four of the major

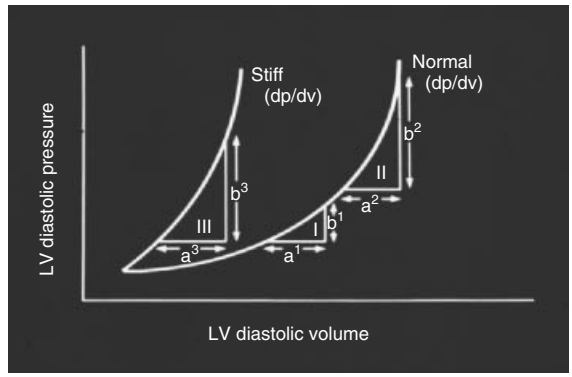

Figure 41.2 Effect of age on the left ventricular (LV) pressure-volume relationship. Note that there is a shift to the left, such that small increases in left ventricular volume are associated with greater increases in left ventricular pressure compared to younger persons. determinants of cardiac output – heart rate, contractility, preload, and afterload – thereby greatly reducing peak cardiac performance and cardiovascular reserve. In addition, cardiovascular ageing fosters the development of systolic hypertension and CAD, the two leading causes of HF in older adults.[1]

Other organ systems

Age-associated changes in other organ systems also contribute to the predilection of older adults to develop HF, and may affect the clinical features and response to therapy (Table 41.2). Renal function declines with age, and older adults are less able to excrete a salt and water load. Pulmonary reserve also declines with age, with decreased vital capacity and increased ventilation-perfusion mismatching resulting in more severe hypoxaemia in the setting of superimposed HF. The central nervous system is less able to maintain cerebral perfusion in response to decreased cardiac output due to impaired autoregulatory capacity, thus increasing the propensity of older HF patients to develop impaired cognition or overt delirium. Thirst is also impaired in older adults, increasing the risk of diuretic-induced dehydration. Sarcopenia, a hallmark of ageing, contributes to impaired exercise tolerance and diminished aerobic capacity in older HF patients. Finally, age-related alterations in the alimentary tract, liver, and kidneys result in substantial changes in the absorption, metabolism, and excretion of virtually all medications.

Clinical features

Symptoms and signs

Exertional dyspnoea, orthopnea, lower extremity swelling, and impaired exercise tolerance are the cardinal symptoms

Table 41.2 Effects of ageing on other organ systems.

Kidneys
Decline in glomerular filtration rate (GFR), ~8 cm^3 min^{-1} per decade
Impaired water and electrolyte homeostasis
Reduced plasma renin and aldosterone activity
Impaired elimination of renally excreted drugs
Lungs
Loss of elastic recoil
Increased ventilation-perfusion (V/Q) mismatching
Reduced vital capacity and minute ventilation
Nervous system
Diminished reflex responsiveness, esp. baroreceptors
Reduced central nervous system autoregulatory capacity
Impaired thirst mechanism
Musculoskeletal system
Loss of muscle mass and strength (sarcopenia)
Loss of bone mass, esp. in women (osteopenia)
Altered pharmacokinetics and pharmacodynamics of most drugs

of HF at both younger and older age. However, with increasing age, which is often accompanied by a progressively more sedentary lifestyle, exertional symptoms become less prominent. Conversely, atypical symptoms, such as confusion, somnolence, irritability, fatigue, anorexia, or diminished activity level, become increasingly more common manifestations of HF, especially after age 80.

Physical signs of HF include elevated jugular venous pressure, hepatojugular reflux, an S_3 gallop, pulmonary rales, hepatomegaly, and dependent oedema. With the exception of rales each of these features occurs less commonly in older HF patients, in part because of the increasing prevalence of HFPEF, in which signs of right HF are a late manifestation and a third heart sound is typically absent. On the other hand, behavioural changes and altered cognition, which may range from subtle abnormalities to overt delirium, frequently accompany HF at elderly age, particularly among institutionalized or hospitalized patients.

Diagnosis

Accurate diagnosis of the HF syndrome at older age is confounded in part by the increasing prevalence of atypical symptoms and signs. In addition, exertional symptoms may be attributable to non-cardiac causes, such as pulmonary disease, anaemia, depression, physical deconditioning, or ageing itself. Likewise, peripheral oedema may be due to venous insufficiency, hepatic or renal disease, or medication side effects (e.g. calcium-channel blockers), and pulmonary crepitus may be due to atelectasis or chronic lung disease. Despite these limitations, careful clinical assessment for the presence of multiple symptoms and signs should lead to the correct diagnosis in most cases.

Chest radiography is indicated when HF is suspected, and it remains the most useful diagnostic test for determining the presence of pulmonary congestion. However, chronic lung disease, altered chest geometry (e.g. due to kyphosis), or poor inspiratory effort may confound interpretation of the chest radiograph in elderly individuals.

Plasma B-type natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) levels have been shown to be a valuable aid in distinguishing dyspnoea due to HF from that related to other causes, such as pulmonary disorders. BNP and NT-proBNP levels tend to be elevated in both systolic HF and HFPEF, and they also correlate with response to therapy and prognosis. However, levels of these peptides also increase with age in healthy individuals without HF, particularly women (Figure 41.3), and as a result, the specificity and predictive accuracy of elevated levels decline with age.[4] Nonetheless, in cases of diagnostic uncertainty, a low or normal BNP or NT-proBNP level effectively excludes acute HF, whereas markedly elevated levels provide strong evidence in support of the diagnosis.

Proper management of HF is critically dependent on establishing the pathophysiology of LV dysfunction (i.e. systolic vs. diastolic), determining the primary and any secondary aetiologies (Table 41.3), and identifying potentially treatable precipitating or contributory factors (Table 41.4). Differentiating systolic from diastolic dysfunction requires an assessment of LV ejection fraction by echocardiography, radionuclide ventriculography, magnetic resonance imaging, or contrast angiography. Among these, echocardiography is the most widely used and clinically useful non-invasive test for evaluating systolic and diastolic function. In addition, echocardiography provides important information about LV chamber size and wall thickness, atrial size, right ventricular function, the presence and

Chemotherapeutic agents
Inflammatory myocarditis
Idiopathic
Hypertrophic
Obstructive
Non-obstructive
Restrictive (esp. amyloid)
Pericardial disease
Constrictive pericarditis
High output syndromes
Chronic anaemia
Thiamine deficiency
Hyperthyroidism
Arteriovenous shunting
Age-related diastolic dysfunction

Table 41.4 Common precipitants of heart failure in older adults.

Myocardial ischaemia or infarction
Uncontrolled hypertension
Dietary sodium excess
Medication non-adherence
Excess fluid intake
Self-induced
Iatrogenic
Arrhythmias
Supraventricular, esp. atrial fibrillation
Ventricular
Bradycardia, esp. sick sinus syndrome
Associated medical conditions
Fever
Infections, esp. pneumonia or sepsis
Hyperthyroidism or hypothyroidism
Anaemia
Renal insufficiency
Thiamine deficiency
Pulmonary embolism
Hypoxemia due to chronic lung disease
Drugs and medications
Alcohol
Beta-adrenergic blockers (incl. ophthalmologicals)
Calcium-channel blockers
Anti-arrhythmic agents
Non-steroidal anti-inflammatory drugs
Glucocorticoids
Mineralocorticoids
Estrogen preparations
Anti-hypertensive agents (e.g. clonidine, minoxodil)

severity of valvular lesions, and pericardial disorders. For these reasons, echocardiography is recommended for all patients with newly diagnosed HF or unexplained disease progression.[5]

Other diagnostic studies that may be indicated in selected patients include an assessment of thyroid function (especially in the presence of AF), an exercise or pharmacologic stress test to evaluate for the presence and severity of ischaemia, and cardiac catheterization if revascularization or other corrective procedure (e.g. valve repair or replacement) is being contemplated.

Aetiology and precipitating factors

Systemic hypertension and CAD account for 70–80% of HF cases at older age.[1] Hypertension is the most common aetiology in older women, particularly those with preserved ejection fraction. In older men, HF is more often attributable to CAD. Other common aetiologies include valvular heart disease (especially aortic stenosis and mitral regurgitation) and non-ischaemic cardiomyopathy (Table 41.3). Importantly, HF in the elderly is frequently multifactorial, and it is thus essential to identify all potentially treatable causes.

In addition to determining aetiology, it is important to identify factors precipitating or contributing to HF exacerbations (Table 41.4). Non-adherence to medications and dietary restrictions is the most common cause of worsening HF, and patients should be closely questioned about their dietary and medication habits. Other common factors contributing to increased symptoms include ischaemia, volume overload due to excess fluid intake (self-inflicted or iatrogenic), tachyarrhythmias (especially AF or flutter), intercurrent infections, anaemia, thyroid disease, and various medications or toxins (e.g. alcohol).

Comorbidity

A hallmark of ageing is the increasing prevalence of multiple comorbid conditions, many of which impact directly or indirectly on the diagnosis, clinical course, treatment, and prognosis of HF in the elderly (Table 41.5). As noted previously, renal function declines with age, and octogenarians often have creatinine clearances of $<60\,cm^3\,min^{-1}$ (i.e. stage III chronic kidney disease), despite 'normal' serum

Table 41.5 Common comorbidities in older patients.

Condition	Implications
Renal dysfunction	Exacerbated by diuretics, ACE inhibitors, ARBs
Anaemia	Worsens symptoms and prognosis
Chronic lung disease	Contributes to uncertainty about diagnosis and volume status
Cognitive dysfunction	Interferes with dietary, medication and activity adherence
Depression, social isolation	Worsens prognosis, interferes with adherence
Postural hypotension, falls	Exacerbated by vasodilators, diuretics, beta-blockers
Arthritis	NSAIDs worsen heart failure, antagonize heart failure medications
Urinary incontinence	Aggravated by diuretics, ACE inhibitors (cough)
Sarcopenia, osteoporosis	Contribute to impaired exercise tolerance
Sensory deprivation	Interferes with adherence
Nutritional disorders	Exacerbated by dietary restrictions
Polypharmacy	Reduced adherence, increased drug interactions
Frailty	Exacerbated by hospitalization; increased fall risk

ACE, angiotensin-converting enzyme; ARBs, angiotensin-receptor blockers; NSAIDs, non-steroidal anti-inflammatory drugs

creatinine levels and in the absence of underlying renal disease. Older patients are also less able to excrete excess sodium and water, and this deficiency may contribute to volume overload. Diuretics tend to be less effective in the elderly, whereas diuretic-induced electrolyte disorders are more common, in part due to reduced capacity of the kidneys to preserve electrolyte homeostasis. Conversely, diuretics, ACE inhibitors, and angiotensin receptor blockers (ARBs) can all contribute to worsening renal function, and older patients are at increased risk for this complication.

Older HF patients are at increased risk for anaemia due to comorbid chronic illnesses (renal disease, occult malignancy), inadequate dietary intake of key nutrients (iron, folate, B_{12}), and use of medications associated with gastrointestinal blood loss (aspirin, warfarin, non-steroidal anti-inflammatory drugs). Anaemia contributes to impaired tissue oxygen deliver and impaired exercise tolerance, and may exacerbate myocardial ischaemia in patients with underlying CAD. Anaemia has also been shown to be an independent predictor of adverse clinical outcomes in patients with HF.

Normal ageing is associated with a decline in maximum voluntary ventilation and an increase in ventilation-perfusion mismatching. In addition, chronic obstructive and restrictive lung diseases further impair pulmonary function in many older adults. Diminished pulmonary function, in turn, contributes to increased dyspnoea and exercise intolerance in older patients with HF, as the lungs are unable to compensate for impaired cardiac performance. In addition, the presence of chronic lung disease often leads to diagnostic uncertainty (is the patient's dyspnoea due to HF, pulmonary disease, or a combination of both?), in part by confounding interpretation of the physical examination and chest radiograph.

Cognitive dysfunction interferes with the patient's ability to participate fully in self-care behaviours, such as weight monitoring and adherence to dietary restrictions and prescribed medications. In more severe cases, cognitive impairment substantially limits the patient's ability to provide a reliable medical history, and may prevent recognition of new or worsening symptoms. Patients with cognitive dysfunction are also at increased risk for developing delirium, which may complicate hospital management and predispose to serious adverse events (e.g. falls, aspiration, infections).

Up to 20% of elderly HF patients have clinically significant depression, which is often unrecognized. Social isolation, primarily due to the death of one's spouse, also occurs with increasing frequency at elderly age. These conditions have both been associated with adverse outcomes in elderly HF patients, including increased mortality and hospitalization rates, in part due to reduced adherence to prescribed medications and other recommended behaviours. In addition, depression has been linked with increased adrenergic tone and ventricular arrhythmias in patients with cardiovascular disease, both of which confer an increased mortality risk in HF patients.

Increased vascular stiffness and impaired baroreflex responsiveness predispose older adults to the development of postural hypotension, while age-related alterations in sinus node function increase the risk of bradyarrhythmias (sick sinus syndrome). In addition, balance and proprioception decline with age. Taken together, these factors greatly increase the risk of falls in older adults. Standard HF therapies, including diuretics, vasodilators, and beta-blockers, all have the potential to further increase the risk of falls and associated morbidity.

Arthritis is the leading cause of chronic disability in older adults, and is widely treated with non-steroidal anti-inflammatory drugs (NSAIDs) available both by prescription and over-the-counter. These agents enhance renal sodium and water reabsorption and have been associated with a significant increase in the risk of hospitalization for HF, even among patients with no prior HF history.[6] NSAIDs also antagonize the effects of diuretics and ACE inhibitors, and may inhibit the beneficial effects of aspirin in patients with CAD. In addition, NSAIDs are a

common cause of gastrointestinal bleeding in older adults, thus potentiating the risk of anaemia.

The prevalence of urinary incontinence increases with age, affecting up to 35% of women and 20% of men over the age of 80. Diuretics and ACE inhibitors (ACE inhibitor cough) may aggravate incontinence in many patients. However, most patients with mild to moderate incontinence do not report the condition to their physicians unless specifically asked. Instead, they will avoid taking their medication rather than risking embarrassment, especially if they are going to be away from home without ready access to a restroom. Although the importance of urinary incontinence as a cause of medication non-adherence in the elderly is unknown, it is likely under-appreciated, as most clinicians do not routinely inquire about this condition.

Sarcopenia contributes to muscle weakness and impaired exercise tolerance in older persons with or without HF. Osteopenia and osteoporosis compromise the structural integrity of the skeletal system (e.g. as a result of compression fractures), further reducing exercise capacity. In addition, the risk of falls and hip fractures is increased, and, as noted above, these risks may be aggravated by several of the medications used to treat HF.

Reduced visual and auditory acuity often interfere with patients' ability to comply with therapeutic recommendations, either because they did not hear the instructions properly, or because they are unable to read printed materials (e.g. medication instructions, pill bottles, nutrition labels). When coupled with social isolation, these deficits can make it particularly difficult for older patients to adhere to HF therapy.

Under-nutrition is common in older adults and is usually multifactorial, with reduced access to nutritional foods (e.g. due to loss of independence, social isolation, limited finances), diminished appetite (due to chronic illness, depression, medications), loss of enjoyment from eating (impaired sense of taste and smell, social isolation), neuromuscular conditions (stroke, Parkinsonism), and mechanical factors (poor dentition, difficulty swallowing) all playing a role. In addition, prevalent medical conditions often lead to the imposition of major dietary restrictions, including protein restriction in patients with hepatic or renal disease, carbohydrate restriction in diabetics, fat and cholesterol restriction in patients with CAD or diabetes, and sodium restriction in patients with hypertension, HF, or renal disease. Moreover, advanced HF itself is often associated with a progressive decline in lean body mass, a condition referred to as cardiac cachexia. Thus, HF *per se*, as well as its treatment (sodium restriction in almost all cases, restriction of other macronutrients in many cases due to prevalent comorbidities), may contribute to the development or progression of under-nutrition in older adults, a condition associated with immune deficiency, frailty and a poor long-term prognosis.

Polypharmacy is common in patients with HF, since drug therapy for HF alone often entails the use of three or more medications, and virtually all elderly HF patients have associated conditions for which they are receiving treatment. Apart from the high cost associated with the use of multiple medications, polypharmacy has an important role in interfering with medication adherence, since the more medications a patient is taking, the less likely it becomes that they are taking their medications correctly. In addition, there is an exponential relation between the number of medications and the risk of drug interactions, such that patients taking 10 or more medications have over a 90% probability of experiencing one or more clinically significant drug interactions.

The prevalence of frailty increases markedly with age, especially among persons over the age of 80, and the cardinal features of frailty – weight loss, weakness, slow movement, low physical activity and exhaustion – overlap significantly with the symptoms of HF.[7] Frailty confers a poor prognosis, as it tends to be associated with progressive physical and functional decline, and it is also a marker for increased risk for iatrogenic complications, such as falls related to medications. Frailty tends to worsen during hospitalization for acute illness (e.g. a HF exacerbation), and frail patients rarely return to their previous level of function following hospital discharge. Thus, HF and frailty interact in a way that is detrimental to both conditions.

Recent studies indicate that both the number and nature of non-cardiac comorbidities have a significant impact on clinical outcomes in older HF patients. In 2003, Braunstein *et al*. examined the prevalence of non-cardiac comorbidities in Medicare beneficiaries hospitalized with HF.[8] As shown in Figure 41.4, 86% of patients had two or more non-cardiac comorbidities, and more than 25% had six or more non-cardiac conditions. In addition, since common geriatric syndromes, such as dementia, depression, incontinence and frailty, are often clinically unrecognized, it is likely

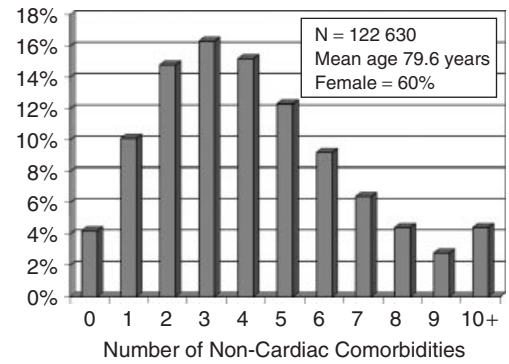

Figure 41.4 Prevalence of non-cardiac comorbidities in Medicare beneficiaries with heart failure. Adapted from Braunstein JB *et al*.[8]

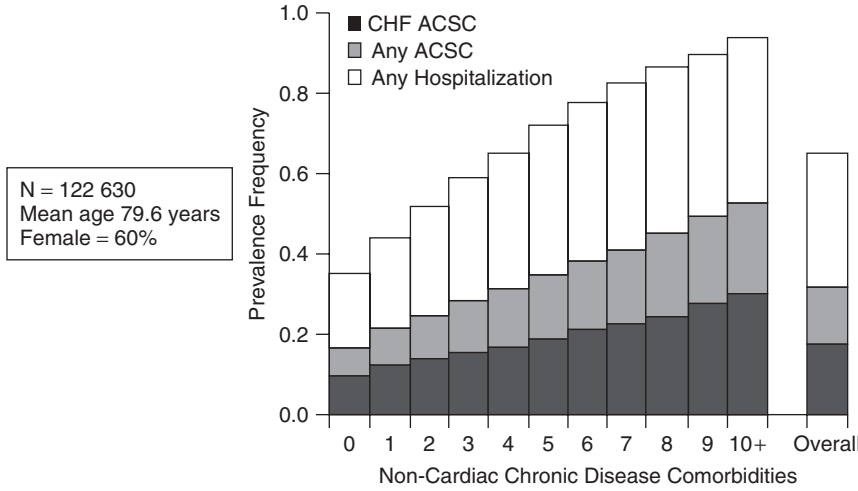

Figure 41.5 Impact of non-cardiac comorbidities on hospital admissions in Medicare beneficiaries with heart failure. ACSC, ambulatory care sensitive conditions; CHF, chronic heart failure. Reproduced from Braunstein JB *et al.*[8] Copyright 2003, with permission from Elsevier.

that the true prevalence of non-cardiac comorbidities is underestimated by Braunstein's data.

Figure 41.5 illustrates the relationship between the number of non-cardiac comorbidities and the number of hospital admissions among HF patients.[8] Overall, the proportion of patients hospitalized annually increased from about 35% among patients with no comorbidities, to over 90% among patients with nine or more comorbidities. Moreover, approximately half of all hospitalizations were considered potentially avoidable (depicted by the shaded regions in the figure), regardless of the number of comorbidities.

Several studies have examined the relationship between specific comorbidities and clinical outcomes. Chronic renal insufficiency and anaemia have both been shown to be independent predictors of mortality in elderly HF patients, and the presence of cognitive dysfunction has been associated with a striking increase in mortality among older patients hospitalized with HF. In addition, the use of NSAIDs has been associated with a 60% increase in the risk of hospitalization for HF among elderly patients with no prior history of heart disease, and a 10-fold increase among patients with pre-existing cardiac conditions.[6]

In summary, older HF patients almost invariably have one or more age-associated conditions that influence the diagnosis, clinical features, and/or management of HF. Conversely, HF and its therapy often have ramifications for the clinical course and treatment of these comorbid conditions. Consideration of the interactions between HF and prevalent comorbidities is thus a critically important aspect of management in the elderly HF patient.

Management

The principal goals of HF therapy are to relieve symptoms, maintain or enhance functional capacity and QOL, preserve independence, and reduce mortality. Although it is often stated that quality of life is more important than quantity of life in the very elderly, there is wide variability in personal preferences concerning these outcomes. Furthermore, since the elderly HF population is characterized by marked heterogeneity in terms of lifestyle, comorbidity, and personal goals and perspectives, management of HF in the elderly must first and foremost be individualized and patient-centred in accordance with each patient's circumstances and needs.

The approach to HF management involves identification and treatment of the underlying aetiology and any contributing factors, implementation of an effective therapeutic regimen, and coordination of care through the use of a multidisciplinary team.

Aetiology and precipitating factors

Although HF in older adults is rarely 'curable', proper treatment of the underlying aetiology often improves symptoms and delays disease progression. Thus, hypertension should be treated aggressively, and CAD should be managed appropriately with medications and/or percutaneous or surgical revascularization. Similarly, therapy for diabetes and dyslipidaemia should be optimized, smoking should be strongly discouraged, and a suitable level of regular physical activity should be prescribed. Alcohol intake should be limited to no more than two drinks per day in men and 1 drink per day in women, and alcohol use should be strictly proscribed in patients with suspected alcoholic cardiomyopathy.

Severe aortic stenosis is a common cause of HF at older age, and aortic valve replacement is effective in reducing mortality and improving QOL. Peri-operative mortality rates are acceptable (less than 10%), and long-term results are excellent, even in octogenarians. More recently, percutaneous aortic valve replacement has been shown to offer an effective alternative to valve replacement in selected patients with prohibitive operative risk.

Severe mitral regurgitation may be amenable to surgical therapy (i.e. valve repair or replacement) in selected patients, but the operative results are somewhat less favourable than for aortic valve surgery. Percutaneous approaches to reducing the severity of mitral regurgitation have recently been developed and offer an alternative to surgery in some cases. Mitral valve replacement is also effective therapy for severe mitral stenosis; rarely, percutaneous mitral balloon valvuloplasty may be feasible in older patients.

Atrial fibrillation is a common precipitant of HF in older patients, especially in the setting of diastolic dysfunction. In patients with recent onset symptomatic AF, many clinicians recommend restoration and maintenance of sinus rhythm if feasible, although the long-term benefits of this approach have not been established. In patients with chronic AF, the ventricular rate should be adequately controlled both at rest and during activity. Bradycardia is a less common cause of HF; when present, implantation of a permanent pacemaker provides definitive therapy (see section on Device therapy). Anaemia, thyroid disease, and other systemic illnesses should be identified and treated accordingly.

The importance of adherence to medications and dietary restrictions, including avoidance of excessive fluid intake, cannot be overemphasized. NSAIDs are widely used by older individuals to treat arthritis and relieve chronic pain, but these agents promote sodium and water retention, interfere with the actions of ACE inhibitors and other antihypertensive agents, and may worsen renal function; their use should be avoided whenever possible.[6] Similarly, the use of other medications that may aggravate HF should be closely monitored.

Pharmacotherapy

The design of an effective therapeutic regimen is based in part on whether the patient has predominantly systolic HF or predominantly HFPEF. Although these two abnormalities frequently co-exist (indeed, virtually all individuals over age 70 have some degree of diastolic dysfunction), for purposes of this discussion patients with an ejection fraction <45% (i.e. moderate or severe LV systolic dysfunction) will be considered as having systolic HF, whereas patients with an ejection fraction ≥45% will be considered as having HFPEF.

Systolic heart failure

In the past 30 years there has been considerable progress in the treatment of systolic HF. Although most studies have either excluded individuals over 75–80 years of age, or have enrolled too few elderly subjects to permit definitive conclusions, the available data indicate that the response of older patients to standard therapies is similar to that of younger patients. Therefore, current recommendations for drug treatment of systolic HF are similar in younger and older patients.[5]

ACE inhibitors

ACE inhibitors are the cornerstone of therapy for LV systolic dysfunction, whether or not clinically overt HF is present.[5] Older patients are more likely than younger patients to have potential contraindications to ACE inhibitors (e.g. renal dysfunction, renal artery stenosis, orthostatic hypotension), and they may also be at increased risk for ACE inhibitor-related side effects, such as worsening renal function, electrolyte disturbances, and hypotension. Nonetheless, a trial of ACE inhibitors is indicated in virtually all older patients with documented LV systolic dysfunction.

In most cases, ACE inhibitor therapy should be initiated at a low dose (e.g. captopril 6.25–12.5 mg tid or enalapril 2.5 mg bid), and the dosage should be gradually titrated upward to the level shown to be effective in clinical trials (captopril 50 mg tid, enalapril 10 mg bid, lisinopril 20 mg qd, ramipril 10 mg qd). Once a maintenance dose has been achieved, substituting a once-daily agent (e.g. lisinopril or ramipril) at equivalent dosage may facilitate adherence. Blood pressure, renal function, and serum potassium levels should be monitored closely during dose titration and periodically during maintenance therapy. In patients unable to tolerate standard ACE-inhibitor dosages due to side effects, dosage reduction is appropriate, as there is evidence that even very low doses of these agents (e.g. lisinopril 2.5–5 mg qd) provide some degree of benefit.

Angiotensin receptor blockers

Angiotensin receptor blockers (ARBs) have a somewhat more favourable side effect profile than ACE inhibitors, and the effects of ARBs on major clinical outcomes (mortality, hospitalizations) are similar to those seen with ACE inhibitors.[9] ARBs have also been shown to reduce mortality and hospitalizations in patients with systolic HF who are intolerant to ACE inhibitors due to cough or other side effects.[10] Compared with an ACE inhibitor alone, combining an ARB with an ACE inhibitor reduces HF admissions but not mortality, while increasing the risk of side effects.[9,11] Based on available evidence, ACE inhibitors are still considered first-line therapy for systolic HF, but ARBs offer an excellent alternative for patients intolerant to ACE inhibitors, and they may also be useful as adjunctive agents in selected patients with persistent symptoms despite conventional treatment.[5]

Hydralazine and isosorbide dinitrate

The combination of hydralazine 75 mg qid and isosorbide dinitrate 30–40 mg qid was associated with decreased mortality in a small trial of HF patients less than 75 years of age. In a more recent study that did not exclude older subjects, the combination was shown to reduce mortality in

African-American patients with symptomatic systolic HF.[12] Based on this study, combination hydralazine-nitrate therapy is recommended for self-declared African-Americans with advanced systolic HF.[5] The combination also provides an alternative therapy for patients who are intolerant to ACE inhibitors and ARBs, for patients with significant renal insufficiency, and as adjunctive therapy in patients who remain highly symptomatic despite standard treatment. Side effects are common with both hydralazine and high-dose nitrates, and the combination is not available in a once-daily formulation.

Beta-blockers

Beta-blockers improve LV function and decrease mortality in a broad population of HF patients, including those with New York Heart Association (NYHA) class IV symptoms and patients up to 80 years of age, and beta-blockers are now considered standard therapy for clinically stable patients without major contraindications.[5] Use of beta-blockers in older patients may be limited by a higher prevalence of bradyarrhythmias and severe chronic lung disease, and older patients may also be more susceptible to the development of fatigue and impaired exercise tolerance during long-term beta-blocker administration.

Carvedilol, metoprolol, and bisoprolol have all been shown to improve outcomes in patients with systolic HF, and one randomized trial found that carvedilol 25 mg twice daily was more effective than metoprolol 50 mg twice daily in reducing mortality.[13] In most cases, beta-blocker treatment should be initiated at low dosages in stable patients upon a background of ACE inhibitor and diuretic therapy. Recommended starting dosages are carvedilol 3.125 mg bid, metoprolol 6.25–12.5 mg bid, and bisoprolol 1.25 mg once daily. The dose should be gradually increased at 2–4 week intervals to achieve maintenance dosages of carvedilol 25–50 mg bid, metoprolol 50–100 mg bid (or, preferably, sustained release metoprolol 100–200 mg daily), or bisoprolol 5–10 mg daily. Lower dosages and a slower titration protocol may be appropriate in patients over 75 years of age. Contraindications to beta-blockade include marked sinus bradycardia (resting heart rate <45–50 bpm), PR interval ≥0.24 s, heart block greater than first degree, systolic blood pressure <90–100 mmHg, active bronchospastic lung disease, and severe decompensated HF.

Digoxin

Digoxin improves symptoms and reduces hospitalizations in patients with symptomatic systolic HF treated with ACE inhibitors and diuretics, but has no effect on total or cardiovascular mortality. The effects of digoxin are similar in younger and older patients, including octogenarians,[14] and digoxin is therefore a useful drug for the treatment of systolic HF in patients of all ages who have limiting symptoms despite standard therapy.

The volume of distribution and renal clearance of digoxin decline with age. In addition, the optimal therapeutic concentration for digoxin appears to be 0.5–0.9 ng ml^{-1};[15] higher concentrations are associated with increased toxicity but no greater efficacy.[15] For most older patients with preserved renal function (estimated creatinine clearance ≥60 $cm^3 min^{-1}$), digoxin 0.125 mg daily provides a therapeutic effect. Lower dosages should be used in patients with renal insufficiency. Although routine monitoring of serum digoxin levels is no longer recommended, it seems reasonable to measure the serum digoxin concentration 2–4 weeks after initiating therapy to ensure that the level does not exceed 0.9 ng ml^{-1}. In addition, a digoxin level should be obtained whenever digoxin toxicity is suspected.

Digoxin side effects include arrhythmias, heart block, gastrointestinal disturbances, and altered neurological function (e.g. visual disturbances). Although older patients are often thought to be at increased risk for digitalis toxicity, this was not confirmed in an analysis from the Digitalis Investigation Group (DIG) trial.[14] On the other hand, digoxin has significant drug interactions with many medications commonly prescribed to older patients. Among these, cholestyramine and phenytoin reduce digoxin levels, whereas amiodarone, amphotericin, calcium preparations, cyclosporine, erythromycin, itraconazole, propafenone, quinidine, reserpine, tetracycline and verapamil all increase serum digoxin concentrations and the risk of digoxin toxicity.

Diuretics

Diuretics are an essential component of therapy for most patients with HF, and diuretics remain the most effective agents for relieving congestion and maintaining euvolemia. Some patients with mild HF can be effectively controlled with a thiazide diuretic, but the majority will require a loop diuretic such as furosemide, bumetanide, or torsemide. In patients with more severe HF or significant renal dysfunction (serum creatinine ≥2.0 mg dl^{-1}), the addition of metolazone 2.5–10 mg daily may be necessary to achieve effective diuresis.

In general, diuretic dosages should be titrated to eliminate signs of pulmonary and systemic venous congestion. Common side effects include worsening renal function (often due to over-diuresis) and electrolyte disorders. To minimize these effects, renal function and serum electrolyte levels (sodium, potassium, magnesium) should be monitored closely during the initiation and titration phase of diuretic use, and periodically thereafter.

Aldosterone antagonists

Spironolactone is a potassium-sparing diuretic that acts by antagonizing aldosterone. The addition of spironolactone 12.5–50 mg daily to standard HF therapy has been shown to reduce mortality and hospital admissions

in patients with NYHA class III–IV systolic HF, with similar benefits in older and younger patients.[16] Eplerenone, a selective aldosterone antagonist, has also been shown to reduce mortality and sudden cardiac death in patients with LV systolic dysfunction following acute myocardial infarction.[17] Spironolactone is contraindicated in patients with severe renal insufficiency or hyperkalaemia, and up to 10% of patients develop painful gynaecomastia. In addition, older patients receiving spironolactone in combination with an ACE inhibitor or ARB may be at increased risk for hyperkalaemia, particularly in the presence of pre-existing renal insufficiency or diabetes, and at doses in excess of 25 mg per day. Combined use of an ACE inhibitor, ARB, and aldosterone antagonist is not recommended.[5]

Approach to treatment

Figure 41.6 provides a suggested approach to the pharmacologic treatment of systolic HF. All patients with LV systolic dysfunction, whether asymptomatic or symptomatic, should receive an ACE inhibitor (or an ARB or alternative vasodilator if ACE inhibitors are contraindicated or not tolerated). Patients with stable symptoms and no contraindications should also receive a beta-blocker, and diuretics should be administered in sufficient doses to maintain euvolemia. Spironolactone should be used in patients with persistent NYHA class III–IV symptoms, and combination therapy with hydralazine-nitrates is indicated in black patients with symptomatic systolic HF. Digoxin and/or additional vasodilator therapy should be considered in patients who remain symptomatic despite the above regimen.

Heart failure with preserved ejection fraction (HFPEF)

Over 50% of elderly HF patients have preserved LV systolic function. However, although there have now been several clinical trials involving patients with HFPEF (Table 41.6), management of this condition remains largely empiric. As with systolic HF, the underlying cardiac disorder and associated contributing conditions should be treated appropriately. In particular, hypertension and CAD should be managed aggressively. Diuretics should be used judiciously to relieve congestion while avoiding over-diuresis and pre-renal azotemia. Topical or oral nitrates may be beneficial in reducing pulmonary congestion and orthopnea.

In the CHARM-preserved trial (Candesartan in Heart failure: Assessment of Reduction in Mortality and morbidity), the ARB candesartan reduced HF admissions by 16% but had no effect on mortality in patients with HF and a LV ejection fraction >40%.[18] The mean age of patients in CHARM-preserved was 67 years, and 807 patients, comprising 27% of the total population, were ≥75 years of age. However, patients with substantial comorbidity were excluded, so the applicability of the study findings to older HF patients encountered in clinical practice remains unknown.

More recently, the I-PRESERVE trial (Irbesartan in Heart Failure with Preserved Systolic Function) randomized 4128 patients (mean age 72 years, 60% women) with HFPEF (LV ejection fraction ≥45%) to the ARB irbesartan or placebo and followed them for a mean of 4.1 years.[19] In this study, irbesartan failed to show a beneficial effect on the primary composite endpoint of all-cause mortality or cardiovascular hospitalization. Irbesartan also had no effect

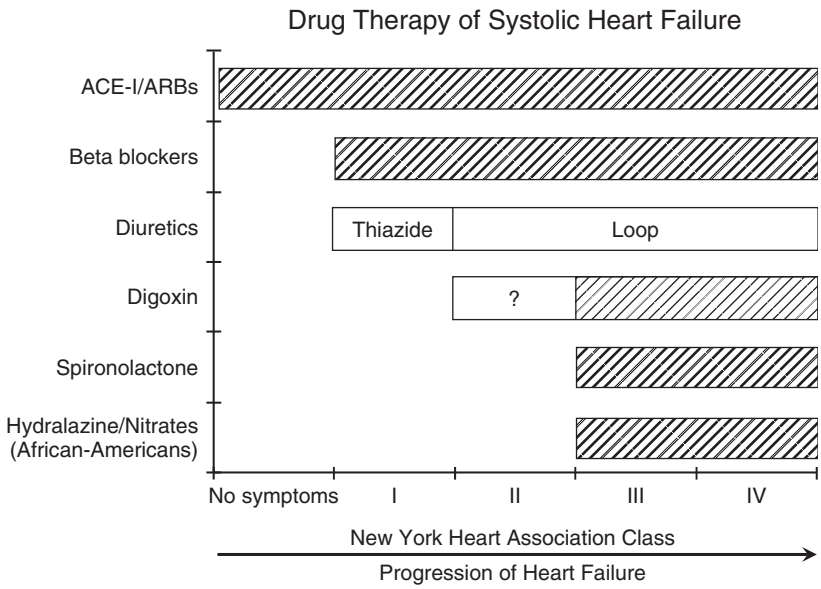

Figure 41.6 Approach to treatment of systolic heart failure; see text for details. Shaded areas refer to therapies proven to be efficacious in prospective randomized clinical trials. ACE-I, angiotensin-converting enzyme inhibitors; ARBs, angiotensin-receptor blockers.

Table 41.6 Treatment of heart failure with preserved ejection fraction: overview of randomized trials.

Trial	Agent	N	Mean age (years)	Follow-up (years)	Main findings
CHARM-Preserved[18]	candesartan	3023	67	3.1	No effect on mortality; HF admissions reduced
I-PRESERVE[19]	irbesartan	4128	72	4.1	No effect on mortality, admissions, or other endpoints
PEP-CHF[20]	perindopril	850	76	2.1	No effect on mortality; HF admissions reduced; improved NYHA class and exercise tolerance
SENIORS[21]	nebivolol	2128	76	1.8	No effect on mortality; decreased cardiovascular admissions
DIG-ancillary[22]	digoxin	988	67	3.1	No effect on mortality or cardiovascular admissions

HF, heart failure; NYHA, New York Heart Association

on any of the pre-specified secondary endpoints, including cardiovascular mortality and admission for HF.

In another study, PEP-CHF (Perindopril in Elderly Patients with CHF), 850 patients age 70 years or older (mean age 76 years, 55% women) with HFPEF were randomized to the ACE-inhibitor perindopril or placebo and followed for a mean of 2.1 years.[20] Although perindopril had no effect on the primary outcome of mortality or HF admission, overall HF admissions were reduced and New York Heart Association class and six-minute walk distance were improved at one year in patients randomized to perindopril. In subgroup analysis, perindopril appeared to have a beneficial effect on the primary outcome in patients ≤age 75, but not in those >75 years of age.

Although beta-blockers are of proven benefit in patients with systolic HF, there are limited data on their use in patients with HFPEF. In the SENIORS trial (Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors), 2128 HF patients ≥70 years of age (mean age 76 years, 35% women) were randomized to the beta-blocker nebivolol or placebo and followed for an average of 21 months.[21] Patients with either systolic HF or HFPEF were included, and the primary composite endpoint was all-cause mortality or cardiovascular hospitalization. Overall, nebivolol was associated with a significant 15% reduction in the primary endpoint. There was no effect on mortality but cardiovascular admissions were reduced, with similar findings in patients with LV ejection fraction >35% versus ≤35%.

Finally, in the DIG ancillary trial (Digitalis Investigation Group), 988 patients (mean age 67 years, 41% women) with HF and LV ejection fraction >45% were randomized to digoxin or placebo and followed for an average of 3.1 years.[22] Overall, digoxin had no effect on the primary composite endpoint of HF death or HF hospitalization; there was also no effect on all-cause mortality, cardiovascular mortality, or cardiovascular hospitalizations.

In summary, despite publication of several prospective clinical trials in older patients with HFPEF, to date no pharmacological intervention has been shown to reduce mortality in this population, and, with the exception of diuretics to relieve congestion, there are currently no class I or class IIa indications for any of these agents in the treatment of HFPEF. Therefore, therapy should be individualized and guided by prevalent comorbidities and the observed response to specific therapeutic interventions.

Device therapy

Although most older HF patients can be effectively managed with behavioural interventions and medications, implantable devices are playing an increasingly important role in the management of selected subgroups of the HF population.

Cardiac pacemakers

Ageing is associated with a progressive decline in the number of functioning sinus node pacemaker cells, often leading to the 'sick sinus syndrome', which is characterized by inappropriate sinus bradycardia, sinus pauses, and chronotropic incompetence (failure to adequately increase heart rate in response to increased demands). Since cardiac output is directly proportional to heart rate (Cardiac Output = Heart Rate x Stroke Volume), age-related bradyarrhythmias may contribute to HF symptoms and impaired exercise tolerance. Because there is no effective medical therapy for sick sinus syndrome, implantation of a pacemaker is appropriate in symptomatic patients. Beta-blockers may precipitate symptomatic bradyarrhythmias in elderly HF patients. However, since beta-blockers improve ventricular function and reduce mortality and hospitalizations in patients with systolic HF, placement of a pacemaker is often preferable to discontinuation of beta-blocker therapy.

Cardiac resynchronization therapy (CRT)

In the past decade, a new role has emerged for pacemakers in treating selected patients with advanced HF. Approximately 30% of HF patients have left bundle branch block or other intraventricular conduction abnormality resulting in significant prolongation of the QRS interval

(≥120 ms). In these patients, LV contraction is often dyssynchronous and out of phase with right ventricular contraction. Biventricular pacing, with one lead pacing the right ventricle and a second lead pacing the left ventricle through retrograde insertion into the coronary sinus, can 'resynchronize' ventricular contraction, thus improving ejection fraction and cardiac output. The addition of atrial pacing may provide further benefit by optimizing the timing of atrial and ventricular contraction. The benefits of CRT in improving ejection fraction, reducing LV cavity size, and enhancing exercise tolerance and QOL have now been documented in several randomized trials involving patients with advanced HF symptoms (New York Heart Association class III–IV), reduced ejection fraction, and prolonged QRS duration.[23] In addition, meta-analysis indicates that CRT is associated with fewer hospitalizations and improved survival.[24] Although few older patients have been enrolled in the CRT trials, observational data suggest that CRT is associated with improved QOL and exercise tolerance in older patients, including octogenarians.[25] Based on these findings, CRT is a reasonable option for carefully selected older patients with advanced HF symptoms despite conventional therapies.

Implantable cardioverter-defibrillators (ICDs)

Approximately 40% of all deaths in patients with HF occur suddenly, and the majority of these are attributable to ventricular tachycardia (VT) and ventricular fibrillation (VF). ICDs have the capacity to recognize VT and VF, and to restore normal rhythm either by pacing techniques (in the case of VT) or by delivering an intracardiac electrical shock (refractory VT or VF). Moreover, these devices have been shown to significantly improve survival in certain high-risk subgroups of the HF population, including those with resuscitated cardiac arrest, symptomatic sustained VT, and ischaemic or non-ischaemic cardiomyopathy with ejection fraction ≤35%.[26]

In the United States, over half of ICDs are implanted in patients 65 years of age or older, including almost 20% in patients age 80 or older. However, despite the established benefits of ICDs in appropriately selected patients, the clinical role of ICDs in elderly HF patients remains a subject of debate. Data supporting the use of ICDs in patients 80 years of age or older is limited, and a recent meta-analysis found that ICDs did not reduce mortality in women.[27] ICDs also do not improve survival during the first year following implantation, so that patients with limited life expectancy (e.g. New York Heart Association class IV HF) are not suitable candidates for an ICD.[5] In addition, the devices are expensive, and QOL may be impaired, especially in patients who receive one or more ICD shocks. There are also ethical questions, such as how and when to turn off the device in the terminal stages of HF, or in cases where another life-threatening illness develops (e.g. stroke or cancer). In part for these reasons, many older patients who fulfil guideline criteria for an ICD may elect to forego the procedure. Although additional study is needed, it is clear that the use of ICDs in older HF patients must be individualized, especially for those 80 years of age or older, limited life expectancy, or impaired quality of life.

Multidisciplinary care

The presence of multiple comorbid conditions, polypharmacy, dietary concerns, and a host of psychosocial and financial issues frequently complicate the management of HF in older patients. Moreover, these factors often contribute to poor outcomes in older adults, including frequent hospitalizations. To address these issues, and to provide comprehensive yet individualized care for older HF patients, a coordinated multidisciplinary approach is recommended. Several randomized trials and meta-analyses have documented the efficacy of multidisciplinary HF disease management programmes in reducing hospitalizations and improving QOL in older patients, and these interventions have also been reported to lower overall medical costs.[28]

Elements of an effective HF disease management programme include patient and caregiver education, enhancement of self-management skills, optimization of pharmacotherapy (including consideration of polypharmacy issues), and close follow-up.[5] The structure of a HF disease management team is similar to that of a multidisciplinary geriatric assessment team, and typically includes a nurse coordinator or case manager, dietician, social worker, clinical pharmacist, home health representative, primary care physician and cardiology consultant. Specific goals of disease management are to improve patient adherence to medications, diet and exercise recommendations by enhancing education and self-management skills; provide close follow-up and improved healthcare access through telephone contacts, home health visits, and nurse or physician office visits; and optimize the medication regimen by promoting physician adherence to recommended HF treatment guidelines,[5] simplifying and consolidating the regimen when feasible, eliminating unnecessary medications, and minimizing the risks for drug–drug and drug–disease interactions.

Exercise

Both HF and normal ageing are associated with reduced exercise capacity, in part due to sarcopenia (loss of muscle mass) and alterations in skeletal muscle blood flow and metabolism. Regular physical activity improves exercise performance in healthy older adults, as well as in those with HF, and regular exercise is now recommended for most older HF patients. In the recently reported

HF-ACTION trial (HF: A Controlled Trial Investigating Outcomes of Exercise Training), 2331 patients (mean age 59 years, 28% women) with systolic HF (mean ejection fraction 25%) were randomized to a supervised exercise programme or usual care and followed for an average of 30 months.[29] Overall, there was no difference between groups in the primary composite outcome of all-cause mortality or all-cause hospitalization. After adjusting for baseline prognostic factors, exercise was associated with a significant 11% reduction in the primary endpoint and a 15% reduction in cardiovascular mortality or HF hospitalization, with similar results in patients $\leq$70 versus >70 years of age. In addition, patients randomized to the exercise group reported modest but significant improvements in QOL that persisted up to four years.[30]

Although supervised exercise programmes have been associated with the greatest improvements in exercise performance, such programmes are not feasible for many older patients due to lack of availability, travel concerns and cost constraints. Therefore, most older HF patients should be encouraged to engage in a self-monitored home exercise programme that includes stretching exercises, resistance exercises and aerobic activities. Stretching increases or maintains muscle flexibility and reduces the risk of injury. A daily stretching routine lasting 15–30 minutes and involving all major muscle groups is recommended. Resistance training increases muscle mass and strength and reduces the risk of falls and frailty. Older adults initiating a strength training programme should use light weights and perform 2 to 3 sets of 8 to 12 repetitions for each of 8 to 12 exercises approximately 2 to 3 times per week; as with stretching, all major muscle groups should be included in the strength training programme.

In addition to improving physical performance and QOL, aerobic exercise may increase the likelihood that older adults will remain independent in activities of daily living. For most older adults, walking is the most suitable form of aerobic exercise, but stationary cycling and swimming are appropriate alternatives. Older adults embarking on an exercise programme should be advised to begin at a comfortable pace and exercise for a comfortable period of time. For HF patients, this may be as little as a few minutes of walking at a slow pace, but patients should not be discouraged by the fact that they are starting at a low level; indeed, data show that the greatest improvements occur in patients with the lowest baseline activity levels. Patients should exercise at least 4 to 5 days per week, gradually increasing the duration of exercise (but not the intensity) until it is possible to exercise comfortably and continuously for 20 to 30 minutes. Once this level of exercise capacity has been achieved, patients may consider further increasing the duration of exercise (e.g. up to 45 minutes) or gradually increasing the intensity. In either case, older HF patients should not exercise strenuously or to exhaustion. Additionally, patients should be instructed to stop exercising and contact their physician if they develop chest pain, undue shortness of breath, dizziness or syncope, or any other symptom that may indicate clinical instability. Finally, contraindications to exercise in elderly HF patients include decompensated HF, unstable coronary disease or arrhythmias, neurological or muscular disorders that preclude participation in an exercise programme, or any other condition that would render exercise unsafe.

End of life

The overall five-year survival rate for older patients with established HF is less than 50%; that is, the prognosis is worse than for most forms of cancer. Clinical features portending a less favourable outcome include older age, more severe symptoms and functional impairment, lower systolic blood pressure, lower LV ejection fraction, underlying CAD, hyponatraemia, anaemia, impaired renal function, and cognitive dysfunction. Older patients with advanced HF, as evidenced by NYHA class III–IV symptoms, have a one-year mortality rate of 25–50%; for these patients, HF can properly be considered a terminal illness. In addition, all HF patients are at risk for sudden arrhythmic death, which may occur during periods of apparent clinical stability. For these reasons, it is appropriate to address end-of-life issues early in the course of HF management, and to reconsider these issues periodically as the disease progresses or when changes in clinical status occur.[5]

Although discussing end-of-life issues is often challenging for healthcare providers as well as patients and families, specific measures should be undertaken to plan for and facilitate end-of-life care.[5] These include the development of an advance directive and appointment of durable power of attorney. The advance directive should be as explicit as possible in defining circumstances under which the patient does not want to be hospitalized, placed on a respirator, subjected to other life-sustaining interventions (e.g. a feeding tube), or resuscitated. Since patients may alter their views about these issues as clinical circumstances evolve, it is important to maintain open communication throughout the disease process.

End-stage HF is frequently accompanied by considerable discomfort and anxiety, and data from the SUPPORT study indicate that most patients and families have concerns about the quality of end-of-life care.[31] A cardinal principle of end-of-life care is to provide adequate relief of pain and suffering through the judicious use of conventional therapies in conjunction with narcotics (e.g. morphine), sedatives (e.g. benzodiazepines), and other comfort measures.[32] Equally important is the provision of emotional support for the patient and family, assisted by nurses, members of the clergy, social service representatives, and other qualified healthcare professionals. In some patients with

terminal HF, institutional or home-based hospice care may be appropriate.[32]

Prevention

In light of the high prevalence and poor prognosis associated with HF in the elderly, it is evident that more effective means for the prevention of this disorder are needed. At present, the most effective preventive strategies involve aggressive treatment of established risk factors for the development of HF, especially hypertension and CAD. Several studies have shown that even modest declines in blood pressure are associated with substantial reductions in incident HF among elderly hypertensive patients (Table 41.7). In the HYVET study (Hypertension in the Very Elderly Trial), for example, treatment of hypertension in patients 80 years of age or older was associated with a 64% reduction in incident HF over a median follow-up of 1.8 years.[33] Likewise, treatment of elevated cholesterol levels with an HMG-CoA reductase inhibitor has been shown to decrease incident HF following an acute coronary event. Similarly, it is likely that smoking cessation and effective control of diabetes will contribute to a reduction in HF.

Future directions

Current treatment of HF in the elderly is characterized by marked under-utilization of proven therapies, insufficient evidence to guide treatment in major patient subgroups (e.g. octogenarians and beyond, nursing home residents, patients with advanced comorbidities, and individuals with HFPEF), and inattention to critically important psychobehavioural issues (e.g. adherence, personal preferences and end-of-life care). Thus, there is a need for additional research aimed at developing more effective strategies for the prevention and treatment of acute and chronic HF in older adults.

As shown in Table 41.8, several new treatments for HF, both pharmacological and technological, are currently under investigation. While rigorous testing is essential for evaluating the impact of each of these new therapeutic modalities, there is hope that many of these interventions will make significant contributions towards reducing the burden of HF in our progressively ageing population.

Key points

- Age-related changes in cardiovascular structure and function coupled with the rising prevalence of cardiovascular diseases at older age lead to progressive increases in the incidence and prevalence of heart failure with advancing age in both men and women.
- Heart failure in older adults often presents with atypical symptoms and signs, such as altered sensorium, behavioural changes, anorexia, or gastrointestinal disturbances.
- Common comorbid conditions and geriatric syndromes frequently interact with heart failure leading to clinically significant alterations in the clinical manifestations and response to therapy in older patients.
- Management of heart failure with reduced ejection fraction is generally similar in older and younger patients, but treatment for heart failure with preserved ejection fraction remains largely empiric due

to the lack of proven benefit from standard heart failure therapies.

- Optimal management of heart failure in older adults, especially those with multiple co-existing conditions or social isolation, is best accomplished utilizing a multidisciplinary team involving a nurse coordinator, geriatric clinical pharmacist, dietician, social worker, and one or more physicians.

[2]University Hospital of Wales, Cardiff and Vale University Health Board, Cardiff, Wales, UK

Introduction

The primary enabling technology that led to the exponential growth in modern cardiac surgery was the development of the heart-lung machine in 1953. Currently, Western economies' estimated needs are 1000 to 1300 cardiac operations per million population. Life expectancy in Western economies has increased significantly during the past 50 years; in Europe it is now 84 years for women and 77 years for men, and in 2008 approximately 18% of the European population were more than 65 years of age. Moreover, cardiovascular disease is the leading cause of morbidity and mortality in the elderly,[1] and it is estimated that 25–40% of octogenarians have symptomatic cardiac disease.[2] Hence the increasing numbers of elderly patients undergoing cardiac surgery (Figure 42.1).[3]

The elderly continue to enjoy an active lifestyle and not unexpectedly want a good QOL, and many feel that a high operative risk, namely death on the operating table is an acceptable alternative to increasing debilitating symptoms in the last few years of life. The decision when to 'offer' or 'deny' cardiac surgery should though be answered in terms of outcome, mortality and morbidity risk in relation to the expected improvement in QOL. Careful preoperative assessment of comorbid risk factors is also essential in the elderly, because of competing comorbid disease mortality risks.

Cardiac surgery outcome in terms of mortality has continually improved as a result of the development of less traumatic heart-lung machines, more effective myocardial protection strategies, and improved peri-operative care. The mean age of patients undergoing cardiac surgery is progressively increasing and many octogenarians are now successfully undergoing cardiac surgery. In the United Kingdom, 22% of patients undergoing heart surgery were over 75 years of age in 2008 compared to less than 9% in 1999 (Figure 42.1).[3]

The demographics of the octogenarian or older patient undergoing cardiac surgery differ to that of the younger patient group,[4] in that patients are more likely to be female (~45%), are less likely to have diabetes (~20%), smoke (~35%) or have chronic lung disease (~10%); these observations are possibly indicative that only in the absence of these risk factors is an individual likely to live long enough to become a nonagenarian.

Age *per se* is not a contraindication for cardiac surgery provided the elderly patient can be discharged without significant disability and loss of independence.

Cardiac surgery outcomes in the elderly

Mortality

The type of cardiac surgery done is customarily grouped in terms of isolated coronary artery bypass grafting (CABG alone), CABG with concomitant valve surgery (CABG + valve), valve repair or replacement alone (valve alone), and Other procedures. Notably, the type of cardiac surgery done changes in the elderly; isolated CABG is the more common procedure in patients under 75 years of age (64% of heart operations), whilst heart valve operations predominate in patients over the age of 85 years (69%) (Figure 42.2).[3]

The mortality of cardiac surgery increases with both the complexity of the required procedure as well as with increasing age. Nevertheless, the crude in-hospital mortality associated with cardiac surgery in patients older than 80 years of age has now decreased to approximately 5–9% for isolated CABG, 8–11% for combined CABG and valve surgery, and 5–7% for isolated valve surgery (Figure 42.3).[3] The lower aforementioned mortality range figures approximate that for patients electively admitted for surgery from home as opposed to patients undergoing urgent surgery because of the severity of their condition, who have a

higher mortality. Nevertheless, elderly patients referred for cardiac surgery almost always have severe disease which if untreated would significantly reduce their life expectancy and result in a worse outcome than the aforementioned mortality rates.

Postoperative complications such as requirement for temporary haemodialysis (incidence: nonagenarian 9.2%, octogenarian 7.7% vs. 3.5% in younger age groups), stroke and prolonged ventilation all increase with age (Figure 42.4).[1] The average length of hospital stay following cardiac surgery in patients less than 60 years of age is 9 days but this increases to more than 15 days in patients older than 85 years.[3]

Nonetheless, the expected medium-term post-cardiac surgery actuarial five-year survival in the octogenarian is 60–75%, and with a significantly improved QOL.[5]

Pre-existing comorbid risk factors associated with increased mortality in octogenarians undergoing open-heart operations should be taken into account when advising patients of the risk of having surgery. These include New York Heart Association (NYHA) dyspnoea class III or IV, female gender, previous myocardial infarction, triple-vessel coronary artery disease, depressed left ventricular ejection fraction, chronic obstructive pulmonary disease, higher left ventricular end-diastolic pressure, preoperative intra-aortic balloon pump (IABP),

congestive heart failure, mitral valve operation, urgency of operation, chronic renal disease, as well as peripheral and cerebrovascular disease.[5]

Morbidity: Neurological dysfunction

The postoperative complication of greatest concern following cardiac surgery is a cerebrovascular accident (CVA), which is usually embolic in aetiology. A stroke significantly reduces postoperative QOL and is also associated with a high late mortality following hospital discharge.

The risk of a peri-operative stroke is higher in the elderly: being 13% in octogenarian compared to 4% in younger patients. Age-related morphological and physiological changes characterized by cerebral atrophy and diminished cerebrovascular reserve capacity, subclinical degenerative brain disease and severe atherosclerosis of the aorta as well as head and neck vessels are multifactor pre-existing comorbid risks contributing to the increased risk of postoperative neurological complications in the elderly (Figure 42.5).[6] Intraoperative manipulation of an atherosclerotic ascending aorta increases the probability of atheroembolism and consequent stroke. It is therefore important to identify elderly patients who are at high risk of sustaining a peri-operative stroke preoperatively in order to institute additional intraoperative protective strategies.[6]

Preoperative identification of patients with carotid artery disease is important, and our practice is to screen patients at risk for atheromatous disease with carotid duplex imaging (Table 42.1). Carotid artery disease is uncommon in the cardiac surgical patient who does not have coronary artery disease.

Patients scheduled for cardiac surgery who have coexisting symptomatic or asymptomatic carotid artery disease should then be assessed as to whether carotid

artery endarterectomy is indicated either prior to or as a combined procedure with their cardiac surgery. A recent meta-analysis of combined versus staged procedure has shown that in stable cardiac patients the safer option is to perform carotid endarterectomy first followed by subsequent coronary artery bypass grafting.

The presence of severe ascending atherosclerotic plaque at the time of cardiac surgery is associated with a 10% incidence of peri-operative or late neurologic events, compared to 4% in patients with normal or only mild ascending aortic atherosclerosis. Intraoperative mechanisms of identifying ascending aortic atherosclerotic plaque are therefore useful in the elderly; either epi-aortic Doppler ultrasound or transoesophageal echocardiography. If significant atherosclerotic plaque is identified, then reducing ascending aortic manipulation such as off-pump surgery without any manipulation of the ascending aorta, cardiopulmonary bypass using single cross-clamp techniques, and the use of ascending aortic filtration devices are available techniques which can potentially reduce the risk of intraoperative atheroembolism.

More minor neurocognitive dysfunction such as memory loss and changes in visual acuity are also common after cardiac surgery and the aetiology is multifactorial. Pre-existing comorbid neurological risk factors, especially confusional states of indeterminate origin, should, however, be considered relative contraindications to cardiac surgery in the elderly, as undergoing open-heart surgery may aggravate them.

Assessment of the elderly patient for cardiac surgery

An improved longer-term prognosis is a frequent indication for cardiac surgery in younger patients; however in the elderly, this is less of an issue. Elderly patients must be assessed individually in terms of the natural history of their disease, symptoms thereof, comorbid diseases, current QOL, and the risk (mortality and morbidity) versus benefit (improved QOL) of any potential surgical intervention.

Operative risk: Estimated mortality for cardiac surgery

Mortality following cardiac surgery usually refers to either in-hospital, that is, deaths occurring within the base hospital during the same admission, or 30-day mortality, that is, deaths within 30 days of surgery. In the United Kingdom, the former definition is currently more commonly used.

Crude mortality fails as a comparative measure of quality between hospitals or surgeons, if there are major variations in case mix. A mechanism of risk stratification based on preoperative factors that increase operative mortality risks, such as age, is therefore essential if referral patterns, allocation of resources, and discouragement of the treatment of high-risk patients are to be avoided. Without risk stratification, surgeons and hospitals treating high-risk patients will appear, on the basis of crude mortality, to have worse results than others.[7]

The estimated risk of undergoing a given cardiac procedure is therefore determined from known preoperative risk factors and calculating the Euro Score (European System for Cardiac Operative Risk Evaluation Score), which is a weighted score that is used preoperatively to provide an estimated predicted operative mortality (Table 42.2).[7] The web site http://www.euroscore.org provides a free multilingual risk calculator for predicting cardiac surgical mortality, by both the additive and newer logistic Euro Score.

The additive Euro Score has been shown to provide a good correlation with actual observed mortality in the lower-risk groups, but is less accurate and tends to underestimate operative morality when the predicted operative mortality risk exceeds 9%. In the higher-risk groups, the alternative logistic Euro Score mathematical model appears to improve prediction. Although the original simple additive model remains a useful more user-friendly clinical tool to predict immediate operative risk (Table 42.2).

In the future, procedural one-year mortality or more will provide additional useful information for predicting 'true' outcome.

Benefit of surgery: Intended improved quality of life (QOL) following surgery

Increased survival is not the primary benefit of cardiac surgery in the elderly and should therefore not necessarily be the primary outcome indicator. Nevertheless, medium-term five-year survival for patients over the age of 80 years is remarkably good; isolated CABG ~70%, isolated AVR ~65% and isolated mitral valve repair ~72%.[3]

More important is assessing any expected improvements in QOL intended by a proposed cardiac surgical procedure,

Table 42.2 Weighted risk factors relevant to a specific individual patient are added and this then provides the Euro Score predicted mortality (%) for that patient to undergo the proposed cardiac surgical procedure (range 0–42%).

Risk factors and definitions	Weighted-score

which is difficult. A perceived improvement in the NYHA dyspnoea score is not sufficient as it does not fully address the broader aspect of QOL and independent lifestyle.

Factors that impact on QOL are mostly physical rather then mental conditions. The SF-36 health survey questionnaire assesses eight general health concepts: physical functioning, bodily pain, role limitation because of personal or emotional problems, emotional well-being, social functioning, energy or fatigue, and general health perceptions. A study of octogenarians who had undergone cardiac surgery showed SF-36 scores equal or better than those of the general population of age greater than 65 years. Moreover, 84–94% of octogenarian operative survivors continue living on their own, and 83–98% indicated that they would in retrospect undergo cardiac surgery again because of the improvements in their lifestyle.[8]

To date preoperative QOL assessments such as the SF-36 questionnaire have not been used to guide preoperative decision-making. An alternative simpler assessment is the EQ-5D or EuroQol, which assesses the level of mobility, self-care, usual activity, pain or discomfort, and anxiety or depression, and may well assist in preoperative decision-making (Table 42.3).[9]

The elderly more frequently have additional coexistent medical conditions, which may frequently worsen, after cardiac surgery. Coexistent medical conditions must therefore be taken into account in terms of the patient's QOL. Diabetes mellitus with end-organ disease and renal failure are the most hazardous risk factors for a postoperative reduced QOL. Diabetes mellitus results in decreased mobility and chronic pain, whilst renal failure directly affects survival. Care should therefore be taken when selecting patients with those comorbidities for cardiac surgery.

A confounding factor in the assessment of the elderly for cardiac surgery, however, is that suboptimal timing of surgery, namely, excessively late referral for surgery, has a significant negative impact on both operative risk and late outcome.[10] The combined effect of delay, deteriorating cardiac status and exacerbating end-organ dysfunction (i.e. renal, pulmonary) may render an otherwise operable candidate beyond salvage.[8,11]

The elderly are more sedentary, may not notice milder symptoms, or may attribute symptoms to increasing age and may thus present late. Complete assessment on initial presentation is critical, and mild symptoms in the elderly should not preclude further investigations such as echocardiography and coronary angiography, in order to more accurately determine the presence and extent of any underlying cardiac disease. The decision whether to operate or not should be done without delay and not on a 'wait and see how symptoms progress' basis if the best surgical outcome is to be achieved.

Coronary artery bypass graft surgery

Coronary artery bypass graft surgery forms the majority of cardiac surgery today and was introduced as a therapeutic option in the early 1960s once myocardial ischaemia (angina pectoris or myocardial infarction) was shown to be due to narrowing of the coronary arteries from atherosclerotic plaque. Prospective randomized clinical trials in coronary artery surgery defined the indications for and benefits of CABG in both relieving symptoms and improving survival. These major trials showed that CABG increases survival in patients shown to have left main stem coronary artery stenosis, triple-vessel disease, or double-vessel disease on coronary angiography and in those with impaired left ventricular function or with left ventricular aneurysms. This applies equally in the elderly (Figure 42.6).[12]

CABG reduces the incidence of fatal myocardial infarction, relieves angina, and increases exercise capacity. However, isolated CABG does not improve symptoms of

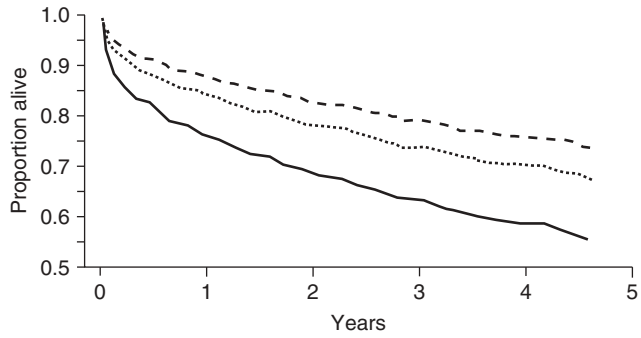

Figure 42.6 Risk-adjusted survival curves for 981 patients, 80 years of age or older, with ischaemic heart disease who underwent either revascularization by coronary artery bypass graft surgery (dashed line) or percutaneous coronary intervention (dotted line) versus continued medical therapy (solid line). Reprinted from Graham *et al.*[12] with permission from American Heart Association, Inc.

congestive heart failure, especially in the absence of proven hibernating or stunned myocardium.

Care though should be taken to not use the degree of symptomatic angina as the basis to refer an elderly patient for coronary angiography, as there is a poor correlation of the degree of angina with the degree of coronary artery narrowing. Up to 42% of patients with left main stem stenosis (the cohort of ischaemic heart disease patients at greatest risk of early death with continued medical therapy) will have only mild or no angina.[13] It is therefore important to make a distinction as to the indications of referral for further investigation as opposed to those for CABG surgery, which are not necessarily the same. Any recent change in angina symptoms should prompt a cardiologic assessment.

Delays in referring for diagnostic coronary angiography should not occur, as this may partly account for the increased prevalence of left main stem disease in octogenarians or nonagenarians (~32%) undergoing CABG as well as need for emergent surgery.[4] Left main stem stenosis of more than 50% remains an indication for CABG in the elderly even in the absence of severe symptoms, as less than 55% of medically treated patients 65 years or older with left main stem stenosis will survive for three years compared to an 87% survival for those undergoing CABG.[13]

In the United Kingdom, the operative mortality for isolated CABG in the elderly (age >75 years) has progressively decreased from 7.2% in 1999 to 3.3% in 2008, representing a reduction of ~50%.[3] Preoperative risk factors associated with increased operative mortality in nonagenarians from the US Society of Thoracic Surgeons database are shown in Table 42.4.[4] Similarly, in Europe, potentially delayed surgery, that is, waiting until the patient requires emergent surgery or reaches NYHA dyspnoea class IV, are important risk factors for an increased operative mortality in octogenarians.[2,11]

Table 42.4 Risk factors for operative mortality in nonagenarians undergoing CABG, listed in decreasing order of discriminatory importance.

Risk factors for CABG in Nonagenarians	Operative mortality
• Emergent surgery	26.6%
• Preoperative need for an IABP	26.3%
• Renal failure (Creatinine >2.0 mg%) or dialysis	20.90%
• Peripheral or cerebrovascular disease	10.60%
• Mitral insufficiency	7.2%

IABP, intra-aortic balloon pump
Source: Data derived from the Society of Thoracic Surgeons National Cardiac Database (1997–2000).[4]

A retrospective study of CABG surgery in octogenarians showed complete revascularization with CABG surgery to be more cost-effective than medical management; three-year survival of 80% in the surgical group versus 64%, QOL index of 84% in the surgical group (similar to an average 55-year-old in the general population) versus 61%, and lower cost per quality adjusted life-year gained in patients managed surgically.[9]

The overall outcome of CABG in the octogenarian can be improved by avoiding excessive delay prior to referral, frequently based on misperceptions that age is a contraindication for cardiac surgery.

Is percutaneous coronary angioplasty a better alternative in the elderly?

Percutaneous coronary revascularization is also associated with a better survival than medical therapy in the octogenarian with significant ischaemic heart disease (Figure 42.6).[12]

Perceived increased risks of surgery in the elderly should not, however, introduce a bias to opting for 'less invasive' percutaneous coronary angioplasty as being a better option in the octogenarian. Complications of coronary angioplasty increase disproportionately in octogenarians and can be associated with a high in-hospital mortality of 8.2%. Coronary anatomy is often more suitable for bypass surgery and incomplete revascularization is an independent predictor of both in-hospital and late mortality.[12]

Elective CABG surgery as opposed to percutaneous interventions is frequently a better option in nonagenarian patients, in the absence of significant associated comorbidity.[4] Coronary artery bypass grafting provides

a more favourable survivorship up to eight years after operation. Age alone should not be a deferent for aggressive treatment of coronary heart disease.

Use of the internal mammary artery as a conduit

CABG surgery was initially done using only reversed long saphenous vein as the bypass conduit between the ascending aorta and coronary artery, implanted distal to the flow limiting atherosclerotic plaque. However, the conduit that provides the best long-term patency is the internal mammary artery, and is today the conduit of choice as a pedicle graft to the left coronary system. Use of the internal mammary artery also confers an immediate survival advantage by reducing operative mortality.

Dissection of the internal mammary artery pedicle prolongs the operation time, is more technically demanding, and may be associated with increased postoperative bleeding, sternal infection in diabetics, and respiratory compromise. These reasons are therefore frequently cited to justify not using this conduit in higher-risk patients, such as the elderly. However, the use of an internal mammary artery has been shown to reduce mortality also in octogenarians undergoing CABG surgery (Figure 42.7).[1,14]

Newer techniques of harvesting the internal mammary artery by a skeletonized method can further reduce the risk of postoperative complications associated with its use. A high 71% use of internal mammary artery conduits in octogenarians as reported by Avery and co-workers, who also report one of the lowest operative mortalities of 2% in non-emergency octogenarian CABG, should be encouraged.[11]

The use of the internal mammary artery is beneficial in octogenarians by both reducing operative mortality and improving longer-term survival. Use of bilateral mammary artery combined with off-pump surgery may in selected elderly patients further reduce complications related to manipulation of highly calcified aorta. Age alone should not be a contraindication to arterial revascularization in selected patients.

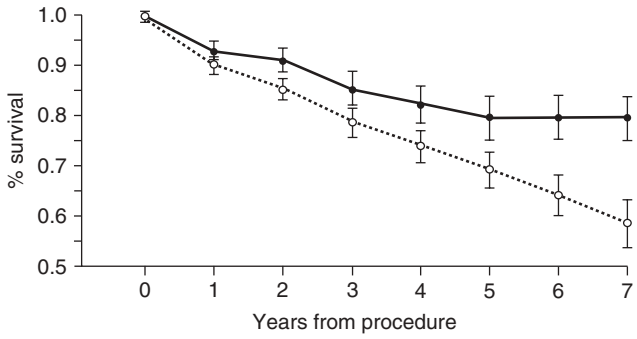

Figure 42.7 Actuarial survival rate of 487 patients 80 years of age or older who underwent coronary artery bypass graft surgery, and grouped according to whether they had received a left internal mammary artery graft to the left anterior descending coronary artery (solid line) versus those in whom only saphenous vein grafts (broken line) had been used. Reprinted from *Morris et al.*[14] Copyright 1996, with permission from Elsevier.

Antithrombotic therapy after coronary artery bypass graft surgery

Graft closure after CABG surgery is largely related to platelet aggregation and intimal hyperplasia. The current recommendation is therefore lifelong aspirin therapy at a dose of 325 mg day^{-1}. Aspirin doses of 75 mg have been suggested to be more effective then higher doses because low dose can 'spare' prostacycline and cause less gastrointestinal toxicity. A lower dose of aspirin has also been associated with diminished risks of major bleeding in acute coronary syndrome trials and this lower dose is now frequently prescribed.[15] It is important to commence aspirin therapy immediately postoperatively as early graft patency is not improved if therapy is delayed for 48–72 hours postoperatively.

Valve surgery

The proportion of patients undergoing cardiac surgery, requiring heart valve surgery (valve or valve + CABG) as opposed to isolated CABG surgery increases with patient age and approaches 70% in patients over the age of 85 years in the United Kingdom (Figure 42.2).[3] In the elderly though, successful cardiac surgery leads to greater improvements in perceived health status in valvular than in coronary artery disease patients.

Aortic valve replacement in the elderly

The predominant valve disease of the elderly is calcific degenerative aortic stenosis and accounts for 60–70% of the valve surgery caseload. Aortic valve cusps are calcified in 26% of adults older than 65 years and valve stenosis is observed in up to 5% of the population over the age of 75.[16] The development of symptoms (angina, syncope, or heart failure) identifies a critical point in the natural history of aortic stenosis, and symptomatic aortic stenosis without surgery is associated with only a 20% three-year survival.[17] In contrast, survival of the elderly patient after successful aortic valve replacement (AVR) surgery is similar to that of the natural population (Figure 42.8), as well as enabling them to return to an independent active life.[18]

Operative mortality for aortic valve surgery in the elderly approaches that obtained in younger patients and it is not until patients reach their 80s that age alone becomes a risk factor. Early mortality in octogenarians undergoing AVR

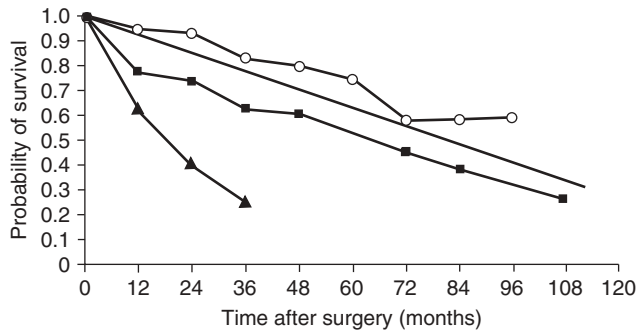

Figure 42.8 Comparative data between an unselected population of 80-year-olds in the United States (solid line), patients over 80 years of age with symptomatic aortic stenosis who did not undergo aortic valve replacement surgery (solid triangles) and 103 octogenarians with aortic stenosis who underwent aortic valve replacement with or without concomitant coronary artery bypass grafts surgery (solid squares). The survival curve of the aforementioned octogenarian patients who survived more than 30 days after surgery (open circles) is also provided. Reprinted from *Gilbert et al.*[18] with permission from the BMJ Publishing Group Ltd.

with or without associated CABG is between 5–11% in the UK.[3] Operative risk is primarily due to comorbid conditions, especially peripheral vascular disease, impaired renal function, previous cardiac surgery, poor left ventricular function and need for urgent surgery.[3,17] Once aortic valve disease is diagnosed in patients aged 80 or more, early referral for surgery should lead to the avoidance of hazardous developments (decreasing left ventricular function, loss of contractile reserve and the necessity for urgent surgery), and hence, to better postoperative outcomes.

Successful AVR surgery offers an excellent long-term outcome with long-term mortality being in most cases of non-cardiac origin. The medium-term five-year survival of octogenarians undergoing AVR is ~65% and for AVR combined with CABG ~55% in the United Kingdom.[3]

Asymptomatic aortic stenosis

The asymptomatic state is difficult to establish in practice in the elderly, due to a gradual decrease in activity or sedentary lifestyle.[16] Nevertheless, 'asymptomatic' aortic stenotic patients who should be referred for surgery include those with severe aortic stenosis (valve area $<1.0\,cm^2$ or an indexed aortic valve area $<0.6\,cm^2\,m^{-2}$ body surface area (BSA)), an abnormal response to exercise, left ventricular systolic dysfunction (left ventricular ejection fraction less than 50%), marked left ventricular hypertrophy ($\geq 15\,mm$ wall thickness), the combination of moderate calcification and a peak jet velocity $>4\,m\,s^{-1}$ as well as a rapid increase in peak aortic jet velocity of $\geq 0.3\,m\,s^{-1}$ within one year or patients with severe ventricular arrhythmias for which no cause other than severe aortic stenosis can be identified.[17]

Transcatheter aortic valve implantation (TAVI)

Octogenarians with symptomatic aortic stenosis who do not undergo surgery have only a 50% one-year survival.[18] However, a number of patients referred for surgery have significant comorbidities and therefore excessively high operative risks for open heart surgery. Percutaneous balloon valvotomy of elderly calcified stenotic valves have been poor; mortality 3–10%, strokes in 10–25%, as well as a 66% incidence of restenosis within six months.[19] Less than 20% of aortic valvuloplasty patients will survive a year and most of them will not improve symptomatically.

Newer percutaneous transcatheter valve replacement techniques were developed for patients turned down for conventional surgery and first used clinically in 2002. The current prostheses used consist of porcine or bovine pericardial valves mounted in either self-expandable nitinol or balloon expandable steel stents.[20]

The majority of transcatheter techniques are done without cardiopulmonary bypass and include either percutaneous transfemoral aortic valve implantation or transapical valve implantation through a mini-thoracotomy. The transfemoral arterial approach replaces the aortic valve retrograde via the femoral artery. Femoral artery size and tortuosity, severe peripheral vascular disease with atheromatous plaque makes this approach unsuitable in some patients. The transapical valve development uses direct balloon catheter implantation from the left ventricular apex, which is accessed through a small incision in the left side of the chest. A short period of rapid ventricular pacing is used with both techniques to decrease cardiac output during deployment of the prosthesis.

Published one-month mortality rates for TAVI range from 6–20%, cerebrovascular accidents in 2–10%, and residual paravalvular leaks in 50% of patients.[20,21] The degree of native valve insufficiency or new retrograde paravalvar leaks is though usually haemodynamically insignificant. The risk of strokes appears lower with the transapical technique by avoiding any manipulation in a calcified aortic arch, although mortality in some series has been higher with this approach.

Catheter-based aortic valve implantation is thus technically possible in elderly patients where conventional aortic valve replacement is not acceptable. However, one-year survival is between 54–80%, and is thus relatively poor in some series.[20,21] A one-year survival of less than 60% overlaps with that of patients treated conservatively and in addition at least one study has shown no significant improvement in QOL six months post-procedure.[21]

Debilitated patients often do not return to an active existence and additional comorbid pathologies with inherent competing mortality risks contribute to outcome. The appropriateness of an intervention directed solely to correcting aortic stenosis in patients turned down

for conventional surgery therefore needs very careful assessment.

Mitral valve surgery in the elderly

Elderly patients are regarded as higher-risk patients for mitral valve surgery; however, higher early and late mortalities are in part due to elderly patients being referred late (more than one year after presenting with significant symptoms) and undergoing surgery later in the history of their mitral valve disease.[10] Mortality doubles in patients undergoing any form of mitral valve surgery if over the age of 70 years compared to those less then 60 years.[3]

The predominant pathology in the elderly (developed economies) is either myxomatous degenerative or ischaemic-related secondary mitral valve regurgitation, and not unexpectedly in the former group, the elderly have significantly more associated coronary artery disease. The pathophysiology of degenerative mitral regurgitation is typically prolapse of the mitral leaflets as a result of elongated or ruptured chordae and mitral annular dilatation. In contrast, ischaemic regurgitation is usually due to restricted motion of the mitral leaflets as a result of segmental or global ventricular dilatation.

Chronic severe mitral regurgitation results in progressive and eventual irreversible left ventricular dilatation and myocardial failure (NYHA class III or IV) that is not reversed by eventual successful valve surgery (Figure 42.9).[10] Hence, early surgery (NYHA class I or II) is recommended for asymptomatic severe non-ischaemic mitral regurgitation regardless of age, if there are signs of left ventricular dysfunction (left ventricular ejection fraction less than 60%), AF or pulmonary hypertension (pulmonary systolic pressure >50 mmHg) and preserved left ventricular function, and especially if there is a high likelihood of mitral valve repair.[16]

The survival advantage of early surgery for severe mitral regurgitation is greater in the elderly than in the younger population.[10] Seven-year freedom from all-cause death in elderly patients (≥ 70 yrs) undergoing mitral valve surgery early (NYHA class I or II) was 77% versus only 44% if undergoing surgery late (NYHA class III or IV). In younger patients (<70 yrs) survival was 88% and 66% respectively.

Mitral valve replacement or repair

Conservative mitral valve repair rather than valve replacement should be done whenever feasible, as this is associated with both a lower operative mortality as well as improved long-term survival, regardless of presenting symptoms. Valve repair preserves the subvalvar apparatus and left ventricular function, thereby reducing mortality from myocardial failure. In addition, late thromboembolic and haemorrhagic complications are less frequent with mitral valve repair. Advances in surgical techniques including artificial Gore-Tex chordae have now made it possible for cardiac surgeons experienced in mitral valve repair to successfully repair more than 80% of degenerative and ischaemic regurgitant mitral valves. If mitral valve repair is not feasible, then replacement with a prosthetic valve, but with preservation of the subvalvar apparatus, is the next best option.

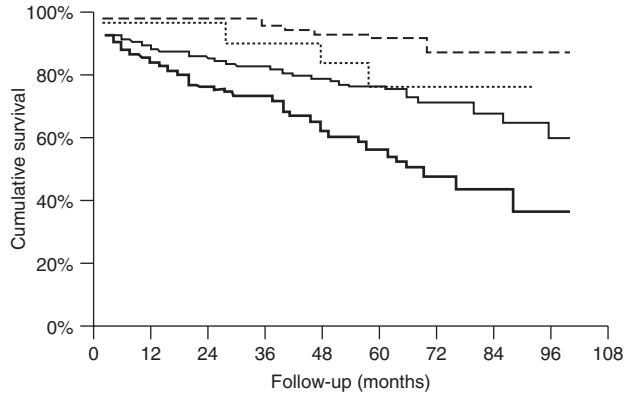

Figure 42.9 Long-term survival of 614 consecutive patients who underwent either mitral valve replacement or repair surgery, and grouped according to their preoperative NYHA dyspnoea class and age. NYHA class I or II sub-grouped according to age <70 years (dashed line) or ≥ 70 years (dotted line), as well as NYHA class III or IV subgrouped according to age <70 years (thin line) or ≥ 70 years (bold line). Reprinted from *Lee et al.*[10] with permission from ICR Publishers Ltd.

The preference for mitral valve repair as opposed to mitral valve replacement applies equally to both the young and elderly patient populations. The UK national data show both a halving of early operative mortality in octogenarians undergoing mitral valve repair compared to those undergoing mitral valve replacement, as well as an improved late survival.[3]

Choice of prosthetic valve: mechanical or biological in the elderly

A multitude of artificial mechanical heart valves have been developed, ranging from the initial obstructive 'ball and cage' valves to 'tilting disc' valves, and now 'bileaflet' mechanical valves made from titanium steel and pyrolytic carbon. Mechanical heart valves though have an associated lifelong thromboembolic risk from blood clots forming on the valve, which is the natural reaction of blood whenever it comes into contact with an artificial surface. This necessitates life-long anticoagulation with vitamin K antagonists (coumarin/warfarin), which in turn creates a risk of life-threatening major haemorrhage. A fine balance thus needs to be maintained for the rest of the patient's life, if mechanical prosthetic valves have been implanted; between too little

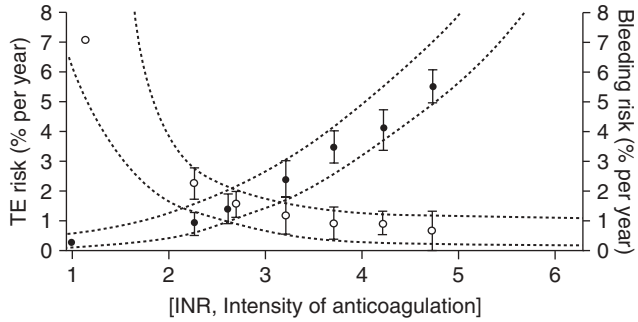

Figure 42.10 The incidence of thromboembolic (TE; open circles) and bleeding (solid circles) complications after 10-year follow-up, and grouped according to the average intensity of oral anticoagulation achieved by INR during the 10 years. The recommended target INR range was 3.0–4.5 in these patients with aortic mechanical St Jude heart valve prostheses. Reprinted from Horstkotte *et al.*[22] with permission from ICR Publishers Ltd.

anticoagulation which increases the risk of clot formation and thromboembolic ischaemic stroke, versus too much with its risk of anticoagulation-related haemorrhage and stroke (Figure 42.10).[22]

Constant lifelong monitoring and maintenance of the patient's serum international normalized ratio (INR) in the recommended range, which is discussed in more detail later in this chapter, is therefore essential in all patients receiving mechanical prosthetic valves. Contraindications to warfarin use therefore preclude the implantation of mechanical prosthetic valves (Table 42.5).[23]

Biological valves predominantly manufactured from bovine pericardium or porcine aortic valves have been developed as an alternative and do not require lifelong anticoagulation unless otherwise indicated. However, biological valves have a limited lifespan because of both calcium and non-calcium-related degeneration. Structural valve deterioration of bioprostheses is also higher in the mitral position than in the aortic position.[24] Fifty percent of 'first-generation' biological heart valves required replacement within 13 years of implantation. It has been thought that there is a reduced incidence of structural deterioration of bioprosthetic valves in the elderly; however, this has been shown to not necessarily be due to improved valve survival in the elderly but rather due to reduced patient survival from other causes. Nevertheless, current commercial, now improved 'third-generation' biological prosthetic valves, based on animal studies, are thought to have significantly improved valve survival compared to these older 'first-generation' bioprostheses. The major advantage of bioprosthetic valves in the elderly is that, unless otherwise indicated, lifelong anticoagulation with vitamin K antagonists is not required. The elderly (particularly >70 yrs) are at greater risk of thromboembolic and haemorrhagic complications secondary to coumarin therapy.[24]

The elderly patients would thus benefit from implantation of a biological as opposed to mechanical prosthetic valve and, therefore, either not requiring anticoagulation or alternatively at a lower therapeutic INR range if other indications for anticoagulation exist, because of the increasing comorbid pathologies associated with the elderly. Mortality from thromboembolic events and anticoagulation-related haemorrhage is three times higher in elderly patients over the age of 65 with mechanical prosthetic valves as compared to those with bioprostheses.[25]

The current recommendation is therefore to select a bioprosthetic heart valve for aortic valve replacements in patients equal or older than 60–65 years of age, and for mitral valve replacements in patients equal or older than 65–70 years (Figure 42.11).[24,26]

Table 42.5 Contraindications to coumarin/warfarin use.

The patient
- Comorbidity; including comorbid medical conditions, falls, frailty, exposure to trauma
- Impaired cognitive function
- Possibly housebound
- Poor expected compliance

The doctor
- Poor appreciation of drug interactions
- Inefficient organization of INR monitoring

The system
- General practice versus hospital facilities; for example, remote location, poor communication, and support
- Inadequate resources and facilities available.

Combined coronary artery bypass graft and valve surgery in the elderly

Previous unproven dictums such as 'do as little as possible/only what is deemed essential' are slowly being disproved in terms of the extent of cardiac surgery undertaken. In CABG surgery, incomplete revascularization is an independent predictor of both in-hospital and late mortality.[12] The survival benefit of attending to coexistent moderate or more ischaemic mitral regurgitation at the time of CABG surgery is well established.

The supporting evidence for 'prophylactic' additional aortic valve replacement for moderate aortic stenosis (aortic valve area 1–1.5 cm^2, and more so if <1.3 cm^2, valve calcification or renal failure) in older patients (aged >60–65 yrs) already accepted for CABG surgery is becoming stronger,

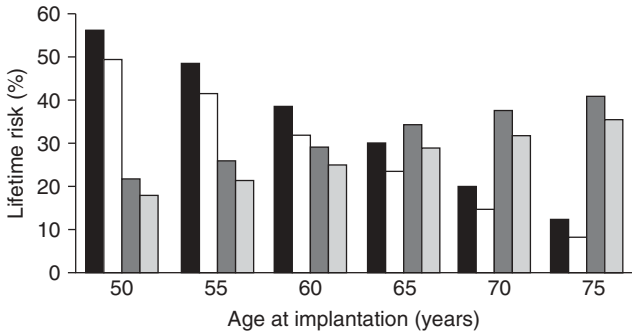

Figure 42.11 Microsimulation meta-analysis of the lifetime risk, according to the age at primary aortic valve implantation, of either structural valve degeneration of biological aortic valves without (solid bar) or with (open bar) concomitant coronary artery bypass graft surgery, or alternatively anticoagulation-related bleeding risks of mechanical aortic valves without (dark shaded bar) or with (light shaded bar) concomitant coronary artery bypass graft surgery. Reprinted from Puvimanasinghe *et al.*[26] Copyright 2003, with permission from Elsevier.

especially when considering the extremely high operative risk of subsequent re-operative valve procedures (~30% mortality), should it become necessary in an octogenarian. The presence of either aortic valve calcification or an aortic jet velocity of 3.0–4.0 m s^{-1} would suggest the likelihood of more rapid progression of aortic stenosis and therefore justification of a concomitant 'prophylactic' aortic valve replacement at the time of the initial CABG referral.

Acceptable surgical results are being obtained with these more complex procedures in the elderly, and should not therefore be denied to the elderly. Careful individual preoperative assessment as previously discussed is, however, essential.

Anticoagulation management in the elderly

Patients at risk for cerebral thromboembolic events include patients with mechanical prosthetic heart valves, AF, reduced left ventricular function (less than 35% ejection fraction), history of previous thromboembolism or hypercoagulable states and these patients should receive anticoagulation with vitamin K antagonists and their INR should be maintained in a range between 2.0 and 5.0.[27] Whether the target INR range is on the lower (INR 2.0–3.0), intermediate (INR 2.5–3.5), or upper (INR 3.0–4.5) side of this range will be dependent on the underlying thromboembolic risk, but will also influence the risk of anticoagulation-related haemorrhagic complications (Figure 42.10). The reason for providing a range is due to the difficulty of maintaining a 'constant' INR in any individual patient.

Warfarin, the most commonly used coumarin derivative, results in anticoagulation by inhibiting the synthesis of factors dependent on vitamin K, and has a considerable variability in its effects due to considerable pharmacokinetic and pharmacodynamic factors (Table 42.6).[23] This therefore demands frequent laboratory measurements of each individual patient's INR, and audits have even still shown that only 50% of patients are within their target range at any specific time point. The half-life of the vitamin K dependent factors range from 6–60 hours, thus any specific warfarin dose takes 2–3 days to produce an effect and this needs to be taken into account when managing warfarin dosage.

Patient self-management using their own 'point-of-care INR monitors' that are now available, especially in patients requiring lifelong anticoagulation, may offer the potential for both simplifying and improving oral anticoagulation management. A recently published meta-analysis of postoperative results and complications showed significant reduction in thromboembolic events, all-cause mortality and major haemorrhage in patients self-managing their INR.[28]

Table 42.6 This is only an illustrative list of interactive factors that influence the efficacy of warfarin.

Patient factors
Enhanced anticoagulant effect
Weight loss, increased age (>80 years), acute illness, impaired liver function, heart failure, renal failure, excess alcohol ingestion
Reduced anticoagulant effect
Weight gain, diarrhoea and vomiting, relative youth (<40 years), Asian or African-Caribbean background
Examples of some drug interactions with warfarin
Reduced protein binding
Aspirin, phenylbutazone, sulfinpyrazone, chlorpromazine
Inhibition of metabolism of warfarin
Cimetadine, erythromycin, sodium valproate
Enhanced metabolism of warfarin
Barbiturates, phenytoin, carbamazepine
Reduced synthesis of factors II, VII, IX, X
Phenytoin, salicylates
Reduced absorption of vitamin K
Broad-spectrum antibiotics, laxatives
Enhanced risk of peptic ulceration
Aspirin, non-steroidal anti-inflammatory drugs, corticosteroids
Thrombolytics
Streptokinase, tissue plasminogen activator
Antiplatelet drugs
Aspirin, non-steroidal anti-inflammatory drugs

Source: Reprinted from Blann AD *et al.* ABC of antithrombotic therapy: An overview of antithrombotic therapy. *BMJ* 2002;**325**:762–5. Copyright 2002, with permission from BMJ Publishing Group Ltd.

Anticoagulation for biological prosthetic valves

The current guidelines in patients with no other thromboembolic risk factors recommend temporary use of warfarin for only the first three months after biological valve implantation.[17] This is still controversial in patients with biological aortic valves, and thus, in these patients, either a temporary low-dose anticoagulation regimen (INR target range of 2.0–3.0), or antiplatelet therapy with aspirin (acetylsalicylic acid 75–100 mg day^{-1}) in patients not having reduced left ventricular ejection fraction (<35%), NYHA class IV, preoperative AF, or a paced rhythm can be used. After the first three postoperative months and provided there are no other thromboembolic risk factors, warfarin therapy can then be discontinued and replaced with aspirin 75–100 mg day^{-1}.[17]

Anticoagulation for mechanical prosthetic valves

Mechanical prosthetic valves in the aortic position (excluding first-generation Starr-Edwards, Lillehei Kaster, Omniscience, and Björk-Shiley valves) are considered to be less thrombogenic than in the mitral position (double the risk). Hence, patients with second- or third-generation mechanical prosthetic valves (St Jude Medical bileaflet, Medtronic-Hall tilting disc, CarboMedics bileaflet) can be maintained at an INR target range of 2.5–3.0 or 3.5 for the aortic position,[17,23,27] and at a slightly higher INR range of 3.0–3.5 or 4.5 for the mitral position.[23,27] The higher top endpoint should probably be used if there are additional thromboembolic risk factors; an enlarged left atrium (>55 mm in diameter), reduced left ventricular ejection fraction (<35%), dilated left ventricle (left ventricular end-diastolic diameter greater than 70 mm), AF, or previous thromboembolic events.

Patients with mechanical prosthetic valves require lifelong constant monitoring of their INR (initially daily then at least every 1–2 weeks depending on individual variance), as diet, coexistent diseases, medication, etc. interact with the efficacy of vitamin K antagonists (Table 42.6). Inadequate anticoagulation monitoring not only increases the risk of thrombosis, but also increases the risk of stroke (3–10%), major bleeding episodes (5%), non-disabling bleeding (14%), as well as recurrent thrombosis (11%). In the event that patients have evidence of prosthetic valve obstruction or thrombosis, they should be referred for emergent reoperation.[17]

Anticoagulant management of patients with mechanical prosthetic valves undergoing non-cardiac surgery

If it is necessary to interrupt oral anticoagulant therapy in patients with mechanical prosthetic heart valves, in preparation for elective surgical procedures, it is recommended to temporarily stop oral vitamin K antagonist therapy for 4–5 days preoperatively. Once the INR is less than <2.0, then either a continuous intravenous heparin infusion (prolonging the activated partial thromboplastin time (APTT) to twice normal) or subcutaneous low-molecular-weight heparin (100 U kg^{-1} every 12 hours) given to prevent thromboembolism.[23,27] The advantage of low molecular-weight heparin is the ability to provide this therapy on an ambulatory basis. However, its effects are only partially neutralized by protamine because of its higher anti-Xa activity, and it should therefore in turn be temporarily stopped 12–18 hours prior to surgery. Oral anticoagulation therapy is then recommenced the day after surgery or as soon as feasible in terms of intestinal function.

The aforementioned guidelines should also be used when patient's (requiring oral anticoagulation) INRs drop below their therapeutic range.

Parenteral vitamin K is not recommended in the treatment of non-life-threatening bleeding associated with warfarin use in patients with mechanical prosthetic valves because of the potential for induced hypercoagulable states.

Anticoagulation for atrial fibrillation (AF)

The efficacy of oral anticoagulation with vitamin K antagonists for preventing stroke in patients with AF has been well documented. Targeting the lowest intensity of anticoagulation to minimize the risk of haemorrhagic complications is, however, particularly important for elderly patients with AF, and, in these patients, an INR target ranging between 2.0 and 3.0 is recommended.[23,27] The risk of anticoagulant-related haemorrhage increases with age (1–2% patients per year, if below 60 years old).[17] Hence, in AF patients more than 75 years old, a target INR range of 1.5–2.5 albeit not as effective, or only aspirin treatment (325 mg day^{-1}) may be considered if there are no other indications for coumadin anticoagulation.

Non-pharmacological curative therapy for atrial fibrillation

Atrial fibrillation is the most common serious cardiac arrhythmia and is associated with a significant risk of cerebral thromboembolism. The prevalence of AF in the general population is approximately 0.4%; however, the prevalence increases markedly with age to approximately 9% in the 80–89-year-old population group. Furthermore, the risk of stroke associated with AF also increases with age from a 1.5% risk at age 50–59 years to 23.5% risk at age 80–89 years. Anticoagulation with warfarin reduces this risk of stroke but imparts a risk of anticoagulation-related haemorrhage and reduces patients' QOL.

The surgical Maze procedure developed by James L. Cox has been able to cure AF in up to 99% of carefully selected patients (predominantly patients with paroxysmal AF), and thereby has essentially abolished the risk of stroke associated with AF. Percutaneous transcatheter ablation of the pulmonary vein ostia, also in carefully selected patients with paroxysmal AF, now offers a less invasive approach and a success rate of approximately 75%.

Newer hyperthermic ablation devices including radiofrequency, microwave, ultrasound, and laser, as well as cryoablation devices have also now been developed to allow surgeons to do more rapid reproducible modified Maze procedures concomitant with other cardiac surgical procedures. Postoperative five-year freedom from AF in 'non-selected' patients with permanent AF of more than one-year duration, undergoing concomitant cardiac surgery, can now be expected in 42–87% of patients depending on underlying coexistent cardiac pathology.[29]

The non-pharmacological cure of AF is currently a rapidly developing field, and clear guidelines as to patient selection are slowly being developed. However, the elderly patient with AF who has the highest risk of stroke may potentially stand to gain the most from this emerging therapeutic option.

Thoracic aortic surgery

The incidence of thoracic aortic aneurysms and aortic dissections increases in the elderly and is a lethal disease. The five-year survival of patients not operated on is approximately 54%, and these patients have a 21–74% risk of acute rupture.[30]

The major factor influencing the risk of either acute rupture, dissection, or death is the diameter of the aneurysm at initial presentation; aneurysms greater than or equal to 6.0 cm in diameter have an annual risk of a negative outcome of 15.6% (Figure 42.12).[30] The risk of rupture with time increases 11-fold with aortic aneurysm size of 5.0–5.9 cm, and 23-fold with size of 6.0 cm or greater.[30] This needs to be compared with the risk of surgery, which has an operative mortality of 5–9% for elective surgery, but as high as 57% for emergency operations in the elderly.

The current accepted guidelines for asymptomatic aneurysms is to operate once an ascending aortic aneurysm diameter is 5.5 cm or more, or if a descending thoracic aortic aneurysm is 6.5 cm or more. However, a smaller diameter of 4.5–5.0 cm is used in patients with Marfan's syndrome or a family history of aortic aneurysms because of the higher incidence of rupture in these subgroups. Additional operative risk factors that need to be taken into account when assessing a patient for surgery on the descending thoracic aorta are the risk of spinal cord injury and paraplegia of 2–8%, which is related to the extent of the aneurysm and is highest in Crawford type II thoracoabdominal aneurysms.[31]

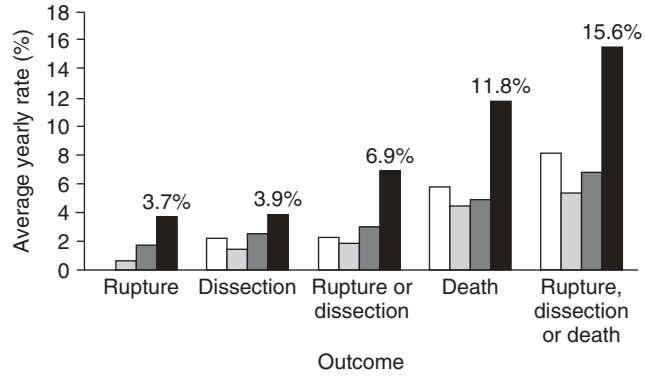

Figure 42.12 The average yearly rate (during the first five years after presentation), of negative outcomes (rupture, dissection or death) as a function of the initial thoracic aortic aneurysm (ascending, arch, descending or thoracoabdominal) size (maximal diameter); 3.5–3.9 cm (clear bar), 4.0–4.9 cm (light shade bar), 5.0–5.9 cm (medium shade bar), equal or greater than 6.0 cm (solid bar). Reprinted from Davies *et al*.[30] Copyright 2002, with permission from Elsevier.

In a large series (mean age 65 years), the risk of an adverse outcome (death, paraplegia, renal failure requiring haemodialysis or stroke) in elective thoracoabdominal aortic aneurysms was 13% and related to preoperative renal insufficiency, increasing age, type II extent, and symptomatic aneurysms.[31] An important conclusion of this study was that the development of any symptoms, no matter how mild or uncharacteristic, in patients with thoracoabdominal aneurysms requires immediate evaluation. The aneurysm must be considered the cause of the symptoms until proven otherwise as it indicates progression into a sub acute phase.

The main approach for these complex aortic repairs has been direct open repair, usually supported by deep hypothermic circulatory arrest. However, newer 'hybrid techniques' that combine surgical and endovascular approaches have been reported with lower morbidity and mortality.

These percutaneous inserted cloth-covered stainless steel stents were initially developed in 1969 and can now be inserted retrograde via the femoral artery into the abdominal and descending thoracic aorta, to seal off some aortic aneurysms. Current trials in appropriately selected patients have shown a procedural mortality of approximately 7% and five-year survival of 68%. In 'good surgical candidates' five-year survival of 78% was similar to conventional open surgical series, suggesting that cloth-covered stents are being increasingly used in patients possibly deemed unfit for conventional surgical interventions.[32] This technology is developing and it is hoped that improved stent design will reduce the risk of distal migration of stents and perigraft leakage, and become the preferred option in the elderly. The importance of the presence of an endoleak

is that it implies that there is no protection against acute rupture.

In patients judged to be poor conventional surgical candidates, five-year survival at 31% was, however, bleak and mainly due to coexistent disease. Moreover, QOL did not improve in patients asymptomatic in terms of their aneurysmal disease as opposed to their comorbid diseases.[32] Recent studies suggest that endografting can be performed as safely in elderly patients with no significant morbidity and mortality as in younger patients. However, at five years post-procedure the mortality in the octogenarian group is double (31.8% vs. 17.1%), although this increased mortality can be explained by the advanced age of the octogenarian who most likely died from other comorbidities. Increased age does not appear to be a risk factor for short- and mid-term morbidity and mortality for patients with stentable thoracic pathology. Older patients do as well after endostenting of the descending thoracic aorta and should be offered this less invasive approach.

Cardiac transplantation

The worldwide results of heart transplantation compiled by the International Society of Heart and Lung Transplantation Registry show that the current one-year and five-year survival following a heart transplant managed with modern immunosuppressive therapy is approximately 80% and 67%, respectively.[3]

A heart transplant is technically a relatively simple operation, but replaces a patient's original terminal heart disease with another disease; the disease of immunosuppression, which though is expected to carry a slightly better chance of survival. Nevertheless, constantly having to take drugs to prevent rejection of the new heart and balancing this against the risks of over-suppressing the body's defence mechanism which makes the patient prone to infection or cancer, becomes even more of an issue in the elderly.

In the United Kingdom, there is no prescribed age limit for acceptance onto a heart transplant programme; however, in practice, few patients above 65 years of age tend to be accepted. The international age distribution shows that less than 5% of heart transplants were in recipients aged 65 or more.[33] Availability of donor organs is the primary limiting factor for heart transplantation worldwide. Improvements in road traffic safety amongst others have resulted in a 40% reduction in the availability of cadaveric cardiothoracic donors in the United Kingdom over the past 10 years. Equitable allocation of donor hearts, an increasingly restricted national resource, is therefore necessary. In 2002–2003, only 32% of patients on an active cardiothoracic transplant waiting list (heart, lung or heart/lung) received an organ transplant.

An alternative option for patients with terminal heart disease not amenable to conventional cardiac surgery for whatever reason, which is now becoming available, is implantation of miniature blood pumps; totally implantable left ventricular assist devices. However, the current costs of these, what in the elderly will be 'destination therapy' devices will probably preclude universal access.

Conclusions

The elderly population has and will continue to increase and up to 40% of octogenarians have symptomatic cardiac disease. In the United Kingdom, 22% of patients undergoing heart surgery were over 75 years of age in 2008 and valve procedures predominate in octogenarians. Cardiac surgery mortality and morbidity outcomes have and will continue to improve and age itself is not a contraindication for cardiac surgery. The crude operative mortality for octogenarians undergoing cardiac surgery is currently less than 5–11% with postoperative five-year survivals of 60–75% being similar to the age-matched natural population. The major morbidity risk is that of peri-operative stroke because of the increased atherosclerotic vascular disease and can be as high as 13%.

Elderly patients must be individually assessed preoperatively in terms of the risk of the intended cardiac surgery; Euro Score-predicted mortality, versus the perceived benefit in their QOL; EuroQol, as well as the influence of other coexistent medical conditions. Although the prime indication for cardiac surgery in the elderly continues to be 'relief of symptoms', excessively late referral has a significant negative impact on both operative risk and late outcome. Mild symptoms need to be promptly investigated, if necessary by echocardiography and angiography, in order to more accurately determine the true extent of any underlying cardiac condition.

The unadjusted operative mortality for isolated CABG in the elderly (age >75 yrs) is ~3.3% and use of the internal mammary artery as a conduit is still recommended even in the octogenarian. Percutaneous coronary stenting or incomplete revascularizations are not necessarily better alternatives in the elderly.

Aortic valve replacement accounts for the majority of valve surgery in the elderly, and operative mortality is primarily related to comorbid conditions. Once again more complete assessment of the 'asymptomatic' patient is essential and early referral preferable. Replacement with a biological as opposed to mechanical prosthetic valve is recommended in the elderly because, unless otherwise indicated, lifelong anticoagulation is not required and the lifespan of current third-generation bioprostheses is greater than most elderly patient's projected lifespan. Percutaneous balloon aortic valvuloplasty is not considered to be a suitable alternative. However, transcatheter aortic valve replacement, usually without the use of cardiopulmonary bypass, is an emerging technique in elderly high-risk

patients deemed to be unsuitable for conventional heart surgery.

Chronic severe mitral valve regurgitation results in progressive irreversible left ventricular dysfunction and the survival advantage of early surgery (NYHA dyspnoea class II) is even greater in the elderly population, especially if mitral valve reparative surgery can be confidently undertaken.

Atrial fibrillation is an increasing problem in the elderly with an associated high risk of stroke. Developments in the non-pharmacological cure of AF are an attractive option in the elderly, who potentially have the most to gain in reverting to normal sinus rhythm and not requiring long-term anticoagulation, especially if concomitant cardiac surgery is already indicated.

Thoracic aortic dissections and aneurysms are more prevalent in the elderly, and untreated will rupture acutely in up to 74% of patients. In principle, patients who are symptomatic or with ascending aortic aneurysms greater than 5.5 cm or descending aneurysms greater than 6.5 cm should be referred for surgery. In appropriately selected patients, percutaneous inserted cloth-covered stents are becoming the preferred technique with the descending thoracic aortic aneurysms especially in the elderly.

Cardiac transplantation is not a realistic option in the elderly patient with terminal heart failure. However, new miniature fully implantable blood pumps may become an option in the future.

Key points

- Age is not a contraindication for cardiac surgery in elderly patients provided they can be discharged without significant disability and loss of independence.
- Elderly patients must be assessed individually in terms of the natural history of their disease, symptoms thereof, current quality of life, and the risk (mortality and morbidity) versus benefit (improved quality of life) of any potential cardiac surgical intervention.
- Referring elderly patients at an earlier stage of the disease process even with mild symptoms can improve the outcome of cardiac surgery in the elderly. Advising cardiac surgery as the last option and recommending a wait-and-see policy based on symptoms results in significantly poorer outcomes.
- Aortic valve replacement surgery if indicated, offers an excellent long-term outcome in elderly patients.
- Elderly patients benefit from implantation of a biological as opposed to mechanical prosthetic valve, if valve replacement is required, as bioprostheses do not require anticoagulation or, alternatively, at a lower therapeutic INR range, if other indications for anticoagulation exist.

CHAPTER 43

Peripheral arterial disease

Leocadio Rodríguez Mañas, Marta Castro Rodríguez and Cristina Alonso Bouzón
Hospital Universitario de Getafe, Madrid, Spain

Introduction

Peripheral arterial disease (PAD) occurs when blood flow reaching limbs is insufficient to fulfill the metabolic necessities of the tissue. This fact often comes from the presence of an occlusive arterial disease, the underlying disease process being atherosclerosis, which affects primarily, but not exclusively, the vascularization of the lower limbs.

Epidemiology

Risk factors for PAD

The factors leading to PAD are mainly the same as those leading to atherosclerosis, a process that directly or indirectly accounts for 70% of all deaths in people older than 70 years. These factors are multiple: genetic factors, metabolic diseases, inflammatory diseases, lifestyle and local and systemic conditions of the vascular system. Among these conditions and diseases are the major risk factors: age, type 2 diabetes mellitus, hypertension, dyslipidaemia, smoking, physical inactivity and abdominal obesity, age being the only non-modifiable factor.

The prevalence of PAD varies depending upon the characteristics of the population and the criteria used to define its presence.[1] There are two main methods to define PAD: the clinical one and the ankle-brachial index (ABI). The clinical method is based on the presence of the most classic symptom of PAD, namely intermittent claudication (IC), characterized by the presence of exertional calf pain that causes the patient to stop walking, resolves within 10 minutes of rest, does not resolve while the patient is walking, and does not begin at rest. The ankle-brachial index (ABI), a ratio of the systolic blood pressures in the lower and upper extremities obtained by Doppler, is the most widely used diagnostic test for detecting PAD. Among the participants in the Cardiovascular Health Study, an epidemiologic evaluation of 5084 community-dwelling men and women 65 years or older, the prevalence of PAD as defined by ABI was 12%, whereas only 2% of participants had IC.[2] The PARTNERS (PAD Awareness, Risk, and Treatment: New Resources for Survival) study, with 6979 men and women from primary care (aged 50–69 years with history of diabetes mellitus or cigarette smoking and 70 years or older), which also used the ABI as the diagnostic criteria, found a prevalence of 29%. Only 11% of these patients with PAD had IC.[3] The majority of the men and women diagnosed with PAD based on the ABI do not have classic symptoms of IC. The prevalence of classic symptoms (Table 43.1) varies from ~10–30% in patients with PAD based on the ABI value.

Age is the main risk factor for PAD. In fact, its prevalence increases dramatically with age. The Cardiovascular Health Study found a prevalence of PAD around 30% in men older than 85 years while it was lower than 10% in men ranging from 65–69 years old. The prevalence of PAD in women aged from 65–69 years old was lower than 5%, but exceeded 35% in those aged 85 or older. This association between older age and higher prevalence of PAD was also observed in both women and men with a history of heart disease and stroke.[2] Data from 2174 subjects aged 40 years and older from The National Health and Nutrition Examination Survey 1999–2000 show a PAD prevalence of 4.3% (95% CI, 3.1–5.5%) in the whole sample, but among those 70 years or over the prevalence was 14.5% (95% CI, 10.8–18.2%).[4]

Age is not only the most important non-modifiable factor which increases the risk of PAD two- to threefold. In addition, the pattern of the disease changes according to age: aorto-iliac disease occurs usually in younger subjects and is more rapidly progressive than distal disease.

Other risk factors besides age are smoking, diabetes, hypertension, dislipemia and black race. In the National Health and Nutrition Examination Survey 1999–2000,[4] more than 60% of individuals with PAD had hypercholesterolaemia, 74% were hypertensive, 26% had diabetes and 33% were current smokers. Approximately 95% had, at least, one of these cardiovascular risk factors and 72% had two or more. When adjusted by age and gender,

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 43.1 Stages and symptoms of PAD.

Fontaine's stages	
Stage	**Clinical**
I	Asymptomatic
IIa	Mild claudication (more than 150 metres)
IIb	Moderate–severe claudication (less than 150 metres)
III	Ischaemic rest pain
IV	Ulceration or gangrene

current smoking (OR 4.46; 95% CI, 2.25–8.84), diabetes (OR 2.71; 95% CI, 1.03–7.12), black race/ethnicity (OR 2.83; 95% CI, 1.48–5.42), low kidney function (OR 2.00; 95% CI, 1.08–3.70), hypertension (OR 1.75; 95% CI, 0.97–3.13) and hypercholesterolaemia (OR 1.68; 95% CI, 1.09–2.57) remained positively associated with prevalent PAD. After adjustment for smoking status, BMI, hypertension, hypercholesterolemia, diabetes and glomerular filtration rate, the smoking status (OR 4.23; 95% CI, 1.95–9.17), black ethnicity (OR 2.39; 95% CI, 1.11–5.12), diabetes (OR 2.08; 95% CI, 1.08–4.28) and low kidney function (OR 2.17; 95% CI, 1.10–4.30) remained significantly associated with the presence of PAD.

Smoking is a major and modifiable risk factor for PAD. Smoking not only predisposes to develop PAD but also increases its severity and affects the prognosis of revascularization interventions. In patients who smoke, PAD affects predominantly proximal arteries, especially the aorta and iliac arteries.[5]

The prevalence of PAD is approximately twice as high for individuals with diagnosed diabetes. Diabetes mellitus is not only a qualitative risk factor but also a quantitative one. In fact, glycaemic control is one of the strongest risk factors of illness: a positive, graded, and independent association between HbA1c and PAD risk has been described in adult people with diabetes.[6] This association is stronger for clinical (symptomatic) PAD, where manifestations may be related to the existence of microvascular disease, than for asymptomatic PAD. The glycaemic control is also associated with the worst consequence of this disease: amputation. In this regard, amputation is 10 times more frequent in diabetic than in non-diabetic patients. This suggests that efforts to improve glycaemic control in persons with diabetes may substantially reduce the risk of PAD. However, the efficacy of an intensive glycaemic control (reaching HbA1c values lower than 7%) to prevent PAD as compared with other less stringent therapeutic goals (~8%) is not established and, in fact, may have adverse consequences. Another important risk factor to develop PAD in diabetic patients is the presence of albuminuria, whatever its magnitude. Diabetes causes predominantly distal occlusive disease, including the arteries of the calves and feet.[5]

Although arterial hypertension contributes to the development of PAD to a lesser extent than either of the two previously mentioned factors, it is also a risk factor that must be controlled. There are limited data regarding the association between hypertension and PAD according to lesion localization.[5]

Black ethnicity is a strong and independent risk factor for PAD. At first, some epidemiological studies suggested a differential relationship between risk factors and prevalence of lower peripheral disease in people from different ethnicities. However, data from recent studies cannot explain the excess risk of PAD in black people by a higher prevalence of diabetes or hypertension, increased BMI or higher levels of some of the new cardiovascular risk factors (interleukin-6, fibrinogen, D-dimer, homocysteine). This suggests that unknown factors may account for the residual differences. In clinical series, PAD in blacks is associated with poorer prognosis after revascularization because of the greater presence of distal lesions involved.[5]

The Cardiovascular Health Study assessed the incidence rate of abnormal ABI over time in a community population (5888 participants, men and women 65 years and older, without PAD) and tried to identify what cardiovascular risk factors were predictors of ABI decline. ABI decline occurred in 9.5% of this elderly cohort over six years and was associated with modifiable vascular disease risk factors: current cigarette use (OR 1.74; 95% CI, 1.02–2.96), hypertension (OR 1.64; 95% CI, 1.18–2.28), diabetes (OR 1.77; 95% CI, 1.14–2.76), higher low-density lipoprotein cholesterol (LDL-C) level (OR 1.60; 95% CI, 1.03–2.51), and lipid-lowering drug use (OR 1.74; 95% CI, 1.05–2.89).[7]

Consequences of PAD

Peripheral arterial disease increases the risk of total mortality. Among these patients, more severe disease, as measured by the ABI, is associated with increased mortality. For example, mortality is higher in patients with an ABI less than 0.50 than in those with an ABI between 0.50 and 0.90. Traditionally, an ABI greater than 1.40 has been considered of little diagnostic value because it was believed that it indicates the presence of non-compressible lower extremity arteries. However, non-compressible arteries may be the manifestation of the presence of calcification of the media layer of the artery, a common condition in patients with diabetes and chronic kidney disease that is associated with increased mortality. Individuals with ABI values greater than 1.40 have a higher prevalence of intermittent claudication and atypical leg symptoms, suggesting an increased prevalence of PAD among these individuals. In fact, an ABI index higher than 1.40 is associated with an increased mortality. In this regard, The Cardiovascular Health Study

found an increase in total mortality in patients with basal ABI greater than 1.40 compared with a normal ABI. The magnitude of this increased mortality risk in people with an ABI greater than 1.40 was similar to that observed in people with an ABI less than 0.90. This suggests that across the spectrum of ABI values, the association between the ABI and mortality appears to be 'U' shaped.[1]

Peripheral arterial disease is a strong predictor of subsequent cardiovascular morbidity and mortality. Associations between PAD and cardiovascular mortality are independent of age, BMI, cigarette smoking, LDL-C, HDL-C, blood pressure, fasting glucose levels and history of angina, myocardial infarction, stroke or other heart problems. This association has been observed in multiple populations (clinical and community settings, general population and special groups like elderly or diabetic patients, subjects with and without classic intermittent claudication, etc). It has been reported over relatively short-term (3–4 years) and long-term (10 years) follow-up. Like the association between PAD and total mortality, the Strong Heart Study found a higher cardiovascular mortality risk if ABI was less than 0.90 or greater than 1.40, describing a 'U' shaped line too. PAD is associated with prevalent cardiovascular disease and adverse cardiovascular disease risk factor profiles. Prospective studies using the ABI show in people with a low ABI, a higher incidence of stroke (mainly in the elderly), fatal and non-fatal coronary disease, heart failure and a poor prognosis in all forms of cardiovascular disease. Because of that, identifying persons at both ends of the ABI distribution may be a useful method for cardiovascular risk stratification and may also be an indication for a comprehensive management of cardiovascular risk factors.[8] However, in the cardiovascular risk stratification, it is not just the grade of PAD that is important. The progression of PAD, measured as the changes in ABI over time, can add information in this evaluation of the cardiovascular risk. Criqui *et al*. demonstrated that progressive PAD (ABI decline >0.15) was significantly and independently associated with an increased cardiovascular risk.[9]

In addition to the classical implications of PAD on the cardiovascular disease, in the elderly PAD also plays a crucial role in determining an impaired functional status. Specifically, elders with PAD have lower physical activity levels, slower walking speed, poorer balance and poorer walking endurance. Data obtained from 1798 participants 60 years and older who participated in the population-based National Health and Nutrition Examination Survey,[10] showed several relevant findings about the relationship between PAD and physical function. Participants were asked about their dependence in performing several tasks (basic activities of daily living, instrumental activities, social activities, general physical activities and capacity to walk one-quarter mile and to walk up 10 steps). Trained health technicians measured ABI, maximal right leg force and gait speed. There were differences in both self-reported functional dependence and performance-based physical measures. Gardner and Montgomery[11] compared two groups of subjects 65 years and older, the first group with symptomatic PAD and the second one without illness. PAD patients had 28% shorter unipedal stance time, 86% higher prevalence of ambulatory stumbling and unsteadiness, and 73% higher prevalence of falling than non-PAD patients. Instability in patients with PAD was exacerbated in those with a worse ambulatory function and lower levels of physical activity. These findings remind us of the old scheme about the theoretical model of the pathway to late-life dependence proposed by Verbrugge.[12] He defined four related but different categories that represent the causal connection between pathology and actual dependence. These are: 'active pathology' (such as PAD), 'impairment' (such as low leg force or low ABI), 'functional limitation' (such as slow gait speed) and 'disability' (such as dependence in activity daily living). As a consequence, for a complete evaluation of an elderly patient with suspected PAD, performance-based physical measures (gait speed, strength, unipodal time, full tandem stance time, etc.) must be included.

Gardner *et al*.[13] followed 43 men limited by intermittent claudication (mean age, 69 years ±7) during 18 months to understand the natural evolution of physical performance in patients with PAD. They experienced a decline in six-minute walk performance, monitored and self-reported physical activity, physical performance, measured and self-reported stability and calf blood flow despite no change in ABI. While it may be assumed that all these changes could cause an impaired balance and a higher prevalence of falling, putting PAD patients at higher risk for serious injury, restricted physical activity, higher cost and more frequent hospitalizations, higher nursing home admissions and greater mortality, the actual clinical consequences and prognostic significance of functional impairment in persons with PAD was unknown until the study by McDermott *et al*.[14] They carried out a prospective observational study with 638 participants followed for a median of 50 months. Among PAD participants, the risk of mobility loss, measured as the hazard ratio (HR), in the lowest versus the two highest quartiles of baseline performance for the six-minute walk test was 9.65 (95% CI, 3.35–27.77, $p < 0.001$). For the Short Physical Performance Battery the adjusted HR was 12.84 (95% CI, 4.64–35.55, $p < 0.001$). They concluded that differences in the rate of mobility loss between PAD persons and healthy subjects appear to be primarily related to poorer lower-extremity performance at baseline. The measures of lower extremity performance predict risk of mobility lost and risk of mortality;[15] they are simple and easy to perform in the office. So, they can be used to identify PAD persons at highest risk of mobility loss.

The 'vulnerability' of these patients could suggest a possible relationship between PAD and frailty. In The Cardiovascular Health Study the ABI was inversely related to frailty status, in elderly people with or without clinical cardiovascular disease.[16] The prevalence of progressively lower levels of ABI increased in each level of frailty (non-frail, pre-frail, frail). These data, along with the other results in the CHS, suggest that cardiovascular disease appears to be an important, but not sole, contributor to frailty.

Finally, the association between PAD and other apparently unlinked diseases must be emphasized. This is the case for depression and dementia. An increased prevalence of depression in patients with PAD has been detected. One explanation could be that the functional impairment accompanying PAD affects QOL and may lead to depressive symptoms.

ABI is associated with the incidence of total dementia, vascular dementia and Alzheimer's disease,[17] as is shown in the data from the Honolulu-Asia Aging Study, a prospective community-based study of Japanese American men, older than 70 years at baseline. The analysis included 2588 men who were free of dementia at the first assessment, had an ABI measurement, and were examined up to twice more for dementia. After adjustment for education, year of birth, high blood pressure, BMI, diabetes mellitus, cholesterol concentration, smoking status, alcohol consumption and apolipoprotein E4 allele, a low ABI was associated with an increased risk of dementia (HR, 1.66; 95% CI, 1.16–2.37) and vascular dementia (HR, 2.25; 95% CI, 1.07–4.73). ABI was weakly associated with Alzheimer's disease (HR, 1.57; 95% CI, 0.98–2.53), particularly in the apolipoprotein E4 carriers (HR, 1.43; 95% CI, 1.02–1.96).

Despite what is claimed, the public is poorly informed about PAD. Current data suggest that PAD detection and treatment are lower than other forms of atherosclerotic disease, although there is evidence to support a prognostic significance and an impact on QOL comparable to other forms of cardiovascular disease.[18] As a consequence it is essential to make an active search of the disease. The Comprehensive Geriatric Assessment (including performance-based measures) plus ABI should be used to stratify the cardiovascular risk and to detect and prioritize the patients in whom an aggressive approach is needed.

Pathophysiology

Atherosclerosis is a long-lasting process of thickening and stiffness of the arteries, whose basic lesion is the atherosclerotic plaque. The evolution of atheroma involves several stages, which once breached, caused the harm. Unfortunately this complex process does not follow an ordered fashion, because even if the lesions develop gradually, the first symptom of many injuries occurs suddenly. Therefore, early diagnosis of atherosclerosis is important. To that end, it is essential to detect disorders associated with endothelial dysfunction and its progression toward atherothrombosis long before they are visible obstructive lesions, which highlights the importance of early detection and treatment of vascular risk factors. It must be remembered that vascular disease is not simply a local process in a concrete plaque, but this is a widespread process that affects the entire vascular tree. This concept has therapeutic implications because it calls for an integrated treatment. Another important aspect of the pathophysiology of atherosclerosis in the elderly, and more specifically of the endothelial dysfunction, is which processes that occur at the endothelium are due to physiological ageing and which ones to the presence of other cardiovascular risk factors. In fact, some of the mechanisms involved in the development of endothelial dysfunction are shared by both ageing and cardiovascular risk factors (diabetes, hypertension, hypercholesterolemia),[19] as shown in Figure 43.1. Moreover, the mechanisms by which vascular risk factors lead to vascular disease may be different in the elderly.

Atherosclerosis is a universal process, although it shows some pathophysiological differences depending on the anatomical location of the occurrence. The atherosclerotic plaques located in the lower limbs are very fibrous and may result in strictures. When associated with a hypercoagulable state this gives rise to the acute event. By contrast, when present at the coronary arteries, the atherosclerotic plaque usually consists of a large extracellular lipid core and a large number of foam cells, coated with a thin cover susceptible to breakage, which is the ultimate cause triggering the acute event. Whatever the underlying process, the final consequence is the same: an imbalance between the needs of the tissues and the support of oxygen and nutrients. If this mismatch happens suddenly, as in the thrombotic event, it leads to acute ischaemia. If the establishment of the stenosis is gradual, allowing the development of collateral circulation, metabolic adaptation of the muscle mass involved and the use of non-ischaemic muscle groups, ischaemia may persist as a chronic state. From the pathophysiological point of view, one can talk about functional ischaemia when blood flow is insufficient to cope with the demand that involves the exercise but it is enough at rest. This functional ischaemia translates clinically into intermittent claudication. The critical ischaemia occurs when the flow is insufficient even at rest, appearing as pain and trophic lesions in the extremities. In this situation there is a need to intervene to restore an adequate blood flow, to avoid the risk of amputation. However, the symptoms will largely depend on the number of affected territories and the level of physical activity performed by each person.

The importance of inflammation in the genesis, progression and outcome of the atherosclerotic disease has emerged over the last two decades, adding to the classic

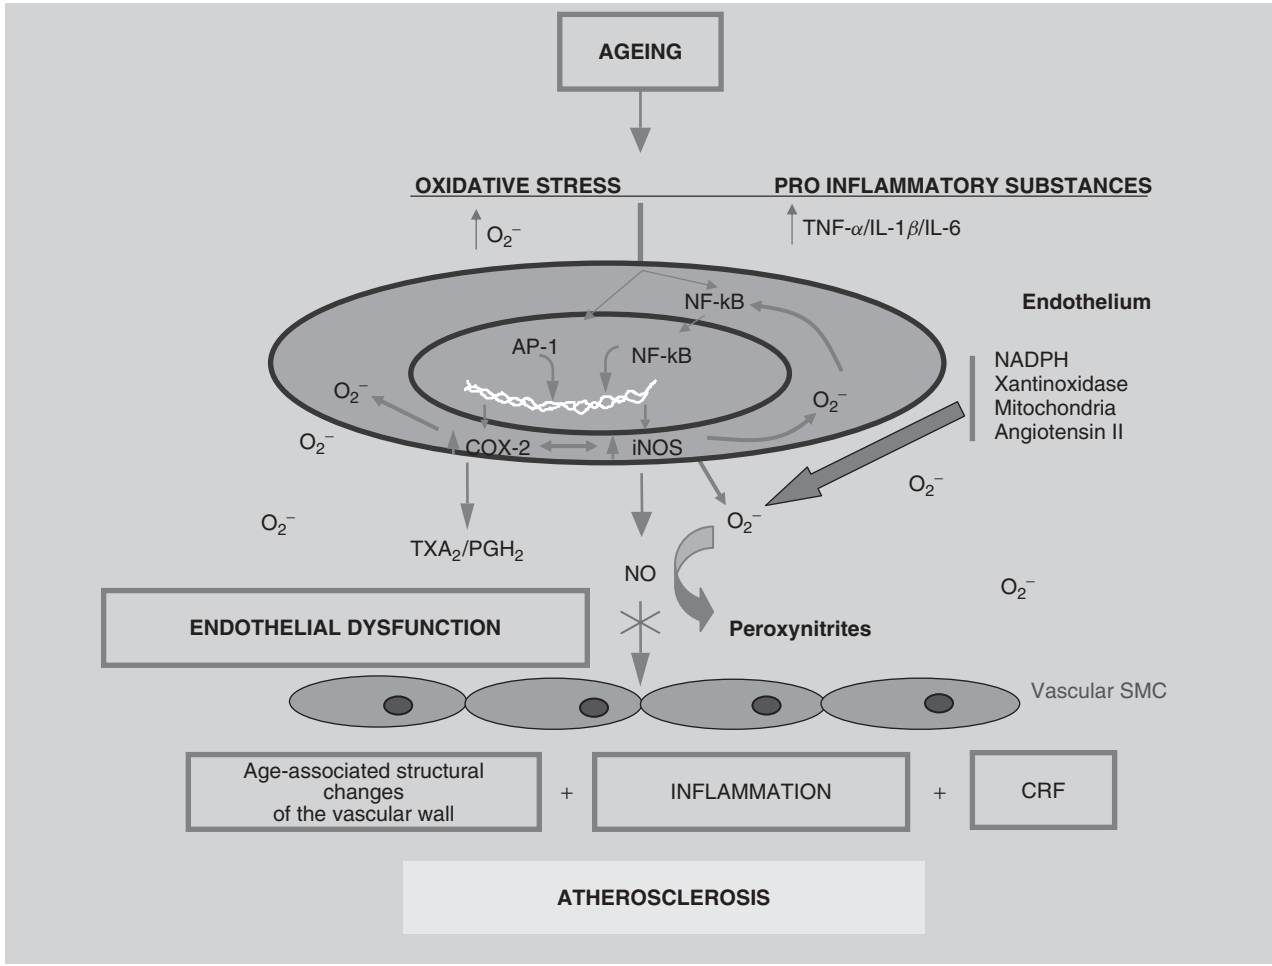

Figure 43.1 Mechanisms of endothelial dysfunction and atherosclerosis in ageing. COX-2, cyclooxygenase-2; CRF, cardiovascular risk factors; IL, interleukin; iNOs, inducible nitric oxide synthase; NO, nitric oxide; O_2-, superoxide anions.

concept according to which atherosclerosis is a mechanical accumulation of lipids and a fibrodegenerative response of the arterial wall by changes in its structure, leading to a progressive failure of tissue perfusion. Currently, atherosclerotis is regarded as a multifactorial disease where metabolic, inflammatory, haemodynamic and haemostatic factors are involved, with both local and systemic roles.

Glyco-oxidation contributes to the development of atherosclerosis in the below-the-knee peripheral artery tree in type 2 diabetes, and very probably also in elderly patients without diabetes. Advanced glycosylation end-products (AGEs) levels increase with ageing and in patients with diabetes. AGEs are elevated in type 2 diabetic patients with PAD as compared with diabetic patients without PAD and control subjects. More precisely, among AGEs components, pentosidine appears to be strongly associated with the peripheral artery status of diabetic patients. In addition, lipid oxidation, estimated by the serum levels of malondialdehyde (MDA), is associated with diabetic peripheral angiopathy. On the other hand, both TRAP and vitamin E levels, which estimate antioxidant capacity, are lower in type 2 diabetic patients with PAD than in those who are diabetic without PAD, and in healthy subjects.

As previously stated, inflammatory mechanisms are also involved in the pathogenesis of acute cardiovascular events. Elevated levels of inflammatory factors may encourage plaque instability and rupture. Higher levels of inflammation are associated with greater functional impairment and faster functional decline in persons with PAD. An explanation for these associations is not still available, but inflammation plays a key role in both atherosclerosis and sarcopenia, and in the age-related reduction in muscle mass and strength.

The presence of several cardiovascular risk factors, which act in a synergistic way, is the main condition for progression of the disease and amputation. In addition to these, there are other independent factors contributing to increased risk of amputation: sensory neuropathy, previous

minor amputations and the use of insulin. Furthermore, other factors very prevalent in the elderly (physical disability, loss of vision or a shortage of social resources), act as facilitators. As is the rule in geriatric medicine, the final outcome is the effect of the pathogenic concurrence of several factors, the main one being involvement of the peripheral nervous system, the microvascular damage and a superimposed infection.

Peripheral neuropathy diminishes algesic perception, putting the skin at risk for conditions such as pressure ulcers and muscle atrophy. As a consequence, changes in the points of support occur, placing pressure onto areas that are not prepared for it. So the heads of the metatarsals may suffer ischaemic necrosis, facilitating the development of osteomyelitis in the event of an underlying ulcer. The autonomic neuropathy facilitates the opening of artery-vein shunts and makes skin hydration difficult.

The relevance of the involvement of microcirculation has been widely discussed. Despite the existence of a thickening of the basement membrane, this factor does not appear to be of clinical significance in the absence of peripheral and autonomic neuropathy. Other factors, directly and indirectly related to vascular injury, cooperate in the development of clinically apparent damage: the ischaemia causes pain, especially in patients with high blood-glucose, difficulty in healing existing injuries and delay in the sterilization of infected lesions. Other mechanisms that can hinder healing include training AGEs or zinc shortfall related to its increased renal elimination in patients with poor glycaemic control. It is quite possible that this mechanism should be enhanced in the elderly. Ischaemia also hinders antibiotic response to infected ulcers.

Finally, other mechanisms associated with hyperglycaemia may participate in the pathogenesis of diabetic foot, but its role is more controversial. This is the case for the decline in chemotaxis, phagocytosis and bacterial lysis.

Diagnosis

Anamnesis and physical assessment

Diagnosis of PAD is based mainly on clinical evaluation and the patient's medical history. Patients frequently minimize symptoms, attributing them to normal ageing. Because of this an active search of intermittent claudication or atypical presentation of PAD must be carried out, distinguishing them from non-vascular causes (pseudoclaudication).[20] The 2005 ACC/AHA guidelines on PAD[20] and the 2007 TASC II consensus document on the management of PAD[21] recommend that the standard review of symptoms should include questions related to a history of walking impairment, symptoms of claudication, ischaemic rest pain, or non-healing wounds in patients ≥70 years of age, those ≥50 years of age with a history of smoking and/or diabetes, or, in TASC II, those with a Framingham risk score of 10–20% at 10 years. A careful history including a comprehensive geriatric assessment should reveal a functional impairment when this is the clinical presentation.

Clinical presentation

Adult patients with PAD often present with the classic symptoms of leg ischaemia. However, elderly patients are often asymptomatic, and, among symptomatic patients, atypical symptoms are more common than claudication.[3]

Many patients with PAD have unrecognized disease as illustrated by the following observations. In the PARTNERS programme cited above, around 45% of the patients with a new diagnosis of PAD had no history of leg symptoms and only 5.5% had classic claudication. In another study that included 239 men and women aged 55 and over with no history of PAD who were recruited from a general internal medicine practice, the ABI was abnormal (<0.90) in 14%. Most of these patients did not report exertional leg symptoms. However, they were not able to walk as far in six minutes as a group of patients without PAD (1362 vs. 1539 feet).

Older patients with PAD have atypical symptoms, usually focused on functional issues, mainly as a result of comorbidities, physical inactivity and alterations in pain perception. Functional capacity is diminished in some patients with PAD even in the absence of claudication, being the principal manifestation of the disease. In addition, a gradual decline in activity level or a progressive loss of independence in the activities of daily life may mask the symptoms of PAD in the elderly.

This issue was addressed in a study of 417 patients with PAD and 259 without disease who underwent measurement of ABI and assessment of functional capacity at baseline and one and two years later.[22] Patients with an ABI <0.50 had a significantly greater annual decline in six-minute walk distance than those with an ABI of 0.50 to <0.90 or those with an ABI of 0.90–1.50 (73 vs. 59 and 13 feet, respectively). In addition, patients with PAD who reported no exertional pain had a greater annual decline in six-minute walk distance than those with typical intermittent claudication (77 vs. 36 feet).

These findings suggest that activity level is an important factor in the evaluation of patients with PAD. Patients with evidence of PAD who report no or few symptoms should be asked about functional capacity and decline in activity over time.

Finally, some patients have atypical symptoms that may mimic other disorders[20] including nerve root compression, spinal stenosis and hip arthritis.

Physical examination

The physical assessment should include an exam with shoes and socks off, paying special attention to pulses (femoral,

popliteo, posterior tibial and pedal), bruits, hair loss, skin colour, temperature, ulcers and trophic skin changes.

We can measure the functional impairment using several validated tests and scores. Walking velocity, time to arise from a seated position or the standing balance score have been related to the presence of subclinical disease and its prognosis.[14,15] The most frequently suggested instruments are the Short Physical Performance Battery (SPPB) and the six-metre walking speed.

The Clinical Guidelines for Type 2 Diabetes Mellitus (European Diabetes Working Party for Older People 2011)[23] suggest that a Comprehensive Geriatric Assessment should be a routine measure in older people with type 2 diabetes at diagnosis and at regular intervals, and recommend as a minimum an annual inspection of the feet by a healthcare professional, including a vascular and neurological examination, even if no symptoms are present. When available, an ABI determination should be done (see below).

Detection of asymptomatic PAD has value because it identifies patients at increased risk of atherosclerosis at other sites. As many as 50% of patients with PAD have at least a 50% stenosis in one renal artery. Thus, patients with asymptomatic PAD, most often detected by ABI, should be assessed to detect clinically significant atherosclerosis in other vascular territories apart from the legs.

Non-invasive tests

These tests help to establish an accurate diagnosis of PAD, to quantify the severity of the disease, to localize the stenosis, to organize a treatment plan and to determine the progression of the disease or its response to treatment.

A variety of non-invasive examinations are available to assess the presence and degree of PAD. They include ABI, exercise treadmill test, segmental limb pressures, segmental volume plethysmography, and ultrasonography. Magnetic resonance imaging may become an important non-invasive method for assessment; however, at the present time costs and time considerations limit its use as a routine screening modality. The two most used methods in the clinical setting are the ABI and ultrasonography.

A relatively simple and inexpensive method to confirm the clinical suspicion of arterial occlusive disease is to measure the resting systolic blood pressures in the ankle and arm, and calculate the ABI, which provides a measure of the severity of PAD.

Calculation of the ABI is performed by measuring the systolic blood pressure (by Doppler probe) in the brachial arteries and in posterior tibial or dorsalis pedis arteries (Figure 43.2). The highest of the four measurements in the ankles and feet is divided by the higher of the two brachial measurements. Depending on the value of this index, several categories are defined:

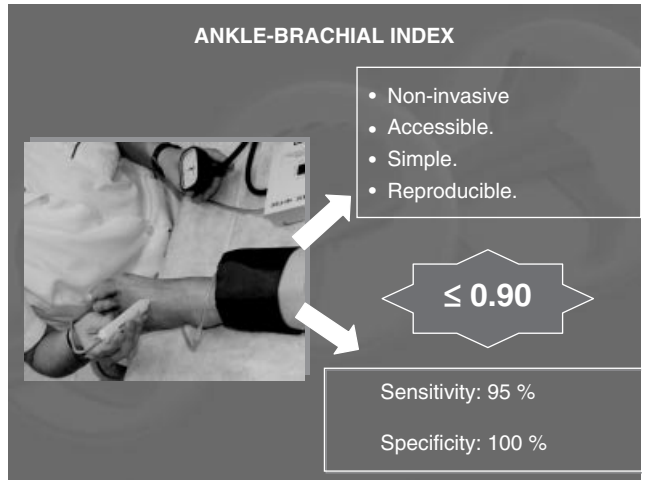

Figure 43.2 Measurement and diagnostic characteristics of the ankle-brachial index (ABI).

- Normal ABI: 1.0–1.3. Values above 1.30 suggest a non-compressible calcified vessel.
- ABI below 0.9 has 95% sensitivity (and 100% specificity) for detecting angiogram-positive PAD and is associated with ≥50% stenosis in one or more major vessels.
- ABI of 0.40–0.90 suggests a degree of arterial obstruction often associated with claudication.
- ABI below 0.4 represents advanced ischaemia.

If ABI is normal at rest but symptoms strongly suggest claudication, ABI and segmental pressures should be obtained before and after exercise on a treadmill.

As it has been previously stated, the ABI correlates with clinical measures of lower extremity function such as walking distance, velocity, balance and overall physical activity. In addition, a low ABI has been associated with a higher risk of coronary heart disease, stroke, transient ischaemic attack, progressive renal insufficiency and all-cause mortality.[8]

A potential source of error with ABI is that calcified vessels may not compress normally, possibly resulting in falsely elevated Doppler signals. Thus, an ABI above 1.3 is suspicious for a calcified vessel. An abnormally high ABI (>1.4) is also associated with higher rates of leg pain, cardiovascular risk and heart failure.

The examination of the lower extremity using the duplex ultrasonography (Doppler) begins at the common femoral artery and proceeds distally to the popliteal artery. An area of stenosis is localized with colour Doppler and assessed by measuring Doppler velocities at several arterial sites.

It has been suggested that the main purpose of duplex ultrasonography is to avoid the diagnostic angiography before intervention in patients with arterial disease proximal to the calf. A meta-analysis of 14 studies found that sensitivity and specificity of this technique for ≥50%

stenosis or occlusion were 86% and 97% for aortoiliac disease and 80% and 98% for femoropopliteal disease.

Invasive tests

At the present time, the contrast angiography is the 'gold standard' for the diagnosis of PAD. It is the definitive method before revascularization procedures. Although it is relatively secure, it is associated with a higher risk of medical complications (bleeding, infection, contrast allergy, etc.) than non-invasive techniques and should be performed only in selected patients (surgical patients).[20]

Treatment

The main aim when treating elderly people with PAD is to avoid the consequences of atherosclerotic disease in lower limbs and other vascular territories, and to prevent the functional decline associated with vascular disease.

Once the diagnosis is established, the patient can be treated medically by means of risk factor modification, exercise, foot care and drugs. If the disease progresses and/or the patient meets a number of established criteria, percutaneous intervention or surgery should be performed.

Risk factors modification

The principal risk factors for the development of PAD are ageing, cigarette smoking, diabetes mellitus, hypertension and hyperlipidaemia. With regard to the reduction of cardiovascular risk in elderly patients with PAD it must be stated that there is no concluding evidence about the relation between the control of risk factors and PAD prognosis. Nevertheless, the role of control of cardiovascular risk factors in the manifestations of atherosclerosis is well established. For this reason, treatment of cardiovascular risk factors is a priority in all patients with PAD, whatever their clinical manifestations.

Cigarette smoking

Cessation of cigarette smoking reduces the progression of disease as shown by lower amputation rates and lower incidences of rest ischaemia among those who quit. It is not clear whether smoking cessation reduces the severity of symptoms of claudication.

According to the recommendations of the 2007 TASC II consensus document, all patients should be strongly advised to stop smoking by their physicians and all patients should be offered nicotine replacement and group counselling sessions. Many patients may benefit from the addition of antidepressant drug therapy, but in older patients special attention should be paid to the adverse effects of this kind of drug on functional status.

Diabetes mellitus

There is no evidence on what is the best control level of cardiovascular risk factors in elderly diabetic patients with PAD. Because of this, treatment goals are similar to those in diabetic elderly patients.[20] No controlled trials have directly evaluated the effects of hypoglycaemic therapy upon the natural history of PAD. Aggressive control of blood glucose in both type 1 and type 2 diabetes reduces the risk of microvascular complications (e.g. nephropathy, retinopathy and neuropathy). However, in the Diabetes Control and Complications Trial of patients with type 1 diabetes, intensive insulin therapy had no effect upon the risk of PAD. The results were similar in the United Kingdom Prospective Diabetes Study in patients with type 2 diabetes.[24]

The 2007 TASC II consensus document on the management of PAD, recommends aggressive control of blood glucose levels with an A1c goal of <7% and as close to 6% as possible in adult patients. However, as previously stated at the beginning of this chapter, less stringent goals may be appropriate for elderly patients (around 7.5–8%, depending on the frailty status) and in those with comorbid conditions.[23]

Hypertension

Hypertension is a major risk factor for PAD. However, there are no data evaluating whether antihypertensive therapy modifies the progression of claudication. Nevertheless, hypertension should be controlled in these patients to reduce morbidity from cardiovascular and cerebrovascular disease.

There has been some concern in the past about the use of beta-blockers in the treatment of hypertension among patients with intermittent claudication, but there appears to be no adverse effect of beta-1 selective blockers on claudication symptoms. As a result, these drugs are not contraindicated in patients with PAD.[20]

There are no therapeutic groups that provide a differential benefit in these patients. Although the HOPE trial suggested that the angiotensin-converting enzyme (ACE) inhibitor ramipril provided added protection against cardiovascular events in patients with cardiovascular disease, including PAD, these benefits are likely to be a consequence of blood pressure reduction in this placebo-controlled trial, rather than a specific benefit of ACE inhibition although there is some evidence that ACE inhibitor therapy may increase walking distance in selected patients with PAD.

The blood pressure goal in these patients should be the same as that in patients with hypertension and established cardiovascular disease: below 130/80, as recommended by the American Heart Association and the European Society of Hypertension-European Society of Cardiology (ESH-ESC), or a higher goal of <140/90 mmHg if we adhere to the recommendations set by the 2007 TASC II consensus document. It must be highlighted than in the very old

person (≥80 yrs) with systolic hypertension there is no evidence about the benefits of decreasing blood pressure below 140 mmHg. By contrast, some studies have raised worries about the possibility of harm when blood pressure is reduced below that threshold.

Hyperlipidaemia

A number of cholesterol-lowering trials in patients with hyperlipidaemia and coronary and/or PAD have evaluated the effects of lipid-lowering therapy on PAD. A 2000 Cochrane meta-analysis of old trials mostly carried out before statins use, which specifically evaluated patients with lower limb atherosclerosis, concluded that lipid-lowering therapy reduced disease progression (as measured by angiography) and alleviated symptoms.

Subsequent studies confirmed these benefits in patients treated with statin therapy. Regression of femoral atherosclerosis, a lower rate of new or worsening intermittent claudication, and improvements in walking distance and pain-free walking time have all been described.

The Scandinavian Simvastatin Survival Study (4S), found that treatment with 20–40 mg day^{-1} of simvastatin reduced the incidence of new or worsening intermittent claudication by 38% (2.3 vs. 3.6% with placebo).[25]

Another randomized, double-blind trial included 354 patients with claudication attributable to PAD who were assigned to atorvastatin (10 or 80 mg day^{-1}) or placebo. At 12 months, there was a significant improvement in pain-free walking time with high-dose atorvastatin and in community-based physical activity with both doses of atorvastatin but there was no change in ABI.

With regard to the goals for lipid levels in elderly patients with PAD, there are no specific recommendations and the recommendations for adult patients[21] can be applied, with some caution. For instance, the recommendation for all patients with PAD to have their LDL-cholesterol lowered to <100 mg dl^{-1} (2.6 mmol l^{-1}), should be qualified in frail patients, where the risk of malnutrition is very high.

Exercise rehabilitation

Several studies have demonstrated the benefit of exercise rehabilitation programmes in reducing symptoms of claudication. A meta-analysis that included only randomized, controlled trials found that lower limb exercise produced a significant increase in maximum walking time (mean difference 6.5 minutes); the benefit was greater than that seen with angioplasty at six months (mean difference 3.3 minutes).[26]

The effect of upper limb exercise was assessed in a subsequent trial in which 104 patients with stable PAD were randomly assigned to twice weekly aerobic exercise training with upper limb or lower limb exercise or a non-exercise training control group. At six months, upper and lower limb exercise was associated with similar increases in claudication distance (51% and 57%), maximal walking distance (29% and 31%), and peak oxygen consumption.

There are several mechanisms by which exercise training may improve claudication, although the available data are insufficient to reach firm conclusions regarding their relative importance: improved endothelial dysfunction via increases in nitric oxide synthase and prostacyclin, reduced local inflammation, increased exercise pain tolerance, induction of vascular angiogenesis, improved muscle metabolism by favourable effects on muscle carnitine metabolism and other metabolic pathways, and reductions in blood viscosity and red cell aggregation.

A separate issue is whether patients with asymptomatic PAD benefit from exercise rehabilitation. This issue was addressed in a study of 156 patients with an ABI ≤0.95, most of whom were asymptomatic (81%), who were randomly assigned to one of three intervention groups: supervised treadmill exercise, lower extremity resistance training, or usual management (control group). At six months participants in the treadmill exercise group significantly increased in their distance walked (36 metres) during a six-minute walk test compared to those in the placebo group.[27]

Although less well studied, exercise may also improve survival. This issue was addressed in a prospective observational study of 225 men and women with PAD evaluated in whom physical activity was measured with a vertical accelerometer.[28] Patients were followed for a mean duration of 57 months at which time 75 patients (33%) had died. Individuals in the highest quartile of accelerometer-measured activity had a significantly lower mortality than those in the lowest quartile (HR 0.29; 95% CI, 0.10–0.83).

Exercise prescription must be done following some guidelines. Patients should be referred to a claudication exercise rehabilitation programme. These programmes consist of a series of sessions lasting 45–60 minutes per session, involving the use of either a motorized treadmill or a track to permit each patient to achieve symptom-limited claudication. The initial session usually includes 35 minutes of intermittent walking; after that, walking is increased by five minutes in each session until 50 minutes of intermittent walking can be accomplished, surrounded by warm-up and cool down sessions of five to ten minutes each. Ideally, the patient must attend at least three sessions per week, with a programme length greater than three months.

Foot care

The use of appropriate footwear to avoid pressure injuries, the use of moisturizing cream to prevent dryness and fissuring, daily inspection and cleansing by the patient and chiropody, are necessary measures to reduce the risk of skin ulceration, necrosis and amputation. Although these

measures are recommended based on the results of some works analysing their effects in diabetic patients, there are no studies evaluating their impact on elderly diabetic patients with PAD.

Pharmacological therapy

Drug therapy of claudication is aimed at symptomatic relief or slowing progression of the natural disease. A number of drugs have been evaluated but, as will be seen, the evidence of benefit is convincing only for antiplatelet agents, mainly aspirin and cilostazol.

Antiplatelet therapy

All patients with evidence for atherosclerosis in other vascular beds should be prescribed an antiplatelet drug. Asymptomatic patients without evidence for atherosclerotic disease elsewhere may be considered for antiplatelet therapy. Aspirin is the agent of choice; clopidogrel may be used if aspirin cannot be tolerated or in the subgroup of patients with symptomatic PAD. Anticoagulant therapy has not shown to improve cardiovascular outcomes in patients with PAD.

Cilostazol

It is a phosphodiesterase inhibitor approved by the Food and Drug Administration (FDA) for the treatment of intermittent claudication. It suppresses platelet aggregation and is a direct arterial vasodilator. The efficacy of cilostazol has been demonstrated in several studies and in a meta-analysis of eight randomized, placebo-controlled trials that included 2702 patients with stable, moderate to severe claudication.[29] In this meta-analysis, treatment with 100 mg twice daily for 12–24 weeks increased maximal and pain-free walking distances by 50% and 67% respectively. Benefit may be noted as early as four weeks.

Side effects noted in clinical studies included headache, loose and soft stools, diarrhoea, dizziness (increasing risk of falls) and palpitations, and is contraindicated in heart failure. It should be taken one-half hour before or two hours after eating, because high-fat meals markedly increase absorption. Several drugs such as diltiazem and omeprazol, as well as grapefruit juice, can increase serum concentrations of cilostazol if taken concurrently. All these features hamper its use in the elderly.

Pentoxifylin

It is a rheologic modifier approved by the FDA for the symptomatic relief of claudication. It is less effective than cilostazol.

Naftidrofuryl

Naftidrofuryl is a 5-hydroxytryptamine-2-receptor antagonist that is currently available only in Europe. The mechanisms of action of this drug are unclear but it is thought to promote glucose uptake and increase adenosine triphosphate levels. A meta-analysis of four trials showed an increase in the time to initial pain development on treadmill-walking over a three- to six-month period. This conclusion was also found in a 2008 Cochrane systematic review.[30]

The 2007 TASC II consensus document on the management of PAD concluded that naftidrofuryl (600 mg day^{-1} orally) can be considered for the treatment of intermittent claudication.[21]

The efficacy of other approaches, including other drugs like ramipril, verapamil, prostaglandins, and other treatments like antichlamydophila therapy or therapeutic angiogenesis, need confirmation in large trials (prostaglandins and antichlamydophila therapy) or are under investigation with controversial results (therapeutic angiogenesis).

Revascularization

There are two important criteria for revascularization: severe disability that limits the patient's ability to work or to perform other activities that are important to the patient, and failure (or predicted failure) to respond to exercise rehabilitation and pharmacological therapy. Endovascular or surgical revascularization therapy is reserved for patients whose functional capacity is compromised only by claudication (not for other comorbidities), patients who do not have a response to exercise and pharmacotherapy and patients for whom the risk-benefit ratio with revascularization is favourable.[20] These patients and the patients with critical and acute limb ischaemia should be referred to a vascular surgeon.

CHAPTER 44

Venous thromboembolism

Gordon D.O. Lowe
University of Glasgow, Glasgow, UK

Epidemiology and pathogenesis

Thromboembolism (venous, cardiac, or arterial) is the commonest cause of death, and a major cause of morbidity, in later life. Like cardiac and arterial thromboembolism, the incidence of venous thromboembolism increases exponentially with age approaching 1% per year by 90 years (Figure 44.1).[1] Almost half of cases occur between 60 and 79 years; and almost a quarter after 80 years (Figure 44.2).[1] This may reflect age-related increases in risk factors and comorbidities (Table 44.1), and in activation of inflammation, endothelium, platelets and coagulation[2,3] combined with age-related decreases in coagulation inhibition,[2,4] fibrinolytic activity and in general mobility.

Venous thromboembolism (VTE) may present as deep vein thrombosis of the leg (DVT) or pulmonary embolism (PE). Case-fatality is largely due to PE; and increases to over 10% in the elderly.[1] Treatment of VTE is also more hazardous in the elderly: the risk of major haemorrhage during anticoagulation increases by nearly 50% for each decade of age.[5,6] Hence prophylaxis of VTE is especially important in the elderly. Because about half of cases occur within three months of hospitalization, routine prophylaxis against hospital-acquired thrombosis is important.

Risk factors for venous thromboembolism in older patients are similar to those in younger patients, with the obvious exception of pregnancy and the puerperium (Table 44.1). There is increasing evidence that the pathogenesis of DVT involves a 'multiple hit model', which starts at conception with multiple, interacting, genetic predispositions (thrombophilias) which thereafter interact throughout life with acquired risk factors which may precipitate thrombosis (Figure 44.3). Once venous thrombosis has occurred, it acts as a strong predictor of the risk of recurrence, especially if idiopathic.

Genetic thrombophilias

Genetic thrombophilias should be suspected clinically if there is a past history, or a family history in blood relatives, of 'premature' (e.g. onset before 40–45 years) DVT, PE or recurrent fetal loss (spontaneous abortion or stillbirth); if there is recurrent venous thromboembolism or thrombophlebitis; or if thromboembolism occurs at an unusual site (upper limb veins, retina, cerebral venous sinuses, mesenteric, portal, or hepatic veins).[8] Protein C or protein S deficiency may also present with coumarin-induced skin necrosis.[8] Congenital deficiencies of the three coagulation inhibitors (antithrombin, protein C, or protein S) are usually due to heterozygosity for autosomal dominant gene defects; they increase the risk of VTE about two- to threefold.[9] The low prevalence of these mutations in non-Western countries may explain their low incidence of DVT and PE.

DVT in the population is also associated with increased plasma levels of the von Willebrand factor – coagulation factor VIII complex;[9] and probably explains why non-O blood group increases the risk of VTE by about 80% (non-O blood group elevates plasma levels of this complex by about 30%).[10] Homozygous homocystinuria has long been recognized as a risk factor for premature arterial and venous thrombosis. More recently, hyperhomocysteinaemia has also been associated with increased risk of both venous and arterial thrombosis: this is partly due to heterozygosity for cystein synthase or methylene-tetrahydrofolate reductase (MTHRF) deficiency (whose cumulative prevalence in the general population is 0.4–1.5%) and partly due to deficiencies of vitamins (folate, cobalamine and pyridoxine) especially in the elderly.[11]There is much current interest in the possibility that dietary supplementation of these vitamins could have a major impact on venous as well as

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

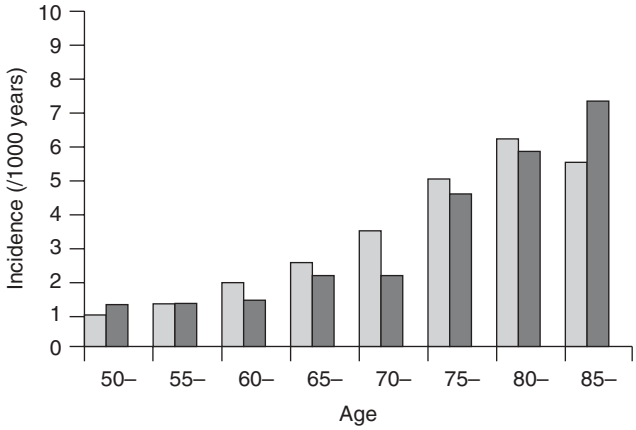

Figure 44.1 Incidence of first venous thromboembolism by age and sex. Rates are shown per 1000 per year, for men (striped bars), for women (solid bars). Reproduced from Rosendaal *et al.*[1] with permission from Wiley-Blackwell.

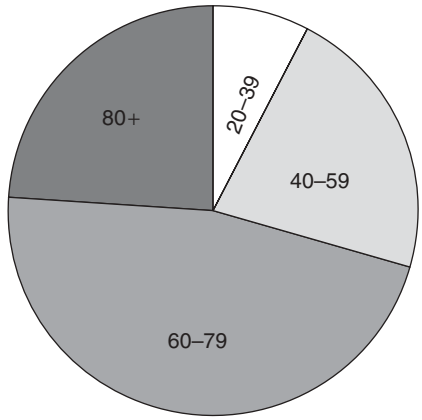

Figure 44.2 Age distribution of patients with venous thromboembolism. Percentage of patients by age group: 20–39 years, 7.5%; 40–59 years, 21.5%; 60–79 years, 45.9%; 80+ years, 23.6%. Reproduced from Rosendaal *et al.*[1] with permission from Wiley-Blackwell.

arterial thrombosis, particularly in the elderly; however, randomized trials have to date been inconclusive.[12]

Acquired risk factors

In recent years it has been increasingly appreciated that risk factors for arterial thrombosis (tobacco-smoking, obesity, diabetes and increased levels of blood lipids) are also risk factors for venous thromboembolism.[9] As with genetic thrombophilias, increased activation of blood coagulation is the most likely explanation.[9] Reduction in blood lipids by statin therapy appears to reduce the risk of VTE, as well as of arterial thrombosis.[13] Aspirin prophylaxis in high-risk persons reduces the risk of VTE, as well as of arterial thrombosis, by about 24%.[14]

Table 44.1 Risk factors for venous thromboembolism.

Patient factors	Disease or surgical procedure
Age	Trauma or surgery, especially of pelvis, hip, lower limb
Smoking	Malignancy, especially pelvic, abdominal, metastatic
Obesity	Heart failure
Blood lipids	Recent myocardial infarction
Immobility (bed rest over 4 days)	Paralysis of lower limb (e.g. stroke)
(Pregnancy)	Infection
(Puerperium)	Inflammatory bowel disease
Estrogen therapy	Nephrotic syndrome
Previous deep vein thrombosis or pulmonary embolism	Polycythemia
Genetic thrombophilias	Paraproteinemia
	Paroxysmal nocturnal haemoglobinuria
	Bechet's disease

Varicose veins increase the risk of postoperative DVT,[15] possibly because they may be a marker of previous (often asymptomatic) DVT in older persons. The increased risks of DVT and PE with increased estrogens, for example hormone replacement therapy,[16,17] suggest common mechanisms, including activated protein-C resistance, low levels of antithrombin and protein S, and high levels of factor IX.[17] These risks are increased in women with thrombophilias.[16,17]

Immobilization (at home or in hospital) in older persons is often due to medical illness (e.g. infection, malignancy, heart failure, myocardial infarction and stroke), trauma, or surgery. The cumulative risk of VTE increases with the duration of immobility, suggesting a role for venous stasis in the inactive leg in the pathogenesis of VTE. Venous stasis also increases in patients with paralyzed legs, heart failure, or polycythemia, which are also risk factors for VTE. Activation of blood coagulation also occurs following trauma, surgery and immobilizing illnesses including infection, malignancy, infarction and haemorrhage. The hypothesis that the combination of immobility and coagulation activation predisposes to DVT formation is supported by the prophylactic efficacy of both mechanical measures which increase leg vein blood flow, and antithrombotic drugs especially anticoagulants, and by the increased efficacy of combinations of mechanical with anticoagulant prophylaxis.

The elderly have a high prevalence of malignant disease, which activates blood coagulation and increases the frequency of both 'spontaneous' and recurrent venous thromboembolism. While the *relative* risk may be lower in patients aged over 70 years, about 5% of VTE events in

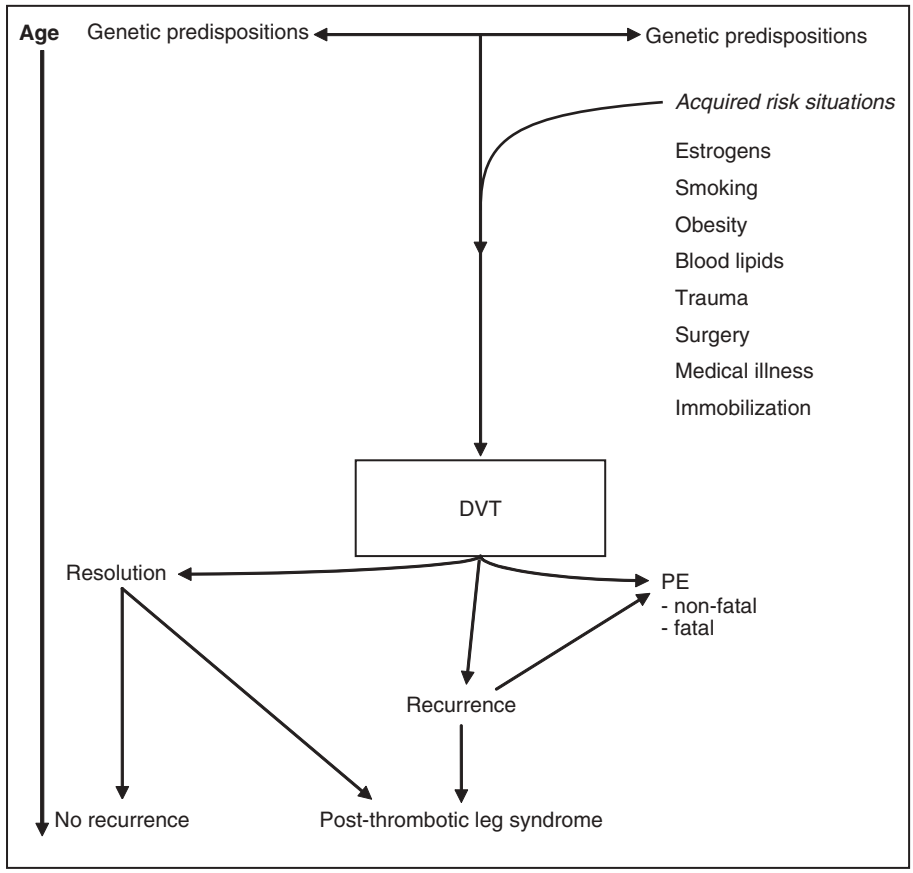

Figure 44.3 Multiple hit model for DVT.

the elderly can be attributed to cancer.[1] Whether or not a routine detailed work-up for cancer (beyond routine history, physical examination, routine blood tests and chest X-ray) improves prognosis is not yet established.

Less common acquired conditions which are associated with increased risk of venous thromboembolism include lupus anticoagulants, which are antiphospholipid antibodies and which usually occur in persons without systemic lupus erythematosis (SLE); inflammatory bowel disease, nephrotic syndrome, Bechet's disease, hyperviscosity (polycythemias, paraproteinemias), and paroxysmal nocturnal haemoglobinuria (Table 44.1).

Primary prophylaxis of VTE

In the great majority of patients dying from PE, previous venous thromboembolism was not diagnosed or treated. DVT is often non-occlusive and hence clinically silent prior to embolization; while non-fatal PE occurring prior to fatal PE may not be recognized clinically, especially in older patients who frequently have pre-existing cardiorespiratory symptoms, for example from heart failure or chronic obstructive airways disease.[18]

The clinical non-recognition of venous thromboembolism prior to fatal PE implies that its detection and treatment cannot have a major impact on its mortality: hence, identification of, and primary prophylaxis in, hospitalized patients (medical and surgical) at high absolute risk of DVT is required for its prevention. Increasingly, healthcare systems in developed countries (including the United Kingdom and North America) mandate routine assessment of all patients admitted to hospital for risk of hospital-acquired thrombosis.[19–22] A risk assessment tool is currently mandated in the United Kingdom.[21,22] Subcutaneous unfractionated or low molecular weight (LMW) heparin prevents about two in three cases of DVT; and also reduces the risk of PE (including fatal PE) in both medical and surgical hospitalized patients.[20–22] All hospital units and services should establish, (and regularly update), local protocols for prophylaxis, based on their national evidence-based guidelines and standards; and audit their performance.

Management of suspected DVT or PE

As with prophylaxis of venous thromboembolism, evidence-based guidelines for diagnosis and management

have been published in the United Kingdom and North America[22–24] from which local protocols, standards and audit should be developed. There is good evidence from randomized trials that full-dose anticoagulation (initially with heparins, followed by oral anticoagulants such as warfarin) is effective in secondary prophylaxis of recurrent thromboembolism, reducing morbidity and mortality. In patients for whom full-dose anticoagulants are contraindicated (usually due to high risk of bleeding), insertion of an inferior vena caval (IVC) filter should be considered to reduce PE risk. However, the costs and morbidity risks of both long-term anticoagulants and IVC filters require that they should be prescribed only to the minority of patients with clinically suspected DVT or PE in whom venous thromboembolism is confirmed by objective tests.

Venous thromboembolism should be suspected in patients with

1 congenital or acquired risk factors (Table 44.1) and

2 clinical symptoms or signs suggestive of either DVT – leg (usually calf, usually unilateral) pain, tenderness, swelling, oedema, warmth, distended superficial veins and/or PE – breathlessness, chest pain, cough, haemoptysis, wheeze, tachycardia, tachypnea, syncope, shock, or cardiac arrest.

In outpatients, the need for routine imaging studies can be reduced in the Accident and Emergency Department by clinical scoring, and a rapid test for fibrin D-dimer. In patients with a low clinical score and normal D-dimer, DVT and PE can be excluded. Other patients should receive heparin therapy (unless strongly contraindicated, e.g. by high risk of bleeding) until diagnostic imaging is performed.

For suspected DVT[22,23] *compressio*n *ultrasound* or *Duplex ultrasound scanning* are non-invasive, specific and sensitive to proximal DVT, but less sensitive to calf DVT. A negative ultrasound test does not exclude the presence of calf DVT, which in about 20% of patients may extend proximally over the subsequent few days and increase the risk of PE. Hence, a negative ultrasound test in patients with clinically suspected DVT should be repeated (usually after 5–7 days), or followed immediately by venography to exclude calf DVT.

Diagnosis of clinically suspected PE [22–24] includes

1 *chest X-ray and ECG* to exclude alternative diagnoses such as myocardial infarction, pneumothorax, or pneumonia;

2 *ventilation perfusion isotope lung scanning* which may be exclusive (normal) or diagnostic (high probability – 'mismatched' major lung segments that are ventilated but not perfused); but which in about 50% of cases is non-diagnostic (intermediate probability);

3 *computerized tomographic pulmonary angiography* (CTPA), contrast pulmonary *angiography* (invasive and not widely available), or *echocardiography* (suspected massive PE).

In contrast to unfractioned heparin, *LMW heparin*s do not require routine coagulation monitoring and have been shown in meta-analyses of randomized trials to have greater efficacy (lower rates of DVT extension, recurrence and mortality) and lesser risk of major bleeding than unfractionated heparin in the initial treatment of DVT.[22–24] Their efficacy as daily, unmonitored subcutaneous injections allows the possibility of outpatient treatment of acute DVT in many cases, provided this is acceptable to patients and their hospital and general practitioners. Many centres now have guideline-based local protocols for this.

*Oral anticoagulant*s (usually warfarin) are required as maintenance treatment following initial heparin treatment of DVT or PE, to reduce the risk of recurrence. They can be started as soon as objective diagnosis is obtained; concomitant heparin treatment should be continued until the target therapeutic range of the International Normalized Ratio (INR) (2.0–3.0) has been achieved for two consecutive days. The routine recommended duration of oral anticoagulant therapy following a first episode of VTE is at least three months.

Newer oral anticoagulants (e.g. dabigatran, rivaroxaban) have advantages, compared to warfarin, of efficacy in fixed dosage hence no need for coagulation monitoring; and lack of interaction with diet or other drugs. They are currently in evaluation.[25]

A significant percentage of patients develop recurrent VTE after discontinuation of oral anticoagulant drugs. Risk factors for recurrence include idiopathic presentation (no recent precipitating risk factors); male sex; continuing risk factors (e.g. estrogen therapy, cancer) and persistently elevated fibrin D-dimer levels.[26–28] Genetic thrombophilias do not appear useful in prediction of recurrence.[26,27] While clinical decision rules are under development and evaluation,[26,27] the decision on prolonged oral anticoagulant therapy, especially in older patients, often requires individualized assessment of risk factors, patient preferences and the risks and burdens of anticoagulants.[27] There are ongoing studies of antiplatelet agents in secondary prevention.[29]

Compression stockings should be prescribed routinely to be worn on the affected leg(s) during the day, long term, to reduce the risk of the post-thrombotic leg syndrome.[22,23]

Considerations in elderly patients

Practical considerations when prescribing oral anticoagulants to the elderly include:[6]

1 Sensitivity to the anticoagulant effect of a given dose increases with age: for example, an average warfarin dose of 4 mg day^{-1} was required in patients 74–90 years old to achieve the same target INR as an average dose of 8 mg day^{-1} in patients aged 19–35.[30]

2 Polypharmacy (including self-medications) increases the risk of drug interactions which alter oral anticoagulant effect, or which increase the risk of bleeding (e.g. aspirin and other non-steroidal anti-inflammatory drugs).

3 Increased prevalence of concurrent or intercurrent illness also increases risk of bleeding (e.g. severe anaemia, renal failure, gastrointestinal bleeding, haemorrhagic stroke, bleeding disorder).

4 Decreased compliance or decreased access to monitoring – whether performed by the general practitioner or hospital anticoagulant clinic – also increases risk of bleeding.

Key points

- Venous thromboembolism is common in elderly patients, especially with obesity, malignancy, heart failure, immobility, trauma, surgery and acute medical illness.
- Consider primary prophylaxis (low-dose heparin, aspirin, or stockings) in acutely immobilized patients, especially those with other risk factors, previous DVT or PE, or known thrombophilia.
- Diagnosis of suspected non-massive DVT or PE involves a formal clinical score and rapid D-dimer in outpatients; proceeding to initial heparin therapy and diagnostic imaging.
- If diagnosis is confirmed, oral anticoagulation with warfarin (target INR 2.0–3.0) is usually given for at least three months.
- Older patients are at increased risk of bleeding on oral anticoagulants.

Cardiac diseases and rehabilitation services

Epidemiology

In 2001, cardiovascular diseases were still the first among the leading causes of death in men and women of all ages in the USA, with coronary heart disease (CHD) alone accounting for 54% of all cardiovascular deaths. The prevalence of cardiovascular diseases – including CHD, stroke and hypertension – increases with age up to more than 70% at age 75 years and older. A surveillance study performed by the National Heart, Blood and Lung Institute in 1987–2000 reported that the incidence of first heart attack is also increasing exponentially with age.[1]

Thanks to the remarkable advances in the management of acute CHD events, chronic heart failure (CHF) and cardiovascular risk factors, the specific mortality for heart disease has been declining continuously during the last two decades, especially among men. Furthermore, preventive medicine has shifted the age at which patients develop CHF but has not reduced, and indeed may have increased, its global epidemiological burden. As a consequence, growing numbers of cardiac patients currently survive longer, but with substantial functional limitations that are secondary to several manifestations of CHD, such as CHF, whose incidence has been increasing steadily, particularly in older populations, suggesting that we now face a real 'CHF epidemic'. The National Health and Nutrition Examination Survey (NHANES) epidemiological study reported that the prevalence of CHF is less than 5% among individuals aged 65 years or younger, but doubles among those older than 75 years,[2] and data from the World Health Organization (WHO) suggest that these figures differ little around the world, at least in more affluent countries.

As is discussed in this chapter, randomized clinical trials, and also meta-analyses and observational studies, have demonstrated that integrated cardiac rehabilitation (CR) programmes are highly effective in accelerating functional recovery and in improving exercise tolerance, adherence with secondary prevention measures, health-related quality of life (HRQOL) and also long-term prognosis after acute cardiac events.[3–6] As a result, the most recent guidelines clearly define the core components and outcome measures of CR and secondary prevention programmes and indicate CR as an integral component of long-term care of patients with CHD and CHF.[7,8]

Utilization of cardiac rehabilitation services: an international perspective

Despite this considerable amount of evidence and the fact that CR programmes are recommended (class I) by the European Society of Cardiology (ESC),[9] American Heart Association (AHA) and American College of Cardiology (ACC)[10] in the management of CHD and CHF,[11] prescription of CR programmes and diffusion of CR services are still relatively limited.

The level of CR service coverage across the European Union could be estimated from a survey of 454 phase 2 (medium-term recovery after hospital discharge) and 383 phase 3 (long-term maintenance) centres in 13 countries. Fewer than 50% of eligible patients participate in CR rehabilitation programmes in most European countries, with services in particularly short supply in countries with the greatest burden of cardiovascular diseases.[12] According to another survey of the European Society of Cardiology, only 67% of patients are prescribed CR soon after coronary artery bypass surgery, and this proportion drops to 49, 35 and 17% among those with recent myocardial infarction, coronary angioplasty or chronic myocardial ischaemia, respectively. Furthermore, utilization of CR services is widely variable cross-nationally, with an average participation after any type of CHD event ranging from 4% in Spain to 71% in Slovenia.[13] In the recently published results of the third EUROASPIRE Survey, the scenario is similar: less than 50% of CHD patients were advised to participate in a CR

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

programme after hospitalization and about 75% of those advised attended at least half of the sessions; in summary, only about one-third of the originally eligible population.[14] More importantly, the data are limited to patients younger than 70 years who, in that survey, were selected for obtaining information on CR service coverage. Given the almost systematic exclusion of older patients that has been reported also by the most recent meta-analyses of CR in patients with CHD[15] or CHF,[16] under-prescription is expected to be even more marked in the older subset of the clinical population of cardiac patients.

Under-prescription of CR is similar in the USA, where only about 20% of appropriate candidates of any age, and about 10–15% of those older than 70 years, are estimated to participate in CR programmes, despite this treatment being acknowledged and recommended as a key component of secondary prevention programmes also in subjects older than 75 years.[17]

Cardiac rehabilitation: definition and aims

CR is defined as the 'sum of activities and interventions required to ensure the best possible physical, mental and social conditions so that patients with chronic or post-acute cardiovascular disease may, by their own efforts, preserve or resume their proper place in society and lead an active life'.[18]

In this perspective, CR and secondary prevention are aimed at (a) preventing the disability that may result from heart disease, particularly in older persons and in those with occupations implying physical exertion, and (b) preventing subsequent cardiovascular events. These goals can best be achieved through programmes combining the use of evidence-based prescription of drug therapy with exercise training and education, counselling, behavioural strategies and psychosocial interventions to help patients optimally control their coronary risk factors.[15] Therefore, CR is an integrated process of care, the aims of which are well beyond the simple functional assessment and prescription of exercise (Table 45.1), and which is currently indicated not only for cardiac patients already disabled or at increased risk of disability, but also for those with a diagnosis of CHD, intermittent claudication or with coronary risk factors. The benefits of CR programmes have been well documented in young and middle-aged CHD patients, whereas older patients rarely have been included in CR programmes and are poorly represented in clinical trials.[19,20] On the other hand, one randomized clinical trial did show that CR is at least as effective in older as in adult patients.[21] Despite such evidence, older patients are still less likely to be referred to formal CR programmes and, when referred but not encouraged enough to participate, in general experience a poor compliance with programmes. At least in part, the scant referral of older patients to CR programmes could be related to their more compromised clinical and functional status, due to frailty and greater burden of comorbidity resulting in disability.

Table 45.1 Aims and role of cardiac rehabilitation as an integrated secondary prevention tool.

- Clinical support to optimize pharmacological and non-pharmacological therapy
- Risk stratification, to define the probability of new events and deterioration of cardiac function, overall functional capacity and quality of life
- Assessment of physical exercise capacity, with exercise prescription in short-term training and long-term maintenance programmes
- Assessment of cardiovascular risk factors and implementation of counselling and education programmes to promote a healthy lifestyle
- Assessment of psychosocial and occupational profile, to design interventions aimed at promoting an active lifestyle
- Clinical and instrumental follow-up, to improve the efficacy of secondary prevention programmes

Although epidemiological data show that patients aged 75 years and older requiring cardiac care are increasing, only limited age-specific data are so far available from observational studies reporting CR in elderly individuals.[22] Most of these data refer to patients with an average age <75 years,[21,23,24] and from studies of post-infarction CR with small numbers over 75 years of age.[21] Nevertheless, several studies have demonstrated that, compared with adults, older patients derive from exercise-based CR similar, and sometimes greater, relative improvements in exercise tolerance and self-reported physical function. Suaya *et al*. recently demonstrated in a large cohort of older US Medicare beneficiaries, who had been hospitalized for CHD events or myocardial revascularization, that CR users had a better five-year survival.[25] After fully adjusting for a series of potential confounders, depending on the analytical procedure, mortality rates were from 21 to 34% lower in CR users than non-users: results similar to those observed in randomized controlled trials and meta-analyses in younger populations. Mortality reductions extended to all demographic and clinical subgroups, including patients with recent myocardial infarction, recent myocardial revascularization or CHF. Interestingly, the benefit was progressively greater with advancing age and reached the maximum at 85 years or more. Unfortunately, only 12% of initial total population was prescribed CR. CR users with 25 or more sessions were 19% less likely to die over 5 years than matched CR users with 24 or fewer sessions ($p<0.001$). The association of number of CR training sessions with outcome has recently been confirmed in another large cohort of older patients.[26]

The progressively shortened in-hospital stay after an acute myocardial infarction (from about 10 to only 4

days in the past 20 years)[27] reduces the risk of physical deconditioning, but also the time available to check physical activity and promote the lifestyle changes that are necessary to reduce cardiovascular risk; this reinforces the need for CR programmes that function as comprehensive, secondary prevention services and are based in-hospital, and also in the community or at home. Chow *et al*., recently have demonstrated that early lifestyle modifications (within 1 month after acute CHD events) strongly predict short-term prognosis, reducing the six-month risk of myocardial infarction/stroke/death.[28] For this reason, behavioural modification should be given priority similar to other preventive medications immediately after acute coronary syndromes.

Owing to better clinical management of cardiac diseases leading to improved survival rates, and to increasing evidence on the beneficial effects of CR in a wide range of cardiac conditions, the delivery of CR has changed remarkably over the past 30 years. In the 1960s, patients recovering from uncomplicated myocardial infarction accounted for almost the totality of referrals for CR. Complicated post-infarction patients or patients recovering from myocardial revascularization have also been enrolled in CR programmes in later years. Patients once considered at too high risk to participate in CR programmes, such as those with persisting myocardial ischaemia, CHF or harmful arrhythmias, are currently enrolled in CR programmes based on more gradual, protracted and, most often, supervised exercise training.[6,29,30] Furthermore, as a result of the progressive ageing of the population, CR should now be provided to increasing numbers of older patients, characterized by more complicated coronary illness, comorbidities,[6,31] functional or cognitive impairment, emotional disorders or social isolation, which all may concur to reduce the enrolment rate in, and adherence to, standardized CR programmes. Paradoxically, although some of these factors represent specific indications to CR, female gender, older age, a low formal education and, most importantly, functional impairment, are all negative predictors of enrolment in CR. Therefore, CR centres have to become familiar with the aims and skills of multidimensional geriatric assessment, to implement strongly individualized programmes that may promote the extension of CR to frail, older individuals.

Studies have proven that CR is at least equally effective in younger and older cardiac patients,[31] even those as old as 86 years,[32] to improve their exercise tolerance and HRQOL. However, no one study has yet demonstrated the efficacy of CR with respect to outcomes that are most typically desirable in geriatric medicine, such as reverting or limiting the progression of functional dependence in frail, older individuals.

Secondary prevention strategies in integrated cardiac rehabilitation programmes

Guidelines indicate that secondary prevention should be based on non-pharmacological and pharmacological interventions that can reduce the risk of new events and disease progression and should be aimed at improving both the prognosis and HRQOL. Non-pharmacological interventions consist of education, counselling and psychosocial interventions targeted at smoking cessation, improving dietary habits, controlling body weight and increasing physical activity and long-term adherence with prescriptions.

Educational principles

A meta-analysis of 37 trials[33] found that CR programmes including psychological and/or educational interventions resulted in a significant reduction in incident cardiovascular events at 1–10 years, with studies with the greatest response to intervention showing the greatest impact. The desirable characteristics of the educational and counselling approach have been outlined after a meta-analysis demonstrating that the most important determinant of effectiveness is the quality of intervention,[34] defined as behaviourally oriented interventions adhering to the five principles of adult learning:

- relevance (tailored to patients' knowledge, beliefs, circumstances)
- individualization (tailored to personal needs)
- feedback (informed regarding progress with learning or change)
- reinforcement (rewarded for progress)
- facilitation (provided with means to take action and/or reduce barriers).

Behavioural techniques such as self-monitoring and personal communication, including written or audiovisual techniques, may further improve the outcome, with information provision alone found to be less effective.

Psychosocial interventions

Some anxiety and depression are found in at least 20–25% of patients with various forms of heart disease but, particularly when they persist, should not be accepted as an appropriate reaction to heart disease. Emotional disorders reduce exercise capacity,[35] HRQOL and adherence to secondary prevention measures and substantially increase the risk of new events. Depressive disorders are probably more common among older patients, who frequently suffer from isolation and financial constraints, which are negative prognostic factors after myocardial infarction. However, the long-term consequences of emotional disorders among older cardiac patients in CR programmes have been poorly addressed, and patients 75 years of age and older are at

higher risk of under-recognition and under-treatment of depressive disorders.

Randomized trials proved that early psychological interventions improve the mood of middle-aged cardiac patients,[36] but information on efficacy at older ages is not available. However, particularly for most severe or disabling cases of persisting depression, psychological support therapies should be used in conjunction with antidepressants. Selective serotonin reuptake inhibitors, such as sertraline, which was proven to be safe and effective in a randomized trial enrolling patients depressed after an acute coronary syndrome, are probably the agents to be preferred.

Smoking cessation

A Cochrane review confirmed the beneficial effects of smoking cessation, which reduces the risk of new events by up to 40%,[37] similarly to what is seen with pharmacological correction of other cardiovascular risk factors. Smoking induces chronic dependence that makes relapses highly probable. Systematic encouragement of smoking cessation is based on the '5A-strategy' of Asking, Assessing, Advising, Assisting, Arranging. In this process, it is necessary to identify smokers, to evaluate the degree of their dependence and their willingness to quit, to support those who are trying to quit with behavioural counselling, prescription of nicotine substitutes and participation in educational meetings, with regular follow-up visits.

Healthy eating and diet

Dietary prescriptions, adapted to local habits and individualized as much as possible, should be aimed at controlling body weight and provision of all elements of proven efficacy in secondary prevention. Dietary habits should be assessed objectively, with the use of reproducible questionnaires and checking individual knowledge of nutrients and of possible substitutes. Education, rather than prescription, should be provided, limiting dietary restrictions to patients with defined metabolic abnormalities. Education and counselling should be provided by professional dieticians, who perform better than physicians in obtaining a long-term reduction in plasma cholesterol levels.

Increasing physical activity

Promoting a long-term increase in usual physical activity is a fundamental objective of integrated CR programmes finalized at secondary prevention. Regular physical exercise improves the lipid profile and delays the progression of CHD in middle-aged, male patients and reduces cardiovascular mortality in the general population. In the Harvard Alumni Health Study,[38] the relative (i.e. perceived) intensity of physical activity was a strong predictor of lower CHD rates, with a clear dose–effect relationship and an effect that was similar, if not superior, among subjects older compared with those younger than 70 years. Interestingly, the absolute intensity of physical activity did not perform as well as the relative intensity in distinguishing CHD risk groups, suggesting that physical activity recommendations need to be individually tailored. Standard recommendations of regular performance of activities at an intensity of at least 3 METs (Metabolic Equivalents, 1 MET corresponding to 3.5 ml of oxygen consumption per kilogram of body weight; see also below) may therefore be inappropriate, especially for older persons.[38]

Long-term adherence and follow-up

Once the process of short-term recovery is complete, the emphasis of CR shifts to long-term maintenance of physical activity, lifestyle changes and prophylactic drug therapy, in the perspective of 'comprehensive cardiac care' as the final goal, following evidence-based recommendations.

A systematic review of 12 randomized trials of secondary prevention programmes in CHD found that structured disease management programmes improve risk factor profiles and secondary preventive treatment, while reducing hospital readmissions and enhancing HRQOL.[39] The programmes included in the review differed considerably: all were multifaceted, with about half including medical and lifestyle treatments, and the rest were predominantly lifestyle and psychosocial interventions. Most were hospital based, but two conducted in UK primary care suggested that a structured approach benefits HRQOL and uptake of secondary prevention. Indeed, long-term adherence with recommendations and prescriptions made during CR is difficult to maintain, usually being reduced to 50–60% at 1 year and to 20–30% at 3 years. Therefore, to enhance long-term maintenance of the goals attained during CR, it is highly recommended that structured care and follow-up are provided in primary care and studies suggest that low-cost, physical training programmes carried out in the community are safe and help patients maintain the physical performance levels they had attained during hospital-based rehabilitation. The GOSPEL study, the results of which have recently been published, is the first trial to demonstrate that a multifactorial, continuously reinforced intervention up to 3 years after post-infarction CR is effective in decreasing the risk of several adverse outcomes, although statistical significance was reached for non-fatal reinfarction only.[7]

The structure of cardiac rehabilitation programmes

CR programmes usually consist of three phases, each representing a different step in the progression of individual patient care: in-hospital care, the early post-discharge and exercise training period and long-term follow-up. Common to each phase and irrespective of which model of CR is chosen, is the need for individually tailored interventions.

Phase I occurs during in-hospital stay, when a 'step change' (any acute coronary event, cardiac surgery or first diagnosis of heart failure) has occurred in a patient's cardiac condition. Medical evaluation and treatment, reassurance and information aimed at reducing emotional distress, risk factor assessment, mobilization and discharge planning are the key elements during this phase.

Phase II includes the early post-discharge period – when baseline assessment and initial counselling on self-management of heart conditions usually take place – and subsequent structured exercise programmes, which are carried out either in a hospital setting or in outpatient clinics or, at least for selected patients, at home.[32] Guidelines[29] suggest that, for greatest secondary prevention success, training must be associated with educational and psychological support and advice on risk factors, such as smoking cessation and weight management, vocational rehabilitation to assist return to work or retirement and referral to a psychologist, cardiologist or exercise physiologist. It has been demonstrated that phase II programmes of integrated, multicomponent CR can be undertaken safely and successfully also in the community.

Phase III involves the long-term maintenance of physical activity and lifestyle changes. Available evidence suggests that both must be sustained for benefits to continue. Membership of a local cardiac support group, which involves exercise in a community centre such as a gymnasium or leisure centre and structured care and follow-up in primary care, may help maintain physical activity and behavioural change.

Baseline assessment

Baseline evaluation is a process of crucial importance that has to be completed prior to enrolment in a cardiac rehabilitation programme. In this process, several clinical, functional and, particularly in older persons, emotional, cognitive and social elements must be taken into account, as they are used to assign the patient to the programme most appropriate for their clinical and functional conditions, to pursue reliable and clinically valuable outcomes, to reduce the probability of programme-related complications and to promote individual adherence to the programme. Exercise training programmes for older persons also need to take into account commonly associated comorbidities that can alter the modalities and intensities of the exercise that is required to produce a training effect. These include, but are not limited to, CHF, arthritis and osteoporosis, chronic lung disease, diabetes and peripheral or cerebrovascular disease.

Risk stratification

Risk stratification and assessment of exercise capacity are the two fundamental steps of baseline evaluation. These two steps are closely linked, as information gathered with assessment of exercise capacity is used not only for an appropriate exercise prescription to each individual patient, but also as one of the criteria for assigning each patient to one risk category. Risk stratification will serve, on the other hand, to optimize pharmacological therapy and possibly to indicate the need for invasive procedures (e.g. coronary angiography and myocardial revascularization; implantation of pacemakers or intracardiac defibrillators), but also as further information to be taken into account for exercise prescription.

In essence, risk stratification relies upon the evaluation of clinical stability, left ventricular function, presence of residual myocardial ischaemia or of sustained ventricular arrhythmias and exercise tolerance. Following the criteria outlined in Table 45.2, patients are classified as at low, intermediate or high risk.

Assessment of exercise capacity

Baseline exercise capacity can be evaluated by several methods, among which the most commonly used are the ergometric stress test, the cardiopulmonary exercise test and the six-minute walk test. Each of them is indicated in different conditions and provides different information.

The *ergometric stress test* is one of the most important diagnostic and prognostic instruments in cardiac patients, with the objectives of determining (a) the exercise capacity, which is used for defining baseline functional capacity, training prescription and evaluation of training results, and (b) the coronary reserve and the inotropic reserve. The cycle ergometer and the treadmill are the most common equipment for exercise stress testing, using protocols that may differ for the type of workload (constant versus increasing), the modality of delivering the workload (continuous versus at intervals), the rate of increase in workload (high versus low) and the type and level of endpoint (predetermined versus symptom-limited, sub-maximum versus maximum). The specificity of the test is reduced with increasing age and its sensitivity, which should theoretically increase with increased prevalence of CHD, may also be reduced. Indeed, it has been reported that a maximum, or symptom-limited, exercise stress test is possible in only about 50% of individuals older than 75 years of age, as a consequence of ageing-associated reduction in exercise capacity, detraining and increased prevalence of comorbidities which may limit exercise capacity. Furthermore, the current use of a predetermined (220 – age), maximum theoretical heart rate to assess the maximum intensity of physical exercise does not represent a robust reference method, particularly in older patients with intrinsic functional limitations. The type of equipment and the protocol should be chosen on an individual basis, in order to adapt to the expected, individual exercise tolerance. The test duration should not exceed 10–12 min and smaller increases in workload (e.g. 10 W per step) are recommended for

Table 45.2 Criteria for baseline risk stratification of candidates to a cardiac rehabilitation programme.

Criterion[a]	Class of risk[a]		
	Low	Intermediate[b]	High[b]
Clinical course	Uncomplicated In-hospital course	Uncomplicated In-hospital course	• Severe complications (e.g. cardiac arrest; shock; cardiac/respiratory failure) during in-hospital course, OR • Persisting clinical instability (e.g. cardiac failure; renal failure)
LVEF (%)	≥50	31–49	≤30
Myocardial ischaemia	NO	YES	YES

patients with expectedly reduced functional capacity. The indications and contraindications and the diagnostic criteria for exercise stress testing are detailed in guidelines of the American College of Cardiology/American Heart Association.

The *cardiopulmonary exercise test* is an ergometric test with simultaneous measurement of oxygen consumption (VO_2), carbon dioxide production (VCO_2), respiratory quotient (VCO_2/VO_2) and pulmonary ventilation. This requires relatively expensive equipment, which needs frequent calibration. Most commonly, the workload is increased by 10 W every 1–2 min. The large variability in measurement of VO_2 – which is influenced by age, gender, level of fitness, severity of disease and comorbidity – is the main limitation to standardizing this test. Nonetheless, $VO_{2\,max}$ is the best available objective measure of aerobic capacity, although cardiac patients only rarely can exercise up to an intensity corresponding to their $VO_{2\,max}$. Therefore, the VO_2 at peak exercise indexed by body weight ($VO_{2\,peak}$, $ml\,min^{-1}\,kg^{-1}$) is a more frequently used measure of exercise tolerance. During exercise, the respiratory quotient increases progressively until it becomes >1, which corresponds to the anaerobic threshold (AT), a useful indicator of the workload that an individual can tolerate without overproducing lactic acid. Unfortunately, it cannot always be identified, particularly in patients with markedly reduced exercise tolerance ($VO_{2\,peak}$ $<10\,ml\,min^{-1}\,kg^{-1}$). This test is particularly indicated to measure exercise tolerance and to define the prognosis of patients with CHF, and $VO_{2\,peak}$ or AT is also used to make the decision on patient inclusion in the waiting list for heart transplant.

With the *six-minute walk test*,[40] exercise tolerance is assessed by measuring the distance that a patient can walk at her/his fastest possible pace in 6 min. A stopwatch, a notepad and a measuring tape are the only materials required. The test has been standardized for application in a linear, enclosed, quiet and seldom travelled corridor, at least 30 m in length, which must be marked throughout its length, to determine the walked distance accurately. Two chairs positioned at the two extremities of the corridor further delimit the path and allow the patient to sit if they become so symptomatic during the test as to need some rest.[40] For safety purposes, the test is best carried out with continuous, telemetric control of heart rate and rhythm and peripheral oxygen saturation, and in association with use of scales aimed at quantifying the perception of fatigue; emergency equipment must be on hand. The main strengths of this test are that it is easy to carry out, does not require any special equipment and is based on a 'natural' activity of common daily life. For these characteristics, the test has been extensively used to evaluate exercise tolerance, especially in CHF and in older

post-infarction or post-surgery patients, particularly when they are disabled to such an extent that they cannot perform reliably in a conventional ergometric stress test. The main limitation, on the other hand, is the low reproducibility, which is essentially due to variable motivation and self-assessment of fatigue and which is improved with the use of standardized encouragement by the test monitor.

The physical exercise training programme

Physical exercise training is the core component of CR programmes, essentially aimed at improving exercise tolerance and, through this goal, at reducing disability, improving quality of life and control of cardiovascular risk factors, thereby reducing long-term morbidity and mortality.

Efficacy and safety are the most important characteristics to be considered in prescribing the physical exercise training in a CR programme. Physical training is effective when it produces measurable benefits at the cardiocirculatory and skeletal muscle level and is safe when it is not associated with either short- or long-term harmful effects.

Baseline assessment data are used to design individually adapted, effective and safe training programmes. To this purpose, all factors that may limit the capability of exercising (e.g. presence and severity of angina or of concurrent diseases, such as disabling osteoarthritis) and the response to the baseline, symptom-limited exercise stress test to be used to calculate the individual training workload, are the elements to be taken into fundamental account. The energy expenditure during physical exercise is influenced by the type of exercise (e.g. isotonic versus isometric), the amount of skeletal muscles involved, aerobic capacity and also by the intensity, duration, frequency and modality of exercise sessions.

Intensity of exercise training sessions

Setting the intensity of exercise is a process of crucial importance, based on individual data and ideally leading to the prescribing of training at an intensity which is adequate for each patient. The intensity of exercise can be measured directly – as the amount of mechanical work produced ($kg\,min^{-1}$; $W\,min^{-1}$; $J\,min^{-1}$) – or indirectly – from measures of energy expenditure (such as kilocalories or METs) or from exercise-related changes in physiological variables (such as heart rate or VO_2). The method based on changes in heart rate is the simplest and the most commonly used in the clinical practice. Following this approach, a training exercise programme is prescribed at an intensity (i.e. load) that produces an increase in heart rate (defined as the 'target' heart rate) to 70–85% of the maximum heart rate that the patient has attained during a symptom-limited, baseline exercise stress test. The beneficial effects of training are maximized, exercise-related complications and lactic acid production in the peripheral organs are minimized and the onset of fatigue is delayed, by maintaining the heart rate within its target range. Alternatively, training is prescribed at an intensity that will produce an increase in VO_2 to 60–80% of the $VO_{2\ peak}$ that the patient has attained at baseline.

To reduce further the risk of complications, it is recommended that the intensity of exercise is increased gradually, allowing a few minutes of warm-up before reaching the training workload. Beyond a generic recommendation of starting a training programme at lower intensities with gradual increments during the following weeks, no conclusive data are available on how adapt the training intensity to an individual patient's clinical and functional profile. For practical purposes, however, it can be suggested that patients with CHD but without inducible myocardial ischaemia or left ventricular systolic dysfunction start their training at an intensity corresponding to 70–85% of maximum heart rate, those with inducible ischaemia exercise at an intensity almost corresponding to the ischaemic threshold, whereas those with systolic left ventricular dysfunction or overt CHF should exercise at lower intensities, that is at 70–80 and 60–70% of maximum heart rate, respectively.

In addition to aerobic exercise, strength exercise is also increasingly being recognized as a useful component of the training programme for selected patients and muscular strength and endurance improve with strength training of moderate intensity in low-risk patients, even at older ages. Information on safety and usefulness of strength training in high-risk patients is still limited, although it has been suggested that low-intensity weight training can be safely and effectively introduced in the circuit training programme for patients with CHD – even in the presence of inducible ischaemia or left ventricular systolic dysfunction – or for patients with CHF.

Duration of exercise training sessions

An individually prescribed duration of exercise sessions may range from 5 to 60 min, being indirectly proportional to the intensity of exercise. The duration of each session is usually shorter in the initial phase of training, to be increased gradually thereafter. An excessively prolonged duration may be associated with increased risk of lactoacidosis and orthopaedic complications. However, a reasonably prolonged exercise is necessary to activate the energy metabolism pathways: it is acknowledged that, for an intensity at about 80% of maximum heart rate, the optimum duration is between 20 and 30 min. A practical method for determining the most appropriate duration of sessions is to use the product of workload and duration of exercise to calculate the energy expenditure, which should be about 250–300 kcal per session or 1000–1500 kcal per week.

Frequency of exercise training sessions

In the initial phase of an exercise programme, when the exercise intensity is gradually increased, daily sessions, on at least 5 days per week, are to be preferred, also to check most accurately the cardiovascular response to exercise. This is particularly important because, during the initial phase of training, exercise-related changes in heart rate and arterial pressure may be substantially different from those observed during the baseline stress test. Following the initial phase, three sessions per week are usually adequate to maintain the training effect. It should be remembered that, if the training programme is interrupted, exercise capacity usually is reduced by 50% within 4–5 weeks.

Modality of exercise training sessions

A training programme can be set up following the continuous, the interval and the circuit training modalities. The continuous training modality, which is particularly effective in increasing cardiovascular and muscular endurance capacities, is carried out at moderate intensities, with a prolonged duration and without periods of recovery. In the interval training modality, periods of exercise at higher intensity are alternated with periods of recovery or of exercise at lower intensity. The circuit training programme is based on a series of different exercises (with or without equipment) carried out in a sequence. Circuit training is a programme of moderate intensity which improves not only the endurance capacity and muscular strength, but also neuromuscular coordination and agility. Despite these multiple positive effects, this training modality is still rarely used in CR. Various equipment (e.g. cycle ergometer or treadmill) and various types of calisthenics have been used in training programmes mostly aimed at enhancing aerobic capacity.

The training is the main phase of the programme, aimed at improving the delivery of oxygen to the working muscles through both enhanced oxygen transportation capacity and extraction and at maximizing caloric expenditure. Continuous and rhythmic exercises involving large muscle groups, such as walking, stepping on a staircase and exercising on a cycle ergometer, are the most effective modalities of aerobic training. Calisthenics, particularly those involving large muscle masses, and also strength training and recreational activities, can also be usefully included.

A 5–10 min cool-down phase at a lower workload should follow the training phase, for a gradual recovery of heart rate and arterial pressure to their baseline levels. A too brisk interruption of exercise can produce arterial hypotension and syncope, especially in older persons with blunted cardiovascular reflexes.

Progression and duration of training programmes

During the course of a training programme, the exercise intensity should be adapted to the patient's improved exercise capacity. Change in heart rate at sub-maximum exercise is the simplest method to be followed for this purpose. However, particularly in older patients and in those treated with beta-blocking agents, these may prove to be unreliable indicators of an improved aerobic capacity. Therefore, use of the Borg's scale, which assesses the rate of perceived exertion (RPE),[41] is a commonly recommended, simple method to confirm additionally that exercise tolerance has improved from baseline. With a maximum possible value of 20 on the scale, patients should exercise at an RPE of 13–15. A reduction in RPE can be the consequence of enhanced cardiovascular and muscular fitness, but also of improved emotional profile and of increased confidence with the schemes of exercises and use of equipment. In any case, when the RPE at sub-maximum workloads is reduced, the intensity of exercise can be safely increased, in order to obtain a further training effect. Assessment of RPE is of particular importance in frail, older patients with CHF or comorbidity or after prolonged bed rest for complicated cardiac surgery. In these subgroups, a standardized and reproducible assessment of perceived fatigue should guide the progression through strictly individualized rehabilitative programmes, initially setting the exercise intensity at an RPE of 9–11, which corresponds to about 60% of maximum heart rate and slowly progressing to an RPE of 12–13 over the following weeks.

The duration of training programmes is one of the most difficult characteristics to be exactly defined. Ideally, a training programme should be prolonged enough to induce positive changes in functional conditions. However, this objective has to confront the organizational constraints of rehabilitation centres, which have to offer access to new patients following turnover programmes. Furthermore, exact information on the relationship between programme duration and attainable outcomes is still lacking, with the exception of documentation on variable increments in non-standardized measures of exercise tolerance reported by training programmes of variable duration. A period of 3–12 weeks is generally recommendable, with longer durations needed for patients at higher risk. At least three sessions per week at high workloads for 4 weeks are the minimum prescription to obtain a measurable and clinically valuable effect, and more sessions are necessary when – for safety reasons when faced with a markedly deteriorated functional profile or unstable clinical conditions – the workload has to be set initially at a low level. Following these general considerations, a programme duration of at least 3 weeks is sufficient for most low-risk patients after uncomplicated infarction or cardiac surgery, whereas for patients at higher risk or with CHF a duration of 4–6 and 8–10 weeks, respectively, is deemed to be more appropriate. The programme duration should be prolonged also for older patients, who are usually trained at lower initial intensities. It should be remembered that the duration of the training programme

is also a function of many other clinical elements, such as the adaptive changes in heart rate and arterial pressure, the absence of symptoms, the RPE, the capacity of obtaining at least a 10–20% increase in exercise tolerance from baseline, the stability of the emotional profile and adherence to the structure of overall preventive programme.

As already mentioned, long-term, community-based physical exercise maintenance programmes are effective in preserving the otherwise declining improvement in exercise tolerance attained with participation in hospital-based rehabilitation programmes.

Safety of training programmes

Patients are admitted to a training programme when in a stable clinical condition and in the absence of absolute contraindications to physical exercise (Table 45.3).

The safety of physical training in CHD patients has long been a source of considerable controversy. Studies in the 1970s–1980s reported an incidence of non-fatal events ranging from 1 event per 34 000 h of exercise-patient to 28 events per 2 350 000 h of exercise-patient, with an incidence of fatal events ranging from 1 event per 116 000 to 1 event per 2 350 000 h of exercise-patient. Lower overall rates and absence of any fatality have been reported in two reviews[42,43] that were based on more recent studies. Whether continuous ECG monitoring may reduce the risk of complications is still unknown. Usually, high-risk patients are constantly monitored during the whole training programme, whereas low-risk patients are monitoring only during the first few sessions. However, studies have suggested that the overall incidence of complications is low and similar across risk categories and that the few complications are represented mostly by 'minor' events such as angina, ST-segment depression or non-sustained cardiac arrhythmias. For the purpose of safety, multiple parameters must be taken under control during exercise training, in particular the linearity of the increase in heart rate and arterial blood pressure, ECG morphology and the RPE. Surveillance and monitoring must be especially close during the initial phase of the programme, when physical detraining or difficulties in learning how to carry out exercises may contribute to abnormal increases in heart rate or arterial pressure. Adapting exercise prescriptions to a limited functional capacity – particularly in older, disabled and comorbid individuals – further contributes to the feasibility and safety of exercise programmes. A skilled staff that includes several different professionals, such as physical therapists, nurses and technicians, and on-site devices and drugs that are necessary for immediate treatment of emergencies are the final elements that support programme safety.

Table 45.3 Contraindications to exercise training.

Absolute	• Acute myocardial infarction • Unstable angina • Uncontrolled ventricular cardiac arrhythmias • Severe aortic stenosis • Unstable heart failure • Pulmonary embolism or infarction • Myocarditis or pericarditis • Aortic dissection
Relative	• Uncontrolled arterial hypertension (SAP/DAP >180/110 mmHg) • Tachy- or bradyarrhythmias • High degree atrioventricular block • Electrolyte abnormalities • Hypertrophic cardiomyopathy • Mental or physical impairment leading to inability to exercise adequately

Exercise training programmes in special cardiac conditions

Cardiac surgery

Exercise training after cardiac surgery can start when the clinical conditions have become stable and it is usually preceded by short programmes of respiratory physical therapy to recover respiratory dynamics and of low-intensity exercise to improve mobility and flexibility. Extensive neurological and cognitive evaluation is particularly recommended in older persons, in whom cerebral complications of prolonged anaesthesia and extracorporeal circulation are more likely to occur. In these patients, an early rehabilitation programme is aimed mainly at improving mobility and independence in activities of daily living. In the absence of specific contraindications that may occur after surgery (e.g. anaemia with Hb $<10\,g\,dl^{-1}$; pleural or pericardial effusion; delayed or complicated healing of surgical wounds), a six-minute walk test is prescribed as soon as the patient is able to walk independently (on average, 10 days after surgery). A baseline, symptom-limited ergometric stress test is carried out 3–4 weeks after surgery, when the sternum has usually stabilized and thoracic pain has relieved. As previously described, data acquired during the stress test are used to select the appropriate intensity for exercise training, which low-risk patients can usually be taught to self-manage at home without risk. As for other categories of cardiac patients, assessment of cardiovascular risk factors, associated with education, counselling and behavioural strategies to help achieve the best optimal control of coronary risk factors, is an essential component of medium- and long-term rehabilitation programmes.

Chronic heart failure

CHF patients must be clinically stable while on optimized drug therapy for at least 1 month before their exercise

capacity can be assessed for potential enrolment in a physical training programme. Particularly in the presence of permanent atrial fibrillation, the cardiopulmonary exercise test is the preferred method for assessment,[30] as it can evaluate aerobic capacity and, hence, exercise capacity also when the heart rate response to exercise is inappropriate or difficult to determine precisely. Endurance training with a cycle ergometer, with the intensity set at 50% of the maximum workload attained in a baseline cardiopulmonary exercise test, 15 min sessions of interval training (exercise for 30 s, followed by 60 s of recovery or very light work), is the most commonly adopted training modality for CHF patients, since it would induce the best possible training effect without excessively increased fatigue or undesirable metabolic effects. Alternative protocols include arm exercises, walking on treadmill, flexibility and respiratory exercises. More recently, studies have demonstrated some positive effects from association of endurance with strength training.[44] Since functional assessment of and exercise prescription to CHF patients require particularly high skills, these patients should participate only in programmes that are run by well experienced rehabilitation centres. At least in the initial phase, the training programme should be carefully supervised. Studies have demonstrated the feasibility, safety and efficacy of home-based, low-intensity training programmes for CHF patients but, again, no specific data are yet available for older individuals.

The physiological effects of aerobic training

Effects of aerobic training in middle-aged and older adults with coronary heart disease

The beneficial physiological effects physical training, namely improved exercise tolerance associated with less fatigue, less angina and increased sense of wellbeing, derive from both peripheral (vascular or skeletal muscle) and central (myocardial) adaptations.

Peripheral adaptations are mainly the consequence of improved skeletal muscle efficiency, leading to improved ability to extract oxygen from entering the blood supply and increased arteriovenous difference during physical exercise. This reduces the need for increasing cardiac output and, hence, the work that the heart has to do to bring an adequate amount of oxygen to the tissues at submaximum exercise. Central adaptations include increases in cardiac dimensions, stroke volume, cardiac output and indexes of left ventricular function,[45,46] which have been reported after training programmes of variable duration in middle-aged patients with CHD. The mechanisms of physiological adaptations to exercise training in older patients may be somewhat different from those seen in middle-aged patients. Probably because of the ageing-associated increase in myocardial and vascular stiffness, adaptability to central remodelling is reduced and exercise-induced adaptations in older coronary patients appear to be almost exclusively localized at the periphery. After 3 months of aerobic training, peak exercise cardiac output, peripheral vascular conductance and hyperaemic calf blood flow were unchanged in older, low-risk patients with CHD, despite the fact that their exercise tolerance, $VO_{2\,max}$ and arteriovenous oxygen difference have increased.[47] Histological analysis of skeletal muscle biopsies showed a marked increase in capillary density and in oxidative enzyme capacity that fully account for improved adaptation to exercise.[47]

Effects of aerobic training in patients with chronic heart failure

Reduced exercise tolerance with increased breathlessness and muscle fatigue are the symptomatic hallmarks in CHF patients, who limit their activity to avoid these symptoms. This may result in further detraining, possibly leading to a vicious circle of progressively reduced exercise tolerance.

The origin of these symptoms is multifactorial, involving central cardiac factors (left ventricular systolic and diastolic dysfunction with increased pulmonary capillary pressure), central pulmonary factors (impaired ventilatory mechanics and increased physiological dead space; altered ventilation/perfusion ratio; hypoxia of ventilatory muscles) and peripheral circulatory and muscular factors (impaired vasodilatation during physical exercise; metabolic and structural alterations of skeletal muscles). Peripheral pathophysiological changes appear to be the most important determinants of exercise capacity in CHF, as systemic and pulmonary haemodynamics correlate poorly with exercise capacity or exertional breathlessness and, while central haemodynamics improve rapidly with drug therapy, improvement in exercise capacity may be delayed for weeks or months.

Skeletal muscle hypoperfusion has been observed in CHF both at rest and during exercise. This is directly related to CHF severity, is the consequence – together with sympathetic overactivity and parasympathetic withdrawal – of increased activity of endothelial ACE and reduced endothelial production of nitric oxide and is responsible for early occurrence of lactacidosis, which, in turn, produces muscular exhaustion and increases the ventilatory needs. It has also been demonstrated that unmyelinated and small myelinated afferents in muscle that are sensitive to metabolic changes related to work ('ergoreceptors') are responsible for the early circulatory response to exercise, including activation of the sympathetic vasoconstrictor drive, and that this reflex is exaggerated in CHF, probably because of sensitization by muscular acidosis during exercise. Limited physical activity, anorexia and increased circulating

substances with known catabolic effect, all contribute to inducing a certain degree of muscular atrophy, which correlates with the reduction in strength and exercise tolerance. However, functional data suggest that muscular atrophy cannot fully account for the reduced exercise tolerance. When strength is measured per unit of muscular area, it correlates poorly with $VO_{2\,max}$ and exercise tolerance. This is consistent with qualitative alterations of muscular fibres, represented by a reduction in slow-reacting, type I fibres – responsible for muscular endurance, with prevalent oxidative metabolism – with a relative increase in fast-reacting type II fibres, whose metabolic pathways rely mainly on glycolysis.

Randomized trials have demonstrated that physical training determines a sustained improvement in functional class, maximum ventilation, exercise capacity[48] and QOL in CHF patients, particularly when enrolled in long-term maintenance programmes. Although some improvement in left ventricular ejection fraction at rest and in maximum stroke volume during exercise has occasionally been described,[48] changes in central haemodynamics after training are generally modest. Thus, also in the case of CHF, the major adaptations to training appear to be peripheral. Many of the peripheral vascular and muscular dysfunctions that concur to reduce exercise tolerance in CHF are fully reverted, or at least partially corrected, by training. In particular, the endothelial production of nitric oxide in response to exercise is remarkably enhanced and the exaggerated ergoreflex activity is attenuated, with both effects contributing to reducing the inappropriately increased peripheral vascular resistance. Exercise training also reduces the concentrations of circulating norepinephrine and atrial natriuretic peptide. Analysis of percutaneous muscular biopsies, coupled with measurement of $VO_{2\,max}$ during a symptom-limited cardiopulmonary exercise test, suggests that structural and functional changes in skeletal muscles are a further determinant of improvement in exercise tolerance observed with training in CHF. Indeed, ultrastructural morphometry demonstrated a training-associated increase in skeletal muscle cell mitochondria, suggesting that the improved functional capacity is linked to an increased oxidative capacity of skeletal muscles and a concomitant reshift to type I fibres.

Evidence-based results of cardiac rehabilitation in different cardiac conditions

Coronary heart disease

Most randomized trials of CR in CHD have included mixed populations of patients with recent myocardial infarction, myocardial revascularization or angina and are based on exercise-only or exercise in addition to psychological and educational interventions, which is usually termed comprehensive CR.

The most recent meta-analysis included 48 trials and 8940 patients.[15] Compared with usual care, CR was associated with a significant 20 and 26% reduction in all-cause and cardiac mortality, respectively, and with larger reductions in plasma lipids, systolic blood pressure and rates of persistent smoking cessation. Rates of non-fatal myocardial infarction and revascularization and changes in high- and low-density lipoprotein cholesterol levels, diastolic pressure or HRQOL were similar with CR and usual care. The effect of CR on total mortality was independent of CHD diagnosis, programme of exercise intervention, length of follow-up, trial quality and trial publication date. In contrast to previous reports of greater benefit with comprehensive rehabilitation than with exercise-only programmes, the benefits were independent of type of rehabilitation programme. The authors suggested[15] that this may be because the follow-up in most studies was too short to observe indirect effects, which may need a longer time to occur. However, there are two alternative explanations. One is that exercise-only CR is likely to include psychological and educational support, even though not offered in a structured manner. The other is that most of the exercise-only trials were conducted in the pre-thrombolytic era, whereas most of the comprehensive trials were more recent. This means that the benefits in the comprehensive rehabilitation trials are likely to be additional to the already great benefit of thrombolysis, prophylactic medication and/or coronary revascularization. Only one trial included in the meta-analysis deliberately enrolled significant numbers of patients older than 75 years of age. In particular, this was the first randomized controlled trial demonstrating the feasibility, safety and efficacy with respect to exercise tolerance and HRQOL of rehabilitation in post-myocardial infarction patients as old as 86 years of age.[32] The uniqueness of this trial is confirmed by the fact that the ages of patients enrolled in other trials ranged from 48 to 71 years and, accordingly, recommendations for further trials including subsets of older patients were made in Taylor *et al*.'s review.[15]

The precise mechanism(s) by which physical exercise training reduces mortality in CHD patients is still to be completely elucidated. Exercise training exerts direct beneficial effects on myocardial oxygen demand, development of coronary collateral vessels and coronary endothelial function, cardiocirculatory autonomic tone, coagulation and clotting factors and inflammatory markers. However, reduction in mortality may also be mediated via the indirect effects of exercise through improvements in the risk factors for atherosclerotic disease.

Cardiac surgery

Although almost two out of three enrollees in CR programmes in Europe are recovering from cardiac surgery, only a few studies have specifically addressed the efficacy of CR after surgery. Furthermore, most meta-analyses have not examined the results of post-surgery CR separately from those in other clinical subsets. These aggregated analyses have demonstrated that CR is associated with a significant reduction in long-term mortality.

Information on the efficacy of post-surgery rehabilitation in older patients is even more limited, despite the demonstration that older age, together with female gender and comorbidity, are independent risk factors for cognitive, neurological and functional complications, prolonged hospital stay, worse long-term prognosis and early hospital readmission after cardiac surgery, which are all elements that would recommend greater participation of older surgical patients in rehabilitation programmes. Nonetheless, a recent review[49] demonstrated that in addition to age, disability, lower formal education, cardiac dysfunction and poor quality of life are all predictors of non-participation in rehabilitation after coronary artery bypass operations, although patients with these conditions would benefit the most from integrated, multicomponent CR programmes.

Chronic heart failure

After the success with newer pharmacological agents such as ACE inhibitors, beta-blockers and anti-aldosteronic agents, a further 'therapeutic revolution' has occurred recently in the management of CHF, consisting of a profound change in recommendations about physical activity. From the previous orientation in favour of restrictions on physical activity, the newest guidelines recommend therapeutic exercise programmes for the current management of CHF.[11] This came after the demonstration that supervised exercise training improves the functional capacity and quality of life of CHF patients, without any risk of unfavourable clinical events or deteriorating cardiac function, but rather with an anti-remodelling effect.

A review pooled the results of 81 studies of exercise training in CHF,[16] which differed considerably in the intensity (from 40 to 90% of $VO_{2\,max}$), the frequency (from one to seven per week) and duration (from 15 to 120 min) of exercise training sessions and in the overall programme duration (from 2 to 104 weeks). Despite these differences and the different characteristics of patients enrolled, a relatively homogeneous and significant improvement in exercise tolerance was reported in all studies. Pooled analysis has also demonstrated the absence of relevant, exercise-related adverse events and significant, positive effects of training on combined endpoints (all-cause mortality plus new events). A meta-analysis[50] including nine randomized trials with 809 patients (395 exercise training versus 406 controls) determined the effect of exercise training programmes of at least 8 weeks with follow-up data for at least 3 months on survival in patients with CHF due to left ventricular systolic dysfunction. Exercise training significantly reduced all-cause mortality and the combined endpoint of hospital readmission by 35 and 28%, respectively, with no statistically significant subgroup treatment-specific effect. Age comparison was limited to patients younger and older than 60 years, since most of those enrolled in randomized trials were younger than 65 years. Moreover, most patients enrolled in randomized trials were highly selected individuals with little or no comorbidity, unlike older cardiac patients seen in everyday clinical practice, and the surrogate endpoints that have frequently been adopted in those trials (e.g. changes in $VO_{2\,max}$) do not provide evidence that such therapy affects outcomes that are especially valuable in older persons, such as functional capacity or quality of life. Several controversies still need to be addressed. Exercise training is recommended for NYHA functional class II or III patients, tailored to the individual's exercise tolerance, because it improves exercise capacity and quality of life. However, ExTraMATCH[50] and the HF-ACTION trial[51] have provided somewhat contradictory results about its effectiveness on morbidity and mortality in stable patients. Limited information about combined aerobic, strength, interval, resistance and respiratory exercise training is available. Although the safety of all of these exercise modalities is undisputed, the question of the most effective training mode remains to be answered.

Key points

- Cardiac rehabilitation is an integral component of secondary prevention and is indicated for patients with a wide variety of cardiac conditions, ranging from coronary artery disease to chronic heart failure.
- The best results are obtained with integrated, multicomponent cardiac rehabilitation programmes, which include exercise training together with counselling and psychosocial measures that may help patients maintain sustained changes towards a healthier lifestyle. Studies suggest also that long-term maintenance programmes carried out in the community after the in-hospital phase may achieve better long-term results.
- Robust evidence from randomized controlled trials and meta-analyses supports the efficacy of cardiac rehabilitation on clinically relevant outcomes such as reduced long-term morbidity and mortality, enhanced functional profile and improved

control of cardiovascular risk factors. A limited number of economic analyses suggest that cardiac rehabilitation is also cost-effective.
- Most of this evidence derives from trials with only small numbers of patients older than 70–75 years of age.
- Future research programmes should therefore be aimed at specifically investigating the efficacy and effectiveness of cardiac rehabilitation in older, frail cardiac patients.

SECTION 5

Respiratory Diseases

CHAPTER 46

Epidemiology of respiratory infection

Joseph M. Mylotte
University at Buffalo, Buffalo, NY, USA

Community-acquired pneumonia

Many studies of community-acquired pneumonia (CAP) in the elderly have focused primarily on hospitalized cases. Marston *et al*.[1] evaluated all adults hospitalized for CAP in 1991 who resided in two counties of the State of Ohio in the USA. The incidence of CAP requiring hospitalization was 266.8 per 100 000 with an overall case-fatality rate of 8.8%. The incidence was higher in males and increased with age. Case-fatality was significantly higher in those ≥65 years of age (12.5%) compared with those aged <65 years (4.6%; $p < 0.001$). Kaplan *et al*.[2] performed a retrospective analysis of Medicare administrative data for 1997 and found that the overall incidence of CAP was 18.3 per 1000 population but increased from 8.4 per 1000 in those aged 65–69 years to 48.5 per 1000 in those aged 90 years and older, and the incidence was higher in males. Overall hospital mortality was 10.6% but mortality doubled with age from 7.8% in those 65–69 years to 15.4% in those 90 years and older.

Fry *et al*.,[3] using data from the National Hospital Discharge Survey in the USA, compared hospitalization rates for CAP among those aged 65 years and older between 1988 and 2002 and found that the rates increased by 20% for those aged 65–74 years and 75–84 years but not for those aged 85 years and older. However, rates of hospitalization were significantly higher in those aged 85 years and older compared with those aged 75–84 years. In a separate analysis of the National Hospital Discharge Survey from 1998 to 2003 there was an overall significant decrease in the rate of hospital discharges for invasive (meningitis and bacteraemia) pneumococcal disease; much of this invasive disease was likely related to pneumonia and most of the decrease was due to a decrease in discharge rates in those aged 65 years and older.[4] The overall decline in hospital discharge rate for invasive pneumococcal disease coincided with the introduction of the conjugated pneumococcal vaccine for children in 2000. The decline in incidence of invasive pneumococcal disease in those aged 65 years and older was also documented by the Active Bacterial Core Surveillance Program of the Centers for Disease Control and Prevention.[5]

Jackson *et al*.[6] provided the first extensive evaluation of rates of CAP in the elderly managed in the community and in the hospital. They evaluated 46 237 people age 65 years and older who were members of a health maintenance organization in one state in the USA between 1998 and 2001. Rates of CAP ranged from 18.2 episodes per 1000 person years for those aged 65–69 years to 59.9 per 1000 for those aged 90 years and older (overall rate 28.4 per 1000 person years). In all age categories, males had a higher rate of pneumonia episodes. In this population, 59% of all episodes of CAP were treated on an outpatient basis. Independent risk factors for CAP included older age, male gender, obstructive lung disease, asthma, diabetes, heart failure and smoking. Among persons hospitalized for treatment, 12.5% died within 30 days of admission whereas only 0.4% of persons treated as outpatients died within 30 days of initial diagnosis. O'Meara *et al*.[7] evaluated the rate of hospitalization for CAP in community-dwelling people aged 65 years and older enrolled in the Cardiovascular Health Study who were followed for a median of 10.7 years. Of 5888 enrollees, approximately 10% were hospitalized with CAP with a hospital mortality of 10%. Among those who survived the CAP episode, the risk of death in subsequent years was significantly higher compared with those with no CAP episodes. Significant predictors of hospitalization for CAP were age, male gender, smoking, history of cardiovascular disease, peripheral vascular disease, diabetes, chronic lung disease and race other than African-American. In a case–control study of community elderly patients enrolled in a health maintenance organization in one state in the USA, risk factors for CAP included presence and severity of cardiopulmonary disease, low weight or recent weight loss and poor functional status; 42% of CAP cases were said to be attributable to cardiopulmonary disease.[8]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Nursing home-acquired pneumonia

In the nursing home setting, the reported incidence of pneumonia has ranged from 0.5 to 3.3 episodes per 1000 resident days in mostly retrospective studies.[9] The variation in the reported rate of nursing home-associated pneumonia (NHAP) may be related to differences in incidence over time, study design, number of facilities studied, completeness of case finding and facility affiliation (federal, community, proprietary, non-proprietary). Intensive prospective studies of NHAP found the incidence to be 0.7 to 1.0 episodes per resident care days.[9]

Multiple studies have identified risk factors for the development of nursing home-acquired pneumonia.[9] These factors include tracheostomy, dementia, dysphagia, tube feeding, depression, change in mental status, malnutrition/weight loss, poor functional status, chronic lung disease, smoking, no vaccinations, poor oral care, sedatives, cardiovascular disease, neurological disease, older age and male gender. The different risk factors that have been identified relate to variations in the definition of pneumonia/case finding, number of episodes studied, number of facilities studied and limitations in data collection/availability of data.

Risk factors for mortality among those with NHAP have been studied extensively. Comparison of the findings of these studies is problematic because some investigators combined pneumonia and bronchitis into a single group for analysis versus studies that focused on pneumonia. In addition, crude mortality varied depending on the site of treatment: 8.8–28% for those treated in a nursing home compared with 17.6–53% for those treated in hospital.[9] With these limitations in mind, the following factors were found to be significantly predictive of mortality: poor functional status, observed/history of aspiration, dementia, respiratory rate >30 breaths per minute, pulse >125 beats per minute, acute change in mental status and acute severity of pneumonia.[9] There is also evidence that there may be significant variations in mortality among facilities. Nicolle *et al*.[10] found significant variations in 21-day mortality in residents of 21 long-term care facilities in Canada prospectively identified with lower respiratory tract infection. This study utilized three different definitions of lower respiratory infection because of variations in diagnostic testing and reporting of clinical data among study facilities. Among the residents with chest radiographs demonstrating pneumonia, factors significantly associated with mortality were change in mental status from baseline, history of stroke, respiratory rate ≥25 breaths per minute, staffing level and number of hours dedicated to infection control efforts. This is the first study to identify facility-level factors that may be contributing to the outcome of NHAP.

Models to predict mortality among nursing home residents with lower respiratory tract infection[11] or with pneumonia[12] have been developed. Carusone *et al*.[13] found that the model developed by Naughton *et al*.[12] accurately predicted outcome only in the more severely ill group, whereas Nicolle *et al*.[10] found that mortality rates at higher predicted levels of severity were not accurately predicted utilizing the same model. van der Steen *et al*.[14] validated the model developed by Mehr *et al*.,[11] which requires laboratory testing that is not routinely performed in the nursing home setting.

Hospital-acquired pneumonia

The burden of hospital-acquired infections falls heavily on the elderly. Rates of hospital infection in general and hospital-acquired pneumonia in particular are significantly higher among the elderly than younger patients.[15] Despite the association between age and the development of hospital-acquired pneumonia, age alone is not the only reason for the increased risk; age may be a surrogate for serious underlying disease or debility, which, in turn, predisposes to pneumonia. In addition, life-saving interventions, such as intubation and mechanical ventilation, also increase the risk of pneumonia.

Tuberculosis

Despite advances in diagnosis, treatment and prevention, tuberculosis continues to cause significant morbidity and mortality worldwide.[16] It has been estimated that one-third of the world's population is infected with *Mycobacterium tuberculosis* and that eight million people are identified with active tuberculosis each year and two million die yearly related to this infection.[17] The elderly continue to be a major reservoir for latent tuberculosis infection and active tuberculosis.[18] It has been estimated that 9.8% of sputum smear positive cases worldwide occur in those aged 65 years and older.[19] In an evaluation of data collected as part of the National Health and Nutrition Examination Survey (NHANES) in 1999–2000, a nationally representative sample of the civilian, non-institutionalized US population, it was estimated that the prevalence of latent tuberculosis infection was 5.6% in those 65 years of age and older; only those in the 45–64-year-old group had a higher prevalence (6.5%).[20]

In 2008, the incidence of tuberculosis in the USA was at a historical low of 4.2 cases per 100 000 population.[21] There was a significant decline in the incidence of tuberculosis in all age groups in the USA beginning in the mid-1990s through 2008. However, the incidence continues to be highest in those aged 65 years and older (6.4 cases per 100 000 in 2008) and 19% of cases in 2008 occurred in those aged 65 years and older.[21] In 2008, of 12 101 cases in which living situation was documented, 2.1% were reported to be in

residents of long-term care facilities.[21] Hence the burden of tuberculosis in the elderly in the USA continues to be substantial. The higher rate of tuberculosis in the elderly in the USA occurs in all racial and ethnic minorities.[16]

Non-influenza viral respiratory infection

Viral respiratory tract infections in general result in morbidity but minimal mortality in adults. In the elderly, however, viral respiratory infections can be more serious, resulting in outbreaks in congregative settings such as nursing homes or daycare centres for seniors with considerable morbidity and mortality.[22] Respiratory infection in this section refers to illnesses manifested primarily by one or more of the following symptoms: cough, nasal congestion, rhinorrhoea, sore throat, hoarseness, fever or wheezing with or without other constitutional symptoms.

Ruben *et al*.,[23] in a population-based study evaluating the development of infections among community-dwelling elderly, found that the overall rate of respiratory infection (including pneumonia) was three episodes per 100 person months of observation, with similar overall rates in males (2.9) and females (3.1) Specific rates of respiratory illnesses (per 100 person months) were common cold 1.3, bronchitis 0.9, otitis 0.2 and pharyngitis 0.1. Falsey *et al*.[24] found that in frail elderly attending a senior daycare programme the overall rate of acute respiratory infection was 10.8 episodes per 100 person months of observation, more than three times the rate for community-dwelling elderly described by Ruben *et al*.[23] Viruses were the most commonly identified aetiological agents, including respiratory syncytial viruses, influenza A virus and coronaviruses. The authors postulated that the higher rate of respiratory infection may be due to a more susceptible population and increased exposure to infectious agents in the daycare setting compared with the community setting.

Nicholson *et al*.[25] assessed the role of rhinovirus infection in a population of ambulatory elderly (60 years and older). Viral infection was documented in 43% of almost 500 episodes of respiratory infection and rhinovirus caused about half of these infections. In a separate analysis,[26] they found that lower respiratory symptoms related to rhinovirus infection in the elderly was significantly associated with current smoking, presence of chronic lung disease diagnosis or the presence of other underlying medical illness. Ellis *et al*.[27] studied residents of 381 nursing homes in Tennessee between 1995 and 1999 and found that respiratory syncytial virus infection increased hospitalization rates, antibiotic use and deaths each winter during the study. Agents such as rhinovirus and coronavirus that commonly cause colds in young adults or healthy elderly and are usually benign may result in hospitalization of frail elderly people with underlying cardiac or lung disease.[28] With the increasing use of molecular technology, an array of new viruses have been identified as causing respiratory illness in the elderly but their epidemiology remains to be elucidated.[29]

Key points

- The incidence of community-acquired pneumonia and associated case-fatality is highest in the elderly.
- Debilitated, bedridden people are at greatest risk for developing pneumonia in the nursing home setting.
- Rates of hospital-acquired pneumonia are higher in the elderly than younger people.
- The incidence of tuberculosis is highest in the elderly in developed countries, especially in the institutionalized setting.
- Common respiratory viral infections may produce severe illness in the frail elderly.

CHAPTER 47

Pneumonia

Joël Belmin
Groupe Hospitalier Pitié-Salpétrière-Charles Foix and Université Pierre et Marie Curie (Paris 6), Ivry-sur-Seine, France

Introduction

Pneumonia is defined as an inflammatory process involving alveoli and terminal bronchioles and related to infectious agents. Infectious lung diseases and especially pneumonia are particularly serious in the elderly and represent the fifth leading cause of death in persons older than 65 years. Pneumonia is a major cause of hospitalization and about two of three patients hospitalized due to pneumonia are older than 70 years of age. The prognosis of pneumonia is severe, with a fatality rate reaching 50% in some series of nosocomial pneumonia.

Pneumonia should be differentiated from other lower respiratory tract infections and especially from acute bronchitis. Bronchitis is an inflammatory response of large bronchi with no involvement of the lung parenchyma. In contrast to pneumonia, bronchitis usually has a benign course, except in patients with chronic obstructive pulmonary disease who might suffer from deterioration of respiratory function.

Several factors may increase the risk of respiratory infection in the elderly (Table 47.1). During ageing, the body's defences against infectious agents are less effective, especially cellular immunity. The ageing respiratory system is particularly exposed to risks of infection because of reduced effectiveness of cough and mucociliary clearance and due to microaspiration. Some lung diseases commonly encountered in the elderly, for example, chronic obstructive pulmonary disease, asthma and sequelae of tuberculosis, may facilitate the occurrence of respiratory infection and also some common situations in geriatrics such as diabetes mellitus, heart failure, neurological diseases, swallowing disorders, use of sedative drugs, especially antipsychotics, gastro-oesophageal reflux, protein–energy malnutrition and enteral nutrition or nasogastric tube. Aspiration of oropharyngeal secretions and microflora, food debris or gastric contents is frequently involved in lower respiratory tract infection in frail elderly people, especially among patients having a neurological disease, dysphagia and/or using psychotropic drugs. Pneumonia is the main specific cause of mortality observed in Alzheimer's disease.

Causative agents

A wide variety of infectious agents may be responsible for respiratory infections in the elderly. Their identification is often difficult in the acute phase of infection, especially in frail elderly patients.

Many bacteria might provoke pneumonia. *Streptococcus pneumoniae* should be a major concern because it is the bacterium most commonly involved in community-acquired pneumonia requiring admission to hospital and its mortality rate is very high among the elderly. Other bacteria frequently involved are Gram-negative bacilli (especially in cases of aspiration, hospitalization or prior antibiotic treatment) and *Staphylococcus aureus. Legionella pneumophila* is rarer but often severe with a high mortality rate among elderly patients. The involvement of anaerobic bacteria seems fairly common, especially in aspiration-related pneumonia. Other bacteria may be involved, such as streptococci, staphylococci, Enterobacteriaceae, *Haemophilus influenzae* and *Mycoplasma pneumoniae*. Multimicrobial pneumonias are common in elderly patients. Hospital-acquired respiratory infections (nosocomial) are often severe because of the resistance of causative bacteria to certain antibiotics and because of the vulnerability of the patients, often weakened by the diseases that brought them to hospital. *Mycobacteria*, especially *M. tuberculosis*, can determine a subacute or chronic respiratory infection. Aspergillosis may be responsible for an infection in the pulmonary sequelae of tuberculosis or lung abscess. Fungal infections of the lung are very rare and relate to subjects with severe immunosuppression.

Viruses may be involved in 10–30% of community-acquired acute pulmonary infection and often occur in an epidemic, particularly in institutions. The agents involved

are influenza (including in patients who received vaccination), respiratory syncytial virus, parainfluenza influenza, rhinovirus and adenovirus.

Patients' age and context of care are factors that influence the frequency of the agents responsible for pneumonia requiring hospitalization. In older patients, *S. pneumonia, H. influenzae* and respiratory viruses are more frequently observed than in younger adults, whereas *Legionella, Mycoplasma* and *Chlamydia* spp. are less frequent. In nursing home patients, aspiration pneumonia, Gram-negative enteric bacilli and multiple anaerobic agents are more frequently observed than in age-matched persons.

In hospital-acquired pneumonia (nosocomial), *S. aureus, Pseudomonas aeruginosa* and enteric Gram-negative bacteria are frequently observed, in addition to resistance to antibiotics. Also, pneumonia might be encountered in patients recently treated with antibiotics, together with complex and/or resistant germs including polymicrobial infection.

Clinical presentation of pneumonia in the elderly

The classical features of acute lobar pneumonia with general malaise, frank hyperthermia, cough and chest pain are rarely complete in the elderly: initially, fever and cough are absent in 30–40% of cases. In many cases, the picture is not typical, with a gradual onset of less marked signs leading to a delayed diagnosis. Elders with pneumonia usually have several respiratory or non-respiratory symptoms, but each of them might be missing. Respiratory symptoms comprise cough, productive or not, purulent sputum, dyspnoea, chest pain and haemoptysis. Non-respiratory symptoms usually comprise fever, anorexia, chills and sweats.

Examination of the patient can show the following findings: tachypnoea (respiratory rate $>30\,\text{min}^{-1}$) tachycardia (heart rate $>110\,\text{min}^{-1}$), fever and hypothermia. Classic auscultatory findings (localized crackles) are very suggestive of the diagnosis of pneumonia, but they may be absent or poorly recognized, because they are very discrete or because of hypoventilation or insufficient cooperation of the patient. The existence of wheezing indicating bronchial obstruction is common.

Other clinical presentations of pneumonia are possible. Severe sepsis with shock, hypotension, cold and clammy skin, altered consciousness and hypothermia should call for an examination of the lungs. Intestinal symptoms are sometimes prominent: abdominal pain, nausea, vomiting, paralytic ileus and diarrhoea. There can also be an isolated delirium or cardiac events such as onset of arrhythmia (atrial fibrillation) or heart failure.

Certain clinical presentations can suggest a specific aetiology. The flu syndrome with headache, diffuse myalgia, arthralgia, pharyngitis and rhinorrhoea orients towards a viral aetiology, especially in an epidemic context. The context of weight loss in recent weeks or months should prompt a search for tuberculosis.

Differential diagnosis of lower respiratory tract infection

Diseases whose clinical presentation can mimic that of pneumonia are numerous, and are outlined below.

Bronchitis

Bronchitis is frequently misdiagnosed as pneumonia. Acute bronchitis shares many symptoms with pneumonia, especially productive cough with purulent sputum. Usually, marked general signs are infrequent and there are no localized crackles. Classically, it is important to distinguish acute bronchitis from pneumonia (Table 47.2) because antibiotics are not indicated for bronchitis occurring in persons free from chronic obstructive pulmonary disease. In fact, in elderly subjects, the distinction between these two entities is sometimes difficult in the initial stage of infection. Indeed, in some subjects with pneumonia, temperature might be normal fever and may be missed and pulmonary auscultation might be difficult. Also, performing a chest radiograph is an important element in differentiating the two diseases. However, it is almost impossible to obtain a chest CT for every outpatient with symptoms of respiratory infection. A more feasible strategy consists in obtaining a chest radiograph 2–3 days after the beginning of the treatment in every patient with a suspected diagnosis of pneumonia: at present, the absence of a chest image suggestive of pneumonia should lead to the consideration of other diagnoses.

Exacerbation of chronic obstructive disease

Exacerbation of chronic pulmonary obstructive disease (COPD) might also be confounded with pneumonia. Exacerbation of COPD is defined by the worsening of

Table 47.2 Main findings in bronchitis and pneumonia.

	Bronchitis	Pneumonia
Marked asthenia, fever >38.5 °C, chills, tachycardia	Infrequent	Frequent
Cough	Yes	Yes
Increased respiratory rate at rest	Infrequent (except in COPD[a])	Frequent
Lung auscultation	Normal or diffuse wheezes	Localized crackles/wheezes
Leukocytosis	Normal or slightly increased	Normal or increased
Chest radiograph	Normal	Opacity or opacities, pleuritis (may be normal at a very early stage)
Chest computed tomography (CT)	Normal	Lung parenchymal opacities, pleuritis
Deterioration of a pre-existing condition	Infrequent (except in COPD)	Frequent

[a]COPD, chronic obstructive pulmonary disease.

cough, expectoration and/or dyspnoea and is easily recognized when COPD has been previously diagnosed. When the diagnosis of COPD has not been established, it is usually suspected by the association of smoking and a history of chronic bronchitis and dyspnoea. Exacerbations can be provoked by non-infectious causes, but also infectious causes including acute bronchitis or pneumonia. Antibiotics are indicated in severe exacerbations defined by an increase in dyspnoea and sputum purulence and volume, and also in exacerbation occurring in severe COPD with chronic respiratory failure.

Heart failure and pulmonary embolism

Heart failure associated with other infectious diseases (endocarditis, urinary tract infection) or a non-infectious disease responsible for fever may be confounded with pneumonia. Plasma brain natriuretic peptide (BNP) determination helps to distinguish dyspnoea related to heart diseases (BNP $>300\,\text{pg}\,\text{ml}^{-1}$) from that related to lung diseases. In elderly people, it is fairly common to observe concomitantly heart failure and pneumonia. Pulmonary embolism can share symptoms with pneumonia such as fever, cough, chest pain and dyspnoea. The normal lung fields on chest radiograph, the context favouring venous thromboembolism or the presence of clinical signs of venous thrombosis suggest the diagnosis of pulmonary embolism. The pulmonary infarction secondary to pulmonary embolism leads to signs shared with those of pneumonia and is very often the site of secondary infection.

Cancer and other diseases of the lungs

Lung cancer can be revealed by a respiratory infection. Massive loss of weight and marked anorexia, the persistence of the radiological image at 12 weeks after the infectious episode and high exposure to tobacco or asbestos are points that must lead to the consideration of the diagnosis of lung cancer and require bronchoscopy and/or a chest CT scan. Other diseases affecting the lungs can manifest the presentation of a lower respiratory tract infection: drug-related pneumonia (amiodarone, carbamazepine), lipid pneumonia (inhalation of a paraffin-based laxative), Wegener's granulomatosis, Churg–Strauss disease and other autoimmune diseases (rheumatoid arthritis, Sjögren's syndrome, coeliac disease). In these situations, the outcome after antibiotic treatment is not the same as that observed during a respiratory infection, which leads to consideration of these diagnoses and that of an infection resistant to prescribed antibiotics.

Hospitalization and further investigations in elderly persons with a suspected diagnosis of community-acquired pneumonia

Facing suspected pneumonia, physicians must quickly answer two questions:

- Should the patient be referred to hospital?
- Are additional tests required?

The answers to these questions depend on the severity of the disease, the patient's frailty and the context of care, and guide the type of treatment for the pneumonia.

Referral to hospital of an elderly person with suspected pneumonia

There are three main reasons that prompt referral to hospital.

First, the diagnosis of pneumonia is unclear and a severe disease is also suspected, such as pulmonary embolism or heart failure. In these conditions, the use of blood tests, ECG and chest X-ray is mandatory in order to select appropriate management.

Second, the diagnosis of pneumonia is likely, but conditions to treat the patient in their usual context of life (home

or nursing home) are not fulfilled. This applies not only for the administration of anti-infective treatment but also for general support of care such as help with activities of daily living, prevention of pressure sores and dehydration and for appropriate follow-up.

The third reason is related to the severity of pneumonia. This can be assessed using simple tools such as the CRB-65 scale (Table 47.3) or the pneumonia severity index (PSI). The scores given by these scales are indicators of mortality rates and can be used to identify low-risk patients who can be treated at home. Stratification of the risk given by the PSI is more precise than that given by the CRB-65. The CRB-65 is a simplified version of another scale, CURB-65, which contains an additional item related to plasma urea and is not suitable for the clinical assessment of patients without blood testing. Although the CRB-65 seems to be simpler, mental status requires the use of another scale, the Abbreviated Mental Test score, which includes 10 more items. The PSI items that can be obtained clinically are listed in Table 47.4. The PSI also contains biological variables which can be used in hospital settings. The Pneumonia Outcome Research Team (PORT) scale is a decision tree derived from the PSI to assess more accurately the mortality risk in young adults, but it is not relevant for older patients. Patients living in nursing homes often have a very high PSI score, owing to the importance of age and comorbid factors in the score. For instance, an 82-year-old man living in a nursing home and with a history of cerebrovascular disease will receive a PSI score of 102. With the CRB-65 scale, every elderly patient will receive at least one point, which indicates that referral to hospital should at least be considered in every elderly patient with suspected pneumonia.

Frail elderly patients with suspected pneumonia often fulfil the criteria for hospitalization for several reasons, such as loss of independence, high number of comorbidities, loneliness and uncertainty of the diagnosis and/or severity of pneumonia (Figure 47.1). Some complications, such as heart failure or acute respiratory failure, are frequent and severe in the elderly. Moreover, regardless of the severity of pneumonia, these patients are exposed to systemic complications such as dehydration, delirium, hyperglycaemia, bedsores and other complications of bed rest and usually require more intense support for activities of daily living during a severe infectious episode. Finally, as with any disease, severe acute respiratory infection in the elderly can cause diseases in cascades, by successive deterioration of chronic diseases that were hitherto balanced.

Table 47.3 The CRB-65 four-item scale to assess the severity of community-acquired pneumonia; each item counts 1 point if present and the CRB-65 score is the sum

- Confusion: new cognitive dysfunction according to Abbreviated Mental Test score
- Respiratory rate ≥ 30 min^{-1}
- Blood pressure: systolic <90 mmHg and/or diastolic ≤ 60 mmHg
- Age ≥ 65 years

If score = 3 or 4: high risk of mortality and urgent admission to hospital is required

If score = 1 or 2: consider hospital referral (especially in a patient with score = 2)

If score = 0 (not applicable in the elderly): treatment at home

Table 47.4 Pneumonia severity index (PSI) simplified for patients aged 65 years or more, clinically assessed without laboratory test results.

Patient characteristics	Points assigned	Patient's points
Age (years)		
Man	Age	
Woman	Age–10	
Nursing home resident	+10	
Comorbidities		
Neoplastic disease	+30	
Liver disease	+20	
Congestive heart failure	+10	
Cerebrovascular disease	+10	
Renal disease	+10	
Initial examination findings		
Altered mental status	+20	
Respiratory rate ≥ 30 min^{-1}	+20	
Systolic BP <90 mmHg	+20	
Temperature <35 or $\geq 40\,^{\circ}$C	+15	
Pulse ≥ 125 min^{-1}	+10	
SaO_2 $<90\%$ (if oxymeter available)	+10	
Score = sum of points		
Score range	*Site of treatment*	*Mortality range (%)*
<70	*Outpatient*	*0.6–0.7*
71–90	*Outpatient*	*0.9–2.8*
91–130	*Inpatient*	*8.2–9.3*
>130	*Inpatient*	*27–29*

Are additional tests required?

Additional investigations to assess the severity of infection and to seek its origin should be widely pursued in severe pneumonia requiring admission to hospital due to pneumonia and in pneumonia acquired in hospital.

Chest imaging

Lung imaging shows the involvement of lung parenchyma that is a major factor in documenting a gold standard

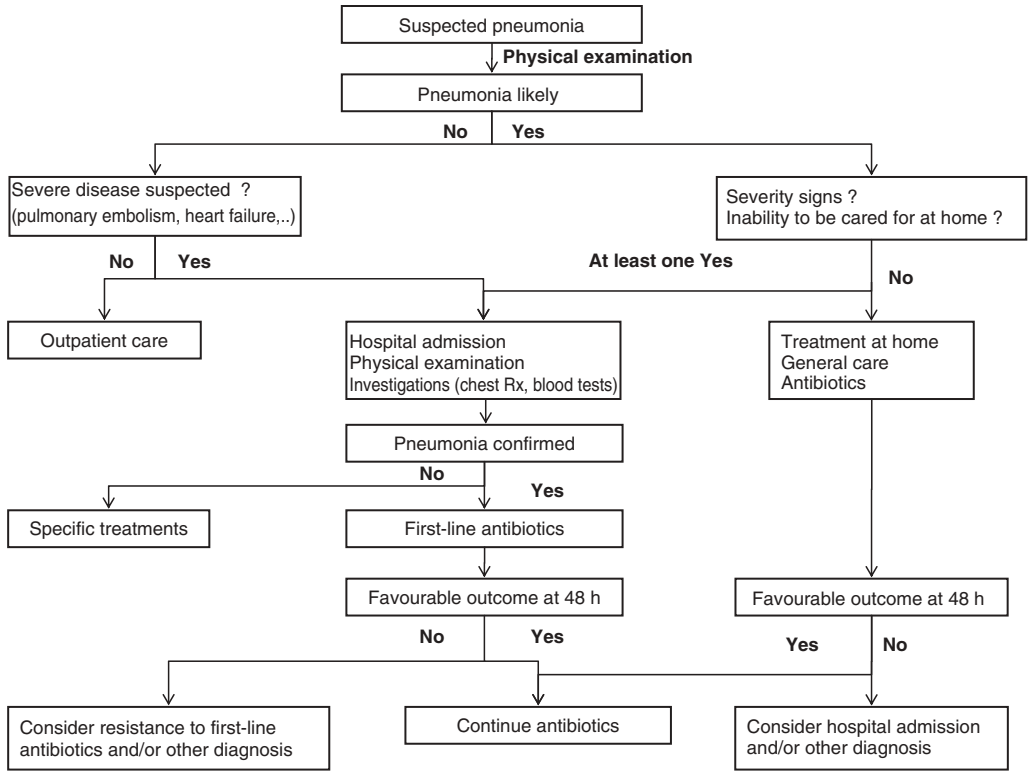

Figure 47.1 Decision tree for hospitalization of frail elderly patients with suspected pneumonia.

diagnosis of pneumonia. The front and lateral chest radiographs search for systematized alveolar-type condensation or a mixed alveolar and interstitial image, less systematized atelectasis or microatelectasis, a peri-hilar interstitial diffuse, interstitial or localized image and more or less systematized. The radiographic type is poorly related to the infectious agent. The absence of a visible parenchymal focus usually indicates the absence of parenchymal infection (bronchitis), but might be observed in acute pneumonia at a very early stage (pneumococcal pneumonia). Chest images should be carefully examined for a discrete image or inconspicuous image, especially retro- or pericardial. A CT scan is indicated in situations difficult to document as parenchymal.

In their guidelines on low respiratory infections, the European Thoracic Society recommends obtaining a chest X-ray in every patient with suspected pneumonia, mainly to differentiate pneumonia from bronchitis. However, it is very difficult to implement this recommendation in every old patient living in the community or living in a nursing home. The guidelines of the British Thoracic Society propose managing patients with community-acquired respiratory infection without a chest X-ray if the diagnosis of pneumonia is likely and if the patient does not require hospital admission. Of course, in patients referred to hospital for suspected pneumonia, whatever the reason, a chest X-ray is recommended to confirm the diagnosis of pneumonia.

In difficult cases and especially when pneumonia is suspected despite a normal chest X-ray, a chest CT scan might help identify pneumonia at a very early stage or pulmonary embolism.

Biological tests

Biological tests and in particular microbiological tests are not recommended for patients having pneumonia which can be managed out of hospital. Biological tests are performed on hospitalized patients with pneumonia.

A blood cell count often shows leukocytosis with neutrophils, which suggests a bacterial origin. However, leukocytosis may be lacking in older patients with bacterial infections, including pneumonia. A frank increase in C-reactive protein is also supportive of a bacterial origin. Electrolytes, urea, creatinine and glycaemia should be measured since abnormalities related to dehydration, renal failure or hyperglycaemia are common. The measurement of oxygen saturation by finger sensor is a simple and non-invasive test that evaluates an immediate impact on the haematosis. In cases of chronic respiratory failure, cyanosis, sweating or loss of consciousness, arterial blood gas should be measured.

Microbiological tests aim to identify the infectious agent. These tests should be widely applied, although it is unusual to obtain immediate findings to guide the choice of fist-line anti-infective drugs. However, they are very useful, especially in cases where the infectious syndrome is not controlled by the first-line drugs. Blood cultures and sputum examination should be carried out in all patients referred to hospital due to pneumonia. Blood cultures may isolate the causative organisms associated with bacteraemia. Bacteriological examination of sputum can be helpful in highlighting unusual germs found in the oral commensal flora, such as pneumococcal or *Legionella* species. It is often difficult to achieve an appropriate sampling of sputum in asthenic or uncooperative patients, although it is essential to obtain secretions from the lower respiratory tract.

A search for pneumococcal urinary antigen or *Legionella* is not recommended immediately in community-acquired pneumonia, except in the context of clinical suspicion or outbreak. This search is recommended in cases of very severe pneumonia which required treatment in an intensive care unit. Urine microscopic examination and culture are not useful in older patients with pneumonia and should not be performed, as they might lead to the finding of bacteria unrelated to respiratory infection due to the high prevalence of asymptomatic bacteriuria and in turn wrongly influence physicians prescribing antibiotics.

Respiratory virus testing is rarely performed in the context of community-acquired infection. In the case of an epidemic occurring in a geriatric facility, a search for respiratory viruses should be made at least in some patients to identify the virus responsible for the epidemic. The procedure of choice is nasal swab. Rapid tests are able to diagnose influenza within hours, whereas conventional viral culture requires 48 h or longer.

Mycobacterium tuberculosis should be searched for in pneumonia associated with weight loss or deterioration of the general condition occurring over several weeks or even months. Suitable samples for examination can be the sputum, gastric fluid or the material aspirated during bronchoscopy. The Mantoux test suggests active tuberculosis when it leads to a large induration with blebs. In case of simple positivity or negativity, it does not confirm or exclude the diagnosis of active pulmonary tuberculosis. The value of the QuantiFERON test or other interferon release assays has not been extensively documented for the diagnosis of active tuberculosis in very old people, many of whom had contact with the germ during their lifetime.

Serological tests are available for the identification of *Legionella, Chlamydia, Mycoplasma* and respiratory viruses. If used, they should be repeated two weeks later. They might be useful for retrospective diagnosis.

Therapy of pneumonia in the elderly

General measures

Some measures are not specific and relate to the management of conditions commonly associated with respiratory infection in the frail elderly, such as dehydration, anorexia and immobilization. They include oral hydration, oral nutritional supplementation if the patient is malnourished, oral care and prevention of pressure ulcers. Intravenous or subcutaneous fluids are often necessary in the case of dehydration. Antipyretics should be given, unless fever $>39.5\,^{\circ}C$ is poorly tolerated. Delirium is frequent and should be managed by non-pharmacological approaches. Venous thrombosis and pulmonary embolism should be prevented with subcutaneous heparin unless contraindicated. Appropriate control of comorbid conditions is also an important objective of the treatment.

Non-infectious treatments for pneumonia

Oxygen therapy by the nasal route is indicated in acute cases whenever there is dyspnoea and/or hypoxaemia, but should be used with caution in cases of chronic respiratory failure with hypercapnia. Respiratory physiotherapy is useful and aims to improve breathing and abdominal drainage of bronchial secretions. Inhaled bronchodilators by β_2-agonists and anticholinergics should be used if signs of bronchial obstruction are present. In bronchial obstruction resistant to inhaled bronchodilators, short-course systemic corticosteroids may improve ventilatory status. The occurrence of a large atelectasis inducing a sudden worsening of dyspnoea is an indication for emergency bronchoscopy for detection of mucus plugs and guided aspiration.

First-line anti-infective agents

Choice of antibiotics

Fist-line antibiotic treatment of bacterial pneumonia depends on the context of care, the severity of the disease and the germs suspected. However, the choice of initial antibiotic treatment remains largely probabilistic unless the causative agent has been identified. Hence it is important to assess the adequacy of initial antibiotic therapy after 48 h, depending on the patient's clinical response and early results of microbiological tests.

For community-acquired bacterial pneumonia, initial antibiotic therapy must be effective on the pneumococcal and *Haemophilus influenzae* species that are the most frequently observed in this context. First-line antibiotics recommended for community-acquired pneumonia in persons with comorbid conditions (which applies to most elderly persons) who do not require admission to hospital are listed in Table 47.5. In most cases, a single oral

Table 47.5 First-line antimicrobial therapy recommended for patients with comorbidities with community-acquired pneumonia treated in the community.

Guidelines	First-line antimicrobial therapy	Alternative choice
American Thoracic Society (ATS) (2001)	[Macrolide or doxycycline] *Plus* β-lactam (oral cefpodoxime, cefuroxime, high-dose amoxicillin, amoxicillin–clavulanate; or parenteral ceftriaxone followed by oral cefpodoxime)	Anti-pneumococcal fluoroquinolone[a] (used alone)
Infectious Diseases Society of America (2003)	Azithromycin *or* clarithromycin *or* respiratory fluoroquinolone[a]	
European Respiratory Society (2005)	Amoxicillin *or* doxycycline	Amoxicillin–clavulanate *or* macrolide *or* levofloxacin (*or* moxifloxacin[b])
Société de Pathologie Infectieuse de Langue Française (2006)	Presumed viral pneumonia during a period of influenza circulation: neuraminidase inhibitors	
	Presumed bacterial pneumonia: amoxicillin–clavulanate (1 g×3 per day)	Presumed bacterial pneumonia: levofloxacin 500 mg per day (*or* moxifloxacin[b])
British Thoracic Society (2009)	Amoxicillin 500 mg×3 per day	Doxycycline *or* clarithromycin

[a] Moxifloxacin, levofloxacin or gemifloxacin.
[b] Use of moxifloxacin has recently been restricted due to adverse effects.

antibiotic can be used: amoxicillin, amoxicillin–clavulanate, an advanced macrolide (azithromycin or clarithromycin), doxycycline or a respiratory fluoroquinolone (levofloxacin, gemifloxacin or moxifloxacin).

In nursing home patients with pneumonia, recommended first-line antibiotics are listed in Table 47.6. Since aspiration pneumonia is frequent in such settings, these regimens should be active against anaerobic bacteria. However, within the ATS recommendation, the regimen constituted by cephalosporin (or high-dose amoxicillin) plus macrolide might not be active against anaerobic bacteria.

Table 47.6 Choice of first-line antibiotics for treatment of community-acquired pneumonia in nursing home patients.

Guidelines	First-line antibiotics
SPILF	Oral amoxicillin–clavulanate (1 g ×3 per day) *or* parenteral ceftriaxone *or* oral levofloxacin (500 mg per day) *or* oral moxifloxacin (400 mg per day)
ATS	[Intravenous β-lactam (cefotaxime, ceftriaxone, ampicillin–sulbactam or high-dose ampicillin) *plus* (intravenous or oral macrolide or doxycycline)] *or* [intravenous anti-pneumococcal fluoroquinolone alone]
IDSA	Respiratory fluoroquinolone alone *or* [oral amoxicillin–clavulanate *plus* (azithromycin or clarithromycin)]

Abbreviations: see Table 47.5

In severe community-acquired pneumonia and in hospital-acquired pneumonia, the use of a broad-spectrum antibiotic regimen is appropriate and the choice depends on prior antibiotics (β-lactam or fluoroquinolone in the past three months) and risk factors for *Pseudomonas* (bronchiectiasis, corticosteroids, recent broad-spectrum antibiotic treatment in the past month, malnutrition) or for other agents (immunosuppression). In these cases, several regimens can be proposed, such as a parenteral third-generation cephalosporin (or *Pseudomonas*-active cephalosporin) associated with a macrolide; a parenteral respiratory fluoroquinolone alone or with a third-generation cephalosporin; imipenem–cilastatin; or piperacillin–tazobactam. Metronidazole or ornidazole should be added to antibiotic regimens which are not active against anaerobic bacteria. In these complex cases, the advice of an infectious disease specialist is important.

When the diagnosis of influenza pneumonia is suspected, the use of neuraminidase inhibitors should be discussed if the symptoms of infection are recent (<48 h). This condition is infrequently encountered except for new cases of pneumonia occurring during an influenza-proven outbreak in a geriatric institution. Oral oseltamivir is preferred in elderly patients with pneumonia, because administration is easier than with inhaled zanamivir.

Handling anti-effective agents in the elderly

When prescribing anti-infective drugs in older patients, it is important to consider the patient's renal function, concomitant drug treatments and previous allergy/intolerance

to antibiotics. The dosage of some anti-infective agents should be reduced in patients with creatinine clearance $<30\,ml\,min^{-1}$: amoxicillin, cefuroxime, ceftazidime, imipenem, ciprofloxacin, levofloxacin, clarithromycin, erythromycin, metronidazole, aminosides and oseltamivir. Drug–drug interactions should be considered mainly with macrolides (warfarin, digoxin, statins).

Antibiotics should be given by the oral route, except in severe infections where the parenteral route is preferred. The intravenous route is the most frequently used, but it should be noted that ceftriaxone can be given by subcutaneous injection.

Follow-up of patients

The 48 h assessment

The expected response to antibiotic therapy is expected to occur within 2–4 days after the beginning of the treatment. Assessment after 48 h of the first-line antibiotic therapy is a very important step. Fever decrease and clinical stability or improvement indicate a favourable response to treatment. In this case, oral antibiotic therapy should be continued and, if parental antibiotics have been used, they should be switched to oral antibiotics of the same pharmacological class. At this time, results of microbiological testing (if done) are available and if positive might influence the course of the treatment.

Management of patients with an unfavourable response is more difficult. Referral to hospital should be proposed to those treated in outpatient settings. Several possibilities should be discussed: pneumonia due to microorganisms resistant to the antibiotics given (including virus or tuberculosis), encysted pleural effusion, non-infectious lung disease, adverse effects of antibiotics or worsening of comorbid conditions. Clinical examination, blood testing, chest X-ray and chest CT scan help in investigating these issues. A search for urine antigen is indicated, if it has not yet been done. Antibiotics should be modified if bacterial infection resistant to the first antibiotic regimen is suspected. The advice of an infectious disease specialist should be obtained if possible.

Further follow-up

The total duration of antibiotic administration is about 10 days, except for azithromycin, which can be used for 5 days. Usually, fever disappears and leukocytosis and C-reactive protein decrease during 2–5 days after the beginning of the treatment. Cough persists longer, but sputum volume and purulence decrease.

In patients for whom the antibiotic regimen was changed at the 48 h assessment, a 10 day duration for the new antibiotic regimen is appropriate. In these patients, an unfavourable outcome during the second antibiotic course is a difficult situation, which should be managed by lung and infectious disease specialists. A search for microorganisms in a more invasive manner, should be reconsidered even after stopping the antibiotics if possible.

In patients with a favourable clinical outcome, it is not necessary to perform a chest X-ray to document the disappearance of the lung opacities. Regression of lung images takes longer in elderly people and might require up to 12 weeks. If a lung cancer associated with pneumonia is then suspected, a chest CT scan and bronchoscopy should be performed.

Prevention of pneumonia in the elderly

The main ways to prevent pneumonia in the elderly are summarized in Table 47.7. Influenza vaccination is indicated in all persons aged 65 years or more. It must be performed each year in early autumn. It can reduce by 50% the risk of developing influenza and by 70% the mortality due to influenza. In France, the vaccine is offered free to all persons aged over 65 years. This vaccine is well tolerated and rarely leads to minor local reactions and systemic reactions. The adjuvant influenza vaccine contains of a substance that stimulates the immune response and enhances the immunogenicity of the vaccine and their use is particularly valuable in the elderly living in institutions and/or weakened by a chronic disease such as diabetes or heart or respiratory failure. Influenza vaccination of healthcare personnel in long-term care settings possibly reduces the incidence of respiratory infection and overall mortality among residents of these institutions, even when the vaccination coverage rate of residents for influenza is high. Health authorities recommend influenza vaccination largely of healthcare personnel in regular contact with elderly patients. It should also encourage employers to offer such personnel easy access to free vaccination. It is logical to recommend the same protection to regular visitors of residents, including family members, stakeholders and staff volunteers.

Table 47.7 Prevention of pneumonia in the elderly.

For elders
Anti-pneumococcal vaccine every 3–5 years
Influenza vaccine each year
If swallowing disorders: treatment and rehabilitation
Avoid sedative drugs (antipsychotics)
Avoid contacts with persons having a respiratory infection and cough or rhinitis
Ask them to wear a facemask
For healthcare staff (and relatives with frequent contacts)
Influenza vaccine each year
If respiratory infection and cough or rhinitis: wear facemask, avoid contacts with elderly people and strengthen hand hygiene

When an outbreak of respiratory infection occurs in a geriatric institution, a search for germs, in particular influenza virus, should be carried out. In influenza outbreaks, the use of neuraminidase inhibitors (oseltamivir in particular) is recommended for cases and also for contacts to stop the outbreak. Given the number needed to treat, the role of influenza virus should be documented by laboratory diagnosis tests.

If an outbreak of influenza occurs in an institution, influenza vaccination should be offered to unvaccinated residents and staff, visits and movement of residents in the institution should be temporarily restricted and group activities should be temporarily stopped. Hand hygiene should be reinforced and residents and staff with symptoms should wear masks. Some of these measures are difficult to implement given the cognitive status of some residents and organizational constraints related to the institution, such as service of meals in a collective dining room. In case of an outbreak of viral pneumonia not related to influenza virus, the same general measures are recommended, but there is no vaccination and/or antiviral treatment.

Pneumococcal vaccination is indicated in all elderly persons living in geriatric institutions and in the elderly living at home and weakened by chronic illness (heart failure, respiratory failure, diabetes). This was shown to reduce the incidence of invasive pneumococcal disease, but its efficacy in preventing pneumonia has been the subject of debate. Recently, a large-scale randomized trial in Japanese nursing homes found a marked decrease in mortality and in pneumonia incidence among vaccinated groups.

Swallowing disorders should be subjected to careful management, ideally guided by a speech therapist. It is important to look systematically at patients with neurological diseases. Initially, adaptation of food is sometimes sufficient: thicker liquids are better tolerated, and also small bites or sips. Water gel can help to maintain hydration when swallowing liquids is difficult. When these small means are insufficient, long-term enteral nutrition by percutaneous gastrostomy should be discussed on a case-by-case basis, knowing that this technique does not protect against the risk of respiratory infection by inhalation and if it fits in an ethical approach. Avoiding unnecessary sedative drugs (in particular benzodiazepines and neuroleptics) and dosage reduction might help to prevent aspiration.

Key points

- Pneumonia is a major cause of hospitalization and about two out of three hospitalizations due to pneumonia are of patients over 70 years of age.
- Pneumonia should be differentiated from other lower respiratory tract infections, especially bronchitis.
- Numerous infective agents provoke pneumonia, especially bacteria and viruses.
- Referral to hospital and further tests are important questions to be decided.
- Therapy includes non-infective treatments and anti-infective agents such as antibiotics.
- Preventive measures include anti-pneumococcal vaccine and influenza vaccine.

CHAPTER 48

Aspiration pneumonia

Takashi Ohrui and Hiroyuki Arai
Institute of Development, Aging and Cancer, Tohoku University, Sendai, Japan

Aspiration pneumonia and aspiration pneumonitis

Pneumonia is a common cause of death among older people despite the availability of potent novel antimicrobials. Whereas the death rate of juvenile pneumonia has decreased nearly to zero, that of old people has remained unchanged over the past 100 years. In other words, the traditional approach has proven a limited success: as Osler put it over 100 years ago, 'pneumonia is actually a friend to the old'.[1] Both the increased incidence of pneumonia and high mortality among older people are a consequence of a number of age-related factors including coexisting illnesses, therapeutic interventions and decreased host defence mechanisms. In these, aspiration is possibly the most important risk factor for pneumonia in the elderly.[2] Aspiration is defined as the inhalation of oropharyngeal or gastric contents into the larynx and the lower respiratory tract. Several pulmonary syndromes may occur after aspiration, depending on the amount and the nature of the aspirated material, frequency of aspiration and the host's response to the aspirated material.[3] Aspiration pneumonia is an infectious process caused by an inhalation of the oropharyngeal secretions that are colonized by pathogenic bacteria, whereas aspiration pneumonitis including Mendelson syndrome is a chemical injury caused by an inhalation of sterile gastric contents.[3] Although there is some overlap between these syndromes, they are distinct clinical entities. This chapter focuses on the pathophysiology and the management of aspiration pneumonia and aspiration pneumonitis.

Mechanisms for development of aspiration pneumonia or aspiration pneumonitis

Aspiration pneumonia

Pneumonia in the elderly is often caused by a non-apparent swallowing disorder.[2] Such 'silent aspiration' frequently occurs and is a more important cause of pneumonia than acute aspiration of gastric content in older people.[4] Silent aspiration of oropharyngeal bacterial pathogens to the lower respiratory tract is an important risk factor for community-acquired pneumonia[5] and also nosocomial pneumonia in the elderly.[6] Normal hosts are less likely to develop pneumonia because they aspirate smaller volumes or are able to clear bacteria rapidly.[7] However, an extremely small volume (0.01 ml) of saliva contains pathogenic numbers of bacteria.[7] Elderly patients with a predisposition to aspiration frequently aspirate oropharyngeal secretions and the development of pneumonia occurs when normal pulmonary defence mechanisms are overwhelmed.[8] Adequate protective reflexes in the airway are important and suppression or absence of these reflexes has led to pneumonia.[8] For example, Nakajoh *et al*. reported that the incidence of pneumonia was higher in patients having both a latency of swallowing response longer than 5 s following stimulation with 1 ml of distilled water and a cough threshold for inhalation of citric acid aerosol higher than a concentration of 1.35 (log mg ml^{-1}).[9] Thus, the progressive loss of protective reflexes (i.e. swallowing and cough reflexes) with age is thought to be one of the mechanisms for aspiration pneumonia, which is often seen in older people.[10] In fact, impaired swallowing and cough reflexes have been shown in patients suffering from aspiration pneumonia.[11] However, re-evaluation of age-related changes in protective reflexes in individuals who lead active daily lives has shown that both reflexes do not decrease with the advance of age,[12,13] indicating that involutional and degenerative changes associated with ageing often result in marginally compensated protective reflexes.[14] Disorders of the central nervous system are more likely to develop in the elderly and pneumonia has been estimated to occur in about one-third of patients with stroke.[15] The most important factor contributing to the development of pneumonia in patients with stroke is suggested to be dysphagia with aspiration.[16] Nakagawa *et al*. have shown that the risk of

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

pneumonia was significantly higher in patients with basal ganglia infarcts than in patients with or without cerebral hemispheric strokes in other locations.[8] They found that multiple episodes of pneumonia occurred only in patients with bilateral basal ganglia infarcts and that there was a higher mortality rate associated with pneumonia in these patients.[8] Delayed triggering of the swallowing reflex occurs in patients with infarcts in the basal ganglia.[14] These results strongly suggest that disruption of basal ganglia functions is critically important in the development of aspiration pneumonia. The pharyngeal, laryngeal and tracheal epithelia, the most important sites for the initiation of swallowing and cough reflexes, have an extensive plexus of nerves that contains substance P.[17,18] Capsaicin desensitization, which diminishes substance P from the airway and upper digestive tract, or an administration of neurokinin (NK)-1 receptor antagonist remarkably attenuated the cough response to tussive stimuli[19,20] and distilled water-induced swallowing reflex in guinea pigs,[21] suggesting an important role of substance P-containing nerves in the initiation of these protective reflexes. Thus, irritation of laryngeal and pharyngeal mucosa by stimuli may activate capsaicin-sensitive sensory nerves, releasing substance P, with the result that protective reflexes are initiated by stimulation of the glossopharyngeal and vagal sensory nerves.[19] Treatment with a dopamine agonist in the rat brings about a heightened striosomal expression of substance P and both dopamine D1 and D2 antagonists decrease substance P.[22] Mice lacking the dopamine D1 receptor[23] and those treated with dopamine D1 receptor antagonist[24] showed abnormal motor activities and feeding and swallowing problems. An impairment of dopamine metabolism in the basal ganglia is observed in patients with infarcts in the basal ganglia.[25] Taking these facts together, the mechanisms of silent aspiration may be speculated as shown in Figure 48.1. Patients with basal ganglia infarcts may suffer from reduced dopamine metabolism, which decreases substance P in the glossopharyngeal and vagal sensory nerves. Reduction in substance P concentration in these nerves impairs both swallowing and cough reflexes, which increases the frequency of silent aspiration. Because the action of swallowing and coughing is a fundamental defence mechanism against aspiration of oropharyngeal contents into the respiratory tract, impairment of both reflexes is one of the major reasons for the development of aspiration pneumonia (see Figure 48.1). In patients with aspiration pneumonia, unlike those with aspiration pneumonitis, the episode of aspiration is generally not witnessed. The diagnosis is therefore inferred when a patient at risk for aspiration has radiographic evidence of an infiltrate in a characteristic bronchopulmonary segment. Elderly persons frequently receive poor oral care, resulting in oropharyngeal colonization by potential respiratory tract pathogens, including Enterobacteriaceae, *Pseudomonas aeruginosa* and *Staphylococcus aureus*. These pathogens are aspirated and may cause pneumonia.[3]

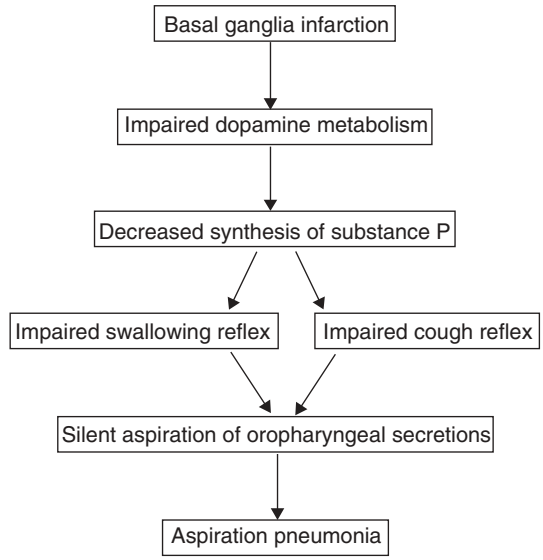

Figure 48.1 Possible mechanisms for development of aspiration pneumonia in patients with basal ganglia infarction.

Aspiration pneumonitis

Aspiration pneumonitis is defined as acute lung injury after the inhalation of regurgitated sterile gastric contents. This syndrome occurs in patients who have a marked disturbance of consciousness such as that resulting from a drug overdose, seizures, a massive cerebrovascular accident or the use of anaesthesia.[3] The syndrome most commonly described as aspiration pneumonitis is Mendelson syndrome.[26] Reflux of gastric fluids into the airway can damage the respiratory tract.[27] Marked damage to the tracheal mucosa can occur even when the volume of aspirated gastric fluid is too small to cause clinically significant aspiration pneumonitis and repeated long periods of aspiration of gastric fluid may even cause interstitial pulmonary fibrosis. Damage is always more severe when the pH of the gastric contents is low, but gastric fluid also contains substances other than acid which cause airway damage and delay healing of the airway epithelial damage.[3,27] Since airway epithelial damage by gastric content probably arises from the additive effects of acidity,[27] treatment of gastroesophageal reflux using antiacids such as histamine-H2 receptor antagonists alone may not improve symptoms caused by aspiration of gastric fluids.[3]

Treatments for aspiration pneumonia and aspiration pneumonitis

Aspiration pneumonia

Antibiotic therapy is unequivocally indicated in patients with aspiration pneumonia. The choice of antibiotics should depend on the setting in which the aspiration occurs and also the patient's general health. However, antibiotic agents with activity against Gram-negative organisms, such as third-generation cephalosporins, fluoroquinolones and piperacillin, are usually required.[3] Kanda *et al*. evaluated an additive effect of angiotensin-converting enzyme (ACE) inhibitor and amantadine to the conventional antibiotic therapy for pneumonia and found that the combined administration of these drugs can shorten the duration of hospitalization and antibiotic use, inhibit methicillin-resistant *Staphylococcus aureus* (MRSA) infection and lower the medical cost for treatment of pneumonia.[28]

Aspiration pneumonitis

Although it is common practice, the prophylactic use of antibiotics in patients in whom aspiration is suspected or witnessed is not recommended.[3] However, empirical antibiotic therapy is appropriate for patients who aspirate gastric contents and who have small-bowel obstruction or other conditions associated with colonization of the gastric contents.[3] Antibiotic therapy should be considered for patients with aspiration pneumonitis that fails to resolve within 48 h after aspiration. Empirical therapy with broad-spectrum agents such as fluoroquinolone or piperacillin is recommended. Corticosteroids have been used for decades in the management of aspiration pneumonitis. However, there are limited data on the role of these agents.[29]

Strategies for the prevention of aspiration pneumonia (Figure 48.2)

Pharmacological therapy

Capsaicin

Because substance P is a neurotransmitter of the swallowing reflex and is depleted in patients with aspiration pneumonia,[30] capsaicin, a pungent substance in red peppers that stimulates sensory nerves, may improve the swallowing reflex in these patients.[2] Ebihara *et al*. measured the swallowing reflex with a bolus injection of 1 ml of distilled water into the pharynx through a nasal catheter and suggested that the addition of a low dose of capsaicin to liquid or food may stimulate the swallowing reflex and help to prevent aspiration pneumonia in the elderly.[31]

3. Sitting position
4. Avoid neuroleptics
5. Handwashing

Figure 48.2 Preventive strategies for aspiration pneumonia.

Angiotensin-converting enzyme (ACE) inhibitors

A well-known adverse effect of ACE inhibitors is a dry cough.[32] Since substance P is degraded by ACE,[33] its action is potentiated by ACE inhibitors.[34] Using ACE inhibitors, substance P might accumulate in the upper respiratory tract because of inhibited ACE activity and cause an increase in the sensitivity of the cough reflex.[2,20] In a similar way to the cough reflex, ACE inhibitors improve the swallowing reflex in older patients with aspiration pneumonia.[2] Sekizawa *et al*. compared the rate of pneumonia in stroke patients with hypertension treated by ACE inhibitors with that in stroke patients treated by other antihypertensive drugs and found that the risk of pneumonia is reduced by about one-third if ACE inhibitors are used for hypertension compared with the use of other antihypertensive drugs.[35] ACE inhibitors, therefore, may have beneficial effects on the prevention of pneumonia in these patients. Arai *et al*. reported that the rate of pneumonia was significantly lower in elderly hypertensive patients given ACE inhibitors than that in those treated with calcium channel blockers.[36] However, Teramoto and Ouchi refuted the advantage of ACE inhibitors over calcium channel blockers in preventing pneumonia in adult and elderly subjects with hypertension.[37] In elderly individuals, the severity of the underlying cerebrovascular disease greatly affects susceptibility to pneumonia. ACE inhibitors could be useful in the prevention of aspiration pneumonia in elderly patients with stroke but not in those without stroke.

Dopamine and amantadine

Delayed triggering of the swallowing reflex occurs in patients with basal ganglia infarctions[2] and an impairment

of dopamine metabolism in the basal ganglia is observed in these patients.[25] Kobayashi *et al*. investigated whether levodopa improves the swallowing reflex in patients with basal ganglia infarctions who had a history of aspiration pneumonia.[38] The subjects were given an intravenous drip infusion of levodopa (50 mg in 20 ml of saline) for 30 min. They found that the administration of levodopa improved the impaired swallowing reflex in these patients. Since dopamine supplementation improves the swallowing reflex in patients with cerebral infarctions, Nakagawa *et al*. investigated whether amantadine, a drug that acts as a dopamine releaser from dopaminergic nerve terminals, lowers the incidence of pneumonia in patients with cerebral infarctions.[39] Patients were randomly assigned amantadine 100 mg per day or no active treatment and were investigated for 3 years. During follow-up, the relative risk of developing pneumonia in patients on no active treatment compared with that in those on amantadine was 5.92. These findings suggest that the risk of pneumonia is lowered by about 20% if amantadine is used in patients with previous stroke. Amantadine may, therefore, have beneficial effects on the prevention of pneumonia in these patients. Of course, other recognized effects of amantadine might also have impacted the incidence of pneumonia in these studies. For example, amantadine improves the conscious state in patients with brain injury[40] and more active stroke patients may be less likely to aspirate. In addition, dopaminergic receptors have been identified in the lower oesophageal sphincter and amantadine might reduce gastroesophageal reflux[41] and thereby lower the risk of aspiration pneumonia. Finally, antiviral effects and prevention of influenza infection might also lower the incidence of pneumonia over a 3 year period. Hence the mechanism by which amantadine might positively affect the incidence of pneumonia remains to be proven.[42]

Cilostazol

Disorders of the central nervous system including dementia and atherosclerotic cerebrovascular disease are more often associated with aspiration than other specific neuromuscular disorders.[2] The mechanisms by which brain injury affects the risk of aspiration are beginning to be delineated. For example, in healthy people, the frequency of swallowing during sleep is slightly less than that when awake,[43] but severe delay of the swallowing reflex during nighttime compared with that during daytime was observed in patients with multiple lacunar infarctions.[44] Cough reflex and spontaneous cough are also suppressed during sleep in patients with evidence of cerebrovascular damage.[2] Hence patients with cerebrovascular disease are particularly susceptible to the development of aspiration pneumonia during sleep. Other evidence exhibiting the importance of cerebrovascular disease comes from studies of patients with silent cerebral infarction, that is, patients with radiographic evidence of infarction without frank signs of neurological impairment. Silent cerebral infarction is fairly common among the elderly. Silent cerebral infarction was observed in 23% of elderly people in the USA, in 42% of older adults in one Japanese study and in 51% in another Japanese study.[2] Not only is silent stroke a risk factor for clinical stroke that obviously increases the risk of aspiration pneumonia, but Nakagawa *et al*. reported that patients with silent cerebral infarction were more likely to develop pneumonia (20%) than were controls (5%) without silent cerebral infarction over a 2 year period.[45] In this study, deep silent infarcts were more closely associated with the incidence of pneumonia (29%) than that in superficial infarcts (7%).[45] Hence silent cerebral infarction should be considered as a potential risk for the development of aspiration pneumonia. Taken together, it is reasonable to propose that treatment aimed at reducing the incidence and severity of cerebrovascular diseases, for example, antihypertensive therapy or anticoagulation and anti-platelet therapy in selected populations, may not only prevent future stroke but also reduce the incidence of aspiration pneumonia. In a comparison between a group receiving cilostazol, an anti-platelet agent, for 3 years and a cilostazol non-receiving group, the incidence of cerebral infarction decreased to 50% in the cilostazol group.[2] Furthermore, the incidence rate of pneumonia also decreased by approximately half.

Folic acid

Folate plays a pivotal role in the synthesis of dopamine and its deficiency is common in older people, especially in institutionalized subjects. Folate deficiency may be an independent marker for increased risk of aspiration pneumonia in older people.[46] Folic acid supplementation may prevent the incidence of pneumonia by improving the swallowing function in these susceptible subjects.[46] Therefore, for older people, in order to prevent pneumonia, nutrition also has to be taken into consideration.

Menthol

Ebihara *et al*. found that menthol stimulation and also cold stimulation restore impaired swallowing reflex in patients with dysphagia through the activation of transient receptor potential (TRP) M8.[47] Thus, an addition of menthol to liquids or food may improve swallowing reflex and help to prevent aspiration pneumonia in the elderly with dysphagia.

Banxia houpu tang

Iwasaki and co-workers reported that a traditional Chinese herbal medicine, banxia houpu tang (BHT), improves both swallowing and cough reflexes in patients with stroke.[48,49] Furthermore, they reported that treatment with BHT reduces the risk of pneumonia and pneumonia-related

mortality in elderly patients with neurodegenerative disorders.[50]

Black pepper oil

Ebihara *et al*. reported that olfactory stimulation by nasal inhalation of volatile black pepper oil (BPO) increases the cerebral blood flow of the right orbito-frontal and left insular cortexes, increases serum levels of substance P and improves swallowing function.[51] Inhalation of BPO might improve swallowing movement and might have benefits in older post-stroke patients with dysphagia, regardless of their consciousness level or physical and mental status.

Mosapride

Percutaneous endoscopic gastrostomy (PEG) is widely used for gastrointestinal tract access to provide artificial feeding in patients with neurological dysphagia. PEG tube placement is frequently requested to address problems of dysphagia with aspiration pneumonia. However, pneumonia is the most common cause of death and might explain the lack of survival benefit in patients fed using a PEG tube. A quantitative scintigraphic study with Tc-99m-labelled enteral infusion demonstrated frequent episodes of gastroesophageal reflux (GER) and subsequent aspiration of gastric contents into the airway in patients with gastrostomy.[52] Mosapride citrate is a gastroprokinetic agent that enhances upper gastrointestinal motility and is known to prevent GER in patients with GER disease. He *et al*. found that mosapride citrate lowers the rate of developing pneumonia after PEG and improves the survival rate in patients with PEG.[53]

Oral hygiene

The microbiological aetiology of aspiration pneumonia is usually traced to organisms that inhabit the oropharynx and aspiration of pharyngeal contents has been suggested as the mechanism by which these bacteria reach the lower respiratory tract.[2] Johanson and Harris speculated that the pulmonary infections caused by bacteria following the introduction of pathogenic organisms by aspiration of oropharyngeal contents is one of the major reasons for pneumonia in the elderly.[54] Since aspiration of bacteria in the oropharyngeal secretions is an important risk factor for nosocomial pneumonia in the elderly, poor oral health may also contribute to the development of pneumonia. Yoneyama *et al*. assessed the rate of pneumonia in elderly people receiving oral care and in those who were not.[55] During 2 years of follow-up, pneumonia was diagnosed in 19% of the participants who did not receive oral care and in 11% of those who received it. The relative risk of developing pneumonia in no active oral care compared with that in oral care was 1.67 (95% CI, 1.01–2.75; $p < 0.05$). Thus, monitoring the attention given to the oral hygiene of dependent patients can probably lower the incidence of aspiration pneumonia. Furthermore, Yoshino *et al*. stimulated the gum-ridge with a brush without toothpaste immediately after a meal.[56] No matter where in their mouth they stimulated, the swallowing reflex improved after the stimulation on the gum-ridge. This result indicates that stimulation in the mouth is transmitted to the brain and certainly improves the swallowing reflex, which is one of the most important defensive reflexes against microorganisms with which the human body is equipped. Brushing in the mouth is not only good for the prevention of dental caries and gumboils but also very good for improving the reflexes. Stimulation of the mouth requires less time and effort than stimulation of the arms and legs. All we need is a small amount of stimulus to care for older people.

Sitting position

GER is very common in general and more common in elderly subjects. It has been estimated that more than one-third of older people have intermittent symptoms of GER. In addition, the supine position, possibly by increasing the likelihood of aspiration of gastric contents into the lung, may lead to pneumonia in patients on mechanical ventilators.[2] Finally, nasogastric tubes promote aspiration of gastric contents by impairing swallowing function, causing stagnation of oropharyngeal secretions and reducing the tone of the lower oesophageal sphincter.[2] The simple approach to all of these problems may involve elevating the position of the bed. Meguro *et al*. showed that elevating the bed after each meal for 2 h may lower the febrile days presumptively caused by aspiration of gastric contents.[57] Matsui *et al*. also emphasized the importance of a patient's sitting position for the prevention of respiratory tract infections.[58]

Avoid neuroleptics

The cough reflex can, of course, be suppressed by sedative drugs. Irwin *et al*. reported a consensus panel report of the American College of Chest Physicians, 'Managing Cough as a Defense Mechanism and as a Symptom,' and did not identify any age-related changes in cough reflex.[59] However, depression of cough reflex by anaesthesia, sedative hypnotics or analgesic narcotics should be considered to be a major risk for aspiration pneumonia in older patients, especially during sleep. Attention to minimizing the use of agents that suppress the cough reflex is crucial in caring for elderly patients. When older people take benzodiazepines, their swallowing reflex will not decrease significantly. However, when they take neuroleptics, which mostly act as a dopamine receptor antagonist, their swallowing reflex clearly does decrease, which makes things even more troublesome and leads to pneumonia.[60]

Handwashing

Gram-negative bacilli and *Staphylococcus aureus* commonly colonize the hands of healthcare providers. Although usually transient, hand colonization may persist, particularly in workers with dermatitis. Handwashing before and after contact with patients is an effective method for removing transient bacteria,[2] but this is often a neglected behaviour by medical personnel. The use of gloves and gowns can significantly reduce nosocomial infection and pneumonia. Hospitals with effective surveillance and infection control programmes have rates of pneumonia 20% lower than hospitals without such programmes. Adherence to infection control practices such as handwashing is fundamental for the prevention of nosocomial pneumonia. Unfortunately, such barrier methods will not be effective in preventing infection with organisms that are part of the critically ill patient's endogenous flora; hence most Gram-negative pneumonias cannot be avoided by isolation methods.[61] Improved handwashing practices and appropriate handling of mechanical feeding, suction and respiratory devices should reduce the spread of infectious agents in institutional settings.

Prevention of pneumonia among the elderly by vaccines

Influenza vaccines

Influenza vaccination is effective in older adults in preventing not only primary influenza pneumonia but also secondary bacterial pneumonia. Although an increased risk of pneumonia mortality is found in patients with limitations in activities of daily living, even bedridden elderly patients can be effectively immunized against influenza and the duration of febrile days and all respiratory conditions associated with influenza can be reduced.[62]

23-Valent pneumococcal vaccines

The efficacy of pneumococcal vaccine among high-risk patients has been the subject of some controversy. Some investigators estimate an ~60–95% prevention rate of pneumonia by 23-valent pneumococcal vaccine in immunocompetent elderly and in other high-risk patients.[63] It is currently recommended in the USA that all adults aged 65 years or older and those at risk because of underlying illnesses receive both of these vaccines. Chiba *et al*. demonstrated that pneumococcal vaccination significantly shortened the overall febrile days and significantly reduced the rate of hospitalization for pneumonia even in bedridden patients.[64] Pneumococcal vaccination is of benefit and recommended for elderly disabled patients at high risk for pneumonia.

Bacillus Calmette–Guérin (BCG) vaccines

The tuberculin skin test is an easy way to check the cell-mediated immunity in elderly people.[65] Almost all Japanese people over 65 years old may have a positive tuberculin skin test. If a person shows negative, it means that his or her cell-mediated immunity is depressed. We undertook a trial to vaccinate bedridden elderly people with BCG vaccine. During follow-up, new pneumonia was diagnosed in 42% of the elderly disabled patients with negative tuberculin responses, in 15% of the tuberculin converted patients by BCG and in 13% of the patients with positive tuberculin responses. BCG inoculation might reactivate the depressed T helper-1 mediated cellular immunity and prevent pneumonia in immobile elderly patients.[66]

Conclusion

Silent aspiration, which is frequently observed in patients with basal ganglia infarctions, might be an important risk factor for pneumonia in elderly patients. Measurement of a swallowing latency is useful for identifying a subject susceptible to pneumonia. The swallowing function might be partly regulated by dopaminergic neurons and substance P-containing sensory nerves. Disruption of the basal ganglia leads to an impairment of the swallowing function and may predispose stroke patients to pneumonia. ACE inhibitors and amantadine may have beneficial effects for the prevention of pneumonia. Similarly, oral care improves swallowing reflexes and lowers the risk of pneumonia. Vaccines are also effective even in disabled elderly patients in a bedridden condition. Since pneumonia in elderly patients frequently recurs and is often lethal, it is important to identify and protect high-risk patients from pneumonia.

Key points

- The main theme is to discuss how aspiration pneumonia develops in older people and to suggest preventive strategies that may reduce the incidence of pneumonia among older adults.
- Silent aspiration of oropharyngeal bacterial pathogens to the lower respiratory tract is one of the most important risk factors for elderly pneumonia. Impairments in swallowing and cough reflexes among older adults, for example, related to cerebral basal ganglia infarctions, increase the risk of pneumonia.
- Since both swallowing and cough reflexes are mediated by endogenous substance P contained in the vagal and glossopharyngeal nerves, pharmacological therapy using ACE inhibitors,

which decrease substance P catabolism, can improve both reflexes and result in the lowering of the risk for pneumonia.

- Since the production of substance P is regulated by dopaminergic neurons in the cerebral basal ganglia, treatment with dopamine analogues or potentiating drugs such as amantadine can reduce the incidence of pneumonia.

CHAPTER 49

Interstitial lung disease and lung cancer

Christopher Dyer
Royal United Hospital, Bath UK

Interstitial lung disease

Background and epidemiology

Interstitial lung disease (ILD) refers to a range of pathologies that stimulate an inflammation or fibrosis of the lung interstitium, which comprises the connective tissues of the alveolar and bronchial epithelium and its surrounding vascular and lymphatic tissues. If the interstitium is damaged, efficient gas exchange will not occur.

There is a wide range of conditions that make up the ILDs (Table 49.1), only a few of which can be discussed in this chapter. Many of these increase in prevalence with advancing age. The most common conditions in older adults are idiopathic pulmonary fibrosis (also known as cryptogenic fibrosing alveolitis), hypersensitivity pneumonitis and the pneumoconioses. Although most ILDs increase their prevalence with age, sarcoidosis and chronic eosinophilic pneumonia appear to be less common with advancing age. There is a paucity of research on the interaction of age and ILDs, hence much of the investigation and treatment strategies are similar for adults of any age except that perhaps bronchoscopies and lung biopsies are less frequently undertaken.

Any patient presenting with respiratory symptoms, especially chronic cough and breathlessness, should have a detailed history taken of occupation, pets (especially birds), hobbies and smoking history. In general, all patients suspected of these conditions should be referred to a respiratory physician for assessment and treatment.

Main clinical features

Most patients present with insidious onset breathlessness, although some will present with a dry cough. Wheeze is uncommon as it usually represents larger airway narrowing. The rapidity of symptom progression may vary markedly.

In severe cases, cyanosis may be present. Findings on examination may be minimal, but clubbing can occur in advanced disease and 'Velcro' crackles may be auscultated in both lung bases in around one-quarter of cases. There may also be signs to suggest an underlying connective tissue disease, such as scleroderma.

Investigations are similar for all such disorders. Pulmonary function tests typically reveal a restrictive disorder for most ILDs such that the FEV_1 is relatively less impaired than the FVC and so the FEV_1/FVC ratio is normal or high. The transfer factor of the lungs for carbon monoxide (TLCO) is reduced, as is total lung capacity (lung volume). Chest radiographs may sometimes be normal, but usually there are subtle features of increased nodularity, increased reticulation or reticulonodular changes. These are more likely to affect the periphery of the lung. The diaphragm and heart borders may appear less distinct or 'shaggy'. Pleural thickening with calcification may be associated with asbestosis. In most cases plain chest radiography is non-diagnostic and consequently most patients need a high-resolution (HR) computed tomographic (CT) scan. The HRCT scan can often determine the cause (especially for idiopathic pulmonary fibrosis), rendering bronchoalveolar lavage and trans-bronchial or open-lung biopsy largely unnecessary in this age group. Furthermore, the presence of co-morbidities or relatively advanced disease with poor lung function in very old patients at presentation may render biopsies risky.

Specific conditions

Idiopathic pulmonary fibrosis (IPF)

This is the commonest form of ILD in old age, with an incidence of five cases per 100 000 population.[1] The cause is unclear, but there are associations with cigarette smoking, gastroesophageal reflux and autoimmune disorders in some patients. Histologically the features seen are referred to as 'usual interstitial pneumonitis (UIP)' and this often

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 49.1 Range of conditions classified as interstitial lung diseases.

Idiopathic pulmonary fibrosis
Fibrosing alveolitis associated with autoimmune disorders
Hypersensitivity pneumonitis (extrinsic allergic alveolitis)
Pneumoconioses
Cryptogenic organizing pneumonia
Wegener's granulomatosis
Drug-induced
Chronic eosinophilic pneumonia

has a distinct radiological appearance on HRCT scan of the thorax. Typically there is fibrotic change in both lungs, with a predilection for the bases and the periphery. Honeycombing of the lung indicates more advanced disease and fibrosis often pulls apart bronchioles, causing so-called 'traction bronchiectasis'.

In fact, IPF is only one type of the so-called 'idiopathic interstitial pneumonias'. Details are outside the scope of this brief review, but a common alternative diagnosis is 'non-specific interstitial pneumonia (NSIP)'. The presence of ground-glass opacification may be more indicative of NSIP, indicating a more cellular reaction and one which may have a higher chance of response to treatment.

Median survival is estimated to be only 3 years for IPF, hence this condition needs to be regarded as a serious one with profound consequences that require a full and frank discussion with the patient.[2] A fall from baseline of >10% in FVC or >15% in TLCO in the first 6–12 months identifies patients with a much higher mortality.[3] Most clinicians are aware of patients who appear to have a better prognosis, with relatively stable lung function over many years, but who may then subsequently deteriorate rapidly over months.[4] Patients with NSIP have a better prognosis than those with UIP. They may survive for up to 10 years depending on the degree of fibrosis present. Treatment consists of high-dose oral corticosteroids and immunosuppressant drugs such as azathioprine and *N*-acetylcysteine, but the evidence base is rather weak.[2] No medical therapy has been shown to improve survival in IPF. Oxygen for symptomatic relief is commonly used in those who are hypoxic or who desaturate on exercise. There appears to be a remarkably high incidence (80–90%) of gastroesophageal reflux in patients with IPF,[5] such that some experts argue for routine treatment with proton pump inhibitors, although clinical trials are lacking.

Hypersensitivity pneumonitis (extrinsic allergic alveolitis)

This refers to an immune-mediated reaction to organic particles, which may occur in susceptible individuals. The response is usually a chronic type 3 hypersensitivity reaction, but an acute type 1 reaction may occur, presenting as acute breathlessness, cough and even fever. Numerous antigens are known to trigger such reactions, but two are particularly common in older adults. Chronic exposure to avian proteins can lead to 'bird fancier's lung' and fungal spores (such as actinomycetes) found in mouldy hay can cause 'farmer's lung'. Because exposure to such antigens may not be obvious, a careful history should be taken, including inquiring about pets, pastimes and occupation. Chest radiography and CT scan may reveal micronodular changes or a ground-glass appearance in the mid and lower zones, progressing to established fibrosis with honeycombing and volume loss in more chronic cases.

Antigen testing can be undertaken to prove exposure, while pulmonary function tests demonstrate restrictive features and volume loss. Management consists of avoiding further exposure to the antigen, although this may not always slow the deterioration of the condition. In common with other physicians, the present author has encountered many patients who are, perhaps understandably, somewhat averse to the thought of being parted from their pet budgerigar! In such cases, asking someone else to clean out the bird's cage could be suggested. Oral corticosteroids may help alleviate symptoms, especially in the acute or subacute stages where a cellular response is still occurring.

Pneumoconioses

This refers to fibrosis or damage to the lung due to inorganic dust. The most common causes are asbestosis, coal dust and silicosis. Coal workers' pneumoconiosis is now rarely seen in the Western world *de novo*, although chronic cases may be encountered in older people. Coal dust causes a combination of fibrosis and centrilobular emphysema (the fibrosis pulling apart the alveolar spaces), occasionally leading to progression even after dust exposure has ended. Progressive massive fibrosis, usually in the upper lobes, is reported but rarely encountered nowadays.

Silicosis is similarly fairly rare in the Western world, but is still common in some developing countries, especially those with a major mining industry. Silicosis may occur due to exposure to common rock dusts (e.g. granite and sandstone) as a result of quarrying, foundry work or mining. Small particles of silica may be inhaled distally into the lungs and ingested by alveolar macrophages which become activated, releasing inflammatory mediators such as cytokines and interleukins which may damage the respiratory cell structure and its interstitial matrix.

Although there is an acute form, symptoms are usually of progressive dyspnoea or symptoms suggestive of chronic obstructive pulmonary disease (COPD) and may occur several years after silica exposure. Radiologically small (<10 mm) nodules may be seen diffusely in the lung, although with an upper lobe predominance. 'Eggshell calcification' of hilar lymph nodes is rather rarely seen. Patients

with silicosis are at increased risk of lung cancer and also tuberculosis, probably due to damage to pulmonary macrophages by particles of silica. Progressive massive fibrosis may occur in severe cases, with lung cavitation.

Asbestosis refers to parenchymal fibrosis in those who have had considerable exposure to asbestos usually many years before the disease is manifest. Bilateral lower zone infiltrates may be seen radiographically and the condition often progresses after exposure has ended. The presence of pleural plaques may also suggest the diagnosis, although this is an entirely separate entity and other conditions, such as COPD, may coexist, confounding the diagnosis.

There is no specific treatment for these conditions, being essentially supportive. In certain countries, compensation may be claimed for industrial exposure.

Lung cancer

Background and epidemiology

The epidemic of lung cancer, apart from mesothelioma, is gradually improving in most Western countries but rates are still increasing in many other parts of the world. Approximately 90% of cases of lung cancer are attributable to tobacco exposure and historical smoking patterns explain this variance. Most recent data from the UK indicate that only 12% of those aged over 65 years of age are current smokers.[6] Mortality rates have declined steeply for all age groups, beginning first with younger men in the 1960s and last for the over 85-year-olds in the late 1980s.[6] For women, this fall began rather later as smoking uptake occurred in a later cohort compared with men. Across the world, countries are at different stages in their lung cancer epidemic due to differing histories of tobacco consumption, hence the rates of lung cancer vary widely. Worldwide it is estimated that 1.4 million people died of lung cancer in 2008.[6]

The majority of lung cancer still occurs in older people, with the incidence reaching a peak at around 75 years of age. This is because approximately 15 years separates initial cellular mutation from clinical presentation and as cells age there is a greater risk that DNA repair mechanisms may be impaired, leading to cancerous transformation.

Long-term cancer mortality rates are still higher in older adults than younger people.[7] Although historical data strongly suggest that lung cancer in old age is poorly assessed and treated,[8] more recent information in this regard is lacking.

Patients with lung cancer of any type should nowadays be referred to and managed by a specialist multidisciplinary team. This usually comprises a respiratory physician, nurse specialist, oncologist, radiologist and pathologist, with strong links to palliative care specialists. Despite this, the 5 year survival rate for all ages is still disappointingly low, at around 7% (2003–2007 UK data[6]).

Main clinical features

Most patients present with similar symptoms whatever their age, including cough, breathlessness, haemoptysis and weight loss. Unfortunately, the condition still tends to be diagnosed at a more advanced stage in older adults than young subjects and it may be complicated by multiple pathology.[9]

The extent of the disease at diagnosis, the functional and cognitive status of the patient and their own wishes for further investigation are even more important in people of advanced age. Care needs to be taken to ensure that important survival benefits and potential improvements in quality of life are not missed due to therapeutic nihilism. For many patients, complete cure is not possible but a more active approach can prove beneficial.

After a history and basic laboratory tests, spirometry should be performed to ascertain baseline lung function. There is little place for sputum cytology as most patients undergo bronchoscopy if a central lesion is identified or CT scan with CT-guided biopsy if feasible for a peripheral lesion. If there is no evidence of metastatic disease, the presence of mediastinal lymph node enlargement is critical in determining whether surgery is an option. This can be clarified using positron emission tomography (PET) scanning, which can also detect extra-thoracic spread. If nodal involvement is suspected, then endo- or trans-bronchial ultrasound-guided needle aspiration can be considered.[10]

Specific conditions

Lung cancer is broadly classified into three types:

1. non-small cell cancer (NSCLC)
2. small cell lung cancer (SCLC)
3. pleural mesothelioma.

Other types of tumour may be occasionally seen, such as carcinoid, but these will not be discussed further here.

Non-small cell lung cancer

NSCLC consists of several types of tumour. They are often grouped together because they have the potential for cure through surgical resection. Squamous cell (or epidermoid) carcinoma is the most common lung cancer among older adults, accounting for up to half of cases in this age group. These tumours often grow slowly and usually arise in central airways. Adenocarcinoma, bronchoalveolar cell carcinoma and large cell carcinoma together make up around one-quarter of cases. Adenocarcinomas arise from bronchial and mucosal glands and, unless identified at an early stage, generally have a worse prognosis than squamous cell carcinoma.

At diagnosis, patients can be divided into those in whom surgical intervention is an option (stages 1 and 2 mainly) and those whose disease is too extensive (stages

3 and 4) or those who are not fit for surgery. Successful surgery will depend particularly on the absence of mediastinal lymph node involvement. It is not possible to discuss the intricacies of lung cancer staging further in this brief review.

A full assessment for surgery should take into account lung function, performance status and comorbidities, and also patient wishes. For older adults, whether there has been a substantial shift in clinical practice towards greater intervention in the last few years is uncertain. There is a paucity of clinical trial data in this age group. However, the development of specialist multidisciplinary lung cancer teams in the UK has led to a more detailed evaluation of such cases in the present author's experience. Most data suggesting a lack of investigation in older adults are over 10 years old, but this does not necessarily mean that interventions are more aggressive. Studies suggest that age *per se* is not an independent prognostic indicator in lung cancer. In terms of survival, a recent overview of several trials considered that patients aged 70 years or more undergoing lung resection responded as well as younger patients in terms of morbidity, mortality and quality of life.[11] The authors found no significant difference in 5 year survival rates following surgery for stage I disease (<70 years, 69–77%; >70 years, 59–78%), although older patients received higher rates of palliative care. In a study of octogenarians undergoing curative lobectomy, the perioperative death rate was 3.7% and the survival rates for patients with stage I disease were 86% at 1 year and 62% at 3 years.[12] For pneumonectomy, perioperative mortality rates for patients aged over 70 years were high in one centre (17%), indicating that great care with patient selection is vital.[13]

Selection for surgery in older adults needs to take account of cardiac and pulmonary status, particularly the presence of significant COPD. Calculating the likely lung function status after surgery is necessary: a predicted postoperative FEV_1 >40% is usually recommended.

NSCLC is generally not very sensitive to chemotherapy, although third-generation single-agent chemotherapy is considered the standard of care for patients with advanced/metastatic disease. A study in older age groups showed that the median survival may be increased from a median of 21 weeks to 27 weeks with chemotherapy, although side effects are slightly more common.[14] Such studies may also suffer from selection bias in that only those patients judged fit enough for chemotherapy might be put forward for inclusion.[15] Prospective studies in this age group are urgently needed. There have been similarly few older adult specific trials of radiotherapy in lung cancer and current treatment is often based on evidence extrapolated from studies treating younger patients. Radiotherapy is usually used for palliation of symptoms such as haemoptysis and chest wall or bony pain and appears well tolerated.[16]

Small cell lung cancer

SCLC accounts for ~15–20% of lung cancers and, as a proportion, is slightly more common in older adults than younger age groups. Small cell tumours invade the submucosa early in their growth and patients usually present with regional or distant metastases at diagnosis. As it is a rapidly growing tumour, it is the most chemo-sensitive of all the lung cancers. The standard treatment for limited-stage disease is platinum-based chemotherapy, combined with radiotherapy, whereas chemotherapy alone is used for extensive-stage disease. Drugs also include etoposide, which is oral and easily administered on an outpatient basis. In the older adult, there are limited prospective data available to guide treatment decisions, but the existing data demonstrate that standard approaches are feasible in older adults who have been thoroughly assessed and informed.[17] Untreated, the median survival for small cell cancer is only 4 months, but chemotherapy can add several months of life which is generally of good quality.[17]

Pleural mesothelioma

Mesothelioma principally affects the pleural lining, although it can affect the peritoneum or rarely the pericardium. It is almost always caused by past exposure to asbestos dust, notably blue asbestos, usually as a hazard of occupation. There is no association with smoking. Due to the long latent period of between 30 and 50 years (and rarely 15–60 years) between exposure and symptoms, peak incidence is found in patients about 70 years old. Death rates for all ages are expected to peak by 2015–2018 in Europe. Whereas the rate is decreasing in younger age groups, it has continued to increase in older age groups, especially those born around 1940.[18] Chest wall pain, breathlessness and weight loss are the commonest presenting symptoms. A chest radiograph may reveal pleural thickening or a pleural effusion. Examination of tapped pleural fluid is diagnostic in relatively few cases. A CT scan of the chest may be highly suggestive and further thoracoscopy may be required to obtain histology, if the patient's condition permits.

In most cases, the prognosis is poor, with a median of 9 months, and treatment modalities are still disappointing. Chemotherapy with pemetrexed and carbocisteine has been shown to improve the survival to a median of 13 months.[19] Those aged over 70 years appear to do as well as those under 70 years, except for some mildly increased haematological toxicity, although regrettably few patients have been studied over the age of 75 years.[20] Multimodality treatment including surgery, radiotherapy and chemotherapy has also been studied. Surgery followed by aggressive chemotherapy may increase the prognosis to around 3 years. Surgery usually involves either extrapleural pneumonectomy or pleurectomy/decortication. These

options will depend on tumour type and how locally advanced the cancer is.[21]

High-quality palliative care is crucial, as with all cancers, including the control of symptoms such as breathlessness and chest wall pain and the many other associated features. Pain in the chest wall is often due to invading tumour and may require opiates, non-steroidals, neuropathic medication or nerve blocks. Counselling is important to support patients and their families, in addition to exploring issues around advanced care planning. The condition is a recognized industrial disease and patients are entitled to claim for compensation.

Key points

- Interstitial lung disease includes idiopathic pulmonary fibrosis, hypersensitivity pneumonitis (extrinsic allergic alveolitis) and pneumoconioses.
- Lung cancer includes non-small cell and small cell lung cancer and pleural mesothelioma.
- Chemotherapy of the various conditions is discussed.
- Most interstitial lung diseases (ILDs) increase in prevalence with age.
- A detailed history, pulmonary function tests and high resolution CT scans will clarify the cause in the majority of cases of ILD.
- The prevalence of lung cancer is falling but most cases are still diagnosed at an advanced stage in older people.
- Older patients with suspected lung cancer should be referred to a specialist team for active investigation.

CHAPTER 50

Chronic obstructive pulmonary disease and asthma

Christopher Dyer
Royal United Hospital, Bath, UK

Chronic obstructive pulmonary disease (COPD)

Epidemiology

The hallmark of COPD is the presence of airflow obstruction that is not fully reversible and which demonstrates little variability over time. It is usually progressive and there may be a range of pathological changes in the lung, including small airways disease and emphysema. The airflow obstruction in COPD is usually insidious in onset and progresses over a number of years or decades. As the airflow obstruction worsens, the risk of complications and exacerbations increases, impairing quality of life.

COPD is the fifth largest cause of disability in the world and is the fourth leading cause of death in the USA. A worldwide prevalence of 10.1% has been estimated, higher in Western countries which have older populations with greater lifetime exposure to tobacco.[1] Despite this, it is known that COPD is underdiagnosed and misdiagnosed, especially in older adults. Based on smoking patterns it is likely that between half and two-thirds of patients with COPD are unknown to their health provider.[2] Older adults may regard breathlessness as part of the ageing process and not seek medical attention. Comorbid conditions, social isolation, depression and a reduction in the perception of breathlessness may also have a role. Furthermore, there may also be a lack of diagnostic equipment such as spirometry in primary care, leading to mislabelling.

COPD is usually caused by cigarette smoking, although passive smoke exposure may also contribute. The Forced Expiratory Volume in 1 second (FEV_1) declines by about 25–30 ml per year after the age of 25 years in healthy adults, but in susceptible smokers that decline exceeds 50 ml per year. COPD is associated with significant comorbidities.

Diagnosis and clinical features

The diagnosis of COPD relies on clinical judgement and the presence of airflow obstruction. The precise definition of airflow obstruction has been the subject of much academic discussion. International consensus guidelines [such as those of the Global Obstructive Lung Disease (GOLD) collaborative] support the diagnosis of airflow obstruction if, on spirometry, the FEV_1/FVC (forced vital capacity) ratio is <0.7 post-bronchodilator. Incorporating the need to assess the patient after bronchodilation reduces the potential for misdiagnosing a reversible lung disease such as asthma. The UK National Institute of Health and Clinical Excellence (NICE) also advises that if the FEV_1 is $\geq 80\%$ of the predicted value, then the diagnosis should only be made in the presence of respiratory symptoms. This is because, as the lung ages, FVC begins to decline later than FEV_1 and at a slower rate, which results in a natural fall in the FEV_1/FVC ratio from about 75 to 70% by 70 years of age.[3] Therefore, a definition which relies purely on the FEV_1/FVC ratio will be less discriminatory in very old people, who may receive an inappropriate label.

A diagnosis of COPD should be entertained in patients with a risk factor (usually smoking) and one or more symptoms of exertional breathlessness, wheeze, chronic cough, chronic sputum production and 'winter bronchitis'.[4] In its early stages, symptoms may be intermittent or limited to a cough productive of clear or white sputum. Patients may also present with wheeze or a 'chest infection' which fails to improve as rapidly as expected. Most patients with COPD have a history of at least 20 pack-years of smoking (one pack-year being the number of cigarettes smoked per day, divided by 20, multiplied by the number of years smoking).

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Clinical examination may reveal little in the early stages, although wheeze may be present. As the condition progresses over years and FEV_1 falls further, lung hyperinflation occurs and hypoxia may develop, being common in those with an FEV_1 <30%. More profound hypoxaemia (i.e. a PO_2 <8 kPa) leads to pulmonary hypertension and right-sided heart failure, often manifest as peripheral oedema, a raised jugular venous pressure and sometimes secondary polycythaemia.

The differential diagnosis of COPD is wide and the most significant features are summarized in Table 50.1. In older adults, comorbidities are common. COPD is a major risk factor for cardiovascular events, independent of smoking.[5] Heart failure is present in 20% of patients with COPD over 65 years of age.[6] Bronchiectasis has also been found on high-resolution computed tomography (CT) scan in up to 29% of patients with confirmed COPD and chronic bronchitis in primary care[7] and may manifest itself as a cause of frequent exacerbations. Osteoporosis is also more common in patients with COPD, partly due to the effects of corticosteroids.

Investigations

Spirometry is considered possible in ~85% of older adults, cognitive impairment being a major reason for inadequate results. Reversibility testing is not usually helpful, except where there may be doubt about a diagnosis of asthma (see later). A chest radiograph should be performed in all suspected new cases of COPD, mainly to exclude other conditions and to ensure that there is no evidence of lung cancer. If signs of cor pulmonale are present on examination, an ECG may show features of right-sided heart strain. Owing to the significant overlap with heart failure, echocardiography should be considered in those with relevant clinical features or a failure to respond to initial treatment. If doubt remains, more detailed tests of lung function can be undertaken, including transfer factor for carbon monoxide (T_LCO) and a CT scan of the thorax if symptoms seem disproportionate to the level of lung function or if abnormalities are seen on the chest radiograph.

Table 50.1 Differential diagnosis of COPD.

Condition	Features
Asthma	Non-smoker, symptoms likely to vary, nocturnal symptoms, reversibility of airflow obstruction
Congestive cardiac failure	History of ischaemic heart disease. Orthopnoea, bibasal crackles on auscultation, chest X-ray evidence of pulmonary oedema and cardiomegaly Restrictive pattern on spirometry
Bronchiectasis	Large-volume purulent sputum, coarse crackles basally, clubbing, airway thickening on chest radiograph
Interstitial lung disease	Dry cough, fine crackles basally, industrial exposure, drug toxicity Restrictive picture on spirometry Impaired lung diffusing capacity
Kyphoscoliosis	Characteristic skeletal abnormalities Paucity of findings on chest examination Restrictive picture on spirometry Normal lung diffusing capacity

Assessing COPD severity

There is a relatively poor association between lung function and health status. Nevertheless, the condition is still generally categorized into different levels of severity according to percent predicted FEV_1 (Table 50.2). Other important aspects to consider in the assessment of an older person with COPD are as follows:

- breathlessness (e.g. MRC dyspnoea scale)
- disability/health status (e.g. Manchester Respiratory ADL scale)
- exercise tolerance (e.g. shuttle walking test or 6 min walk)
- BMI
- oxygen saturations if FEV_1 is <50% or signs of cor pulmonale
- anxiety and depression [e.g. Hospital Anxiety and Depression Scale (HADS)]
- exacerbation rates.

Management of COPD – stable state

Stopping smoking has been shown to reduce significantly the age-related decline in FEV_1. It is vital that patients who continue to smoke are encouraged to stop and are

Table 50.2 International classification of severity of airflow obstruction.

Post-bronchodilator FEV_1/FVC	FEV_1 predicted (%)	Severity of airflow obstruction
<0.7	≥80	Stage 1 – mild
<0.7	50–79	Stage 2 – moderate
<0.7	30–49	Stage 3 – severe
<0.7	<30	Stage 4 – very severe

supported throughout this process, with the help of appropriate therapies such as nicotine replacement therapy, bupropion or varenicline. Quit rates are as good if not better in older adults than in their younger counterparts. Pneumococcal and annual influenza vaccination should be offered to all patients.

COPD should be managed by a multidisciplinary team, many aspects of which are incorporated into pulmonary rehabilitation programme. Patients with more severe airflow obstruction may be considered for enrolment in a chronic disease management programme, with support at home by specialist nurses. The use of patient self-management plans is vital, including advice about recognizing and treating exacerbations. As the condition progresses, there should also be the opportunity to discuss advance planning and end-of-life care wishes.

Pharmacological management of stable COPD

Treatment is targeted at reducing breathlessness and limiting the sequelae of COPD, by impacting positively on health status and exacerbation rates. Over the past few years, it has been appreciated that preventing an exacerbation is of particular importance, due to its impact on lung function, health status and mortality. The GOLD guidelines suggest that frequent exacerbations should be considered present if there is one or more per year for the past 3 years, whereas NICE suggest two in the previous 12 months, and this should guide treatment decisions. Treatment options may seem complex but are simpler when displayed as an algorithm (Figure 50.1).

Breathlessness and wheeze are initially treated using a short-acting inhaled bronchodilator as required (either a β_2-agonist, e.g. salbutamol, and/or an antimuscarinic, e.g. ipratropium bromide). If patients with stage 2 disease ($FEV_1 \geq 50\%$) are still symptomatic or exacerbate frequently despite this, guidelines advise the regular use of a long-acting β_2-agonist (LABA) (e.g. salmeterol or formoterol) or a long-acting muscarinic antagonist (LAMA) (e.g. tiotropium). The latter is certainly more effective than regular ipratropium bromide. There is strong evidence that LABAs and LAMAs have a positive impact on symptoms, health status and exacerbation rates. Furthermore, tiotropium has been associated with a small reduction in all-cause mortality.[8]

In stage 3 disease ($FEV_1 < 50\%$), where a patient remains breathless or where there are repeated exacerbations, despite a LABA, then there are two main options. First, an inhaled corticosteroid (e.g. beclomethasone, budesonide, fluticasone) could be added to the LABA in a combination inhaler (e.g. Seretide, Symbicort). A Cochrane review has shown that this combination reduces exacerbations by 9% and mortality by about 20% compared with steroids alone in stable COPD.[9] Unfortunately, clinical trials have shown a small but significant increase in the risk of non-fatal pneumonia in patients receiving inhaled corticosteroids, but this does not outweigh the benefits of their use.[10] Second, a LAMA (currently tiotropium) may be added to an existing LABA.

In patients who remain breathless or who exacerbate frequently, regardless of FEV_1, a LAMA could be added in addition to an inhaled LABA–corticosteroid combination or vice versa.

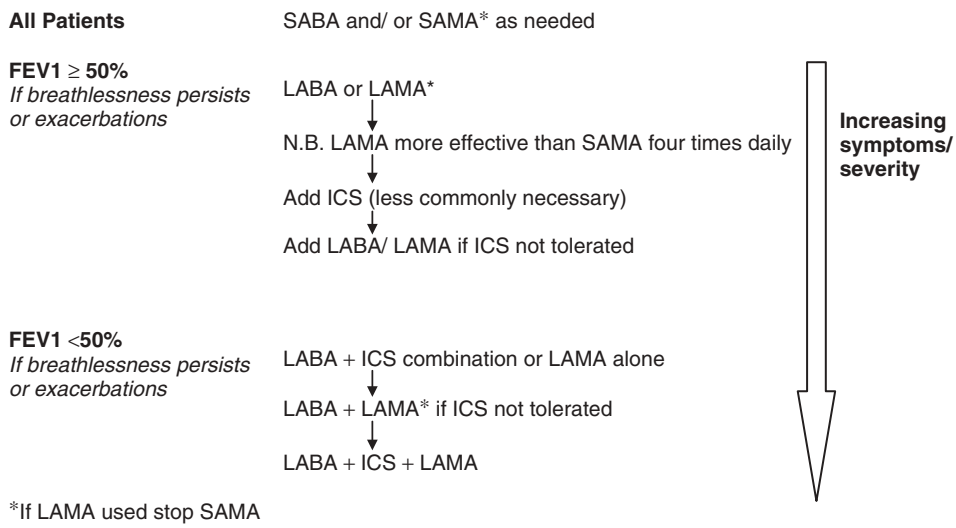

Figure 50.1 Inhaled medication in COPD. ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; LAMA, long-acting muscarinic agonist; SABA, short-acting β_2-agonist; SAMA, short-acting muscarinic agonist.

It is important to determine whether new treatments improve symptoms, exercise tolerance and ability to perform ADLs, rather than simply alter lung function, which is less relevant. If treatments are used primarily to minimize exacerbations, then they should be continued in a preventive capacity, whereas those given for symptom improvement could be discontinued if ineffective after a month's trial.

If symptoms persist or for patients unable to use inhalers correctly, a theophylline may be considered; slow-release preparations are preferred. Doses should generally be kept low in older people to avoid gastrointestinal side effects and the risk of drug interactions, particularly antibiotics during exacerbations. In addition, a trial of mucolytic therapy can be considered if sputum viscosity is increased. Nebulized bronchodilators may be of help for those patients with very advanced disease (who could be offered a symptomatic trial) or where the inhaler technique is so poor that no other relief is possible. In a few patients with advanced COPD, maintenance oral corticosteroids may be considered, but in general the risks outweigh the benefits.

Finally, it is important to recognize when a patient is in their last year of life so that they can be included in an end-of-life care register and offered appropriate palliation, including the use of opioids and benzodiazepines to ease symptoms of breathlessness that has failed to respond to medical therapy. All too frequently, the decision to move from an active to a palliative approach is made too late.

Long-term oxygen therapy (LTOT)

In severe COPD and in anyone with signs of cor pulmonale, referral for home oxygen should be considered. Short-burst therapy may improve symptoms of breathlessness if exercise desaturation is noted, and LTOT for at least 15 h per day has been shown to improve survival in patients with severe COPD and persistent hypoxaemia.[11] A simple screening test is to refer those with an oxygen saturation of <93%, or <95% and possible cor pulmonale. LTOT should be prescribed in a period of clinical stability to current non-smokers if the following conditions are met:

- PaO_2 <7.3 kPa, or
- PaO_2 7.3–8.0 kPa with evidence of secondary polycythaemia, pulmonary hypertension, peripheral oedema or nocturnal hypoxaemia.

Key questions remain concerning the benefit of oxygen therapy in improving quality of life and symptoms, issues which are especially pertinent to frail older patients. There remains a paucity of data regarding the benefits of LTOT in advanced old age, as randomized controlled trials have not been repeated in this group to date. The NOTT study did report improvements in polycythaemia and neuropsychiatric functioning.[11] Small improvements in cognitive function have been noted in a few studies, but these have generally been small and have not been in the oldest age groups. In some studies (mean age around 70 years), QOL and activities of daily living have not been shown to be better in those on LTOT,[12,13] but more recently a study did demonstrate small improvements in quality of life with LTOT after six months.[14] In the author's clinical practice, many patients do appear to derive symptomatic/qualitative benefit, but some do not. The addition to a patient's home of extra machinery and lengths of oxygen tubing may create a falls hazard. There may also be issues around safety in those with cognitive impairment or poor manual dexterity, although this has been poorly studied. Concerns such as these should be flagged up as experienced engineers will help with installation of switching mechanisms to divert the supply to individual rooms, reducing the risk of tripping. Logistical issues for patients on LTOT who reside in care homes must be considered, as should the training and support of care staff. Care home residents using concentrators overnight may need to have portable oxygen with conserver or free-standing cylinders if the day room facility is far from their bedroom.

Approximately 50% of patients receiving LTOT remain alive at 3 years.[15] Death tends to occur earlier in those with low BMI and comorbidities.[16] In older adults with COPD, the main factors predicting mortality are disability, low BMI, lung function and use of LTOT.[17]

Management of an exacerbation of COPD

Acute exacerbations of COPD are characterized by increased breathlessness, cough, increased sputum volume or purulence, wheeze and chest tightness. They account for up to 10% of all medical admissions to UK hospitals[18] and severe exacerbations are associated with an adverse effect on an individual's health status.[19] The outcome for patients admitted to hospital has probably improved slightly over the past few years, but about one-third are readmitted within 30 days and 15% have died at 3 months.[20] Exacerbations may be caused by viruses, bacteria or environmental pollutants, although in many cases the cause will remain unclear. The most common bacterial causes of exacerbations are *Haemophilus influenzae, Streptococcus pneumoniae* and *Moraxella catarrhalis*.

Using antibiotics for exacerbations where there is increased cough and purulent sputum reduces mortality by 77% and decreases the risk of treatment failure by 53%.[21] A meta-analysis has shown that antibiotics reduce in-hospital mortality compared with placebo.[22] Local guidelines will determine the initial choice of antibiotic therapy, but amoxicillin or doxycycline are commonly used. It is reasonable, however, to withhold antibiotics if there is no sputum purulence and only one of increased

sputum volume or breathlessness.[23] There is a small but definite risk in giving too much oxygen to a patient with longstanding CO_2 retention (depressing the hypoxic drive and worsening acidosis), hence target saturations of 88–92% are advised.

Initial management with oral corticosteroids has been shown to reduce length of hospital stay and treatment failure compared with placebo[24] and so should be offered as standard. Treatment should be continued for 7–14 days depending on severity. For those using frequent courses of corticosteroids, prevention of osteoporosis should be considered.

For admitted patients, non-invasive ventilation (NIV) is considered in those with pH <7.35 despite maximum medical therapy. Compared with standard treatment, NIV reduces mortality, need for intubation and length of stay compared with standard therapy.[21]

Many hospitals have early supported discharge teams specifically for patients with COPD; some also provide an admission avoidance service. These have been shown to have similar clinical outcomes but also reduce length of stay and cost. Such services will provide daily patient review at home, with oxygen, nebulizers and medication as appropriate. Patient selection is crucial, especially in the older adult where a full assessment of functional and social situation is required. Typically, patients without acidosis and where there is good social support are suitable.

Asthma

Epidemiology

Asthma is a chronic inflammatory disorder associated with bronchial hyper-responsiveness and variable airways obstruction. It usually causes episodic symptoms of wheezing, cough, chest tightness and dyspnoea. The airflow obstruction may be fully or partially reversible either spontaneously or with treatment. Laennec (1781–1826), who invented the stethoscope, is believed to have provided the first case report of asthma in old age, occurring in an 82-year-old man who had had attacks of breathlessness for the previous 30 years. Yet until the late 1970s, it was generally thought that asthma in older people was rare. Several studies have since refuted this and have revealed an underdiagnosis of asthma in this age group. A cross-sectional survey of 6000 people aged 65 years and over in the UK was conducted with pulmonary function testing and found a prevalence of known asthma of 1.1%, and a further 2.4% of men and 1.2% of women had definite untreated asthma.[25] Most of these subjects were found to have moderate or severe disease. Untreated asthma was most common in individuals who actually had current symptoms of breathlessness or wheeze. Elsewhere, a prevalence of around 5% probable current asthma has been reported, with one study reporting that 39% of such patients were not taking any respiratory medication.[26] Reasons for underdiagnosis are likely to include under-reporting, activity limitation, social isolation, depression and a misconception that asthma is rare.

That the condition can be severe in older adults is certain. Hospital admission rates are higher for this age group than any other. A recent US review of epidemiological literature highlighted the fact that 50% of asthma deaths occur in people aged 65 years or over and that mortality may still be rising in this group.[27] The reasons for this are not clear, but the mode of presentation may be different, the risk of misdiagnosis higher, comorbidities are more common and undertreatment is more likely.[26]

About half of all older people with asthma will have noted their initial symptoms after the age of 40 years and 20% after the age of 60 years.[28] Asthma can start for the first time at any age and one US study found that the age- and gender-adjusted incidence was 103/100 000 in residents aged 65–74 years, 81/100 000 in those aged 75–84 years and 58/100 000 in residents older than 85 years.[29] This is not far below the incidence for younger age groups. There is some evidence to suggest that patients with longstanding asthma have more severe airflow obstruction than patients with more recent onset disease, but that in those with recent onset disease the subsequent decline in lung function may be worse.[30]

The cause of asthma at any age is still not clear. There may be host factors such as genetic susceptibility, atopy and obesity and environmental factors such as possible viral infections, pollution and occupational triggers. However, most research has been conducted in children and very little in older adults. In contrast to younger adults, asthma in old age is rarely associated with atopy, although there are cases where it does occur.[31] However, there is still a weak correlation with serum immunoglobulin E (IgE), lung function and bronchial hyper-responsiveness in older asthmatics, even though IgE levels do fall with advancing age. Most asthma in old age is regarded as 'intrinsic' and is more likely to start in adult life rather than in childhood. In this latter group, dysregulation of autonomic airway smooth muscle and changes in β-adrenoceptor activity have been reported.[32,33] Inflammation is still considered to be a central feature of 'intrinsic' asthma, involving eosinophils, T cells and specific cytokines such as interleukin-4. The result is airway smooth muscle contraction and oedema, mucus secretion and, if inadequately treated, airway remodelling. There is recent evidence for this in undertreated middle-aged people with asthma whose lung function declined faster than those on regular anti-inflammatory medication.[34] Ultimately, this could lead to irreversible disease and the phenotypic appearance of COPD, characterized by airflow obstruction that does not vary markedly over time.

Clinical features and diagnosis

There is no gold standard for the diagnosis of asthma. A good clinical history is paramount, followed by simple investigations and trials of treatment as necessary. Typical presenting features of asthma in all age groups include intermittent cough, particularly at night, shortness of breath, wheezing, chest tightness, sputum production and reduced exercise tolerance. These may be associated with viral or environmental triggers, exercise and emotions. Significant diurnal variation may be present in many cases, but in some the symptoms may be more persistent. The BTS/SIGN guidelines[35] recommend determining the probability of asthma, based on a number of factors, but in older adults these are less clear cut. There may be diagnostic confusion with other conditions such as COPD and heart failure. Older adults have less perception of bronchoconstriction and may also have a poorer appreciation of the severity of their disease.[36] Bronchial irritability symptoms such as cough and wheeze on exposure to conditions such as fumes and cold air are less commonly reported. Probing for signs of symptom variability is important, as it is an important distinction from COPD, which exhibits (predominantly) fixed airflow obstruction. However, the two conditions may also coexist, such as in a patient with asthma who smokes.[37] A thorough physical examination is important to exclude other diagnoses and in asthma may reveal wheeze or hyperinflation, but could be entirely normal.

Investigations should include a chest radiograph and spirometry. In patients without airflow obstruction (FEV_1/FVC ratio >0.7) the differential diagnosis would include gastro-oesophageal reflux, rhinitis, chronic cough and hyperventilation syndromes. It is always wise to check that there is not an underlying restrictive disorder such as pulmonary fibrosis (the FEV_1/FVC ratio will usually be normal or high and there may be chest signs). If asthma is still suspected, peak expiratory flow (PEF) monitoring can be undertaken for perhaps a two-week period. Most older adults, unless very frail, should be able to keep a reasonable record; indeed, they may be more meticulous than younger people. However, the greater the airflow obstruction the greater is the relative degree of PEF variability, and PEF variability itself also appears to increase with age. Records should be kept at least morning and night with the percentage difference between the mean morning result and the best results (of three attempts) obtained indicating the diurnal variation. A 20% change is suggestive of asthma and this can then be followed by trials of treatment to see whether the variation improves.

For patients with airflow obstruction the key is to determine whether this is fixed and varies little over time (COPD) or whether it is wholly or partially reversible. Older patients with chronic asthma tend to have only partially reversible airflow, probably as a result of damage to the airways due to unrecognized inflammation as discussed above. Where the differential diagnosis includes COPD or where COPD could be a comorbidity (e.g. in a former heavy smoker), then reversibility testing should be tried. A >400 ml improvement in FEV_1 following a β_2-agonist or a two-week trial of corticosteroids is generally considered strong evidence for asthma. Smaller improvements can occur in COPD patients and in some cases it may not be possible to differentiate the two conditions fully. Use of more discriminatory tests such as static lung volumes and T_LCO may be useful in such cases. A rise in total lung capacity is rare in asthma but is typical of more severe COPD. A decreased T_LCO indicates a loss of the alveolar-capillary surface which may be seen in emphysema (COPD) and not asthma. Where the result is equivocal, a trial of inhaled or oral corticosteroids may be conducted with PEF monitoring.

Management

The goals of asthma treatment in older adults are as follows:

1. to minimize or eliminate symptoms and maintain control
2. to improve quality of life and maximize activity levels
3. to prevent exacerbations
4. to treat the underlying inflammation, thereby reducing the risk of developing irreversible airflow obstruction.

Guidelines emphasize the need for 'zero tolerance' of any symptoms, such as night-time waking or cough. This approach has not been tested in the older age group where symptoms may be more chronic and stubborn.

Although treatment for older adults is influenced by the severity of symptoms, the fact that older adults may have a lower perception of bronchoconstriction should also be kept in mind. Hence they may notice symptoms later than younger adults, possibly leading to a delayed recognition of an exacerbation of airway obstruction. Therefore, there could be a delay in the self-administration of bronchodilator medications or a request for medical advice. This is particularly true during sleep at night, where the response to respiratory stimuli is already attenuated. Furthermore, morning dips of peak flow are particularly poorly perceived in older adults.[38] For this reason, it is prudent to advise the use of short-acting bronchodilators regularly rather than as needed. Inhaled β_2-agonists are the initial medication of choice. Antimuscarinics (e.g. ipratropium bromide) are of only limited benefit in asthma generally, but may be more successful in older adults as there is a decline in β_2-adrenoceptor density, which may make anticholinergic action relatively greater. Short-acting oral β_2-agonists are available for the small number of people unable to use any form of inhaler; however, tachycardia severely limits their use.

Inhaled glucocorticoids are the most effective maintenance therapy for asthma and many patients will

derive a good response with levels of beclomethasone (or equivalent) of 400μg daily. At this dose, the risk of systemic side effects is minimal, whereas above this dose there may be a small increase in the risk of vertebral fracture, this effect probably being less with budesonide, ciclesonide and fluticasone. Furthermore, if good control is achieved with these drugs, it may minimize the need for oral corticosteroids with their inherently greater risk profile. A spacer device will also reduce the chance of oropharyngeal candidiasis and dysphonia, while tobacco smoking limits the efficacy of inhaled glucocorticoids and must be discouraged.

Greater asthma control can be achieved with the addition of a LABA (salmeterol or formoterol) rather than stepping up the dose of an inhaled glucocorticoid. LABAs should not be used as monotherapy in asthma as they do not influence airway inflammation. For those who are still symptomatic, leukotriene modifiers are simple oral medications which have a relatively low level of side effects (reports of an association with Churg–Strauss syndrome have been largely dispelled). There is some evidence that they are effective in older adults. Controlled-release theophyllines may also be added, if asthma control is inadequate despite a high-dose inhaled steroid and LABA combination. Theophyllines have weak bronchodilator and anti-inflammatory properties, but are less potent than LABAs and have a narrow therapeutic index. It is also worth remembering that certain drugs such as beta-blockers (including topical glaucoma medication), verapamil, aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) can worsen asthma symptoms.

Asthma control should be monitored by an assessment of the adequacy of symptom relief, particularly at night-time and by PEF monitoring where possible.

Inhaler technique

If good asthma control is to be achieved, it is important to consider whether the medication is being taken correctly or at all. In older people in particular, ensuring an effective inhaler technique is of the utmost importance, as without it all attempts to manage the condition are rendered useless. A full review of inhaled devices in older people is beyond the scope of this chapter, but an excellent account has recently been published by Allen.[39] Most older patients with normal cognition and no physical limitation will be able to learn to use an inhaler correctly. Difficulties in learning and coordination will be present in around 20% of cases, so it is vital to observe and correct technical faults. Further reinforcement at intervals is also important, which is partly why regular review of patients with asthma and COPD by skilled trainers is recommended in international guidelines.

One major limitation to a successful inhaler technique is poor manual dexterity, including a weak hand grip, poor coordination and impaired vision. Careful training and the use of adapters fitted to the ends of inhalers may be useful. There are many different inhaler devices available and although there is no clear winner, there may be some advantage in trying less technically complex devices.

Other key limitations are dyspraxia and cognitive impairment. More recently, impaired executive function has also been found to limit the acquisition of inhaler skills and there is an especially high incidence of this in hospitalized patients. For these individuals, the simpler the device the more chance there is of success. It is known that most patients with an abbreviated mental test score of <7 out of 10 or a Mini-Mental State Examination score of <24 out of 30 are unable to use inhalers correctly. In particular, very few, if any, patients with cognitive impairment will be able to use a metered-dose inhaler (MDI) correctly as it is a complex five-stage device.[40] In those with minor cognitive problems, it may be possible to master a four-stage inhaler correctly (MDI with a spacer) and a few patients with moderate impairment may be able to coordinate a three-stage (breath-activated) device. Being unable to copy overlapping pentagons is highly predictive of an inability to acquire an adequate inhaler technique. Carers may be able to help those with physical limitations or dementia, and nebulizers may be an alternative when all other options have been exhausted.

Key points

- COPD and asthma are common causes of symptoms and impaired health status in older adults.
- Both conditions are underdiagnosed and misdiagnosed.
- Careful history taking and spirometry can usually distinguish COPD from asthma and exclude other comorbid conditions.

CHAPTER 51

Pulmonary hypertension

Dennis J. Shale
Cardiff University, University Hospital of Wales, Cardiff, Wales, UK

Introduction

This chapter considers the pathology, pathophysiology and clinical aspects of pulmonary hypertension with reference to the ageing population. Elderly individuals may present with pulmonary hypertension due to any of the recognized causes, but owing to the high prevalence of cardiovascular disease, including ischaemic heart disease and chronic heart failure and respiratory disease, in particular chronic obstructive pulmonary disease (COPD), they are the main causes met with in this age group (Table 51.1).

Definition

Pulmonary hypertension is defined on the basis of haemodynamic characteristics as a mean pulmonary arterial pressure >25 mmHg at rest as assessed directly by right heart catheterization, the currently accepted 'gold standard' diagnostic method. This is a widely accepted definition that has been used in randomized controlled trials of treatment and in the pulmonary arterial hypertension registry.[1] However, recent studies in healthy individuals have shown that mean pulmonary artery pressure is 14 ± 3 mmHg with an upper limit of normal suggested to be 20 mmHg.[2] It remains unclear what the implications are for those individuals with pressures between 20 and 24 mmHg. Furthermore, the definition of pulmonary hypertension during exercise is unclear and is set rather arbitrarily at >30 mmHg.

Echocardiography is widely used in individual patients to assess the likelihood of pulmonary hypertension based on findings of impaired right ventricular function, altered haemodynamics and an estimate of pulmonary artery pressure. This is a useful assessment for suspected disease, but is too insensitive to detect mild severity pulmonary hypertension. Therefore, echocardiography is not used to define or screen for pulmonary hypertension.

Classification of pulmonary hypertension

Pulmonary artery pressure depends on multiple factors, including pulmonary vascular resistance, cardiac output and pulmonary capillary wedge pressure. Using these components, it is possible to classify pulmonary hypertension on a pathophysiological basis into pre- and post-capillary forms. Based on this classification, pulmonary hypertension was previously categorized on clinical grounds into primary and secondary types where the former did not have a clearly defined underlying cause. This classification from the 1950s has been gradually replaced by the findings of research into pulmonary hypertension, which has led to new thinking and the description of mechanisms and management strategies, particularly for primary pulmonary hypertension.

The Evian classification in 1998 grouped categories of pulmonary hypertension on the basis of shared clinical features, pathology and therapeutic options. Five groups were defined which had the effect of stimulating basic and clinical trials work in cohorts of well-defined patient types. The Third World Symposium on Pulmonary Hypertension (2003) refined the Evian scheme to incorporate an expanding understanding of the Group 1 disorder pulmonary arterial hypertension (PAH). In 2008, a further refinement was made at the Fourth World Symposium on Pulmonary Hypertension and is the classification used in this chapter.[1,3]

This increased interest in pulmonary hypertension has provided the basis for the development of expert guidelines from North America and Europe. Detailed outlines of classification and management strategies can be found in a number of these documents.[1,3,4] Thus, pulmonary hypertension is a haemodynamically defined state due to a range of pathophysiological changes that occur in the pulmonary vasculature and is associated with various clinically defined

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 51.1 Classification of pulmonary hypertension based on the Fourth World Symposium on Pulmonary Hypertension (2008).

Group 1. Pulmonary arterial hypertension (PAH)
Idiopathic (IPAH)
Hereditable (HPAH)
Drug and toxin induced
Associated PAH (APAH) with:
Collagen vascular disease
Congenital heart disease
HIV infection
Portal hypertension
Schistosomiasis
Chronic haemolytic anaemia
Group 1′. Pulmonary veno-occlusive disease (PVOD) and pulmonary capillary haemangiomatosis
Group 2. Pulmonary hypertension due to left-sided heart disease
Left ventricular systolic or diastolic dysfunction, valvular heart disease
Group 3. Pulmonary hypertension due to lung disease and hypoxia
Chronic obstructive pulmonary disease
Interstitial lung disease
Mixed obstructive and restrictive disease
Sleep disordered breathing
Alveolar hypoventilation ventilation/chronic high-altitude exposure
Group 4. Chronic thromboembolic pulmonary hypertension (CTEPH)
Group 5. Pulmonary hypertension where causation is unknown
Haematological disorders, e.g. myeloproliferative diseases, splenectomy
Systemic disorders, e.g. lymphangioleiomyomatosis
Metabolic disorders, e.g. glycogen storage disorders, thyroid disorders
Others, e.g. chronic renal failure on dialysis, tumour emboli

conditions and is currently classified into six clinical groups (Table 51.1).

Epidemiology of pulmonary hypertension

There are few comparative data on the prevalence of different forms of pulmonary hypertension. An echocardiographic survey reported a 10.5% prevalence of pulmonary hypertension, defined as pulmonary artery systolic pressure >40 mmHg, in a group of 4579 patients. Within the group with pulmonary hypertension, ~79% had left heart disease and 10% had lung disease and hypoxia, while PAH constituted ~4% and chronic thromboembolic pulmonary hypertension (CTEPH) made up less than 1% of the group.[5]

Common features of pulmonary hypertension

Clinical presentation

The clinical presentation and investigation of pulmonary hypertension are similar for the various groups despite differences in pathology and underlying causes. The symptoms of pulmonary hypertension are non-specific and include breathlessness, a reduced exercise tolerance, weakness, fatigue, angina-like chest pain, syncope and abdominal distension. Initially, symptoms are reported on exertion, but with progression patients will report similar symptoms at rest. Later in the progress of the disorder, physical signs include a left-sided parasternal heave, an accentuated pulmonary valve component to the second heart sound and a pansystolic murmur of tricuspid regurgitation. In addition, a diastolic murmur of pulmonary regurgitation and a right ventricular third sound may be detected. Further features include jugular venous distension, hepatomegaly, peripheral oedema, cyanosis and cool extremities in the more advanced stages of the disease. Examination of the chest usually reveals perfectly normal breath sounds, but hyperinflation, hyper-resonance and a reduced breath sound intensity may indicate the presence of COPD, and fine mid to late inspiratory crackles may indicate pulmonary fibrosis or left ventricular failure. Other peripheral features may give guidance to the cause of pulmonary hypertension, for example, systemic sclerosis with telangectasia, digital ulceration.

Investigations

Electrocardiogram

The electrocardiogram (ECG) may suggest or support the presence of pulmonary hypertension demonstrating right ventricular hypertrophy and strain and right atrial dilatation. In patients with idiopathic PAH (IPAH), right ventricular hypertrophy is present in nearly 90% of subjects with right axis deviation in ~80%. Hence the absence of such findings does not exclude pulmonary hypertension and does not exclude the potential for underlying haemodynamic abnormalities. The sensitivity and specificity of the ECG makes it a poor screening tool for the detection of significant pulmonary hypertension.

Chest radiograph

The key findings are central arterial dilatation with pruning or loss of the peripheral pulmonary vessels. There may be evidence of right atrial and right ventricular enlargement, particularly in more advanced disease. The extent of radiographic abnormalities does not correlate with the level of pulmonary hypertension. In the majority of patients with IPAH, ~90% of chest radiographs will be abnormal from the time of diagnosis. The chest radiograph allows moderate to

severe lung disease and pulmonary venous hypertension due to left heart disease to be excluded or considered as the cause of pulmonary hypertension.

Pulmonary function tests and arterial gas analysis

These investigations are important as they may help to exclude underlying airways or parenchymal lung disease. Spirometry with reversibility testing or use of the post-bronchodilator FEV_1/FVC <70% criterion can be used to rule out the presence of COPD as a cause of hypoxaemia-based pulmonary hypertension. Furthermore, these investigations allow the detection of restrictive lung disease, such as interstitial lung disease. Confirmation of parenchymal lung disease, such as in predominantly emphysematous COPD and interstitial lung disease, can be determined from measurement of static lung volumes and gas transfer indices, including the transfer factor of the lungs for carbon monoxide (TLCO) and the carbon monoxide alveolar volume corrected coefficient (KCO). The physiological implication of such lung disease can be assessed from arterial gas analysis. Further evidence of parenchymal lung disease can be determined by high-resolution computed tomographic (CT) scanning. Overnight oximetry or polysomnography allows the exclusion of a number of sleep-related respiratory problems, such as obstructive sleep apnoea syndrome. Patients with PAH usually have deranged TLCO and mild to moderate reduction of lung volumes. Arterial oxygen tension in PAH is usually normal or only slightly less than normal at rest and carbon dioxide tension is decreased due to alveolar hyperventilation.

Echocardiography

This is a mandatory investigation in suspected pulmonary hypertension because a number of echocardiographic variables relate to right ventricular haemodynamics including pulmonary artery pressure, which can be estimated on the basis of the peak velocity of a tricuspid regurgitant jet. A number of extra measures can be made, such as the right ventricle to pulmonary artery systolic pressure gradient. The detection of pulmonary artery pressure is not accurate enough using this methodology to provide a suitable screening tool for mild or asymptomatic pulmonary hypertension. In the elderly, where left heart disease is likely to be the most common cause of pulmonary hypertension, echocardiographic assessment is a valuable non-invasive method. However, echocardiography can be useful in detecting the cause of suspected or confirmed pulmonary hypertension in that two-dimensional and contrast examinations may identify the presence of congenital heart disease with a shunt or dilatation of the pulmonary artery despite only moderate pulmonary hypertension. Use of transoesophageal echocardiography or cardiac magnetic resonance imaging may help to define further the nature of the problem. Left ventricular diastolic dysfunction can be assessed through the use of Doppler echocardiography.

Ventilation perfusion lung scanning

This is a recommended investigation in all patients with pulmonary hypertension to detect the presence of CTEPH, the potentially curable form of pulmonary hypertension. This is considered to be the screening method of choice for this disorder because of greater sensitivity than CT scans. A normal or low probability V/Q scan excludes CTEPH with a sensitivity of 90–100% and a specificity of 94–100%, whereas in PAH the VQ scan may be normal or show small peripheral unmatched defects in perfusion, a finding which can also occur in pulmonary veno-occlusive disease. Isotopic V/Q scanning is of little or no value in patients with airways obstruction where lung parenchymal changes lead to characteristic matched perfusion and ventilation defects.

High-resolution computed tomographic scanning

High-resolution CT scanning is useful in defining the presence of lung disease such as the emphysematous changes in COPD and the typical changes in interstitial lung disease including ground-glass shadowing, honeycombing and traction bronchiectasis. It may also be useful when investigating pulmonary veno-occlusive disease where characteristic changes of interstitial oedema with central ground-glass opacification may be seen.

Contrast computed tomographic angiography

This investigation is helpful in determining the presence of surgically accessible thromboemboli in CTEPH and can delineate typical angiographic findings such as complete obstruction or the presence of webs or bands and intimal irregularities. It is also the investigation of choice for suspected pulmonary embolism in the presence of parenchymal lung disease.

Cardiac magnetic resonance imagining

This imaging modality allows a direct assessment of right ventricular size, function and morphology. It also provides an opportunity for the non-invasive assessment of blood flow, which includes stroke volume, cardiac output, distensability of the pulmonary artery and right ventricular mass. It has the advantage of allowing repeated assessment of right heart haemodynamics and left ventricular function.

Right heart catheterization

This is necessary to confirm the diagnosis of PAH and to assess the severity of the haemodynamic impairment. Important variables that need to be assessed include the systolic, diastolic and mean pulmonary artery pressure, right atrial pressure, the pulmonary capillary wedge pressure and the right ventricular pressure. Patients with pulmonary

hypertension from other causes likely to under go transplantation should also have a right heart study. In the majority of older patients with pulmonary hypertension, the underlying cause is clear-cut and treatment is not dependent on right heart catheterization and precise knowledge of their pulmonary haemodynamic status.

Other investigations

Routine biochemistry, haematology and thyroid function tests are recommended in all patients in addition to determining their hepatitis and HIV status. Antinuclear antibodies are present in ~40% of IPAH patients, although usually at a low titre, and a number of autoantibodies should be looked for in an attempt to determine the presence of systemic sclerosis. A thrombophilia screen is important and should be performed in all patients where CTEPH is suspected. An abdominal ultrasound should be carried out to demonstrate or exclude cirrhosis or portal hypertension.

Management

There are general measures that apply to the management of most cases of pulmonary hypertension, irrespective of cause. Specific aspects of management will be discussed in the consideration of the each clinical group.

Lifestyle

General advice on activities of daily living, physical activity and diet are important in terms of general support and will help individuals adapt to and cope with the changes imposed by progressive disability. Additionally, contact with support groups may help to address the issue of increasing social isolation and the risk of anxiety or depression which commonly occur in such patients. Patients should be advised to remain active within the limitations imposed by their symptoms. In COPD, interstitial lung disease, chronic heart failure and PAH, there is evidence that supervised programmes of exercise reconditioning or full rehabilitation can improve control of breathing, exercise performance and quality of life. Combined with dietary advice, rehabilitation programmes may have an impact on the loss of peripheral skeletal muscle mass, which occurs fairly commonly in PAH, left heart disease and respiratory causes of pulmonary hypertension.[6]

Travel

There are clear guidelines regarding the assessment for and the prescription of supplementary in-flight oxygen in respiratory conditions. In general, any patient receiving oxygen therapy while living at sea level is likely to need supplementary oxygen at routine cabin pressure to maintain arterial oxygen tension and saturation. In general, a flow rate of 1–2 l min^{-1} will be sufficient.[7]

Infection

Patients with chronic lung conditions, chronic heart failure and PAH are at heightened risk of respiratory infection and pneumonia. Although there is a lack of trial evidence for all groups of pulmonary hypertension, it is generally recommended that patients receive influenza and pneumococcal immunization.

Surgery

Either elective or emergency surgical intervention in patients with pulmonary hypertension is likely to carry an increased risk of death or significant postoperative morbidity. In general, elective procedures should be undertaken with local anaesthesia whenever possible and be planned with anaesthetist colleagues.

Medical treatment

In addition to specific pharmacological treatments, especially for PAH, there are some general options that may be needed across the spectrum of pulmonary hypertension. These include the prescription of diuretics, digoxin, anticoagulants and oxygen, which may be needed intermittently or long term as background problems, such as COPD or left heart disease progress.

Pathology and pathophysiology of pulmonary hypertension

Group 1. Pulmonary arterial hypertension

The underlying mechanisms that lead to the pathological picture in this group are still largely unknown, but it is likely to be of a multifactorial origin in which there is an interaction between functional and structural components of the pulmonary vasculature. The key feature of increased pulmonary vascular resistance is likely to be due to mechanisms that lead to enhanced vasoconstriction. Much of the excessive vasoconstriction has been related to endothelial dysfunction with impaired production of vasodilator and antiproliferative factors such as nitric oxide and prostacyclin. There is also evidence of simultaneous over-expression of vasoconstrictor and proliferative substances such as thromboxane A2 and endothelin-1. This change in the balance of vasodilator and vasoconstrictor agents both leads to an elevation of vascular tone and may promote vascular remodelling by proliferative changes which enhance injury and healing mechanisms, including cellular proliferation and obstructive remodelling of the pulmonary wall, and

the presence of inflammation and the development of local thrombosis. It is probable that inflammation also has a key mechanistic role and involves complex cellular inactions between vessel wall cell populations, which is associated with a increased production of extracellular matrix proteins in the adventitia of the vessel walls. As part of the activation of the inflammatory pathways, it is likely that prothrombotic abnormalities occur that lead to the presence of thrombi in the small distal pulmonary arteries.

The characteristic pathological changes in this group are medial hypertrophy, proliferative and fibrotic changes in the intima with adventitial thickening with varying degrees of perivascular inflammatory infiltration. Complex lesions, including dilatation and plexiform formation, and thrombotic lesions may also occur. The predominant site for pathological lesions in this group of pulmonary hypertension is in the distal pulmonary arteries, generally $<500\,\mu m$ in diameter. The pulmonary veins are not usually affected in this group.

Group 1′. Pulmonary veno-occlusive disease (PVOD)

Based on histological grounds, this subgroup represents up to 10% of IPAH. The characteristic lesions are in the septal veins and the preseptal venules, which include occlusive fibrotic lesions and muscularization of the vessel walls. Varying amounts of capillary proliferation may occur with some alveolar haemorrhage and pulmonary oedema. The lymphatic system may be involved with dilatation of lymphatics and lymphadenopathy due to the vascularization of the lymph node sinus and inflammatory cell infiltration. In addition, the distal pulmonary arteries may be involved with intimal fibrosis and medial hypertrophy and occasionally complex lesions.

Group 2. Pulmonary hypertension associated with left heart disease

Amongst the mechanisms likely to increase pulmonary artery pressure is the backward transmission of the cardiac pressure elevation leading to a post-capillary passive form of pulmonary hypertension. In this variety of pulmonary hypertension, the transpulmonary pressure gradient and the pulmonary vascular resistance are within the normal range, although in some situations there is an increase in the transpulmonary pressure gradient when the pulmonary artery pressure is greater than the pulmonary capillary wedge pressure and an increase in pulmonary vascular resistance occurs from what is described as post-capillary reactive or 'out of proportion' pulmonary hypertension. The increase in pulmonary vascular resistance is likely to be due to increased vasomotor tone and possible fixed structural obstructive remodelling of the pulmonary artery resistance vessels. The increase in vasomotive tone is reversible and this is an important issue in terms of treatment while structural changes do not respond to treatment. The factors underlying these changes are not clearly understood. The characteristic changes in pulmonary vasculature in this group consist of enlarged and thickened pulmonary veins with capillary dilatation. This is associated with interstitial oedema, alveolar haemorrhage and enlargement of the lymphatics with associated enlargement of draining lymph nodes. The distal pulmonary arteries can also be affected and show features of intimal fibrosis and medial hypertrophy.

Group 3. Pulmonary hypertension secondary to lung disease and/or hypoxia

There are multiple mechanisms underlying the pathophysiological characteristics of this group, which include hypoxic vasoconstriction, the mechanical stress of hyperinflation of the lungs, the reduction of the pulmonary capillary bed coupled with chronic inflammatory changes and the likely toxic effects of cigarette smoke. There is some evidence to support an endothelium-based vasoconstrictor–vasodilator imbalance. The characteristic pathological features are in the distal pulmonary arteries where there is intimal obstructive proliferation and medial hypertrophy. Depending on the nature of the underlying lung disease, there will be a variable degree of destruction of the vascular bed, particularly in emphysematous or fibrotic areas.

Group 4. Chronic thromboembolic pulmonary hypertension (CTEPH)

The late effects of acute embolic events is the continued mechanical obstruction of the pulmonary arteries, which is likely to be the key pathophysiological process. However, there are complex background factors related to the presence of clot and systemic coagulation abnormalities leading to an enhanced risk of further thrombosis, both systemically and within the pulmonary vasculature. The characteristic lesions in this form of pulmonary hypertension are organized thrombi attached to the medial layer in the elastic pulmonary arteries, which replaces the normal intimal coat. There may be partial or complete occlusion of the lumen due to varying degrees of stenosis, web formation and band formation. In non-occluded areas, an arteriopathic change indistinguishable from that seen in PAH and plexiform lesions may be seen. In areas of complete obstruction, collateral vessels from bronchial, intercostal, diaphragmatic and coronary arteries may reperfuse the areas distal to the obstruction. The disorder can be considered as having a dual basis in the pulmonary vasculature with major pulmonary vessel obstruction and remodelling which is followed by secondary small vessel arteriopathic changes.

The latter component may offer options for treatment interventions similar to those in PAH, and some successes have been reported with such treatments.

Group 5. Pulmonary hypertension with unclear or multifactorial components

The underlying pathophysiological mechanisms of this group are likely to be multiple and generally are poorly understood. This group is extremely heterogeneous and therefore different pathological pictures are seen depending on the precise aetiological origin of the problem.

Clinical aspects of subgroups of pulmonary hypertension

Group 1. Pulmonary arterial hypertension

This is the area in the spectrum of pulmonary hypertension in which major advances in understanding of disease processes and treatment have occurred in the last 10 years. The group comprises heterogeneous disorders which share similar clinical and haemodynamic features with almost identical changes in the pulmonary microcirculation. As a consequence of the pathological processes, there is an increase in pulmonary vascular resistance which leads to right ventricular overload, hypertrophy and dilatation that progresses eventually to right ventricular failure and death. The right ventricle, which normally functions at the relatively low pulmonary arterial pressures, fails because of the limited ability of myocardial contractility to adapt to the increased resistance to outflow. This failure to respond to chronic overload leads to right heart failure with the clinical indicators of increased right atrial pressure, a reduced cardiac index and raised pulmonary arterial pressure. The increased afterload with mismatched ventricular contractility and loss of right ventricular function is a major determinant of heart failure in other forms of pulmonary hypertension.

Idiopathic PAH (IPAH) describes cases where there is no identified risk factor or family history of PAH. Hereditable PAH (HPAH) is associated with specific mutations in the bone morphogenetic protein receptor 2 (BMPR2) gene in approximately 70% of cases. However, similar germ line mutations may occur in up to 40% of patients with IPAH, indicating a potential degree of mechanistic overlap between these subgroups. Other less common mutations have been reported, such as in the transforming growth factor β gene in patients with PAH associated with hereditary telangectasia. Group 1 also includes pulmonary arterial hypertension related to drugs and toxins, such as aminorex, fenfluramine and toxic rapeseed oil, and constitutes part of the group now called associated pulmonary arterial hypertension (APAH). This group of heterogeneous disorders have a similar clinical presentation to that of IPAH and identical histological characteristics, which include the development of plexiform lesions. Based on reports from centres specializing in care of PAH, APAH accounts for approximately half the patients with PAH.

Other APAH groups are important and may be met with in older patients as a component of other underlying conditions. Collagen vascular diseases are an important subgroup in the APAH spectrum, with pulmonary hypertension being reported in rheumatoid disease, Sjogren syndrome, polymyositis, systemic lupus erythematosus, mixed connective tissue disease and systemic sclerosis. The association is most clearly established with systemic sclerosis and may have a poorer outcome than other types of PAH. Using echocardiography and right heart catheterization, pulmonary hypertension has been shown have a prevalence of up to 12% in patients with systemic sclerosis, which is probably greater than in other collagen vascular diseases. Portal hypertension, HIV infection, congenital heart disease, schistosomiasis and chronic haemolytic anaemia may be linked to APAH and require full investigation in all age groups. Full investigation is important because pulmonary hypertension may have other causes in these disorders where pulmonary fibrosis may occur, diastolic left ventricular dysfunction is common and there may be primary cardiac involvement.

Diagnosis

As in other types of pulmonary hypertension, the objective is to define the precise group into which the disorder fits. In PAH, this classification of each case is of major importance as medical management strategies are available. Hence here diagnosis is to exclude other groups and to confirm PAH, and key investigations include echocardiography, lung function tests and various imaging techniques. In the diagnosis of suspected PAH, the investigations need to cover the spectrum of likely causes and should include the possibility of referral to a specialist centre for full diagnosis and management.

Medical treatment

The majority of advances in the medical treatment of pulmonary hypertension have been made in PAH, with little progress in the more common forms of pulmonary hypertension encountered in patients with disorders such as left heart disease, pulmonary disorders or CTEPH. However, such medication is increasingly used in these disorders despite the lack of good clinical trials. Currently, the efficacy of such treatment is unclear, as are the safety issues involved. In general terms, guidelines suggest that the use of agents proven in PAH should not be used for routine treatment in other forms of pulmonary hypertension except in specialist centres.

Endothelin receptor antagonists

Endothelin-1 is a potent vasoconstrictor and mitogenic agent acting on two classes of receptors on smooth muscle and endothelial cells where its inhibition might be expected to exert some benefit in PAH. There are three main agents in this group: bosentan, an endothelin A and B receptor antagonist, sitaxentan and ambrisentan, both endothelin-A receptor antagonists. They have all been shown to have beneficial effects on aspects of pulmonary haemodynamics and wellbeing in short- to medium-term studies and there appears to be little difference in efficacy between these agents.[8] The major problem encountered with these agents has been elevation of hepatic enzymes, peripheral oedema, headache and nasal congestion and multiple drug interactions, such as warfarin, requiring the dose to be increased, ciclosporin, macrolide antibiotics and statins.

Prostacyclin analogues

Prostacyclin is a metabolite of arachidonic acid generated by the endothelium which is a potent vasodilator and inhibitor of platelet aggregation.[9] The analogue epoprostenol is given by continuous intravenous infusion and improves symptoms and exercise tolerance and in IPAH has been shown to improve survival.[10] The adverse profile of this agent includes flushing, rashes, joint pain and leg discomfort, with loose stools and headaches, and with rebound pulmonary hypertension if stopped suddenly. Iloprost is a stable inhaled and injectable prostacyclin analogue which has been shown to improve exercise capacity and pulmonary haemodynamics in PAH.[11] Adverse effects include flushing, headaches and cough. The main drawback of iloprost is its short duration of action, which may reduce its overall efficacy and necessitate frequent inhalations up to 6–9 times per day. Treprostinil and beraprost are other agents in this class showing promise in terms of treatment outcomes and improvements in stability and route of administration.

Phosphodiesterase 5 inhibitors

Sildenafil has been approved for use in patients with PAH. There have been favourable reports of benefits for patients with IPAH and APAH linked to connective tissue disorders and congenital heart disease.[12,13] Other agents in this class showing similar benefits are tadalafil and vardenafil. The main limiting factor in the use of drugs in this class are headache, flushing, dyspepsia, nasal congestion and epistaxis. An important class interaction is with nitrates, which may cause severe systemic hypotension.

Combination therapy

Combinations of the above agents have been shown to confer some extra benefits in the treatment of PAH. The potential for long-term benefits remains unknown and the issue of adverse events related to drug interactions is such that this therapy is recommended to be undertaken only in specialist pulmonary hypertension centres.[1,3,14]

Group 1′. Pulmonary veno-occlusive disease and pulmonary capillary haemangiomatosis

This subgroup is without classification, although it shares some of the characteristics with IPAH. Outcomes are generally poorer then in the other subgroups of PAH and there is little evidence that treatment with drugs effective in PAH are of value. Hence lung or heart–lung transplantation is the major treatment.[15]

Group 2. Pulmonary hypertension due to left heart disease (Table 51.2)

Left heart disease is a common cause of pulmonary hypertension in the elderly and should be considered equally with respiratory causes. The main associations are with left ventricular systolic and diastolic dysfunction and valvular disease, most commonly involving the mitral valve.[16] Pulmonary hypertension has been reported in up to 60% of patients with severe systolic dysfunction and in up to 70% of those with isolated diastolic dysfunction. Pulmonary hypertension carries a poor prognosis for patients with chronic heart failure; mortality rates after 28 months of follow up are as high as 57% in patients with moderate pulmonary hypertension compared with 17% in those without pulmonary hypertension.[17]

Diagnosis

The diagnostic approach is similar to that for patients with other forms of pulmonary hypertension. Doppler

Table 51.2 Key aspects of the diagnosis and management of pulmonary hypertension associated with left heart disease.

Left heart disease may not be clinically evident, e.g. when isolated left ventricular diastolic dysfunction is present
Where appropriate right and left heart catheterization may be needed to establish the diagnosis and to exclude the possibility of PAH
Patients with an elevated pulmonary capillary wedge pressure or trans-pulmonary gradient require an assessment of vasodilator treatment on left ventricular afterload to identify an active pulmonary arterial component
Left heart disease should be treated according to established criteria and guidelines
Patients with end-stage heart disease and pulmonary hypertension may be candidates for a heart transplantation or heart lung transplantation
Drugs approved for PAH are not recommended in this group of patients as outcomes from long term clinical trials are not available

echocardiography is the key assessment when pulmonary hypertension is suspected. Left ventricular diastolic dysfunction should be ascertained in those with a dilated left atrium or atrial fibrillation and Doppler signals suggestive of changes in left ventricular haemodynamics. The following echocardiographic features of pulmonary hypertension associated with left ventricular diastolic dysfunction include evidence of left atrial enlargement, concentric remodelling of the left ventricle, left ventricular hypertrophy and evidence of elevated left ventricular filling pressures.

Treatment

There is no specific treatment for pulmonary hypertension related to left heart disease. However, a variety of therapeutic options including diuretics, nitrates, hydralazine, ACE inhibitors and other interventions including left ventricular assist devices, corrective valvular surgery, resynchronization therapy and heart transplantation have been used to lower pulmonary artery pressure through reducing the left ventricular filling pressure. Hence, for the majority of patients the management of pulmonary hypertension secondary to left heart disease should be the optimal treatment of the underlying cardiac disease in accordance with accepted guidelines. Patients with end-stage heart disease and chronic heart failure with accompanying pulmonary hypertension may be candidates for a heart transplantation or heart–lung transplantation.

A few studies have examined the efficacy of drugs currently recommended in PAH. Randomized controlled trials with epoprostenol and bosentan for advanced heart failure had to be terminated early due to the increased rate of adverse events in the treated group compared with conventional therapy. It has been suggested from small studies that sildenafil may improve exercise capacity and quality of life. Current international guidelines do not recommend the use of PAH-specific drugs in this form of pulmonary hypertension until more robust and longer term studies have been completed.[1]

Group 3. Pulmonary hypertension due to lung disease and/or hypoxia (Table 51.3)

Pulmonary hypertension is a common late component of respiratory diseases where hypoxia is a prominent feature, such as COPD, interstitial lung disease and obstructive sleep apnoea. The presence of pulmonary hypertension in patients with COPD leads to a reduced survival and more frequent symptomatic exacerbations. It is also a poor prognostic factor in patients with interstitial lung disease and pulmonary artery pressure is an important predictor of mortality.

The prevalence of pulmonary hypertension in COPD depends on the definition of COPD and its severity and also the definition of pulmonary hypertension. The majority of studies of pulmonary haemodynamics in this area are generally in patients with advanced lung disease, indicated by severe or very severe airways obstruction with a forced expiratory volume in 1 s (FEV_1) less than 40% predicted.[18] In a group of 120 patients with a mean FEV_1 of 27% predicted, pulmonary hypertension, defined as a mean pulmonary artery pressure >20 mmHg, occurred in 91% of the patients. However, the majority of these patients had only mild to moderate severity pulmonary hypertension with pulmonary artery pressures of 20–35 mmHg.[19] An interesting finding was the overlap of probable left heart disease with airways obstruction In this group, the mean pulmonary artery pressure was more closely related to pulmonary capillary wedge pressure than it was to FEV_1 or arterial oxygen tension, which suggests that there was significant left ventricular diastolic dysfunction in this severe COPD subgroup. This may be explained by increased aortic stiffness, which occurs in COPD and is a predictor of diastolic dysfunction in such patients.[20,21] In a larger study of nearly 1000 patients with COPD, severe pulmonary hypertension with a mean pulmonary artery pressure of >40 mmHg occurred in only 27 patients out of 998 and the majority of these patients had alternative causes for their pulmonary hypertension. This group of patients with COPD had much less severe airways obstruction than in the smaller study with an FEV_1 of ~50% predicted, although they had evidence of hyperventilation,

Table 51.3 Key aspects of the diagnosis and management of pulmonary hypertension in chronic lung disease.

Suspect pulmonary hypertension when:
Symptoms are more severe than expected from impairment of lung function
Right heart dysfunction is present
Profound hypoxaemia, hyperventilation or a low transfer factor is present
Doppler echocardiography is the best non-invasive assessment
Right heart catheterization only if pulmonary hypertension is likely to affect the management of the chronic lung disease
Appropriate patients with severe pulmonary hypertension, >35 mmHg with or without right heart failure may benefit from review at a specialist pulmonary hypertension centre
Treat lung disease optimally according to National Guidelines, including long-term oxygen therapy for severe chronic hypoxaemia
There is no evidence of benefit or safety in pulmonary hypertension secondary to chronic lung disease for drugs used in the treatment of PAH. Use of such drugs should be initiated and monitored at a specialist pulmonary hypertension centre

hypoxaemia and a reduced diffusion capacity. Importantly, the survival time of these patients was less than that in the other patients with COPD and pulmonary artery pressures between 20 and 40 or <20 mmHg.[22] This finding suggests that there is a subset of patients with 'out-of-proportion' pulmonary hypertension. These two studies have been complemented by further studies which again have shown high levels of pulmonary hypertension in patients with severe airways obstruction, but the in the majority of patients only mild to moderate elevation of pulmonary artery pressure. Again, a subset of patients with 'out-of-proportion' pulmonary hypertension was identified.[23] The importance of identifying this subgroup is their poorer survival and, because they appear to share some features with IPAH, they may be potentially treatable with medication proven to be effective in PAH. The true prevalence of pulmonary hypertension in COPD remains unknown, but it has been suggested that if a cut-off mean pulmonary artery pressure of >20 mmHg is taken as the basis for defining pulmonary hypertension, then the prevalence is in the region of 100–150 per million patients.

Important features of pulmonary hypertension in COPD that distinguish it from PAH are that in general the degree of pulmonary hypertension is in the mild to moderate range, generally <35 mmHg, that the progression of pulmonary hypertension is slow in these patients and that they develop right ventricular diastolic dysfunction with the features of cor pulmonale dominating. Cardiovascular complications also separate PAH from COPD-related pulmonary hypertension. Low cardiac output due to right ventricular forward failure is common in late-stage PAH, but is uncommon in COPD, where the link to death due to a cardiovascular mechanism is often the outcome of ischaemic heart disease.

Diagnosis

Similarly to the diagnosis of other forms of pulmonary hypertension, Doppler echocardiography is the best option for non-invasive diagnosis. Systolic pulmonary artery pressure can be estimated from the maximum velocity of the tricuspid regurgitant jet. A key limitation of this approach is that many patients have a degree of hyperinflation and the estimated pressure is not reliable for diagnosis of mild pulmonary hypertension. In the setting of dilated left atrium, atrial fibrillation or characteristic changes in mitral flow profile or pulmonary venous flow profile and left ventricular hypertrophy, then diastolic dysfunction should be suspected and sought.

'Out-of-proportion' pulmonary hypertension should be considered in patients with COPD of milder severity airways obstruction who demonstrate severe hypoxaemia, hypocapnia and a decreased TLCO with severe pulmonary hypertension and no other apparent cause.

Treatment

Currently, there is no specific therapy for pulmonary hypertension associated with chronic lung diseases including COPD and interstitial lung disease. Treatment of airways obstruction should be optimized with both lifestyle modification, such as smoking cessation and exercise prescription, and appropriate pharmacotherapy according to national and international guidelines.[18]

As alveolar hypoxia is a major factor in the development of pulmonary hypertension, this should be addressed with long-term oxygen therapy (LTOT). Two studies, the Nocturnal Oxygen Therapy Trial (NOTT) in the USA and the Medical Research Council (MRC) trial in the UK both demonstrated improved survival for patients with late-stage severe COPD. Both studies included an initial assessment of pulmonary haemodynamics and a follow-up assessment in a subgroup of patients after a period of time on treatment. In the MRC group, over 1 year LTOT was associated with no increase in mean pulmonary artery pressure compared with controls receiving air, where mean pulmonary artery pressure increased by 2.8 mmHg per year. In the NOTT study, LTOT for >18 h per day was associated with a reduction in mean pulmonary artery pressure both at rest and during exercise, whereas LTOT for 10–12 h per day had no effect. In addition, LTOT will partially reduce the progression of pulmonary hypertension in COPD, but pulmonary artery pressure rarely returns to normal values with this treatment and the structural abnormalities of the pulmonary vasculature remain largely unchanged. There is no evidence that earlier use of LTOT in patients with COPD and isolated episodes of hypoxaemia, such as during sleep, has any effect on the development of pulmonary hypertension and oxygen should be prescribed within defined guidelines. Thus LTOT for >16 h per day, the UK recommendation, will generally stabilize pulmonary hypertension and may slow its progression in COPD. The role of LTOT in interstitial lung disease and other respiratory disorders is much less clear, as trials have not been carried out to demonstrate benefit.

Drugs with demonstrated specific benefits in PAH have not being fully assessed in patients with pulmonary hypertension secondary to respiratory disease; there are few studies to support their use and those published have been uncontrolled. Use of vasodilator agents is not recommended owing the potential impairment of gas exchange if hypoxic pulmonary vasoconstriction is reduced. Further properly constructed randomized controlled trials of treatment are required before drugs for PAH can be recommended for use in pulmonary hypertension secondary to respiratory disease.

Patients with 'out-of-proportion' pulmonary hypertension associated with lung disease should be referred to specialist centres for further investigation and the possibility of treatment with PAH-specific drug therapy.

Group 4. Pulmonary hypertension secondary to venous thromboembolism (Table 51.4)

Chronic thromboembolic pulmonary hypertension (CTEPH) results from a single or recurrent thromboemboli arising from sites of venous thrombosis, which lead to non-resolving pulmonary vascular obstruction. It is associated with considerable morbidity and mortality and is estimated to occur in 0.15–0.5% of patients surviving an acute pulmonary embolism, but a prospective study cohort revealed that 3.8% of survivors developed CTEPH within 2 years of the acute embolic event. However, such estimates are of limited value as the many patients with CTEPH do not experience an acute pulmonary embolus. The cumulative incidence after an acute pulmonary embolus has been suggested to be in the region of 1–4% between 2 and 4 years after the initial embolic event. Because of the hidden nature of the problem in most patients, it is essential to consider this as a diagnosis as soon as any evidence of pulmonary hypertension occurs. Accepted risk factors for CTEPH include splenectomy, central lines, inflammatory bowel disease and ventriculoatrial shunts.

There is evidence that pulmonary emboli either in their overt acute form or in an occult form trigger a cascade of events that lead to CTEPH. In the majority of patients following a pulmonary embolus, there is a return to normal haemodynamics within 4–6 weeks.[24] However, based on lung perfusion and echocardiographic analysis, up to 25% of patients will have evidence of persistent pulmonary hypertension or abnormal lung perfusion patterns.[24] Hence it is likely that there is incomplete recovery from acute pulmonary embolus and that this is often unrecognized and leads to the risk of developing CTEPH.

Table 51.4 Key aspects of the diagnosis and management of pulmonary hypertension secondary to chronic thromboembolism.

Ventilation perfusion scans necessary for unexplained pulmonary hypertension as normal or near-normal perfusion largely excludes CTEPH
Patients with a history or findings suggesting CTEPH and are candidates for pulmonary endarterectomy should be referred to centres with expertise in investigation and surgery in this condition
Pulmonary endarterectomy is the preferred and only curative treatment for CTEPH
In severely compromised patients, surgery may not be an immediate option. Medical therapy with a range of treatments to improve haemodynamics and clinical performance should be undertaken, ideally at a specialist centre
Patients with inoperable disease, such as with peripheral thromboembolism, may be candidates for medical therapy and should be reviewed at a specialist centre
Some patients with CTEPH may benefit from drugs currently used in PAH, but there are no definitive studies and such care should be delivered in specialist centres

Diagnosis

In the setting of a known previous pulmonary embolus, persistent or recurrent breathlessness should be regarded as indicating the potential for CTEPH. The key investigation is currently two-dimensional echocardiography with Doppler flow studies to evaluate the likelihood of raised pulmonary artery pressure, defined as a pressure >25 mmHg at rest or >30 mmHg with exercise. If a raised pulmonary artery pressure is present, further evaluation should include oxygenation, full pulmonary function testing, a high-resolution CT scan of the chest, ventilation perfusion scanning of the lungs and cardiac catheterization.[1,4] The definitive investigation for CTEPH is right heart catheterization, which gives the direct measurement of pulmonary pressures. The measurement of circulating amino-terminal pro-brain natriuretic peptide and troponin have been used to exclude both preclinical and symptomatic CTEPH in patients known to have previously had a pulmonary embolus. The use of a VQ scan is essential because it has a higher sensitivity than a CT pulmonary angiogram in detecting the presence of CTEPH.

Treatment

Diagnosis of CTEPH is an indication for life-long anticoagulant prophylaxis with warfarin. It is generally recommended that the international normalized ratio (INR) is kept between 2 and 3 to prevent further thromboembolic episodes.

Surgical treatment

This is the treatment of choice, because CTEPH is potentially curable with pulmonary endarterectomy.[25] Selection of patients for surgical treatment is important, with reported mortality rates for patients undergoing this treatment ranging from 5 to 24%. An important factor in this wide range is that most patients present in a late phase of their disease and may not be suitable for endarterectomy or are of borderline suitability. The presence of predominantly distal embolization and in patients with severe comorbidities, who are not candidates for surgical correction, medical treatment options need to be explored. The outcomes of surgery are generally good with regard to quality of life, overall functional status, haemodynamics and right heart function. However, an important determinant of the outcome of surgery is the extent of small vessel arteriopathy.[26,27] Up to 15% of patients operated on will have continuing pulmonary hypertension and should be considered suitable for additional medical therapy.

Medical treatment

Three major pathways of treatment have been used in patients with advanced CTEPH or peripheral emboli not suitable for surgical intervention. These agents can be used as monotherapy or in combinations. The individual treatments are endothelium receptor antagonists (ERAS), prostacyclin analogues and phosphodiesterase inhibitors to inhibit breakdown of nitric oxide. Most reports of such treatment in CTEPH are open label and currently only one randomized controlled trial has been reported with improvements in pulmonary vascular resistance at 4 months, but with no improvement in the 6 min walking distance, which suggest little improvement in functional capacity. Additionally, there was no difference to placebo in terms of time to clinical deterioration in a group of inoperable CTEPH patients. At present, there is insufficient evidence for the introduction of such drugs into the general care of CTEPH and their use is recommended to stay within specialist centres and in clinical trials of treatment.[1,4]

Group 5. Pulmonary hypertension where cause is unknown

The clinical presentation of pulmonary hypertension is similar to that in other groups, as are the diagnosis and investigations. The association of pulmonary hypertension with other disorders complicates the issue of treatment, which should be of the associated disorder. Little is known of the use of PAH recommended drugs in this group and referral to a specialist centre may be appropriate.

Conclusion

Pulmonary hypertension is not uncommon in the elderly and is usually associated with cardiovascular and respiratory disorders, although other causes should be considered. In the majority of patients, the treatment is of the underlying disorder, but in more complex cases referral to specialist centres is an important option.

Key points

- Pulmonary hypertension occurs in the setting of left heart disease with either ventricular dysfunction or valvular decompensation and chronic destructive respiratory diseases, such as chronic obstructive pulmonary disease and chronic thromboembolic disease.
- Recent increased knowledge of pathophysiological mechanisms underlying pulmonary hypertension and the development of new investigative tools have led to a clinicopathological classification of pulmonary hypertension.
- Pulmonary arterial hypertension is a group of hereditable, idiopathic and other specific forms of pulmonary hypertension that lead to small arteriolar disease. There have been significant developments in the treatment of this group, which as yet have not become part of the accepted standard treatment of the other groups of pulmonary hypertension.
- The elderly may develop pulmonary hypertension from any of the recognized causes, but still the major associations will be with cardiorespiratory disease.

CHAPTER 52

Pulmonary rehabilitation

Peter Spiegler and Jonathan Ilowite
Winthrop University Hospital, Mineola, NY, USA

Introduction

Pulmonary rehabilitation is 'an evidence-based, multidisciplinary and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities'.[1] Pulmonary rehabilitation has been used for decades, but its acceptance has only recently become widespread. In part, this is due to the experience with lung volume reduction surgery (LVRS) for chronic obstructive pulmonary disease (COPD). In the National Emphysema Treatment Trial (NETT), pulmonary rehabilitation was a component of standard therapy for patients undergoing surgery. In a review of the experience of NETT patients in pulmonary rehabilitation, in addition to demonstrating the efficacy of LVRS in a subset of patients with severe emphysema, it showed that widespread use of pulmonary rehabilitation resulted in substantial benefit for patients with COPD.[2] This was the first study to demonstrate the efficacy of pulmonary rehabilitation across a large number of sites. Based on this, pulmonary rehabilitation has become standard of care both before and after LVRS. In addition, patients must participate in pulmonary rehabilitation both before and after lung transplantation.

Pulmonary rehabilitation has been slow to gain acceptance. It has never been shown to improve survival in patients with COPD. In addition, no consistent improvement in lung function has been demonstrated and oxygenation does not improve with pulmonary rehabilitation. Unfortunately, in the past, many practitioners interpreted these results as indicating that pulmonary rehabilitation was not beneficial. This was a result of a misconception about the goals of pulmonary rehabilitation. Patients with chronic lung disease suffer from chronic dyspnea, which leads to a reduction in daily activities and increased social isolation. This can contribute to the development of mood disturbances, which are very common in patients with COPD. When these outcomes are studied, the benefits of pulmonary rehabilitation become clear. Multiple studies of pulmonary rehabilitation have demonstrated significant improvements in exercise tolerance, endurance, symptoms of dyspnea, psychosocial well-being and quality of life, all of which are meaningful endpoints for patients suffering from this chronic disease. Awareness of pulmonary rehabilitation varies by region and even from practitioner to practitioner in a given area. In the USA, the Centers for Medicare and Medicaid Services recently granted a procedure code and national coverage determination for pulmonary rehabilitation. This has also raised awareness of pulmonary rehabilitation, partly as a business opportunity, but has also validated the hard work of many professionals who have advocated the benefits of this treatment modality.

Organization

There are no specific guidelines for the organization or structure of a pulmonary rehabilitation programme. A multidisciplinary approach is required with involvement from nursing, physical therapy, occupational therapy and respiratory therapy. Psychologists or social workers may also be employed, in addition to nutritionists and recreational therapists. A physician serves as the medical director. The medical director's role includes performing the initial screening, writing the exercise prescription and monitoring the patients' progress through the programme. The director is also available for emergency situations. The director acts as an educator to the staff and patients and may also be a research coordinator. One member of the team serves as the programme director and is responsible for the day-to-day management of the programme, recruitment and marketing.

The location of the programme varies. Although it is most often based in the outpatient setting as either a hospital-based or free-standing facility, it can also be performed in an inpatient setting or even at the patient's home. A typical programme lasts for 8–12 weeks with 2 h sessions performed two to three times per week. Components of

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

a pulmonary rehabilitation programme include exercise, education and psychosocial support.

Patient selection

In general, patients with symptomatic chronic lung disease are likely to benefit from pulmonary rehabilitation. It was initially developed for patients with COPD over 30 years ago and much of the literature on the effects of pulmonary rehabilitation is based on its effect in this patient population. Recently, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) classified COPD into four stages, depending on the magnitude of reduction in the forced expiratory volume in 1 s (FEV_1).[3] Patients with GOLD class II–IV [FEV_1 <80% of predicted with a forced vital capacity (FVC) to FEV_1 ratio of less than 70%] are eligible to participate in pulmonary rehabilitation.

The prevalence of COPD increases steadily with age. It is difficult to get an accurate estimate of COPD prevalence in the elderly because the FEV_1/FVC ratio declines with age. As a result, some elderly normal patients may be classified as having COPD by the GOLD criteria. The National Center for Health Statistics in the USA estimated the incidence of COPD in elderly adults at just less than 10%.[4] Rates in other countries may vary and many other factors may contribute to prevalence rates. For example, in China, prevalence rates increase significantly with age with 2.3% of those aged 40–49 years meeting the spirometric definition of COPD, whereas in those over 70 years of age the prevalence was 20.4%.[5] Urban versus rural location, body mass index, level of education and amount of ventilation in a person's kitchen also affected prevalence rates.

Not surprisingly, elderly patients with COPD comprise the majority of patients participating in most pulmonary rehabilitation programmes. In recent years, there has been increased interest in extending pulmonary rehabilitation to patients with other respiratory conditions. These patients also suffer from deconditioning, dyspnea, impaired health status and quality of life. Pulmonary rehabilitation has been used in patients with restrictive and interstitial lung diseases, bronchiectasis, asthma, chest wall disorders and pulmonary hypertension.[6–9]

Historically, pulmonary hypertension has been considered a contraindication to pulmonary hypertension. With exercise, especially static, resistive exercise, there is a significant increase in right and left ventricular overload. In patients with pulmonary hypertension, due to fixed pulmonary vascular constriction, this may lead to a dramatic rise in pulmonary arterial pressure without a rise in cardiac output, which may lead to circulatory failure. Recent experience has not supported this notion. Many patients with pulmonary hypertension related to other chronic pulmonary conditions (World Health Organization group III) exercise in pulmonary rehabilitation without complication. Furthermore, with the advent of numerous advanced therapies for pulmonary arterial hypertension (World Health Organization group I), it seems that these patients may exercise safely at submaximal exercise levels.

Owing to the increased utilization and literature now supporting the use of pulmonary rehabilitation for other chronic respiratory conditions, the latest version of the American College of Chest Physicians and American Association of Cardiovascular and Pulmonary Rehabilitation (ACCP/AACVPR) practice guidelines for pulmonary rehabilitation state that 'pulmonary rehabilitation is appropriate for any stable patient with a chronic lung disease who is disabled by respiratory symptoms'.[10]

Components of pulmonary rehabilitation

Exercise

Exercise training is the cornerstone of pulmonary rehabilitation. Patients with chronic dyspnea frequently have low activity levels. With progressive dyspnea, disuse atrophy develops resulting in significant skeletal muscle deconditioning. This, in turn, leads to further curtailment of activities with worsening of symptoms. Numerous studies have demonstrated improvements in dyspnea and exercise capacity in patients with COPD. These studies do not demonstrate a corresponding increase in lung function, indicating that these gains are related to a conditioning effect.

Exercise can focus on either endurance training or strength training. Both are beneficial for patients with chronic lung disease. Activities such as walking or biking require endurance training and patients will show significant improvements in 6 min walk distances after pulmonary rehabilitation. Many patients with chronic lung disease complain of shortness of breath on getting out of a chair, lifting objects or reaching over their heads. As a result, strength training has been added to pulmonary rehabilitation programmes; however, the scientific basis for doing so is limited, with studies demonstrating that strength training increases muscle mass but with no clear clinical benefit.

Anabolic steroids have been investigated in patients with COPD. These patients often have reduced muscle mass compared with age-matched, healthy controls. In several studies of testosterone, nandrolone and stanozolol, there have been variable improvements in lean muscle mass but no improvement in endurance or symptoms of shortness of breath. As a result, these are not recommended as adjunctive treatment in pulmonary rehabilitation.

Pre-enrolment cardiopulmonary exercise testing is performed to help design an exercise programme for patients. Exercise sessions usually last from 20 to 40 min at a

time. Exercise can be of either high or low intensity. High-intensity exercise produces greater improvements in exercise capacity than low-intensity exercise during pulmonary rehabilitation but, in general, is not as well tolerated. This is especially true in elderly patients who may have coexisting neurological disorders or gait instability affecting the ability to perform high-intensity exercise. Other issues related to age that may influence the ability to perform exercise include limited shoulder mobility, tremor and medication effect. Despite this, pulmonary rehabilitation has been shown to be as effective in older patients as it is in younger patients.[11] Older patients (aged >70 years) showed similar improvements in walk distances, dyspnea and quality of life scores to those of younger patients.

Education

Education is an integral component of pulmonary rehabilitation. Patients benefit from an understanding of their disease and learn how to recognize symptoms of an exacerbation. Better coping skills, better understanding of the physiological and psychological aspects of chronic pulmonary disease, better adherence and understanding of medications and other treatments and smoking cessation are also potential benefits of the educational component of pulmonary rehabilitation. Education, however, is no substitute for exercise in pulmonary rehabilitation. A number of randomized studies have compared education and exercise in patients with COPD. In these studies, dyspnea and exercise tolerance were greater in the exercise treatment arm whereas little benefit was seen in those receiving education alone.

Specific topics of the education component of pulmonary rehabilitation can include a review of available medications, teaching of inhaler technique, lung function, basic pathophysiology of pulmonary diseases, oxygen therapy including travel, nutrition and stress management. In addition, pulmonary rehabilitation can provide a unique opportunity to discuss advanced directives including educating patients on healthcare proxies, living wills, palliative care and physician–patient communication regarding end-of-life issues.

Psychosocial support

Anxiety, depression and difficulty in coping with the progressive, debilitating nature of chronic lung disease are common in these patients. In part, this is due to loss of independence as symptoms worsen. This can lead to progressive social isolation and a sense of hopelessness. The elderly are particularly at risk since their spouses may also be disabled or no longer surviving. In addition, their children may be grown up and not available to help with their daily activities. Chronic dyspnea can lead to both anxiety and panic. This can cause patients to avoid leaving their homes due to fear of being away from a comfortable environment in which they can pace themselves and have ready access to medication if needed. This can worsen social isolation and contribute to depression.

Depression is commonly identified in patients participating in a pulmonary rehabilitation programme. There is limited literature on the effect of pulmonary rehabilitation on psychological outcomes. In a few trials, following pulmonary rehabilitation, patients had fewer symptoms of anxiety and depression and showed improved cognitive function.[12] The latest ACCP/AACVPR guidelines on pulmonary rehabilitation recently raised the evidence grade for psychosocial support in pulmonary rehabilitation to grade 2B (weak recommendation with moderate supporting evidence).

Psychological support during pulmonary rehabilitation can be in the form of regularly scheduled support groups focusing on specific topics such as stress reduction, coping skills or control of panic. Family sessions are often also included in these programmes. Group sessions, progressive relaxation techniques and hypnosis have all been tried in these, with anecdotal reports of success.

Outcomes

Studies of pulmonary rehabilitation have consistently shown improvements in exercise tolerance as measured in walking distance, quality of life and dyspnea. As mentioned above, these programmes also seem to help patients control anxiety and reduce symptoms of depression. Measures of peak exercise capacity, such as maximal oxygen consumption, with exercise are not clearly improved with pulmonary rehabilitation, but sustainable exercise, reflected by the 6 min walk distance, correlates with improved quality of life. Most of these improvements can be accounted for by changes in muscle strength and oxidative capacity. Improvements in dyspnea and exercise tolerance can also be due to both a reduction in fear and desensitization to dyspnea which occur independently of training effect.[13] Despite these effects on exercise capacity and quality of life, there is no effect on survival in patients with chronic lung disease. Pulmonary rehabilitation also has no effect on pulmonary function or oxygen requirements. Because of this, pulmonary rehabilitation should be considered as one of many potential treatments available to the physician but it is not a replacement for effective pharmacological therapy.

Another significant effect of pulmonary rehabilitation, and one that helped third-party payers agree to reimburse for pulmonary rehabilitation, is the effect that it has on reducing healthcare utilization. In a single centre in Wales, patients completing pulmonary rehabilitation had fewer hospital days (10.4 versus 21) for the year following

rehabilitation compared with patients not participating in pulmonary rehabilitation.[14] In the USA, similar results were seen in California. At 10 sites throughout the state, there was a significant reduction in hospital days the year after rehabilitation compared with the year before (3.4 versus 10). There were also fewer physician visits, telephone calls and urgent care visits the year following pulmonary rehabilitation.[15]

Maintenance following pulmonary rehabilitation

The benefits of pulmonary rehabilitation, although significant, are generally lost over time. Both in our experience and in multiple trials of pulmonary rehabilitation, the gains made generally fade over ~12–18 months following completion.[16] The benefits in dyspnea and quality of life usually last longer than those in improved exercise capacity. This may be related to the educational components of pulmonary rehabilitation and the sense of mastery that patients acquire during the programme. This is more enduring than the physiological effect of exercise training that occurs during pulmonary rehabilitation. It is common for patients, after a short-term, high-intensity programme, to return to a sedentary lifestyle. Some highly motivated patients will follow a post-rehabilitation exercise programme and have sustained benefits, but this is not the norm.

Some pulmonary rehabilitation centres have developed maintenance programmes to allow patients to exercise in a structured programme. This also maintains the social element of the rehabilitation environment, which acts as a motivating factor. These programmes are not as well standardized or rigorous as formal pulmonary rehabilitation programmes. Education and psychological support are usually not included in maintenance programmes.

There are many challenges to developing maintenance programmes, the foremost of which is lack of reimbursement. There is little literature supporting the use of maintenance programmes. Difficulties in assessing the efficacy of maintenance programmes include the effects of intercurrent illness which is likely to occur over a prolonged course of maintenance, loss of interest, difficulties in transportation and cost of the programme to patients. Any outcomes of maintenance will be biased by the fact that only the most motivated patients will participate over a prolonged period.

Pulmonary rehabilitation ultimately is an attempt to generate a lifestyle change for patients by using education and exercise that are specifically designed to maximally benefit those with chronic respiratory disease. Unfortunately, it is difficult to achieve lifestyle changes during a short, 6–12 week programme. Inpatients who underwent repeated pulmonary rehabilitation programmes on a yearly basis had similar benefits compared with the initial cycle; however, these benefits dissipated over the following year. Long-term lifestyle modification requires a short-term, high-intensity intervention followed by continued reinforcement. Therefore, although rehabilitation has significant effects on quality of life and exercise capacity, without some form of maintenance patients are likely to gradually return to their previous level of disability.

Conclusion

Pulmonary rehabilitation produces improvements in exercise capacity and respiratory symptoms in patients with chronic respiratory disease, even in those receiving optimal medical therapy. Spurred in part by the experience with lung volume reduction surgery, pulmonary rehabilitation has become recognized as standard of care for patients with COPD. Unlike lung volume reduction or transplantation, which is indicated for only a small percentage of patients with COPD, pulmonary rehabilitation can be used in a wide range of patients with COPD. Furthermore, because of the significant benefits in patients with COPD, it is also being increasingly utilized for patients with other respiratory conditions, with similar success.

Key points

- Dyspnea is multifactorial and not necessarily related to impaired lung function alone. Deconditioning, changes in skeletal muscle function with COPD, electrolyte imbalance and the cardiovascular effects of hyperinflation also contribute to exercise intolerance.
- Pulmonary rehabilitation is a multidisciplinary programme which specifically addresses many of these issues in patients with chronic respiratory disease.
- Pulmonary rehabilitation improves exercise capacity, dyspnea and quality of life in patients with chronic respiratory disease. It also helps to reduce healthcare utilization.
- The effects of pulmonary rehabilitation gradually fade without continued reinforcement. Maintenance programmes may help sustain the gains made during pulmonary rehabilitation.
- Although initially developed for patients with COPD, pulmonary rehabilitation should be considered for all patients with symptomatic chronic respiratory disease.

SECTION 6

CNS Disorders

CHAPTER 53

Neurological signs of ageing

Andrew J. Larner
Walton Centre for Neurology and Neurosurgery, Liverpool, UK

Introduction

Any attempt to describe the neurological signs of ageing immediately prompts a number of challenging questions. Perhaps the most pertinent of these is how to ascribe neurological signs observed in later life to normal ageing *per se*, rather than concurrent (and possibly subclinical) age-related neurological conditions such as cerebrovascular disease, Alzheimer's disease (AD), Parkinson's disease or combinations thereof. Differing quantitatively or qualitatively from normal ageing, such diseases fall within the purview of geriatric neurology. From the clinical perspective, this is not merely a question of dry academic interest, since disease-related changes might be amenable to disease-specific therapeutic interventions, whereas age-related change might require acceptance as part of the human condition, perhaps abetted by sympathetic attempts at neurorehabilitation.

To define the neurological signs of normal ageing, one requires a definition of 'normal', which will determine the optimal requirements for a study which aims to describe such signs. The one absolute of studies of ageing is substantial heterogeneity, in both control and age-related disease groups. Hence it must be decided if individuals selected for study should be free of all age-related disease and medication use. Such individuals may be described as having undergone 'successful' ageing or 'optimal' ageing. By contrast, the category of 'typical' ageing accepts common age-associated disease (and medication use) as physiologically typical of the ageing process. Such definitions may be informed by biological models of ageing, such as senescence (age as a disease) or lifespan (age as development) models. Considerations of this nature will also determine the locus of study populations (community based, hospital based, nursing home based) and whether an attempt should be made to include all relevant subjects or only those who volunteer for study.

'Successful' ageing or 'optimal' ageing occurs in 'supernormals,' individuals whose function or performance clusters at the upper end of any normal distribution. Genetically, these individuals may differ from those undergoing 'typical' or 'normal' ageing. Relatively greater or lesser vulnerability of ageing tissues to disease processes and relative preservation or loss of neural regenerative capacities with ageing[1] may also be relevant.

Study logistics also need careful consideration. Cross-sectional studies, in which, for example, 20-year-olds are compared with 50- and 80 year-olds, with assessment occurring at one time point, may overestimate age-related changes because of cohort effects such as differences in education or nutrition. Moreover, with lack of follow-up, it may be that 'normals' in the older age groups were in fact in the subclinical phase of age-related disease. Longitudinal studies of cohorts which might address such difficulties, by following individuals for many years with repeated examinations at successive time points, risk underestimating change due to loss of subjects to follow-up. Such studies are also expensive, sometimes prohibitively so.

The definition of signs to be examined and standardization of testing procedures are also fundamental requirements. Disagreement between experienced examiners in the interpretation of neurological signs is well recognized.[2,3] Hence prespecified operationalization of neurological examination and agreement on scoring or quantitation of signs are required for robust results.[4] Without specifying these parameters, it is difficult to realize a quantitative measure of the sensitivity and specificity of neurological signs with respect to ageing.

Similar arguments apply to age-related changes in investigation findings, such as neuroimaging and electrodiagnostic studies, and likewise to the definition of the neuroanatomical substrates of change in neurological signs with ageing. For example, cerebral atrophy on structural brain imaging or in postmortem tissue is not an uncommon

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

finding in cognitively normal older individuals and is not in itself an inevitable signature of AD.[5,6]

Neurological signs of ageing

An early and comprehensive review of the neurology of old age was given by Critchley in his three Goulstonian Lectures delivered to the Royal College of Physicians of London in March 1931.[7] Since then, many reviews have appeared, some indicating the need to revise the designation of 'senile' for certain signs in favour of aetiological explanations which may carry therapeutic implications.

Some neurological signs particularly associated with ageing are briefly described (summarized in Table 53.1), along with details of their investigational correlates and neuroanatomical substrates where these are known. Techniques for eliciting neurological signs and their semiological value are not covered here.[8] The description follows the traditional, and somewhat arbitrary, sequence of the neurological examination.

Table 53.1 Topographical overview of age-related neurological signs.

Cognitive function:
- Loss of processing speed, cognitive flexibility, efficiency of working memory (sustained attention)
- Preservation of vocabulary, remotely learned information including semantic networks and well-encoded new information

Cranial nerves:
- I: olfactory sense diminished
- II: presbyopia; reductions in visual acuity, depth and motion perception, contrast sensitivity
- III, IV, VI; senile miosis; restricted upward conjugate gaze
- VIII: presbycusis; impaired vestibulospinal reflexes

Motor system:
- Appearance: loss of muscle bulk; 'senile tremor'
- Tone: rigidity, *gegenhalten*/paratonia; mild parkinsonism
- Power: decline in maximum muscle strength
- Coordination: impaired speed of movement
- Reflexes: depressed or absent phasic muscle stretch reflexes (especially ankle jerk); depressed cutaneous reflexes (e.g. abdominal); emergence of primitive or developmental reflexes (glabellar, snout, palmomental, grasp)

Sensory system:
- Decreased sensitivity to vibratory perception, +/− pain, temperature, proprioception

Cognitive function

Ageing has both structural and functional effects on the brain.[9] Serial registered magnetic resonance imaging scans show that there is a decrease in global and regional (temporal lobe, hippocampus) brain volumes, the rate of which may increase after the age of 70 years.[5] Hence brain atrophy *per se* is not specific for the diagnosis of pathological change, an assumption which may lead to clinical misdiagnosis of AD if undue weight is placed on structural neuroimaging findings.[6] The neuroanatomical correlates of this volume loss are uncertain, possibly including neuronal loss or shrinkage, dendritic pruning and synaptic loss and white matter change. There is also evidence for plasticity in the ageing brain, with dendritic sprouting which may help to maintain synaptic numbers, although such compensatory abilities may decline with age. Vascular change becomes more frequent in the ageing brain, as manifested by leukoaraiosis (small vessel ischaemic change in white matter) and silent infarcts, possibly related to rises in blood pressure. These changes may not only reflect brain ageing but may also contribute to pathological disorders, both AD and vascular cognitive impairment. Interaction of AD-type pathology with vascular changes may lower the threshold for the clinical appearance of cognitive decline.[10]

Neuropathological studies of ageing brain have focused on both positive and negative phenomena. Of the former, neurofibrillary pathology (neurofibrillary tangles, neuropil threads) and senile neuritic plaques, hallmarks of the AD brain, may be seen in cognitively normal older individuals. The development of neurofibrillary pathology follows a relatively stereotyped hierarchical pattern with age, appearing first in the transentorhinal cortex.[11] Spread to hippocampal and association cortex is associated with progressive appearance of cognitive decline. Senile plaques have a broader and more variable distribution; a significant burden may be associated with normal cognition. Negative phenomena include neuronal and synaptic loss. There is relative preservation of cortical and hippocampal neuronal populations with ageing, although subcortical structures such as the basal forebrain, locus ceruleus and substantia nigra do show neuronal losses.

What are the functional consequences of these changes? Typical cognitive ageing involves losses in processing speed, cognitive flexibility and the efficiency of working memory (or sustained attention). In other words, it may take more time and/or more trials to learn new information. Other cognitive domains, such as access to remotely learned information including semantic networks and retention of well-encoded new information, are spared with typical ageing. Hence impairments in these latter domains may be sensitive indicators of pathology rather than physiology.[12] Memory decline in healthy ageing may be secondary to a decline in processing speed and efficiency: controlling for processing speed may attenuate or eliminate age-related differences in memory performance, unlike the situation with memory impairment in dementia. Longitudinal studies of neuropsychological function, such as the Mayo's

Older Americans Normative Studies, indicate that there is considerable variability in normal older adults across different skills and consistency across different domains may not necessarily be observed.[12] Clearly this needs to be taken into account when assessing whether perceived cognitive decline is pathological or normal, that is, in defining neuropsychological norms for ageing. Likewise, norms may need to be age weighted rather than age corrected to detect cognitive impairment related to AD, the prevalence of which increases exponentially with increasing age. Many other situational influences may also impact on testing of cognitive skills, such as fatigue, emotional status, medication use and stress. These also need to be taken into account when considering the results of cognitive testing, as may factors such as educational and background experience. Many norms are also culturally-weighted.

Age-related cognitive decline may exist in individuals who do not fulfil validated criteria for the diagnosis of dementia or AD.[13] Various terms have been used over the years to describe this state, dating back to Krol's 'benign senescent forgetfulness' and including age-associated memory impairment (AAMI), age-associated cognitive decline (AACD), cognitive impairment, no dementia (CIND) and mild cognitive impairment (MCI). Some consensus has developed around the concept of MCI, criteria for which are the presence of a memory complaint, preferably corroborated by an informant; evidence of objective memory impairment for age and level of education; largely normal general cognitive function; essentially intact activities of daily living; and failure to fulfil criteria for dementia.[14] MCI is certainly a heterogeneous clinical entity, some examples of which certainly represent 'prodromal AD'. The annual conversion rate of MCI to AD is ~5–10%, such that most individuals with MCI do not progress to dementia even after 10 years of follow-up.[15] Updated diagnostic criteria for AD[16] seek to abolish the MCI category altogether in favour of an earlier, biologically based, diagnosis of AD, even without the clinical correlate of dementia which was insisted upon in earlier criteria.[13] This is logical if the hope is for earlier diagnosis and intervention to prevent cognitive decline to dementia. However, as yet no disease-modifying intervention has been discovered in the clinical arena, cholinesterase inhibitors proving robustly negative in trials aimed at slowing MCI to AD conversion and other interventions (blockers of amyloid production such as secretase inhibitors, immunotherapies to prevent amyloid deposition, tau aggregation inhibitors) remain at the clinical trial stage.

Since ageing *per se* is a significant risk factor for dementia, the ageing of the world population has important clinical, social and economic implications.[17] Primary and secondary prevention measures, perhaps facilitated by predicting risk of dementia in 20 years time based on factors such as age, education, blood pressure, cholesterol and obesity,[18] may be a more appropriate public health strategy, emphasizing a life-long, lifestyle approach to cognitive well-being.

Cranial nerves, including special senses

Olfaction (olfactory nerve; cranial nerve I)

Olfactory function diminishes with age, as does the sense of taste, which depends to a great extent on olfaction. Damage to the olfactory epithelium by pollutants or microbes is cumulative throughout life, affecting olfactory receptor neurones and cells further up the olfactory pathway. Impaired olfaction may also be an early sign of age-related disease, occurring in both Alzheimer's disease and Parkinson's disease. There is early involvement of the olfactory pathways by both neurofibrillary[11] and α-synuclein[19] pathology. Hence so-called age-related olfactory decline might in fact represent the early changes of a subclinical dementing disorder.[20]

Visual system: neuro-ophthalmology (optic, oculomotor, trochlear and abducens nerves; cranial nerves II, III, IV, VI)

Presbyopia is an age-related impairment of accommodation, attributed to increased rigidity of the lens, leading to hyperopia (far-sightedness). Age-related changes have also been documented in visual acuity, visual field, depth perception, contrast sensitivity, motion perception and perception of self-motion with reference to external space (optical flow). The pupils become progressively smaller ('senile miosis') and their reflex responses to light and accommodation become sluggish. Opacities in the lens and the vitreous may contribute to impaired visual acuity, including contrast sensitivity. Poor visual acuity may contribute to falls in the elderly. Whether photoreceptor loss from the retina may also be a factor in these changes is uncertain, but it may be relevant to diminished dark adaptation. Ocular changes such as cataracts and macular degeneration may obviously contribute to age-related visual impairment.[21]

Eye movements may become more restricted with age, particularly upward conjugate gaze (also observed in parkinsonism) and convergence. Bell's phenomenon, the reflex upward and outward deviation of the eyes in response to attempted forced closure of the eyelids, may be lost.

Other visual symptoms observed in ageing populations may reflect age-related neurodegenerative disease, for example the visual hallucinations of dementia with Lewy bodies (formed) or Creutzfeldt–Jakob disease (simple; Heidenhain variant) and the visual agnosia of Alzheimer's disease which may sometimes be the presenting feature (posterior cortical atrophy, visual variant of AD).

Hearing and balance (vestibulocochlear nerve; cranial nerve VIII)

Presbycusis is an age-related decline in hearing perception (i.e. increased auditory threshold), especially for mid-to-high frequencies and occurring bilaterally, which may also lead to reduced speech discrimination. It is believed to result primarily from loss of cochlear hair cells in the organ of Corti, although other structural changes in the auditory pathways may contribute, such as thickening of the basilar membrane, atrophy of the stria vascularis and degeneration of neurones in the spiral ganglion, cochlear nuclei and auditory centres in the brain. The latter may account for difficulties understanding speech which are greater than expected from audiometric thresholds *per se*.[22]

Age-related decline may occur in vestibular functions. Specifically, reductions in the ability to detect head position and motion in space, to elicit vestibulospinal reflexes which trigger automatic postural responses when the head position is changed and to solve sensory conflicts, are not uncommon. The neuroanatomical correlate may be loss of vestibular hair cells and nerve fibres and neuronal loss in the medial, lateral and inferior vestibular nuclei in the brainstem.

Sensorimotor function: motor systems

Appearance

A progressive loss of muscle bulk occurs with ageing, which is diffuse but most noticeable in intrinsic hand and foot muscles.[7] This is thought to be neurogenic, since electrophysiological studies show features of ongoing chronic partial denervation with compensatory reinnervation with ageing. Muscle fibres deprived of the trophic support of their innervating axons will atrophy.[1] Muscle biopsies in clinically normal elderly individuals confirm neurogenic change to be more apparent than myopathic change, with variation in fibre size (type I or types I and II fibre atrophy) and fibre type grouping suggestive of reinnervation. Degeneration of alpha motor neurones within the anterior (ventral) horns of the cervical and lumbar spinal cord is said to be the neuropathological correlate of these changes. However, fasciculations, a reliable sign of anterior horn cell disease, are not apparently a feature of normal ageing: if fasciculations reflect motor axonal instability due to recent reinnervation and collateral axonal sprouting, rather than an effect of denervation *per se*, then the electrophysiological and histological predominance of denervation over reinnervation might explain the absence of fasciculations in the elderly. The finding of fasciculations should therefore always prompt investigations for a pathological cause, such as motor neurone disease, compressive cervical radiculomyelopathy or multifocal motor neuropathy.

Tremor of the limbs and/or jaw has sometimes been given the label 'senile', since it is more prevalent in the elderly. The epithet conceals ignorance of the genesis of these signs. Limb tremor may be one feature of the extrapyramidal (parkinsonian) syndrome seen with increasing age in community-dwelling healthy individuals,[23] although the possible diagnosis of essential tremor should also be borne in mind, particularly if these tremors are worse with volitional activity. A diagnosis of essential tremor may have implications for therapy. Jaw tremor, often associated with the loss of teeth, has sometimes been labelled edentulous tremor. Tardive dyskinesia associated with previous neuroleptic use enters the differential diagnosis. Other movement disorders such as athetosis and chorea in the elderly have also been labelled 'senile',[7] but an attempt to ascertain an aetiological diagnosis should be made. Myoclonus, a common sign in advanced dementia, practically never occurs in normal old age.

Tone

Rigidity, an increase in resistance to passive movement around a joint which is constant throughout the range of joint displacement ('lead-pipe rigidity') and not related to the velocity of joint movement (cf. spasticity), is one feature of the extrapyramidal syndrome or parkinsonism. Akinesia, comprising bradykinesia (slowness in initiation and performance of movement) and hypokinesia (small amplitude of movements), is the defining and obligatory feature of parkinsonism. Tremor and postural abnormality, along with rigidity, may also occur as cardinal features of the syndrome of parkinsonism. A population based study of 467 individuals aged over 65 years in East Boston, USA, who underwent a structured neurological examination, found parkinsonism (defined as the presence of two or more of the following four signs: bradykinesia, gait disturbance, rigidity and tremor) in 159 individuals. The prevalence of parkinsonism increased with age.[23] The neuropathological correlate of these clinical findings may be the progressive spread of α-synuclein-immunopositive Lewy bodies and Lewy neurites, which have been reported in the brains of ageing but asymptomatic individuals.[19]

In addition to rigidity of extrapyramidal origin, another form of increased tone may be observed in older patients: 'superadded hypertonus of a quasi-volitional nature due to the patient's failure to relax as soon as his limbs are under examination'.[7] This clinical finding may be described as paratonia, paratonic rigidity or *gegenhalten*. The anatomical

correlate is bilateral frontal lobe pathology, most usually diffuse (small vessel) ischaemic cerebrovascular disease. Some authors classify paratonia as a release sign.[4]

Power

A meta-analysis investigating the relation between age and the prevalence of a variety of neurological signs, encompassing 50 studies involving 9996 individuals, found that the prevalence of decreased muscle strength did not rise with increasing age.[24] However, other authorities opine that decline in muscle strength appears progressively with ageing. Loss of muscle bulk (muscle wasting) is thought by some to be insufficient to explain the extent of weakness, although, as for wasting, neurogenic changes are thought to be the relevant neuroanatomical substrate. The oxidative capacity of exercising old muscle is reported to be less than that of young muscle. Strength may also be dependent on the integration of central mechanisms which may also be impaired with ageing due to loss of motor cortex cells, pruning of pyramidal cell dendritic trees and loss of synapses. Non-neurological factors such as age-related joint pain and deformity may contribute to an apparent loss of muscle power.

Coordination

Coordination refers to the rate, range, timing and direction of movement. Impairments in the speed of movement develop with advancing age, for example in hand or foot tapping. Activities of daily living such as dressing take more time in older individuals. These findings may reflect changes in muscle strength, the bradykinesia of the extrapyramidal syndrome (parkinsonism) which becomes more prevalent with age[23] or a combination of these. Cerebellar signs per se (finger–nose, heel–shin or gait ataxia) were noted to be rather uncommon in old age by Critchley.[7]

Reflexes

Phasic muscle stretch reflexes ('deep tendon reflexes')

The previously mentioned meta-analysis investigating the relation between age and the prevalence of a variety of neurological signs found that the prevalence of absent ankle reflexes was increased in healthy persons older than 60 years, although the majority (≥65%) retained their ankle jerks. The prevalence of absent knee, triceps or biceps reflexes did not rise with increasing age.[24] Variability of clinical findings may be related in part to the timing or method (plantar strike, Achilles tendon strike) of eliciting the ankle reflexes and whether reinforcement (Jendrassik manoeuvre) is performed. Furthermore, there is interobserver variation in the assessment of reflexes, with a biasing effect of prior clinical knowledge.[2]

Although typically regarded as part of the motor examination, the monosynaptic reflex arc encompasses both sensory and motor components. Both elements may be affected by age. Neurophysiological studies show not only a reduction in the amplitude of sensory nerve action potentials with ageing but also slowing of nerve conduction velocities, which reflect conduction in the large myelinated fibres that subserve the efferent limb of the monosynaptic reflex arc.

Superficial or cutaneous reflexes

Included within this rubric are abdominal reflexes, cremasteric reflexes (seldom examined) and plantar responses.

It is said that abdominal reflexes may become depressed with age *per se*, but other factors known to lead to their loss may contribute, such as obesity, previous abdominal surgery and a history of multiple pregnancies. Corticospinal pathway damage (upper motor neurone lesions) above T6 may lead to loss of all superficial abdominal reflexes, and lesions at or below T10 lead to selective loss of the lower reflexes with preservation of the upper and middle reflexes, in which case Beevor's sign (upward movement of the umbilicus in a supine patient attempting to flex the head on to the chest against the resistance of the examiner's hand) may also be present. All abdominal reflexes are preserved with cord lesions below T12. However, long tract signs in the legs are likely to be more obvious than abdominal reflex change with cord lesions at any level.[8]

Extension ('dorsiflexion') of the big toe when the lateral border of the foot is stroked with a blunt object, Babinski's sign, is deemed a reliable sign of upper motor neurone pathology other than in infants below about 24–36 months of age (hence this may also be regarded as a primitive or developmental reflex). No consistent changes have been documented with normal ageing,[25] although it is often difficult for even experienced practitioners to form a definite judgment on the plantar response and its reproducibility is also questionable.[3] Assessment of the response may be confounded by withdrawal of the foot in ticklish individuals. Differentiation from the striatal toe (tonic extension) seen in some parkinsonian syndromes is also important.

Primitive or developmental reflexes; 'frontal release' signs

A number of entities may be placed within this rubric of release signs,[4] including paratonia. The category may be further subdivided into prehensile and nociceptive reflexes;

the former includes the sucking reflex (tactile and visual), hand grasp reflex, foot grasp reflex (tonic foot response) and the rooting reflex; the last includes the snout reflex, glabellar (blink) reflex and palmomental (palm–chin) reflex. Corneomandibular and nuchocephalic responses are also described as primitive or developmental.[4]

Such reflexes may occur in normal individuals with ageing. For example, in a study of 2029 elderly volunteers aged 50–93 years, a significant increase in all the signs in patients over the age of 70 years was found,[26] and similar findings have been reported by others.[4] Of course, in the absence of longitudinal follow-up, it is possible that some of these 'control' patients may have had preclinical AD. Hence, although such signs occur more frequently in those with AD, their sensitivity and specificity for the diagnosis are poor.

Station and gait: postural responses

No neurological examination is complete without examination of the patient's gait, and this is particularly important in the elderly, since they are more prone to falls. Although some may be ascribed to pathological processes such as cervical myelopathy, Parkinson's disease or peripheral neuropathy, or to be due to environmental factors such as uneven floors, obstacles or poor lighting, many defy such explanation.

Walking has two major components, equilibrium (maintaining an upright posture) and locomotion (gait ignition and stepping). Changes in both functions occur with ageing. A framework to classify impaired gait in the elderly has been suggested.[27]

Maintaining balance while standing on one leg with the eyes closed shows significant change with ageing. Increased postural sway also occurs with ageing. Sway may be related to sensory impairments in the feet, particularly proprioception, with additional contributions from poor visual acuity and changes in vestibular function. Postural righting responses may be slowed and of reduced amplitude.

For the maintenance of static balance, somatosensory function is the most important system;[28] if impaired, reliance on visual function becomes more prominent. When both somatosensory and visual inputs are impaired, leaving vestibular function as the primary sense for balance control, difficulties are immediately apparent. Age-related changes in balance control subsystems are common, involving not only the sensory systems (somatosensory, visual and vestibular function), but also motor systems (strength, range of motion, coordination) and cognitive functions (sensory adaptation, attention), all of which may contribute to balance problems and falls in the elderly. However, such changes are neither inevitable nor irreversible, permitting the possibility of improvements in balance and mobility and a reduced incidence of falls in older adults.

Critchley's assertion that *marche à petits pas*, characterized by loss of elasticity, shortened steps and broadened base, was 'almost characteristic of healthy old age'[7] is no longer tenable, such changes now being thought to reflect pathological small vessel ischaemic cerebrovascular disease.[27] The changes in gait and stance more commonly seen with ageing are akin to those of parkinsonism, with slightly stooped posture, reduced arm swing and mild shortening of steps. In a community-based study of parkinsonism in the elderly, individuals with parkinsonism showed a twofold increased risk of death over a mean follow-up of 9.2 years and this was strongly related to gait disturbance.[23] Other gait disorders such as frontal gait disorder, cautious gait and isolated gait ignition failure (previously labelled gait apraxia) remain poorly understood but possibly reflect pathology within cortical motor pathways, perhaps in combination with other factors.

Sensorimotor function: sensory systems

Somatosensory function

A decrease in the sensitivity of vibratory perception is the most prominent age-related finding on sensory examination, particularly distally and more so in the legs than the arms. The previously mentioned meta-analysis investigating the relation between age and the prevalence of a variety of neurological signs found that the prevalence of absent vibration sense at the big toes or ankles increased in healthy persons older than 60 years although the majority ($\geq$65%) retained distal vibration sensation. In general, the prevalence of decreased pain or touch sense, absent vibration at the knees or fingers and decreased position sense did not rise with increasing age.[24]

Spatial acuity, as measured by two-point threshold measurement, may be reduced, especially distally. An increase in perceptual threshold for vibration, and also for thermal pain, may be found, whereas light touch tactile threshold is comparatively preserved.[28]

Distal degeneration of sensory axons is thought to be the neuroanatomical correlate of impaired distal sensation, reflected functionally in the reduction in amplitude of sensory nerve action potentials, with absence of sural responses in some individuals.[28] A reduction in sensory nerve conduction velocity may also be seen, although this is of course a relatively blunt instrument since it examines function in only the fastest conducting myelinated nerve fibres. Morphologically, ageing sural (i.e. sensory) nerves show a reduced density of myelinated and unmyelinated nerves and increased endoneurial collagen in individuals over the age of 60 years, in addition to changes indicative of nerve regeneration and degeneration and demyelination and remyelination. Ageing is also associated with reduplication of vascular basement membranes and thickening

of perineurial basement membranes.[29] These age-related changes may contribute to the cryptogenic sensory and sensorimotor neuropathies occurring in the elderly that tend not to progress rapidly and seldom lead to significant motor disability.[30]

Conclusion

The previous tendency to label cognitive, motor and sensory neurological changes occurring in the elderly as 'senile', implying a relationship to ageing *per se* and hence not requiring further elucidation, has been rightly replaced with a desire to search for aetiological explanations for such changes. Nonetheless, some common neurological signs occurring with ageing defy explanation and hence by exclusion may be labelled 'age related'. Undoubtedly, structural and functional changes occur within the nervous system with ageing and awareness of the consequent neurological signs will guide physicians in their appropriate management of these changes. The key skill which physicians must learn is to juxtapose a knowledge of the signs of normal ageing with those of incipient neurological disease.

Key points

- Ageing may have various meanings (successful, optimal, typical), which should be taken into account when considering which signs may be judged representative of 'normal' ageing.
- Ageing is associated with cognitive changes, specifically slower learning of new information and decline in delayed recall. These changes may reflect slowed processing speed and attentional function, rather than more rapid forgetting, and may be qualitatively different to the memory problems seen in pathological conditions such as Alzheimer's disease.
- The typical motor changes seen with ageing include distal muscle wasting and weakness, with diminution or loss of distal reflexes. The typical sensory changes seen with ageing include loss of distal vibratory sensibility; other modalities such as pain and proprioception may also be involved.

CHAPTER 54

Sleep apnoea and sleep disorders

Paul Montgomery and Lindsay Dianne Shepard
University of Oxford, Oxford, UK

Background

Prevalence

The prevalence of sleep problems in adulthood increases with age.[1–6] In the general population, the most common types of sleep problems reported are insomnia (difficulties in initiating and/or maintaining sleep) and early morning waking with an inability to return to sleep. By survey, half of elderly individuals report some extent of sleep difficulties, including trouble initiating sleep, poorer sleep efficiency, increased time in bed, more night-time awakenings, earlier wake-up times and more daytime naps.[7] Older adults primarily report difficulty in maintaining sleep and, although not all sleep changes are pathological in later life, severe sleep disturbances may lead to depression (see below), cognitive impairments and stress to partners.[2,8]

Insomnia is supposedly the most prevalent sleep disturbance in the elderly, with up to 40–50% of those aged over 60 years reporting difficulty sleeping,[5] with an annual incidence rate of 5% in those over 65 years old.[9] General prevalence rates of insomnia in people aged 65 years and over are reported to range between 12 and 40%.[10] Interestingly, prevalence rates of insomnia are higher when coexisting medical or psychiatric illness is taken into account.[1,11,12] Foley *et al*.[9] reported that only 7% of the incident cases of insomnia in the elderly occur without a comorbid condition. Furthermore, lifestyle changes related to retirement, the increased incidence of health problems and the use of medication all place older people at increased risk of disrupted sleep.[13] The relationship between sleep problems and depression in the elderly is strong, but prone to confounding influences.[1] Sleep disturbances may also be comorbid with (but not necessarily causative of) dementia, while Alzheimer-related deterioration of suprachiasmatic nucleus neurons could cause still further disturbance in sleep–wake cycle disorders.[14]

Basic issues concerning sleep in the elderly

In spite of the high prevalence of sleep disorders in the elderly, relatively little is known about them. This may be because gerontologists, in common with many other clinicians, are taught very little about sleep at either undergraduate or postgraduate levels.[15–18]

In short, sleep is a reversible state of reduced awareness of and responsiveness to the environment, which usually occurs when lying down quietly with little movement. The functions of sleep are still being debated, with a range of theories postulating physical and psychological restoration and recovery, energy conservation and a range of biological purposes. No single theory encapsulates all of these functions, and it is likely that sleep serves many purposes. For most people, a significant lack of sleep impairs both physical and psychological functioning.

Sleep problems may relate to the quality, duration or timing of sleep. Asking patients whether they feel sleepy during the day, whether they feel refreshed in the morning and whether they are sleeping at socially appropriate times provides good indicators of whether these important aspects of sleep are acceptable.

There are essentially three main sleep problems: too much, too little and the so-called *parasomnia*s (things that go bump in the night!). However, the *International Classification of Sleep Disorders*, 2nd edition,[19] lists more than 80 sleep disorders. This chapter focuses on the most common sleep disorders faced by people aged over 65 years and considers diagnostic and treatment issues relevant to each of them.

A variety of factors may give rise to the sleep problems reported (and often under-reported) by the elderly.[2,20] Principally, these are: medical illnesses, both chronic and acute; the effects of medication; psychiatric problems; primary sleep disorders; social changes; and behaviour patterns that are not conducive to good sleep. These problems may

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

be exacerbated by poor handling of these problems by the patient, his or her family, doctors and other healthcare workers.

The consequences of sleep problems can be serious and costly. Lack of sleep and sedative medications have been shown to be associated with falls and accidents.[21–24] The risk of medication side effects and complications related to surgery could also be detrimental in the elderly population.[25] Sleep-related breathing problems, or sleep apnoea, have serious cardiovascular, pulmonary and central nervous system (CNS) effects.[26] In patients with dementia, sleep disorders frequently lead to nursing home placement. Experimental studies of total sleep loss indicate that this is associated with a negative impact on mood and cognitive functioning, although as with most sleep problems, individual variations can be substantial. For ethical reasons, the number of studies in this area is limited. Partial sleep loss has been better researched and these studies are likely to be more relevant to daily life and clinical practice. A loss of sleep of between 1 and 2 h per night has been shown to lead to irritability and poor concentration. When sleep loss is prolonged, disorientation, hallucinations and inappropriate behaviour may be reported.[27–31] It is important that sleep disorders are diagnosed properly and treated accordingly in view of their consequences to patients and also carers. These problems also impact healthcare costs,[32] further justifying medical attention. Table 54.1 gives a brief guide to these problems and their treatments.

Sleep structure

Normal sleep consists of a number of stages that can be simplified into rapid eye movement (REM) sleep and non-rapid eye movement (NREM) sleep. REM sleep is generally associated with dreaming together with lability of heart rate, blood pressure and respiration. Brain metabolism is highest in this stage of sleep, with a low-voltage, mixed-frequency non-α electroencephalogram (EEG). Spontaneous rapid eye movements are seen and skeletal muscle tone is virtually absent. REM sleep makes up ~25% of total sleep time in adults and it is when most dreaming occurs. REM sleep episodes occur in ~90 min cycles, with each episode increasing in duration as the night progresses. It is sometimes known as paradoxical sleep since the EEG is most like wakefulness and yet there is very little physical activity.

NREM sleep is subdivided into four stages of increasing depth and dominates the first half of a normal night. Stage 1 occurs at sleep onset or following arousal from another stage of sleep. The EEG is of low voltage with mixed frequencies and reduced α-activity compared with the awake state. It makes up ~5% of the total sleep time. Stage 2 contains more slow-wave activity and sleep spindles and K complexes are seen. It makes up ~50% of overnight sleep. Stage 3, also about 5% of sleep time, is yet more slow-wave EEG activity and stage 4 is the slowest activity and makes up ~15% of sleep. Together, stages 3 and 4 are known as slow-wave sleep. These are the deepest forms of sleep from which awakening is especially difficult. Arousal disorders such as sleep-walking and confusional arousals arise

Table 54.1 Common sleep problems and their treatments in the elderly.

Sleep disorder	Clinical features	Diagnostic method	Treatment	Comments
Sleep apnoea	Reports of stopping breathing for short periods during sleep; daytime sleepiness; loud snoring; obesity	History; physical examination; polysomnography	CPAP; weight loss	Intermittent airway closure; more common in men; sedatives unhelpful
Restless legs syndrome	Motor restlessness; pacing at night	History	Dopaminergics; benzodiazepines	More common with iron deficiency; PLMD often also present
Periodic limb movement disorder	Legs kicking in sleep; arousals from sleep; daytime sleepiness	Polysomnography	Dopaminergics	May extend to other muscle groups; may occur during wakefulness also
REM sleep behaviour disorder	Apparent acting-out of dreams	History and polysomnography	Clonazepam	Mostly idiopathic; injury to bed-partner should be considered
Advanced sleep phase	Falling asleep and waking too early	History/diary (with actigraphy)	Psychological; bright light; (melatonin)	More common in institutionalized elderly
The insomnias	Difficulty initiating or maintaining sleep	History/diary (with actigraphy)	Psychological; medication (for acute insomnia only)	Consider the type of insomnia with medication

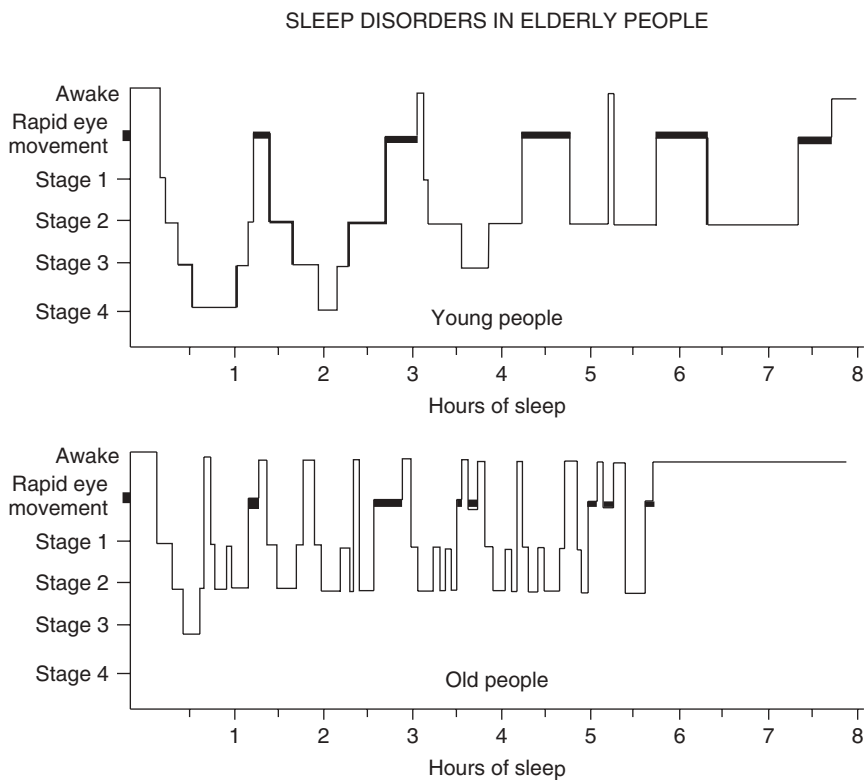

Figure 54.1 Sleep hypnogram for a young adult and an 80-year-old. Horizontal axis = time; vertical axis = sleep stage. These subjects fall from wakefulness into slow-wave non-REM sleep in stages 1–4 before their first REM phase where most dreaming occurs. The first half of the night is dominated by slow-wave sleep and the second half by REM sleep. Thus, a patient who is limiting their sleep is more likely to be deficient in REM sleep and, therefore, more likely to have cognitive difficulties. Note the shorter, more fragmented sleep in the elderly compared with the young adult.

in slow-wave sleep. These sleep stages are summarized in Figure 54.1, which shows a summative hypnogram for a 25-year-old adult and an otherwise healthy 80-year-old person for comparison.

The most striking differences are that the younger person sleeps for a longer time, with fewer wakes during the night. The elderly person sleeps less and this sleep is highly fragmented with many arousals, some of which are for a considerable time. The older person also has very much less deep NREM sleep. Whether the older person needs less sleep at night or simply cannot get it is not currently known, but it may go some way in explaining why high levels of daytime sleepiness in the elderly is so common.[2] Overall, it can be seen that sleep efficiency (the ratio of time asleep to time in bed) has fallen. The reduction in deep sleep and its replacement with lighter stage 2 sleep is of clinical significance as it is reflected in perception of sleep quality.[33]

The noise threshold required to waken an older person appears to be lower than in younger adults despite reductions in hearing sensitivity,[34] although a study looking at this issue in people living near Heathrow Airport indicated that bed-partner behaviour was more influential than noise.[35] Perhaps the elderly have a general increase in sensitivity to external stimuli, which decreases sleep quality.

Whether these sleep problems are related to gender is not yet properly understood. It appears that women report more sleep problems, although men have objectively more disordered sleep. This may be due to women reporting their sleep problems more frequently.[36]

The timing of sleep in the elderly is often phase advanced, that is, they generally go to sleep early and wake up earlier than they would like. The early morning waking may lead to sleep deprivation and excessive daytime sleepiness. Conversely, some older people may develop a phase delay, that is, becoming 'night owls' with bedtime delayed until late. This behaviour may have been accommodated in youth when the cues of bright morning light and other environmental influences were stronger; however, deterioration of light perception has weakened these cues. These patients may go on to develop very irregular sleep–wake cycles, which can be difficult to treat.

Dementia

Dementia presents additional challenges to physicians because many of the sleep changes seen in the normal ageing population are amplified. Compared with controls, older people with dementia have a longer sleep latency (time between going to bed and getting to sleep), wake up in the night more frequently and for longer periods and are more likely to fall asleep during the day.[37–39] Circadian rhythm problems are also more common and 10% of older people with dementia actually sleep more

during the day than during the night. These changes are often accompanied by episodes of night-time agitation and sundowning, which are among the most common reasons for admission to a nursing home.[40] While there is some evidence of a possible link between sleep problems and dementia,[37] individual differences are great and do not discriminate effectively between dementia and non-dementia patients. The possible causal mechanism is thought to include a degeneration of the neurons in the suprachiasmatic nuclei. Whatever the organic origin, it is likely that behavioural factors will influence sleep problems. There is good evidence that a regular day–night pattern of activity with minimal naps and optimal daytime stimulation is helpful. An exhausted carer leaving their demented relative to sleep during the day in order to give themselves a much-needed break may make life considerably worse in both the short and medium term.

Sleep disturbances in the elderly with dementia should be treated according to the specific disorder and symptom.[7]

Institutionalization

The link between institutionalized living and sleep disturbance is perhaps best demonstrated by the high levels of hypnotic drug consumption that have been found in hospitals and nursing homes.[41] Within these institutions, sleep disturbance may be related to the act of admission itself. A period of adjustment may be required (3–4 days), as is common in many other settings where people do not sleep normally when their usual night-time environment changes. Hypnotics should not be prescribed for people who cannot sleep in a new institution unless they also have other problems. Moving to an institution is likely to be contemporaneous with a life event such as the death of a partner, discomfort or pain, any of which may have a negative effect on sleep. Noise has been shown to be a significant factor in the sleep of the institutionalized elderly and, often, noise levels in such homes are excessive. Institutions that fail to stimulate residents during the day and that have routines that are not conducive to sleep may be more likely to have sleep-disordered residents.

Assessment

As sleep can be influenced by medical conditions, chronic diseases, psychiatric disorders, medications and a host of other conditions, the first step in treating sleep disturbances in the elderly is to identify or assess the underlying problem.[42] Subjective enquiries about the sleep of elderly patients should be made routinely as they are at special risk of sleep disorders, which they tend to under-report and see as normal and untreatable. More detail on the assessment of sleep disorders can be found elsewhere.[43]

All patients should be screened by being asked whether they sleep enough and whether their sleep is of good quality. They should be asked if they are sleepy during the day and whether their nocturnal sleep is disturbed at all. Information may be corroborated by carers or bed-partners. If any of these enquiries are positive, a fuller sleep history should be taken. This should include details of the nature of the sleep complaint, its onset and so on. Contributing factors and patterns of occurrence should be explored. The impacts of both sleep problems and previous treatments on patients and their families should be assessed. Patients should be taken through their 24 h schedules, which may elicit helpful information about timing and other aspects of their sleep. If justified, clinicians may then consider giving patients sleep diaries to complete. Sleep diaries can be helpful in understanding the times a patient goes to bed, gets to sleep, wakes in the night, wakes in the morning and gets up. Using sleep diaries, estimates can be made of sleep latency and efficiency (times between getting to bed and getting to sleep and ratio of time asleep to time in bed, respectively). There are many versions of sleep diaries available (for an example, see http://science.education.nih.gov/supplements/nih3/sleep/guide/nih_sleep_masters.pdf), but it may be helpful to customize one to attend to the particularly relevant points raised in the clinical interview. An example diary is given as Figure 54.2.

From the physical examination, attention should be paid to any systemic illness, including cardiorespiratory disease or neurological disorder such as Parkinson's disease or stroke, which may disturb sleep. Obesity or craniofacial abnormalities may suggest upper airway obstruction and any psychiatric problems (particularly depression and anxiety) should be noted during the physical examination.

Objective investigations of sleep are not justified for all sleep disorders.[44] The main indications for them are sleep apnoea, narcolepsy or periodic limb movements (PLMs). If details of parasomnias (such as REM-sleep behaviour

Day of the week	Example day
When did you rise from bed this morning?	8 a.m.
What time did you get into bed last night?	Midnight
How long did it take you to fall asleep? (min)	45 min
How many times did you wake during the night?	3
How long was each wake during the night? (mins)	10, 10, 20
How long did you sleep altogether? (h min)	6 h 35 min
How much alcohol (if any) did you drink last night?	1 glass wine
How many sleeping pills, if any, did you take to help you sleep last night?	None
How much caffeine did you consume yesterday? (tea, coffee, coke etc.)	2 cappuccinos, 1 tin Coke

Figure 54.2 Sleep diary.

disorder) are unclear from clinical interview, an objective check on the clinical impression is required. Generally, objective investigation is in the form of polysomnography (PSG) in a sleep laboratory, although home PSG is becoming better established and validated. When this is more accepted and widely available, home PSG may diminish the so-called *first night effect*, which is common when patients spend their first night in a sleep laboratory. PSG studies should include an EEG, an electrooculogram and an electromyogram in order to compile an overnight hypnogram such as in Figure 54.1.

Commonly, PSG is extended to include respiratory variables where sleep-related breathing disorders (SRBD) are suspected and anterior tibialis electromyogram if period limb movements of restless leg syndrome (RLS) are suspected.

Alternative objective measurements of sleep can be made using actigraphy, small wristwatch-sized motion detectors that distinguish wake and sleep and so are useful for circadian rhythm disorders and insomnia.[45]

Diagnosis and treatment

In general, current evidence indicates that non-pharmacological treatments, such as cognitive behavioural therapy (CBT) or sleep education, are more effective in the treatment of sleep disturbances in the elderly.[23,25,46] Bright light therapy and physical exercise have also been shown to be effective in improving sleep outcomes in the elderly.[47,48] Although some evidence supports the use of pharmacology in the treatment of selected sleep disorders, most studies are limited by small, mixed samples and short trial periods of a few days.[23] The most prevalent sleep disorders and their relative treatment options will be considered in greater detail here.

Apnoea, sleep-related breathing disorders (SRBD)

The most common sleep-related breathing problems are apnoeas (temporary cessations of breathing) and hypopnoeas (a form of shallow rapid breathing). They can be due to an occlusion of the airway (obstructive sleep apnoea) or reduced respiratory drive (central sleep apnoea). The most obvious features of these are stopping of breathing followed by gasps for breath during sleep episodes and excessive daytime sleepiness, both of which increase with age. These events can occur hundreds of times each night and commonly impair daytime functioning significantly because the patient is aroused during each episode and is, therefore, deprived of sleep and deep NREM sleep. The main risk factors for apnoea are male gender and obesity.

The clinical importance of SRBD is substantially demonstrated by numerous studies over the past 30 years. The presence of five or more apnoeic episodes per hour is generally considered pathological. It has been reported that one in 10 adults aged between 30 and 60 years stops breathing 10 or more times per hour, whereas 60% of people aged over 65 years do this.[49,50] The reasons for this may be due to the elderly having physiological changes such as longer soft palates, larger pharyngeal fat pads and lower response of genioglossal muscle to negative pressure stimulation.[51] An Australian study[52] reported that 72% of patients with dementia had clinically significant apnoea (>5 events per hour) compared with 46% of controls. Oxygen desaturation experienced during apnoeas may compromise neuropsychological functioning in dementing illness, although reports of this vary in the literature.[53] Sleep apnoea patients who also have congestive heart failure have a mean survival time of less than 2.71 years compared with 4.04 years in patients with congestive heart failure alone.[54]

Patients suspected of having sleep apnoea may be evaluated in a sleep laboratory where monitoring of the electroencephalogram, blood oxygen saturation, airflow and chest and abdomen respiratory efforts can be performed to confirm the diagnosis.

The treatments of choice for sleep apnoea are continuous positive airways pressure (CPAP), which requires a device that pushes air into the airway to keep it open at night, positive airway pressure (PAP) therapy, bilevel PAP, autotitrating CPAP or autotitrating bilevel PAP.[55] These devices have been found acceptable in older patients, including those with mild Alzheimer's disease. In this latter group, snoring and daytime sleepiness were reduced; depressive symptoms in both patients and carers improved.

Oral appliances that move the mandible forward or pull the tongue forward during the night may also be used to treat sleep apnoea. However, these do not always work well with dentures and may not be appropriate for all older adults. Avoiding alcohol and hypnotics can be helpful as these are respiratory depressants. Weight loss may be an effective intervention since obesity is one of the biggest predictors of apnoea. Changing sleep position from the back to the side can be effective if it can be shown that the apnoeas occur only when patients sleep on their backs. Surgical interventions are not usually recommended because of the possible risks and complications.

Periodic limb movements in sleep (PLMs) and restless leg syndrome (RLS)

PLMs is a condition in which the legs kick or jerk for between 0.5 and 5 s at 4–90 s intervals throughout the night. PLMs causes fragmented sleep (especially the loss of deeper slow-wave sleep) and patients report insomnia and excessive daytime sleepiness. This idiopathic disorder also increases with increasing age,[56] with prevalence among

elderly people living at home at about 45% and with the prevalence of restless leg syndrome in older adults almost doubling from its 10% prevalence in younger adults.[57,58] However, not all people with PLMs experience disturbed sleep, although the quality of their sleep can be greatly impaired by this disorder, which usually comes to light from partner complaints.

RLS is a related disorder where patients experience irritating 'creepy–crawly' leg sensations that are relieved only by moving the legs. It can occur prior to sleep onset and in the daytime when the person is relaxed. RLS can significantly interfere with the onset of sleep. Risk factors for both PLMs and RLS include not only increasing age but also renal failure and iron deficiency (serum ferritin level $<50\,n\,ml^{-1}$). Both disorders can be diagnosed from patient and partner reports of these clinical symptoms and confirmed by electromyography in a sleep laboratory if necessary.

Both PLMs and RLS can be treated with medication, usually carbidopa–levodopa (25–100 mg) and other dopaminergic agents. Comorbid low iron level may need to be corrected for a satisfactory response. Pergolide, at a very low dose (0.05–0.5 mg), has also been used for these disorders. Some patients report that soaking the legs and feet in a warm bath or taking regular exercise provides some relief.

REM-sleep behaviour disorder (RBD)

REM-sleep behaviour disorder is a rare condition that occurs mostly in the elderly and primarily in men.[59,60] In patients with RBD, muscle tone is preserved in REM sleep; patients may be able to act out their dreams. In suspected cases, patients should be seen urgently because they risk harming themselves and those around them. Treatment at bedtime with a low dose of a long-acting benzodiazepine such as clonazepam is generally effective. Clonzapem has been shown in non-randomized trials to result in partial or complete cessation of abnormal nocturnal motor movements in 90% of patients.[61]

Circadian rhythm disorders

In adults with normal circadian rhythms, sleepiness occurs at around 11 p.m. and persists for around 8 h. This period is associated with a decrease in core body temperature, which is thought to be a cause of sleepiness. These cycles are thought to be related to changes in the levels of light. As ageing occurs, the circadian rhythm seems to advance so that sleepiness occurs earlier in the evening and morning waking occurs correspondingly earlier. Most older adults try to stay awake even though they feel sleepy in the early part of the evening. However, they still wake up earlier as their core body temperature rises, leading to sleep deficiency and excessive daytime sleepiness and/or naps during the day. Some elderly people doze off in the early evening, have sleep onset problems at bedtime and wake early; this cycle may impair their daytime functioning still further. These sleep phase problems are common in many groups of patients, notably visually impaired people, and treatment of these problems can be difficult as these dysfunctional patterns of sleep can become entrenched.

Treatment of advanced sleep phase (sleeping too early) involves delaying the sleep cycle. Strong social and environmental cues such as meals at regular times, exposure to light and exercise are most important. This may be accomplished artificially using bright light, although evidence for this intervention is limited in patients both with and without dementia.[47] Usually, a light source of at least 10 000 lux (which is far greater than is normal indoors) should be used late in the day (say 4 p.m.). Light exposure may delay the circadian rhythm so patients become sleepy later in the evening and sleep later in the morning, also improving their sleep continuity. Both healthy community-living older adults and nursing home patients have been found to delay their circadian rhythms successfully and improve their wake–sleep cycle through evening light exposure.[62,63] If patients continue to wake early and want to go outdoors, they should be encouraged to wear sunglasses lest the early light exposure shifts their sleep phase still earlier. Bright light treatment is, however, contraindicated in patients with mania. Alternative treatments include melatonin, which is a hormone released by the pineal gland. Convincing research evidence here is even more limited. There is little consensus regarding effective dosage, but some studies purport that melatonin replacement therapy may also improve sleep efficiency in the elderly.[64–67] An intervention employing bright light therapy and melatonin treatment has also been tested in elderly patients with dementia and shown to improve some cognitive and non-cognitive symptoms of dementia and also sleep efficiency.[68] According to systematic review and meta-analysis, the short-term use of melatonin is not effective in treating most primary sleep disorders, but may be effective in treating delayed sleep phase syndrome and circadian rhythm disorders.[69] As there is no evidence regarding the safety of long-term use, however, clinicians should exercise caution in its prescription.

The insomnias

According to a recent cross-sectional study of prevalence, primary insomnia affects approximately one-fifth of people over the age of 65 years. It is also more frequent in females and related to the coexistence of other health problems, medication and inadequate sleep hygiene.[70] The

International Classification of Sleep Disorders[19] defines 11 subtypes of insomnia, that is, disorders of initiating or maintaining sleep. However, in day-to-day practice, the technology required to diagnose each of them precisely limits the value of this system. It is, nevertheless, important to consider the type of insomnia with which the patient presents. The main types are psychophysiological insomnia (with psychosomatic arousal, excessive concern about sleep adequacy and somatized tension), inadequate sleep hygiene (where the sleep problem appears to be caused or maintained by dysfunctional practices around sleep) and sleep-state misperception (where the insomnia diagnosis is not supported by objective findings).

A wide range of medical conditions is associated with the insomnias, including arthritis and cancer. Neurological problems such as dementia, RLS and Parkinson's disease are also associated with it and, in the elderly, congestive heart failure, asthma, gastroesophageal reflux, urinary incontinence, nocturia and benign prostatic hyperplasia are commonly comorbid with insomnia. Depression is strongly linked with insomnia in both directions, that is, as both cause and effect. Anxiety disorders, prevalent in the elderly, may in part be caused by bereavement, social changes and relocation, but insomnia is associated with all of them. Overall, about 20% of patients with insomnia have depression and about 90% of patients with depression report a sleep disturbance.[7] There are several drugs that cause insomnia, including alcohol, nicotine, CNS stimulants, β-blockers, corticosteroids, bronchodilators, calcium channel blockers and thyroid hormones. Alcohol is often used to induce sleep, but its effect is short-lived and leads to early waking. Adjusting the dose or time of day when medications are taken can improve a patient's insomnia; for example, wake-promoting drugs could be taken earlier in the day and sedating drugs later.

Evaluation of insomnia should be based on a good sleep history, augmented by a sleep diary and a physical examination. Initially, medical and psychiatric problems should receive attention and, if the insomnia remains, identification of an underlying cause should be attempted before direct treatment for insomnia is indicated. Non-pharmacological treatments such as sleep hygiene and education integrated into a cognitive behavioural framework have been shown to be effective in the treatment of insomnia[10,71] and should be considered first for chronic insomnia to reduce polypharmacy especially in view of the other drugs commonly taken by the elderly.[46] Sleep hygiene should aim to establish: regular sleep and wake times; avoidance of excessive time in bed awake (sleep restriction); stimulus control in the form of a clear routine leading up to sleep; daily activity and exercise; appropriate use of caffeine (avoidance after 4 p.m.); limited alcohol and nicotine use; and elimination of loud noise, excessive light and uncomfortable room temperature. Inaccurate attributions should be challenged and corrected about what sleep is, how common problems can be and how sleep changes with age. Even if poor sleep habits are not responsible for insomnia, the elimination of such habits will avoid their role in the maintenance of the problem.

There is some evidence from other populations that written information can be an effective way of delivering these sorts of treatments, although no good trials have been conducted with the elderly.[72] Further studies with other populations have shown that the concurrent treatment of comorbid conditions (i.e. depression and insomnia) can lead to better overall response.[73] Cognitive behavioural intervention for insomnia includes stimulus control, aiming to set up conditions conducive to sleep for the patient. It typically involves removing any sleep-incompatible stimuli from the bedroom and the patient is told to get up if not asleep within 20 min of getting into bed. It is essentially a conditioning treatment that develops strong associations between the bedroom and sleep while extinguishing associations between sleep and any other place. CBT, in the treatment of insomnia, has been shown to be equally effective as pharmacology with better long-term outcomes,[10,23,74,75] and also to improve pharmacological outcomes.[76] As such, CBT has been deemed the most effective treatment for insomnia.[71].

Sleep restriction limits the amount of sleep to the length of time that the person is likely to sleep. It aims to improve sleep efficiency (ratio of time asleep to time in bed) by either increasing time asleep or reducing time in bed. Most patients want to increase their time in bed, even though this may not be physiologically necessary. By asking patients to use a sleep diary carefully, sleep efficiency can be calculated and sleep compressed and, if necessary, expanded later provided that efficiency is maintained. It can be difficult to persuade elderly patients to accept this treatment as it is based on a key time when they must get up, however little sleep they may have had. In this way, their increasing tiredness will increase the drive for sleep.

Other cognitive behavioural techniques currently with less (although increasing) research evidence to support them include imagery and relaxation, paradoxical intention and thought suppression. Daily exercise is thought to be important in promoting good sleep, although firm evidence for it is again limited.[48]

In acute insomnia, some patients may benefit from short-term use of sleep-promoting medications.[77] Over-the-counter antihistamines should be used with caution because of their long duration of action and their anticholinergic effects in the elderly. These may cause confusion, constipation and urinary retention.[78] Furthermore, the NIH 71

Table 54.2 Common pharmacological options.

Agent	Dose/timing	Comments
Non-benzodiazepine hypnotics		
Zolpidem tartrate (Ambien)	5–10 mg at bedtime	Can be used for sleep-onset and maintenance insomnia (as half-life is 1.5–4.5 h)
Zaleplon (Sonata)	5–10 mg at bedtime	Can be used for sleep-onset and maintenance insomnia (as half-life is 1 h)
Benzodiazepines		
Temazepam (Restoril)	7.5 mg	Exclude obstructive sleep apnoea before prescribing
Antidepressants for insomnia and depression		
Sertraline.HCl (Zoloft)	50 mg in the morning	Well tolerated
Fluoxetine.HCl (Sarafem)	20 mg in the morning	As for sertraline; however, consider lower doses in patients over 65 years old with concurrent disease or multiple medications
Mirtazepine	15 mg at bedtime	For use with depression and severe insomnia and anxiety

conference concluded that owing to the lack of systematic evidence and the potential risk of adverse effects, the use of antihistamines is not recommended, particularly for older adults. Among the hypnotics, the treatment of choice is a short-acting benzodiazepine receptor agonist. Short-term use and low doses are recommended.[79] Occasional use reduces the possibility of withdrawal effects. The option to use such a drug may reduce anxiety about sleep in the patient and therefore be beneficial. In cases of excessive daytime sleepiness, referral to a sleep specialist is indicated, as this symptom can be dangerous.

The choice of sedative–hypnotic agent for insomnia should be based on issues of efficacy, including whether it consolidates fragmented sleep, whether it can be administered at different times in the night and the effect on next-day functioning. Thus, a short half-life with few withdrawal symptoms and minimal adverse events with no tolerance should be key considerations. Some common options are listed in Table 54.2.

It should be stressed that among a physician's first set of treatment goals should be the improvement of sleep hygiene in the patient, moving on to drug treatment only if this proves insufficient. The following drug treatments have been shown to be effective in older adults with a low propensity for causing withdrawal, dependence, tolerance or clinical residual effect: the newer selective short-acting type-1 GABA benzodiazepine receptor agonists (BzRAs), including zolpidem[80–82] and zaleplon.[83,84] The primary effects involve decreasing sleep onset time and/or increasing total sleep time.

Key points

- It is necessary to ask directly about sleep problems lest they go unnoticed and untreated. Carefully considered sleep diaries and histories are essential diagnostic tools in this area.
- Non-pharmacological interventions such as sleep hygiene and cognitive behavioural treatments should be considered first.
- In dementia, encouraging a regular schedule including exercise and light meals (especially later in the day) but excluding alcohol and caffeine in the evening is helpful.
- Comorbid problems such as pain or depression and current medications should be considered as possible causes.
- Short half-life medications such as zolpidem and zaleplon may be considered for short-term use.

CHAPTER 55

Headache

Stephen D. Silberstein and William B. Young
Thomas Jefferson University, Philadelphia, PA, USA

Introduction

The International Headache Society (IHS) classification, ICHD-II,[1] divides headaches into two broad categories: primary and secondary headache disorders. Secondary headaches are attributed to another disease and can be caused by intracranial or extracranial structural abnormalities or by systemic or metabolic conditions. In the primary headache disorders, the headache itself is the illness (Table 55.1). The primary headache disorders include migraine, tension-type headache (TTH) and trigeminal autonomic cephalalgias (including cluster headache). Migraine is further subdivided into two groups: migraine with and without aura. TTH is subclassified as either episodic tension-type headache (ETTH) or chronic tension-type headache (CTTH). Cluster headache is similarly divided into the episodic and chronic varieties. Chronic daily headache (CDH), a term in common use, is subclassified into CTTH, chronic migraine (CM), hemicrania continua (HC) and new daily persistent headache (NDPH), and is often associated with acute medication overuse.

Headache prevalence is age dependent. Migraine prevalence peaks near age 40 years and declines afterward (Figure 55.1). With ageing, not only is there a change in prevalence of the primary headache disorder but also a shift to new or organic causes of headache.[2] Migraine incidence and prevalence decrease, whereas brain tumours, subdural haematomas and other structural causes of headache increase. Elderly patients have more comorbid medical illness and some headache disorders, such as giant cell arteritis (GCA), occur principally in the elderly (Table 55.2).

Headache is common in the elderly. The 1 year prevalence of headache in an elderly Italian population (aged 55–94 years) was 40.5%; TTH 45.8%, migraine headache 5.7% and trigeminal neuralgia 1.6% In this population, headaches caused significant impairment of health-related quality of life.[3] The complaint of 'frequent headache' was found in 11% of elderly women and 5% of elderly men participating in a health screening programme; however, these patients were commonly found to have other diseases or somatic or psychological symptoms.[2] These facts justify a lowered threshold for ordering tests when older patients present with headache, particularly if the headaches are of recent onset, are atypical or are associated with neurological findings. Headaches that begin after age 65 years are more often secondary.

The evaluation of the elderly patient with headache must be directed to rule out serious secondary causes of headache such as tumour, subdural haematoma, stroke, transient ischaemic attack and giant cell arteritis. In the elderly patient, when the diagnosis is not obvious, neuroimaging and a sedimentation rate should be considered[2] (Table 55.3). In this chapter, we discuss the primary headache disorders as they relate to the older patient, some of the more important secondary headache disorders and finally cranial neuralgias.

Diagnosis and clinical description of headaches

The criteria for headache diagnosis were updated by the IHS in 2004.[1] The first step in establishing a diagnosis is a complete history, which should include the following information: the age at headache onset; the time of onset (day, season); the location, severity and type of pain; the attack frequency (including any change in frequency); associated symptoms; precipitating and relieving factors; the patient's sleep habits; and the family history. In addition, a complete medication history should be taken to evaluate the doses, duration of use and effectiveness of previous headache medications, and also to determine if any medications that could exacerbate headaches are being used or overused.

The patient should keep a diary to record any changes in headache between office visits, especially if medication was modified. A diary will make the patient more aware of the disease process and also help the physician to evaluate

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 55.1 IHS migraine classification.

1 Migraine
- 1.1 Migraine without aura
- 1.2 Migraine with aura
  - 1.2.1 Typical aura with migraine headache
  - 1.2.2 Typical aura with non-migraine headache
  - 1.2.3 Typical aura without headache
  - 1.2.4 Familial hemiplegic migraine (FHM)
  - 1.2.5 Sporadic hemiplegic migraine
  - 1.2.6 Basilar-type migraine
- 1.3 Childhood periodic syndromes that are commonly precursors of migraine
  - 1.3.1 Cyclical vomiting
  - 1.3.2 Abdominal migraine
  - 1.3.3 Benign paroxysmal vertigo of childhood
- 1.4 Retinal migraine
- 1.5 Complications of migraine
  - 1.5.1 Chronic migraine
  - 1.5.2 Status migrainosus
  - 1.5.3 Persistent aura without infarction
  - 1.5.4 Migrainous infarction
  - 1.5.5 Migraine-triggered seizures
- 1.6 Probable migraine
  - 1.6.1 Probable migraine without aura
  - 1.6.2 Probable migraine with aura
  - 1.6.5 Probable chronic migraine

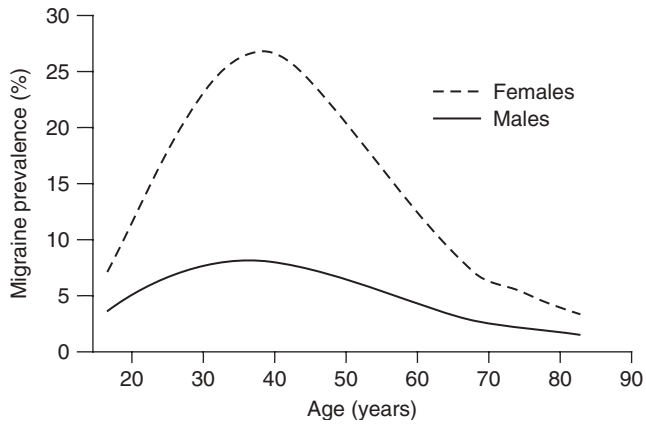

Figure 55.1 Migraine prevalence by age. Prevalence increased from 12 to 38 years of age in both women and men; the peak was considerably higher among women. Reprinted from S.D. Silberstein and R.B. Lipton, Headache epidemiology: emphasis on migraine. *Neurologic Clinics*, 1996;**14**:421–34, Copyright 1996, with permission from Elsevier.

the effectiveness and adverse effects of treatment. Patients should bring their medications with them periodically to check for compliance and to see if other physicians have prescribed any additional medications.

Table 55.2 Headache in the elderly.

Less common	Equally common	More common	Typically in the elderly
Migraine	Cluster headache	Intracranial lesions	Giant cell arteritis
Tension-type headache	Cervicogenic headaches	Medication-induced (except rebound)	Hypnic headache
		'Metabolic headache'	Headache of Parkinson's disease
		Anaemia	Trigeminal neuralgia
		Hypoxia	
		Hypercalcaemia	
		Hyponatraemia	
		Chronic renal failure	
		Cerebrovascular disease	

Table 55.3 Worrisome headache flags (SNOOP).

System symptoms (fever, weight loss) or
Secondary risk factors (HIV, systemic cancer)
Neurological symptoms or abnormal signs (confusion, impaired alertness or consciousness)
Onset – sudden, abrupt or split-second
Older – new onset and progressive headache, especially in middle-age >50 years (giant cell arteritis)
Previous headache history – first headache or different (change in attack frequency, severity or clinical features)

Primary headaches in the elderly

Migraine

Migraine occurs in 18% of women, 6% of men and 4% of children in the USA;[4] 62% of migraineurs also have TTH. Migraine usually begins in the first three decades of life and prevalence peaks in the fifth decade. The prognosis for migraine sufferers is good, since migraine prevalence decreases with increasing age. Although migraine can begin after age 50 years, a secondary organic cause must be considered when this occurs. In one study, only one of 193 patients with headache beginning after age 65 years had migraine. Cull[5] collected 10 patients with migraine onset after age 60 years, two of whom had strokes on computed tomography (CT) finding. The ratio of migraine with aura to migraine without aura was reversed (86%:14%) among new onset migraine patients older than age 40 years.

Whether this is due to referral patterns or biological factors is uncertain.

Migraine prevalence decreases with menopause, although the prevalence does not fall to premenarchal levels. The frequency of migraine aura without headache (migraine equivalents) in the elderly is unknown. In community-based studies, migraine prevalence varied from 0.3% in China (age >70 years) to 12% in Boston (age >65 years). In some, but not all, studies migraine prevalence continued to decrease in the very elderly.[4]

Clinical features of migraine

Migraine is an episodic headache disorder whose diagnosis depends on the characteristics of the pain and associated features. The ICHD-II criteria for migraine without aura (Table 55.4) require the patient to have at least five headache attacks.[1] With time, the associated symptoms of migraine decrease, in part accounting for the decrease in migraine prevalence, since the headaches may no longer meet ICHD-II migraine criteria. The migraine aura may occur without the headache and migraine may remit or become transformed into CM (with or without medication overuse).

A diagnosis of migraine with aura (classic migraine) requires the patient to have at least two attacks with at least three of the characteristics listed in Table 55.5. If the aura lasts longer than 1 h but less than 1 week, the condition is called *migraine with prolonged aura*.[1] Migraine is more than just an aura and a headache. Some patients have four phases: the premonitory phase, the aura, the headache and the postdrome. About 60% of patients have a prodrome, which occurs hours to days before the headache. During this time, patients may have various psychological, sensory, constitutional or autonomic symptoms. Not all patients experience a prodrome, but if they do, their prodromal symptoms are usually the same each time. The symptoms can continue into the aura and headache phases.[6] The aura develops over 5–20 min, lasts from 20 to 30 min and consists of focal neurological symptoms that accompany the headache or occur up to 1 h before it begins. About 20% of migraineurs experience an aura, which may be visual, sensory or motor or involve speech disturbances. Visual symptoms are the most common and include scintillations (fluorescent flashes of light in the visual field), fortification spectra or teichopsia (alternating light and dark lines in the visual field), photopsia (flashing lights) and positive (bright geometric lights in the visual field) and negative (blind spots that may move across the visual field) scotomata. Sensory symptoms include numbness, tingling or paraesthesias of the face or hand.

Motor symptoms are usually hemiparetic, while language disturbances consist of difficulty in speaking (aphasia) or understanding.[6] The headache can begin at any time during the day. The pain usually develops gradually and then subsides after 4–72 h. A headache lasting longer than 72 h defines status migrainosus. The pain is usually located in the temples, but it can occur anywhere in the face or head

Table 55.4 Migraine without aura.

Diagnostic criteria

A At least 5 attacks fulfilling criteria B–D
B Headache attacks lasting 4–72 h (untreated or unsuccessfully treated)
C Headache has at least two of the following characteristics:
  1 Unilateral location
  2 Pulsating quality
  3 Moderate or severe pain intensity
  4 Aggravation by or causing avoidance of routine physical activity (e.g. walking or climbing stairs)
D During headache at least one of the following:
  1 Nausea and/or vomiting
  2 Photophobia and phonophobia
E Not attributed to another disorder

Table 55.5 Migraine with aura.

Diagnostic criteria

A At least 2 attacks fulfilling criterion B
B Migraine aura fulfilling criteria B and C for one of the subforms 1.2.1–1.2.6
C Not attributed to another disorder

1.2.1 Typical aura with migraine headache

Diagnostic criteria

A At least 2 attacks fulfilling criteria B–D
B Aura consisting of at least one of the following, but no motor weakness
  1 Fully reversible visual symptoms including positive features (e.g. flickering lights, spots or lines) and/or negative features (i.e. loss of vision)
  2 Fully reversible sensory symptoms including positive features (i.e. pins and needles) and/or negative features (i.e. numbness)
  3 Fully reversible dysphasic speech disturbance
C At least two of the following:
  1 Homonymous visual symptoms and/or unilateral sensory symptoms
  2 At least one aura symptom develops gradually over ≥ 5 min and/or different aura symptoms occur in succession over ≥ 5 min
  3 Each symptom lasts ≥ 5 and ≤ 60 min
D Headache fulfilling criteria B–D for 1.1 *Migraine without aura* begins during the aura or follows aura within 60 min
E Not attributed to another disorder

and may radiate down the neck and shoulder. The pain is moderate to severe in intensity and usually described as throbbing or pulsating. Pain is usually unilateral, but may begin as or become bilateral. Strictly unilateral headaches are not of concern since they occur in 20% of migraineurs. Accompanying symptoms are common: most patients are anorectic and have nausea; some vomit or have diarrhoea. Photophobia and phonophobia cause patients to seek relief in a dark, quiet room to decrease sensory stimulation. Most patients have 1–4 attacks per month. After the headache phase, some patients experience a postdrome or recovery phase that may last up to 24 h. Some patients feel tired, others feel alert, some feel depressed, others feel euphoric, some feel worn out, and some feel refreshed. Some may complain of poor concentration, food intolerance or scalp tenderness. Medications that are more commonly used by the elderly may exacerbate or trigger migraine. Analgesic, ergotamine or triptan overuse can cause CDH in patients of all ages. Nitroglycerine and other nitrates may exacerbate migraine. Estrogen replacement therapy may either exacerbate or ameliorate migraine. Reserpine, an antihypertensive agent, is a recognized migraine trigger.

Migraine equivalents of the elderly

In the elderly, migraine aura without headache (acephalic migraine) is also called *late-life migraine accompaniments*. It may occur for the first time in a patient over the age of 40 years.[7] Its diagnosis is particularly treacherous in patients with no prior history of migraine and should be made by exclusion unless the symptoms are pathognomonic of the migraine aura (e.g. scintillating scotomata lasting 30 min). Features are listed in Table 55.6. The headaches are usually absent or mild, if present at all, and neuroimaging is normal. The IHS diagnostic criteria are the same as in Table 55.5, migraine with aura, except for no headache.[1] Cerebrovascular disease (cerebral embolism or thrombosis, carotid or vertebral dissection, subclavian steal syndrome), epilepsy, polycythaemia, lupus anticoagulant, hyperviscosity syndrome and psychiatric spells must always be considered in the differential diagnosis and must be ruled out by the appropriate studies.[2] A syndrome of recurrent somatosensory aura, sometimes followed by a headache and associated with small cortical subarachnoid haemorrhage, has recently been described; 3–7 episodes occurred over 2 days to 5 months.[8]

Table 55.6 Migraine equivalents.

1	Gradual appearance of focal neurological symptoms' spread or intensification over a period of minutes
2	Positive visual symptoms characteristic of 'classic' migraine, specifically fortification spectra (scintillating scotoma), flashing lights, dazzles
3	Previous similar symptoms associated with a more severe headache
4	Serial progression from one accompaniment to another
5	The occurrence of two or more identical spells
6	A duration of 15–25 min
7	Occurrence of a 'flurry' of accompaniments
8	A generally benign course without permanent sequelae

Table 55.7 Migraine treatment.

Acute (symptomatic)	
	Specific – for migraine only
	Non-specific – for any pain disorder or associated symptoms
Preventive (prophylactic)	
	Pre-emptive – immediately prior to triggering event
	Short-term – for a limited time
	Chronic – continuous

Treatment of migraine headache in the elderly

Headache treatment begins with making the diagnosis and explaining it to the patient, since all treatment depends on establishing a therapeutic relationship. Drug treatment may be acute, preventive or both, supplemented by nonpharmacological treatment (Table 55.7). Acute migraine treatments are listed in Table 55.8. Because of an increased risk of cardiovascular disease, ergot alkaloids, triptans and other vasoconstrictors, such as isometheptane mucate (present in Midrin), must be used with caution, if at all, in the elderly. Benzodiazepines and barbiturates may cause excessive sedation; the long-acting benzodiazepines, in particular, may cause excessive side effects due to slowed metabolic clearance. Antiemetic drugs and neuroleptics are more likely to cause tardive dyskinesia in the elderly. Even nonsteroidal anti-inflammatory drugs (NSAIDs) may cause cognitive side effects and are associated with an increased risk of gastrointestinal bleeding [9].

Preventive treatments (Table 55.9) may also cause more side effects and be less well tolerated in the elderly. Therefore, they should be started at a very low dose and increased slowly. The tertiary amine tricyclic antidepressant agents, such as amitriptyline and doxepin, which are potent anticholinergic agents, should be used with caution. They can exacerbate glaucoma, produce visual blurring and cause problems with cognition. Nortriptyline, a secondary amine, is a reasonable alternative and generally has less pronounced side effects. The selective serotonin reuptake inhibitors, although not as effective, are very safe in the elderly. Antihypertensive drugs may cause more hypotension or lethargy in the elderly than in younger patients. Divalproex sodium and topiramate have a particularly good benefit-to-side effect profile in the elderly.

Table 55.8 Acute medications: efficacy, side effects, relative contraindications and indications[a].

Drug	Efficacy[b]	Side effects[b]	Comorbid	
			Relative contraindications	Relative indication
Acetaminophen	1+	1+	Liver disease	Pregnancy
Aspirin	1+	1+	Kidney disease, ulcer disease, PUD, gastritis (age <15 years)	CAD, TIA
Butalbital, caffeine and analgesics	2+	2+	Use of other sedative; history of medication overuse	
Caffeine adjuvant	2+	1+	Sensitivity to caffeine	
Isometheptene	2+	1+	Uncontrolled HTN, CAD, PVD	
Opioids	3+	3+	Drug or substance abuse	Pregnancy; rescue medication
NSAIDs	2+	1+	Kidney disease, PUD, gastritis	
Dihydroergotamine			CAD, PVD, uncontrolled HTN	Orthostatic hypotension, prominent nausea or vomiting
Injections	4+	2+		
Intranasal	3+	1+		
Ergotamine			Prominent nausea or vomiting, CAD, PVD, uncontrolled HTN	
Tablets	2+	2+		
Suppositories	3+	3+		
Triptans			CAD, PVD, uncontrolled HTN	
Almotriptan				
Tablets	3+	1+

[a]PUD, peptic ulcer disease; PVD, peripheral vascular disease; CAD, coronary artery disease; TIA, transient ischaemic attack; HTN, hypertension; NSAIDs, non-steroidal anti-inflammatory drugs; s.c., subcutaneous.
[b]Ratings are on a scale from 1+ (lowest) to 4+ (highest) based on response rates and consistency of response in double-blind placebo-controlled trials and our clinical experience.

Methysergide (no longer available in the USA) and methylergonovine are relatively contraindicated because they are vasoconstrictors and may cause cardiac ischaemia.[9]

Non-pharmacological treatment in the elderly, as in all patients, is attractive because it avoids medications that may present risks or cause excessive side effects. Elimination of triggers, proper diet, regular sleep and avoidance of excess caffeine and overuse of over-the-counter medications are useful modalities for all patients. Biofeedback may not be as effective in the elderly patient. The most important non-pharmacological approach involves the meticulous identification and treatment of comorbid medical and psychiatric conditions. Cervical triggers and other sources of pain should be treated with physical modalities if possible. Depression is extremely common and should be addressed.[9]

Tension-type headache (TTH)

TTH is the most common headache type, with a lifetime prevalence of 69% in men and 88% in women.[4] TTH can begin at any age, but onset during adolescence or young

Table 55.9 Prevention.

Table 55.10 Tension-type headache (IHS classification).

2.2 Frequent episodic tension-type headache

Diagnostic criteria

A At least 10 episodes occurring on ≥1 but <15 days per month for at least 3 months (≥12 and <180 days per year) and fulfilling criteria B–D
B Headache lasting from 30 min to 7 days
C Headache has at least two of the following characteristics:
  1 Bilateral location
  2 Pressing/tightening (non-pulsating) quality
  3 Mild or moderate intensity
  4 Not aggravated by routine physical activity such as walking or climbing stairs
D Both of the following:
  1 No nausea or vomiting (anorexia may occur)
  2 Photophobia and phonophobia are absent or one but not the other is present
E Not attributed to another disorder

2.3 Chronic tension-type headache

Diagnostic criteria

A Headache occurring on ≥15 days per month on average for >3 months (≥180 days per year) and fulfilling criteria B–D
B Headache lasts for hours or may be continuous
C Headache has at least two of the following characteristics:
  1 Bilateral location
  2 Pressing/tightening (non-pulsating) quality
  3 Mild or moderate intensity
  4 Not aggravated by routine physical activity such as walking or climbing stairs
D Both of the following:
  1 No nausea or vomiting (anorexia may occur)
  2 Photophobia and phonophobia are absent or one but not the other is present
E Not attributed to another disorder

adulthood is most common. Headache prevalence declines with increasing age; severity decreases in the women who continue to report headaches but does not change in men. Approximately 10% of patients acquire TTH after age 50 years. The IHS criteria for TTH are listed in Table 55.10. The headache may be shorter or longer in duration than migraine. TTH is mild or moderate in intensity and has no accompanying autonomic symptoms. The cause of this common disorder is unknown, but it is not related to muscular tension (patients with migraine have more muscle tension than patients with TTH).

Treatment of TTH in the elderly

Acute TTH often responds to non-pharmacological treatment. If the headache does not respond to this approach and medication is needed, many patients self-medicate with over-the-counter analgesics (aspirin, acetaminophen, ibuprofen, naproxen), with or without caffeine. Combination analgesics contain sedatives or caffeine and their use should be limited, as overuse may cause dependence. Narcotic analgesics and benzodiazepines should be avoided owing to their abuse potential. Overusing acute medications, including butalbital and analgesics, can cause ETTH to convert to CTTH.[9] Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to acute medication overuse. Antidepressants, the medication of choice, should be started at a low dose and increased slowly every 3–7 days.

Chronic daily headache

CDH may be due to CTTH, CM, HC or NDPH and is often associated with acute medication overuse (Table 55.11). It is important to determine the subtype of CDH so that the appropriate treatment can be chosen. When concurrent depression and medication dependence accompany CDH, treatment is difficult and detoxification may be required. Refractory medication overuse headaches (MOHs) may occur when analgesics or triptans are taken more frequently than three days per week or opioids or ergotamine tartrate more often than two days per week. To avoid this situation, all acute medications must be used within defined limits.[4]

Patients overusing acute medications must be detoxified. This can be done as an outpatient by slowly tapering the offending medication if their use is not excessive, there are no risk factors and the patient can tolerate it. If the patient cannot tolerate the taper, NSAIDs or a short course (about 2 weeks) of corticosteroids may be useful. Clonidine (0.1–0.3 mg b.i.d.–t.i.d.) is helpful for treating the symptoms of opioid withdrawal and phenobarbital helps with withdrawal from short-acting barbiturates. Refractory patients often require hospitalization. Repetitive intravenous (i.v.)

Table 55.11 Chronic daily headache.

Primary
Headache duration >4 h
Transformed migraine (TM)
Chronic tension-type headache (CTTH)
New daily persistent headache (NDPH)
Hemicrania continua (HC)
Headache duration <4 h
Cluster headache
Chronic paroxysmal hemicrania
Hypnic headache
Idiopathic stabbing headache
Secondary
Post-traumatic headache (PTH)
Cervical spine disorders
Headache associated with vascular disorders [arteriovenous malformation, arteritis (including giant cell arteritis), dissection, subdural haematoma]
Headache associated with nonvascular intracranial disorders [intracranial hypertension, infection (EBV, HIV), neoplasm]
Other (temporomandibular joint disorder; sinus infection)

Table 55.12 Cluster headache.

3.1 Cluster

Diagnostic criteria

A At least 5 attacks fulfilling criteria B–D

B Severe or very severe unilateral orbital, supraorbital and/or temporal pain lasting 15–180 min if untreated

C Headache is accompanied by at least one of the following:
- 1 Ipsilateral conjunctival injection and/or lacrimation
- 2 Ipsilateral nasal congestion and/or rhinorrhoea
- 3 Ipsilateral eyelid oedema
- 4 Ipsilateral forehead and facial sweating
- 5 Ipsilateral miosis and/or ptosis
- 6 A sense of restlessness or agitation

D Attacks have a frequency from one every other day to 8 per day

E Not attributed to another disorder

3.1.1 Episodic cluster

Diagnostic criteria

A Attacks fulfilling criteria A–E for 3.1 *Cluster headache*

B At least two cluster periods lasting 7–365 days and separated by pain-free remission periods of ≥ 1 month

3.1.2 Chronic cluster

Diagnostic criteria

A Attacks fulfilling criteria A–E for 3.1 *Cluster headache*

B Attacks recur over >1 year without remission periods or with remission periods lasting <1 month

DHE should be used with caution because of the potential for cardiac ischaemia. High-dose i.v. corticosteroids and neuroleptics can be used instead.[4]

Cluster headache

Cluster headache prevalence is much lower than that of migraine or TTH, with a rate of 0.01–0.24% in various populations. Prevalence is higher in men (70–90%) than in women and in Caucasians than African-Americans. The most common form of cluster headache is episodic (only about 10% of cluster patients have chronic cluster headache) (Table 55.12). Cluster headache can begin at any age: it most commonly begins in the late 20s, rarely in childhood and occasionally (10%) in patients in their 60s. The prognosis of cluster headaches is guarded; it is a chronic headache disorder that may last for the patient's entire life [10].

Episodic cluster has bouts lasting 1 week to 1 year with remission periods lasting at least 1 month, whereas chronic cluster has no remission periods or remissions that last less than 1 month. Untreated, the attacks generally last from 30 to 90 min, but they may also last up to 180 min. Most patients have one or two cluster periods per year that last 2–3 months, with 1–2 attacks per day. Episodic cluster can evolve into chronic cluster. Cluster attacks may begin with slight discomfort that rapidly increases (within 15 min) to excruciating pain. Patients may say 'It's like driving a hot poker into my eye'. The attacks often occur at the same time each day and frequently awaken patients from sleep. Lacrimation, the most common associated symptom, is reported by about 83% of patients. Patients with cluster headaches should avoid alcohol and nitroglycerine. Most cluster headache patients require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only abortive medication. In addition, ergotamine, DHE and sumatriptan are risky in the elderly, and oxygen inhalation, although safe, may just postpone, rather than abort, the attack. Preventive therapy for episodic cluster, in order of preference, includes calcium channel blockers, divalproex, topiramate, lithium, corticosteroids and melatonin. Long-term corticosteroids are not appropriate for chronic cluster.[10] Refractory cases have been treated with greater occipital nerve stimulation and even deep brain hypothalamic stimulation.

Hypnic headache

Hypnic headache (Table 55.13) is a rare, strictly nocturnal headache that occurs in older persons (mean age 63 years). The headache typically awakens the patient from sleep and can occur at the same time on one or more occasions per night. The headaches are usually throbbing and bilateral, last ~1 h and may be associated with nausea. There are usually no associated autonomic features. Lithium carbonate, at a low dose of 300–600 mg at bedtime, is an effective treatment. Other treatments include caffeine and indomethacin.[11]

Table 55.13 Hypnic headache.

4.5 Hypnic headache
Diagnostic criteria
A Dull headache fulfilling criteria B–D
B Develops only during sleep and awakens patient
C At least two of the following characteristics:
1 Occurs >15 times per month
2 Lasts ≥ 15 minutes after waking
3 First occurs after age of 50 years
D No autonomic symptoms and no more than one of nausea, photophobia or phonophobia
E Not attributed to another disorder

Secondary headache disorders

Headache associated with cerebrovascular disease

Stroke incidence increases with age. In one study, headache was a feature of 17 of 29 (59%) infarcts. It is more common in large artery occlusive disease than cerebral embolism and less common in lacunar infarction. Headache in carotid artery occlusion is usually located around the eye of the occluded side. Headache location is unreliable to localize a stroke, especially for vertebrobasilar disease.

About 50% of headaches are severe enough to be 'troubling'; they may last from 8 to 24 h. Headache is present in 23–68% of patients with intraparenchymal haemorrhage; the highest headache frequency occurs in cerebellar and lobar haemorrhages. It is not clear how often the headache location predicts the site of the haemorrhage. The frequency of headache in transient ischaemic attacks (TIAs) varies from 6 to 44%. Headache was noted in 15 of 34 TIA patients occurring during, immediately before or after the neurological event. Migraine headaches occurred independent of the TIAs in 38% of these patients. It is possible that late-onset migraine is a marker for cerebrovascular disease.

Giant cell arteritis (see Chapter 94, Diseases of the joints)

GCA has a prevalence of 133 per 100 000 individuals over the age of 50 years, with women affected three times more often than men. Headache, the most frequent symptom, is present in 70–90% of patients. Pain can be intermittent or constant. The headache is often located over the temples and associated with scalp tenderness. Symptoms of polymyalgia rheumatica, which include muscle pain and joint stiffness, are present in 25% of patients. Other common symptoms include fever, weight loss, night sweats, masseter claudication, tongue ischaemia, amaurosis fugax (which may be bilateral in half), permanent blindness (often without warning) or partial visual loss due to anterior ischaemic optic neuropathy. Amaurosis fugax is particularly ominous; if it is not treated, about half of patients will become blind.

Induration and tenderness of the temporal or occipital scalp arteries are the most common signs of GCA. Optic disc oedema and visual loss may occur. Altitudinal defects and central scotomas breaking into the periphery are frequently seen. Diplopia is rare and, when present, is due to extraocular muscle ischaemia. True cranial nerve palsy is very uncommon. Arterial bruits or diminished pulses are present in one-third of patients. Aortic arch syndrome may occur with rupture.

The most consistent laboratory abnormality is an elevation of the erythrocyte sedimentation rate (measured by the Westergren method). Wall et al. reported that 41% of patients had a value $>100\,\text{mm h}^{-1}$ and 89% had a value $>50\,\text{mm h}^{-1}$.[12] Elevated C-reactive protein, mild liver function abnormalities and mild hyperchromic or hypochromic anaemia are common. Temporal artery biopsy, the diagnostic gold standard, should be performed within 1 week of initiating steroid treatment. Colour-coded duplex sonography helps identify the most appropriate part of the superficial temporal artery to biopsy. A long piece of artery should be obtained and multiple sections examined to improve yield. If the biopsy is negative and the index of suspicion is high, more sections should be examined and a second temporal artery biopsy done. Corticosteroids should be started as soon as possible to prevent blindness.

Headache associated with mass lesions

Headache frequently accompanies subdural haematoma: in one series it occurred in 62% of patients. Headache occurs at presentation in up to half of patients with brain tumours and develops during the course of the disease in 60%. Headache is partly dependent on tumour location: it is a rare initial symptom in patients with pituitary tumours, craniopharyngiomas or cerebellopontine angle tumours. In older, pre-CT or MRI series of brain tumour patients, headache occurred as often without as it did with elevated intracranial pressure. The headache, although usually generalized, could overlie the tumour.

Postulated mechanisms of headache development include traction on pain-sensitive intracerebral vessels, transient herniation of hippocampal gyri, traction on cranial or cervical nerves, elevation of intracranial pressure or activation of a quiescent headache disorder. Although increased cerebrospinal fluid (CSF) pressure is not necessary for headache development, it clearly plays a role in a group of patients with central nervous system neoplasms.

In a modern series, 111 consecutive patients with primary (34%) or metastatic (66%) brain tumour were

diagnosed with neuroimaging. Increased intracranial pressure was defined by the presence of papilloedema, obstructive hydrocephalus, communicating hydrocephalus from leptomeningeal metastasis or a lumbar puncture opening pressure >250 mm of CSF. Headache, present in 48% of both primary and metastatic tumours, was similar to TTH in 77% of patients and to migraine in 9%. Unlike true TTH, brain tumour headaches were worsened by bending in 32% and nausea or vomiting was present in 40%.

About 86% of patients with increased intracranial pressure had headache that was typically frontal in location and pressure-like or aching in character. Only 1% had a unilateral headache. The headache was constant in 61%. The pain was severe in intensity, associated with nausea and vomiting and resistant to common analgesics. Ataxia was present in 61%. In contrast, only 36% of patients with a supratentorial tumour without increased intracranial pressure had headache. These headaches were milder and more likely to be intermittent (however, they were constant in 20% of patients). Nausea, vomiting and ataxia were much less common.

Patients with a history of prior headache were more likely to have brain tumour headache. In many cases this headache was similar in character to the prior headache, but it was more severe or frequent or associated with neurological signs or symptoms.

In another prospective study of patients with brain tumour, only 8% had headache as their first and isolated clinical manifestation at the time of diagnosis; 31% had headache, but only one of the original patients continued to have headache as an isolated symptom.

There is a significant overlap between brain tumour headache and migraine and TTH. Any neurological sign or symptom that occurs with a headache and cannot be easily explained by the aura of migraine, a headache of recent onset or a headache that has changed in character requires a thorough evaluation, particularly if the headache is severe or is accompanied by nausea or vomiting. Increased headache frequency and morning or nocturnal headache associated with vomiting can be seen with both migraine and brain tumour. Brain tumour headache is more common in patients with a history of prior headache, increased intracranial pressure and large tumours with a midline shift.

In space-occupying lesions other than brain tumours, such as subdural haematomas and brain abscesses, headache is a more frequent and earlier symptom. McKissock[13] reported that 81% of 216 patients with chronic subdural haematoma had headache, with a lesser prevalence in acute (11%) and subacute (53%) subdural haematomas. The difference in headache prevalence between tumour and subdural haematoma is believed to be due to the more rapid evolution and greater extent of the haematomas. The lesser occurrence of headache in acute and subacute subdural haematomas compared with chronic subdural haematoma may be due to the underlying traumatic cerebral changes in the former obtunding consciousness early and making it difficult to elicit a history of headache. The headache is often ipsilateral to the subdural haematoma or brain tumour.

Patients with brain abscesses often have a progressively severe, intractable headache. In published clinical series, headache was present in 70–90% of patients. The higher headache prevalence in abscess, compared with tumour, may be due to its faster evolution, the associated meningeal reaction and the occasional low-grade fever that may accompany abscess.

Parkinson's disease (see Chapter 63, Parkinson's disease)

The association between Parkinson's disease and headache is controversial. In one series, headache occurred in 41% of patients with Parkinson's disease and 13% of controls. Another controlled series found no difference in headache prevalence. Possible headache mechanisms include comorbid depression and muscle rigidity. In one study of early-morning occipital headache in Parkinson's disease, headache failed to improve with treatment directed at muscle spasm, but did improve with levodopa.

Medication-induced and toxic headache

Medications used for the treatment of coexisting disease may trigger headaches. These include nitrates, some calcium channel blockers, estrogens and progestins, histamine receptor blockers, theophylline and NSAIDs. Overuse of caffeine, analgesics, narcotics, ergotamine and triptans can lead to CDH.

Carbon monoxide poisoning frequently presents with headache. Headache is moderate in intensity, has no characteristic location and may be accompanied by weakness, lethargy, confusion, photophobia or phonophobia. Often other members of the household have similar symptoms.[14]

Post-traumatic headache

Age is probably neither protective nor conducive to the development of post-traumatic headache after mild head injury. The features of post-traumatic headache are variable and diagnosis requires the onset of a new kind of headache (substantially different from previous headaches) within 7 days of the head injury or of regaining consciousness from the head trauma. Increasing age is associated with less rapid and less complete recovery.

Table 55.14 Cervicogenic headache.

11.2.1 Cervicogenic headache

Diagnostic criteria

A Pain, referred from a source in the neck and perceived in one or more regions of the head and/or face, fulfilling criteria C and D

B Clinical, laboratory and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck known to be, or generally accepted as, a valid cause of headache

C Evidence that the pain can be attributed to the neck disorder or lesion based on at least one of the following:
  1 Demonstration of clinical signs that implicate a source of pain in the neck
  2 Abolition of headache following diagnostic blockade of a cervical structure or its nerve supply using placebo or other adequate controls

D Pain resolves within 3 months after successful treatment of the causative disorder or lesion

Headaches associated with disorders of the cervical spine

The association between disease of the spine and headache is controversial. The IHS has adopted restrictive criteria for these headaches. Generally accepted causes of headache related to cervical spine lesions, and also currently controversial causes, are listed in Table 55.14. Many of the non-controversial causes of cervicogenic headache (such as Paget's disease and tumours) are more common in the elderly. Radiographic spondylosis worsens with age but its relationship to headache is uncertain. If the patient has non-headache indications for MRI or EMG, such as myelopathy or radiculopathy, these disorders can be diagnosed and treated on their own merit. Tender spots can be treated with an injection of local anaesthetic and corticosteroids.

Glaucoma

Primary open-angle glaucoma, the most common cause of glaucoma, is rarely painful. Miotic eyedrops used in its treatment may produce brow ache. Acute angle closure glaucoma is less common and may produce intense eye pain that radiates widely and may be associated with nausea and sinus area pain; it is often associated with a red eye, fixed mid-pupil position, corneal cloudiness and a red sclera. Laser iridotomy is curative. Secondary angle closure glaucoma resulting from diabetes or carotid insufficiency may produce a deep, boring, unrelenting pain associated with a red eye and poor vision. To make the diagnosis of glaucoma-related headache, the pain should develop simultaneously with the glaucoma and be relieved within 72 h of effective treatment.

Sinusitis

Acute purulent sinusitis produces severe headache associated with purulent nasal discharge. A dangerous exception to this rule is sphenoid sinusitis, which may present as a severe, intractable, progressive headache.

Other head and facial pain syndromes affecting the elderly

Trigeminal neuralgia

Trigeminal neuralgia is the most common neuralgic syndrome, with a peak incidence in the sixth and seventh decades (Table 55.15). Secondary trigeminal neuralgia usually presents at a younger age. Trigeminal neuralgia is typically unilateral, but is bilateral in 4% of patients. Symptoms include repetitive jolts of electric-like pain in the distribution of one or more divisions of the trigeminal nerve. The paroxysms of pain are characteristically induced by touching a 'trigger zone' in the relevant division of the fifth cranial nerve. Brushing the teeth, chewing, talking or even a wisp of air on the face can trigger an attack. Between paroxysms, a sustained, deep, dull ache may be present.

Pretrigeminal neuralgia is a dull, continuous, achy pain in the jaw, which may be provoked by pressure about the face or mouth, and may evolve into trigeminal neuralgia. It may account for many of the cases of trigeminal neuralgia diagnosed after multiple dental procedures, since the clinical features are not distinctive.

The diagnosis of trigeminal neuralgia is established by typical clinical features and an examination that is negative except for positive trigger points; diagnostic studies are generally normal. Impaired sensation in the distribution of the fifth nerve suggests a structural, demyelinating or compressive trigeminal nerve lesion. Aneurysms, GCA, intracranial tumours, dental mandibular malignancy or cranial malignancy can produce the symptoms of trigeminal neuralgia associated with decreased facial sensation. Multiple sclerosis, dental pathology or a dental procedure can produce a

Table 55.15 Cranial neuralgias.

13.1.1 Classical trigeminal neuralgia

Diagnostic criteria

A Paroxysmal attacks of pain lasting from a fraction of a second to 2 min, affecting one or more divisions of the trigeminal nerve and fulfilling criteria B and C

B Pain has at least one of the following characteristics:
  1 Intense, sharp, superficial or stabbing
  2 Precipitated from trigger areas or by trigger factors

C Attacks are stereotyped in the individual patient

D There is no clinically evident neurological deficit

E Not attributed to another disorder

pattern of pain indistinguishable from trigeminal neuralgia. The natural history of trigeminal neuralgia is variable. Periodic remissions are common, but permanent spontaneous remissions are rare. Over 50% of patients have a remission that lasts 6 months or more.

Trigeminal neuralgia is thought to be due to focal demyelination of the trigeminal nerve. In 80–90% of cases, this is caused by vascular compression from abnormal arterial loops near the root entry zone of the nerve. Aberrant neuronal activity may arise from these injured areas, which could promote changes in the trigeminal nucleus caudalis.

Medical treatment is usually successful (Figure 55.2, Table 55.16). Drugs used include gabapentin, carbamazepine, oxcarbazepine, phenytoin, baclofen, valproic acid, clonazepam and pimozide, alone or in combination. Combination therapy is often effective and necessary. Phenytoin can be given intravenously to control especially painful paroxysms.

If medication fails to control symptoms adequately, ablative procedures should be considered. Alcohol or glycerol injections may be used. More proximal injections produce better long-term results. Gasserian ganglion injections have a 5 year recurrence rate of 41–86%. Retrogasserian glycerol injections can produce mild facial numbness, but painful dysaesthesias are rare and anaesthesia dolorosa is absent. The mean recurrence time varies from 6 to 47 months. Percutaneous balloon compression of the trigeminal ganglia may be similarly effective. Radiofrequency gangliolysis provides relief in 82–100% of patients and has a recurrence rate between 9 and 28%. Major complications are rare; loss of corneal reflex occurs in as many as 70% of patients and masseteric weakness occurs in approximately half, but improves over 3–6 months. Minor paraesthesias occur in about 10%, but anaesthesia dolorosa is rare.

The Janetta procedure, performed via an occipital craniotomy, separates aberrant blood vessels, if present, from the trigeminal nerve root. Long-term benefit is reported in over 80% of patients, with recurrence rates of 1–6%. Surgical mortality is 1% and serious morbidity 7%. Because of this, other less invasive surgical procedures, such as percutaneous glycerol injection and radiofrequency rhizotomy, which have less morbidity, are often tried first, even though they may be only temporarily effective. More recently, several radiosurgical techniques aimed at the trigeminal nerve root adjacent to the pons have been successful.

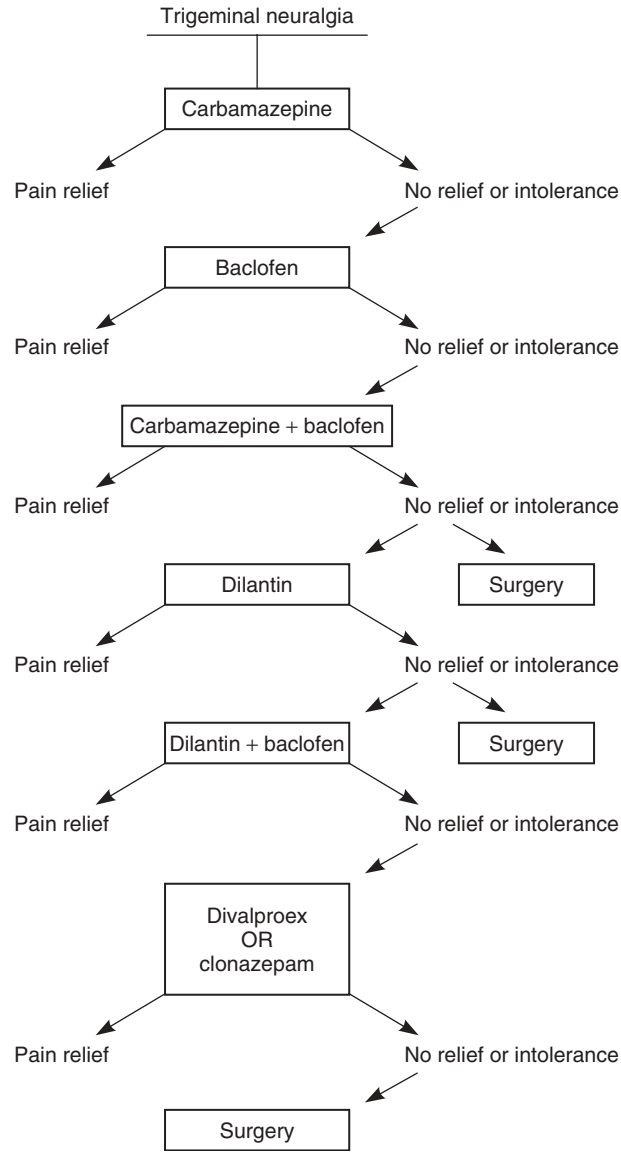

Figure 55.2 A proposed algorithm for the medical treatment of trigeminal neuralgia. Once the patient has been pain free for 3–6 months on a medication, the drug should be slowly tapered off to avoid medicating during spontaneous remission. If the pain recurs, the medication is reinstituted. Individual needs may dictate earlier surgery. Modified from J.C. Masdeu, Medical treatment and clinical pharmacology. In: R.L. Rovit, R. Murali and P.J. Jannetta (eds), *Trigeminal Neuralgia*, Williams and Wilkins, Baltimore, 1990, pp. 79–84.

Glossopharyngeal neuralgia

Glossopharyngeal neuralgia (Table 55.17) is less common than trigeminal neuralgia. The unilateral pain occurs in the distribution of the glossopharyngeal and vagus nerves in and around the ear, jaw, throat, tongue or larynx. Radiation from the oropharynx to the ear is common. Paroxysms of jabbing or electric pain last for about 1 min and may be accompanied by deep, continuous pain between paroxysms.

Table 55.16 Characteristics of antineuralgic drugs.

Drug	Bioavailability (%)	Time to maximum concentration (h)	Half-life (h)	Time to steady-state concentration (days)	Therapeutic 'target' range^{-1}) (μmol l^{-1})
Baclofen	–	3–8	3–4	1	–
Carbamazepine	>70	2–8	11–27	5	24–43
Clonazepam	100	1–2	24–48	12	30–270
Lamotrigine	100	2–3	18–30	8	4–16
Oxcarbazepine	100	1–2	14–26	7	35–110
Phenytoin	98	4–8	15–20	14	20–80
Valproic acid	99	1–4	6–17	5	200–700

Table 55.17 Glossopharyngeal neuralgia.

13.2.1 Classical glossopharyngeal neuralgia

Diagnostic criteria

A Paroxysmal attacks of facial pain lasting from a fraction of a second to 2 min and fulfilling criteria B and C

B Pain has all of the following characteristics:
  1 Unilateral location
  2 Distribution within the posterior part of the tongue, tonsillar fossa, pharynx or beneath the angle of the lower jaw and/or in the ear
  3 Sharp, stabbing and severe
  4 Precipitated by swallowing, chewing, talking, coughing and/or yawning

C Attacks are stereotyped in the individual patient

D There is no clinically evident neurological deficit

E Not attributed to another disorder

Patients may have as many as 30–40 attacks per day and may be awakened from sleep. Paroxysms of pain may be triggered by chewing, talking, yawning, coughing or swallowing cold liquids. Stimulation of the external auditory canal and postauricular area may also provoke pain. In ~2% of cases, syncope (secondary to bradycardia or asystole) and seizures (from cerebral ischaemia) have occurred. Atropine prevents syncope, which suggests that vagal afferent discharge is its mechanism.

The diagnosis of glossopharyngeal neuralgia is clinical. Neurological examination is usually normal. Other disorders are ruled out by history, physical examination and diagnostic testing. The assumed cause of glossopharyngeal neuralgia is nerve compression from aberrant blood vessels. Symptomatic causes of a glossopharyngeal neuralgia-like syndrome include cerebellopontine angle tumour, nasopharyngeal carcinoma, carotid aneurysm, peritonsillar abscess and compression from an osteophytic stylohyoid ligament lateral to the glossopharyngeal nerve.

Table 55.18 Chronic postherpetic neuralgia.

13.15.2 Postherpetic neuralgia

Diagnostic criteria

A Head or facial pain in the distribution of a nerve or nerve division

B Herpetic eruption in the territory of the same nerve

C Pain preceded herpetic eruption by <7 days

D Pain persists after 3 months

The best diagnostic test involves anaesthetizing the tonsil and pharynx, which can temporarily terminate a painful paroxysm and confirm the diagnosis. Drug treatment is the same as for trigeminal neuralgia. Surgical treatment involves intracranial sectioning of the glossopharyngeal nerve and the upper rootlets of the vagus at the jugular foramen. A microvascular decompression procedure has been described.[15]

Postherpetic neuralgia

Postherpetic neuralgia (Table 55.18) follows an attack of acute herpes zoster, evolving as the acute attack subsides. One definition is the presence of pain more than 1 month after the eruption of zoster. Old age, diabetes mellitus, ophthalmic herpes zoster and a compromised immunological system increase the risk for postherpetic neuralgia. Postherpetic neuralgia is a significant cause of head pain in the elderly.

Acute zoster often begins with paraesthesias and pain in the affected region, followed 4–5 days later by a vesicular eruption. Most patients have a deep aching or burning pain, paraesthesias and dysaesthesias. Some may have hyperaesthesia or electric shock-like pains. Typical involvement in the head occurs unilaterally in the distribution of the ophthalmic or maxillary divisions of the trigeminal nerve or at the occipitocervical junction. Ophthalmic herpes may be associated with diplopia due to involvement of cranial nerves III, IV and VI. Geniculate herpes is associated with

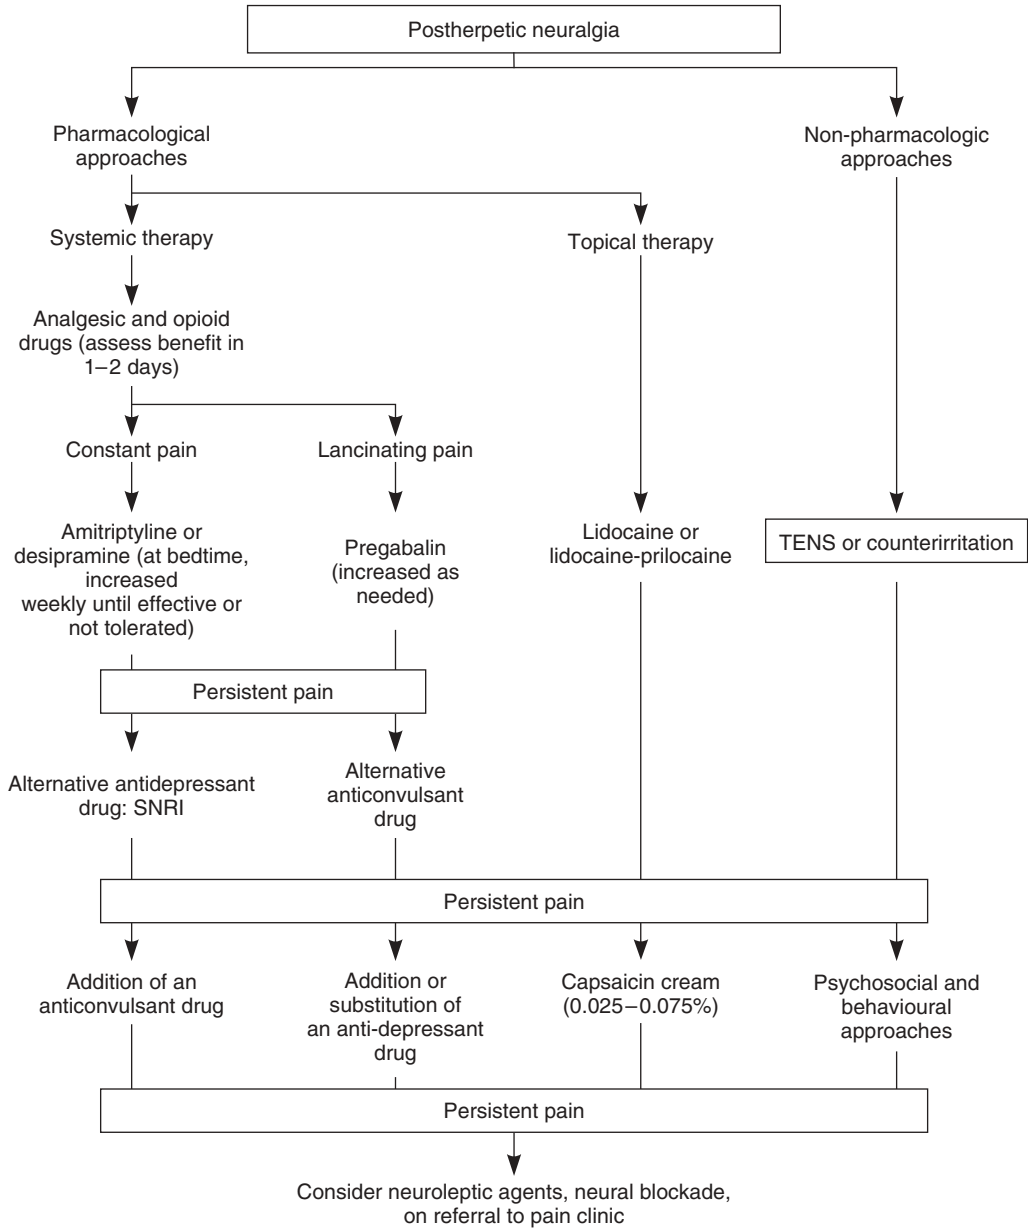

Figure 55.3 Algorithm for the treatment of persistent postherpetic pain. Modified from Kost and Straus.[16]

facial palsy (CN VII). Vesicles are often seen in the external auditory canal.

The incidence of postherpetic neuralgia depends on its definition, which varies from pain persisting for 1 month to pain persisting for 6 months. Age, severity and the presence of uraemia correlate with developing postherpetic neuralgia. It is more common in the elderly, occurring in 5% of patients with acute zoster who are below 40 years of age, in 50% of those in the seventh decade and in 75% of those above 70 years of age. Slow, spontaneous improvement of pain occurs in most patients; in 3 years, 56% of patients are either completely pain free or have non-troublesome pain.

The pain occurs in areas overlying abnormal hyperaesthetic skin and has three components: (1) constant, deep, burning pain; (2) repetitive stabs and needle pricking sensations; and (3) superficial, sharp, radiating or itch sensation provoked by light touch. Sleep is often interrupted. Postherpetic neuralgia may reflect a deafferentation pain syndrome and may be accompanied by increased sympathetic activity.

Topical therapies such as compresses of Burow's solution, colloidal oatmeal or calamine lotion are used to treat acute zoster. The skin should be protected with sterile dressings. Oral glucocorticoids may lead to faster resolution of acute zoster pain, but it is not clear if they have

any value in preventing or attenuating postherpetic neuralgia. Antiviral agents may attenuate acute herpes zoster in immunocompromised patients. Acyclovir used for 21 days may ameliorate pain in the acute phase. Famciclovir, valacyclovir and brivudin may be superior to acyclovir. Acyclovir and famciclovir have not been proven to reduce the risk of postherpetic neuralgia. Epidural blockade or sympathetic blockade may help pain acutely and may reduce postherpetic neuralgia.

Postherpetic neuralgia should be treated as soon as the diagnosis is made. Amitriptyline is commonly used, but nortriptyline or desipramine may be preferable, since they have fewer anticholinergic side effects. Gabapentin and pregabalin were studied in several double-blind, placebo-controlled trials to control pain (at doses of gabapentin from 2400 to 3600 mg per day or pregabalin at 600 mg per day). Capsaicin, a substance-P depleter, may be of some benefit, but burning may limit its usefulness. Topical NSAIDs may be useful. Local anaesthetic preparations are also effective. Peripheral and central surgical techniques are of little, if any, value (Figure 55.3)[16].

Key points

- The International Headache Society (IHS) divides headaches into two broad categories: primary and secondary headache disorders.
- With ageing, not only is there a change in prevalence of the primary headache disorder but also a shift to new or organic causes of headache.
- Headache is common in the elderly.
- The evaluation of the elderly patient with headache must be directed to rule out serious secondary causes of headache such as tumour, subdural haematoma, stroke, transient ischaemic attack and temporal arteritis.
- Medications that are more commonly used by the elderly may exacerbate or trigger migraine.
- In the elderly, migraine aura without headache (acephalic migraine) is also called late-life migraine accompaniments.
- Hypnic headache is a rare, strictly nocturnal headache that occurs in older persons.
- Giant cell arteritis occurs in 3–9 per 100 000 patients over the age of 50 years, with women affected three times more often than men.
- The association between Parkinson's disease and headache is controversial.
- Trigeminal neuralgia is the most common neuralgic syndrome in the elderly, with a peak incidence in the sixth and seventh decades.

CHAPTER 56

Normal pressure hydrocephalus

Dennis S. Oh[1] and Peter McL. Black[2]

[1]Tufts University School of Medicine, Springfield, MA, USA
[2]Harvard Medical School, Boston, MA, USA

Introduction

Normal pressure hydrocephalus (NPH) is a condition that is characterized by the clinical triad of gait disturbance, cognitive decline and urinary incontinence. It is further supported by imaging evidence of ventriculomegaly. The typical age group involved is above 60 years, although it can occur as early as 50 years,. Because it generally occurs in the geriatric population, detection may be challenging as the symptoms overlap with those of other degenerative neurological conditions and sometimes the decline may even be attributed simply to old age. It is therefore important that NPH be kept in mind when evaluating relevant patients. Its incidence has been estimated at 1.8 cases per 100 000,[1] but others have it higher at 5.5 per 100 000.[2] One study even estimated that the prevalence may be 14% in assisted-living facilities.[3] Regardless of the numbers, many feel that it is an under-recognized condition so there has been a push to highlight its importance not just among healthcare providers but also the general population so that family members may bring potential patients to medical attention.

NPH is widely accepted to have been first identified in 1965,[4] but it was recognized as early as 1957 by Dr. Salomon Hakim, who is regarded as the father of NPH.[5] The name was derived from his observation that such patients did not present with papilloedema and had normal cerebrospinal fluid (CSF) pressures on lumbar puncture. It was a revolutionary discovery as it gave new hope that a degenerative neurological condition could now be reversed through simple CSF diversion. It should be noted that although the term 'normal pressure hydrocephalus' is widely used, changing concepts have given rise to questions on the validity of this nomenclature. Some authors have suggested, for example, that CSF pressure in NPH is not exactly 'normal' as some show abnormalities in CSF dynamics.[6] Terms such as 'chronic hydrocephalus' have been proposed, but thus far none have been convincing enough to cause a shift away from the widely used term 'NPH'.[7]

Aetiology and pathophysiology

Hydrocephalus by definition is an excessive accumulation of CSF in the ventricular system. What leads to this condition can be a host of causes ranging from haemorrhage to neoplasm. However, its aetiology can be roughly divided into two categories: non-communicating, wherein there is a blockage in the ventricular system (e.g. aqueductal stenosis); and communicating, which can result either from a decrease in CSF resorption (scarring after subarachnoid haemorrhage) or from CSF overproduction (e.g. choroid plexus papilloma). In the realm of geriatrics, it is virtually never a consequence of CSF overproduction. As far as NPH is concerned, it is commonly accepted that fluid build-up is due to impairment of the brain's CSF resorptive capacity – an idea that is known as the bulk flow theory. This can occur at the level of the arachnoid granulations along the skull base and over the hemispheres.[8] Some authors feel that resorption also occurs in the brain parenchyma through capillaries and venules[9,10] and resorptive problems can also be at this level. Among the known causes of NPH are subarachnoid haemorrhage, trauma and meningitis, all of which can lead to scarring of the arachnoid granulations in the subarachnoid space. Such conditions are commonly referred to as secondary NPH.

In over half of NPH patients, however, there is no identifiable cause. The development of idiopathic NPH remains unclear, but it appears to involve the interplay of several factors such as cerebral ischaemia, decreased vascular compliance, decreased cerebral blood flow to periventricular regions and brain atrophy. MR flow quantification studies showed lower venous compliance in NPH patients, which could lead to increased resistance to CSF outflow and cerebral ischaemia in the concerned areas.[11] Indeed, it has been shown that after shunting, cortical vein compliance is improved in patients who respond to the procedure.[12] The bulk flow theory is easily understandable but others feel that it is an oversimplification. It appears inadequate in

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

explaining certain characteristics such as why CSF pressure can remain normal and why some patients improve with endoscopic third ventriculostomy (ETV), which does not involve diverting fluid volume away from the intracranial space. An alternative theory known as the hydrodynamic concept of hydrocephalus has been gaining traction. It holds that a decrease in intracranial compliance allows an increased transmission of systolic pressure to the brain parenchyma, which in turn becomes distended against the unforgiving skull.[13] Creating a hole on the floor of the third ventricle (ETV) thus allows for 'venting' of the increased systolic pressure and CSF to the subarachnoid space. The thought is that the aqueduct of Sylvius is too narrow and inadequate for venting.

There are other factors that influence the pathophysiology of NPH. Cerebral blood flow has been shown to be decreased in patients with idiopathic NPH, particularly in periventricular regions[14] and also the basal ganglia and thalamus.[15] Idiopathic NPH patients have also been found to have brain atrophy in addition to hydrocephalic features.[16] More recently, there has been an increasing awareness of the role that metabolic disturbances play in the genesis of NPH symptoms. For instance, accumulation of beta-amyloid and disturbance in cholinergic neurotransmission may contribute to cognitive and memory decline.[17] This would explain why cognitive function sometimes does not improve after shunting. It is also suggested that deterioration of striatal GABAergic neurons and lower dopamine levels in the substantia nigra could lead to motor dysfunction. This idea would account for the observation that patients who initially show gait improvement after shunting later regress despite proof that the shunt is working or even after valve pressure adjustments. Although we do not fully understand the interplay of the multiple factors that affect NPH patients, it is clear that NPH symptoms do not simply evolve from problems in CSF dynamics.

Clinical presentation

Although NPH has traditionally been associated with neurosurgeons because of its ultimate treatment, the evaluation and workup that lead to surgery require the involvement of many other medical professionals. It may be the primary care provider who casts the first suspicion or the geriatric specialist who pushes for further workup. Then there is the neuropsychologist who delineates the condition by performing neurocognitive evaluations. However, it can be argued that it is the neurologist who holds the central position as he or she has the deepest knowledge of other similar conditions that allow for better differentiation and diagnosis of NPH.[18]

It is easy to say that NPH presents with the classic triad of gait disturbance, urinary incontinence and mental decline. However, it can be challenging to assess the character of each of these symptoms since there are other conditions that may produce NPH's components. For instance, gait disturbance can be seen in movement disorders and a common differential is Parkinson's disease. Memory or cognitive decline can be seen in Alzheimer's disease; in fact, it is the more common consideration. As for bladder incontinence, there are a host of urological and neurological reasons that can be suspected. Having said all that, there are typical characteristics that we can look for when evaluating a patient who presents with these symptoms.

The most prominent symptom is usually the progressive difficulty in ambulation. It is typically described as a wide-based gait that is slow and unsteady. The patient usually walks in small steps and has poor floor clearance, that is, they do this with their feet clearing the floor at a low height. Others describe it as a feeling that the feet are glued to the floor, commonly referred to as 'magnetic feet'. The degree of gait disturbance depends on the severity of the NPH and patients who are in the early stages of the disease can walk almost normally except for some unsteadiness. It is not uncommon to encounter patients who are still highly functional and simply report a gait disturbance on walking a certain distance or against an incline. Conversely, patients with severe NPH can be so debilitated that they are unable to stand without support. Despite the advanced and severe state, their response to shunting can be very dramatic so they are not to be dismissed or given up on.

Mental decline is usually in the form of problems with memory, particularly short-term memory. It may also involve a decrease in mental alertness and an overall slowing of thought processes. The process may be so gradual that nobody notices it or it is attributed to ageing. It is important to ask family members aside from the patient because it may not be apparent to the patient himself or herself. The physician may also find it difficult to detect during the finite visit, whereas family members are able to share their observations of the patient over a longer period of time and across varying situations. Family members are crucial to the history-taking in this sense.

Urinary incontinence may start as progressive urgency, but many will have frank incontinence by the time of consultation. It is a symptom that the examiner needs specifically to ask about because it may not be recognized by the elderly patient or family members as significant. They may not realize that it is related to the overall neurological condition or the patient may be somewhat embarrassed to say that he or she is already on adult diapers. Of the clinical triad of symptoms, urinary incontinence is usually the last to develop. It is considered to be a symptom of late-stage NPH.[19]

Differential diagnosis

When dealing with the geriatric population, it is not hard to imagine that NPH symptomatology in an elderly patient

can be easily mistaken for, and brushed aside as, part of the ageing process. Awareness of this condition is not as prevalent as it should be and many patients do not come to medical attention. Indeed, one can only wonder how many patients have gone undiagnosed and have potentially missed out on a better quality of life had they been shunted.

Another challenge to identifying NPH is related to its differential diagnoses. These include Parkinson's disease, Alzheimer's disease, vascular dementia and spinal stenosis. Most commonly, it can be difficult to differentiate from Parkinson's and Alzheimer's disease. Gait similarities in NPH and Parkinson's disease include short steps and leg rigidity.[20] The typical tremor of Parkinson's disease may help make this diagnosis, but sometimes patients with NPH can also have confusing tremors. In general, it is possible to differentiate between the two by the gait patterns. NPH is characterized by reduced stride length, reduced step height and balance difficulty. Parkinson's disease patients have a shuffling gait with impaired arm swing and walk with their hips and knees slightly flexed and trunk bent forward.[21] In comparing Alzheimer's disease and NPH, the dementia is not as pronounced as in Alzheimer's disease. However, it is not uncommon to find NPH patients with concurrent Alzheimer's disease.[22] It is important to identify patients with both Alzheimer's disease and NPH, because this particular subset tends to respond poorly to shunting.[23] Given these challenges in differential diagnosis, we again emphasize the crucial role that neurologists and neuropsychologists play in the evaluation of potential NPH patients.

Diagnostic modalities

Numerous tests have been developed over the years to help in the diagnosis of NPH. Some have stuck and become incorporated into regular practice whereas others have passed on to the realm of historical interest. It is fascinating to see how the evolution of these tests reflects the dynamic ideas that have been elucidated with regard to its pathophysiology over the past five decades. As in many medical conditions, diagnostic tests are not meant to replace good history taking and physical examination. In fact, clinical acumen and computed tomography/magnetic resonance imaging (CT/MRI) play a primary role in clinching the diagnosis. However, it is important to note that the diagnostic workup for NPH is as much about diagnosis as it is about determining whether a patient will respond well to surgery. For this reason, a number of other diagnostic modalities have been developed to predict shunt responsiveness. There is still significant variability in practice as far as usage is concerned, depending on ideological and logistical differences from place to place.

CT/MRI

Imaging via CT or MRI remains the main diagnostic tool in NPH. The finding that is demonstrated is ventriculomegaly (Figure 56.1). Whereas a head CT is able to show enlarged ventricles, MRI gives additional information that may contribute to the evaluation of a patient. For instance, white matter changes in the subcortical and periventricular areas have been associated with NPH. These abnormalities appear on MRI as T2 hyperintensities (Figure 56.2). An MRI can also show flattened gyri and effaced sulci that indicate tightness in the intracranial compartment. It is important to remember, however,, that even if the arachnoid space looks 'spacious', it does not necessarily rule out the condition. MRI may also provide details that may be helpful in excluding other disease entities. For these reasons, it is probably better to order an MRI whenever feasible and it is unnecessary first to go through a CT scan. However, in places where MRI is not readily available, CT scanning is adequate for the purpose of demonstrating ventriculomegaly. It is also easier and cheaper to use CT in the postoperative period when checking for shunt position or monitoring for formation of subdural collections after shunt valve reprogramming (see below).

In the elderly population, it is common to find cerebral atrophy. This age-related thinning of the cerebral mantle is accompanied by a reciprocal dilatation of the CSF spaces including the ventricles, a finding that is commonly referred to as '*ex vacuo* dilatation'. Whether it is a CT or an MRI of

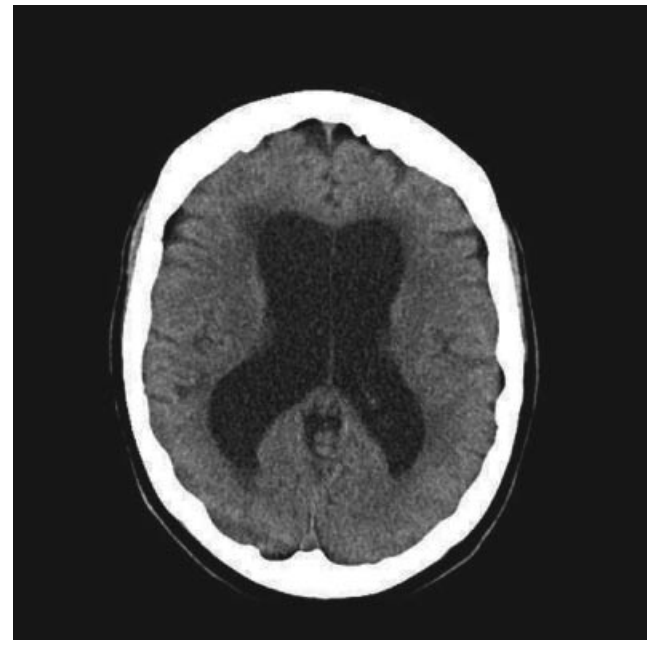

Figure 56.1 CT scan showing typical features of NPH, with ventricular enlargement out of proportion to cerebral atrophy.

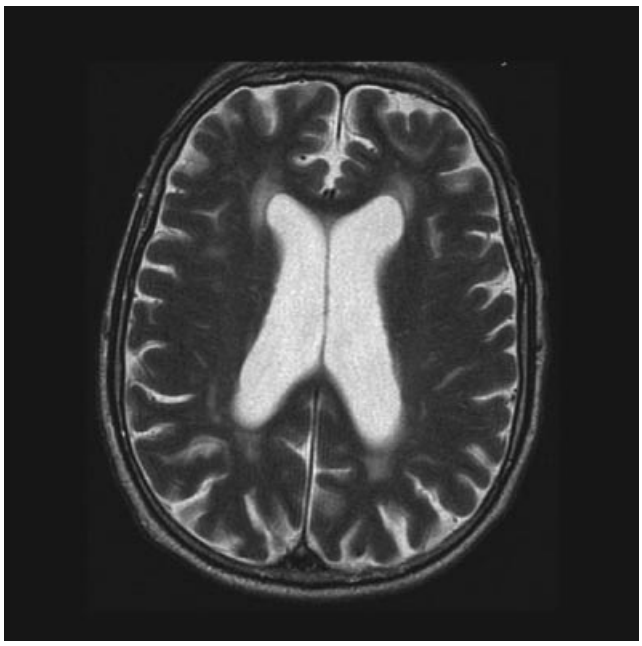

Figure 56.2 T2 sequence MRI showing white matter changes that may be seen in NPH.

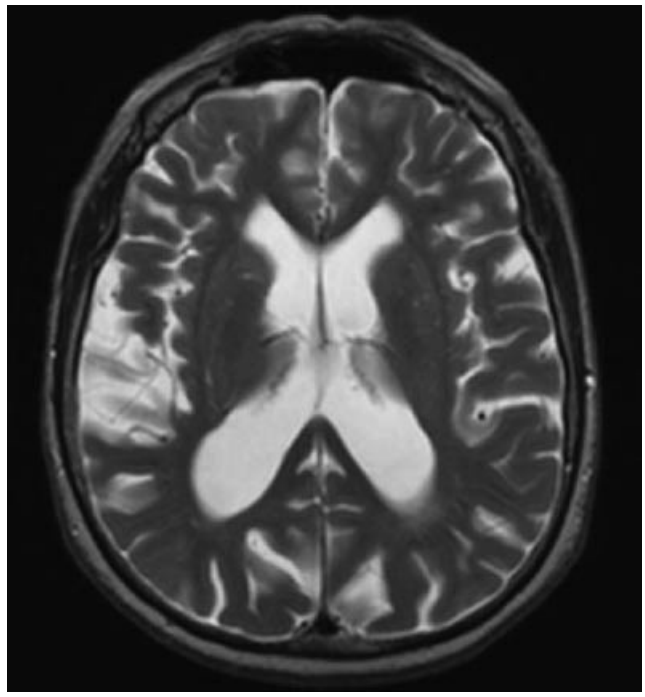

Figure 56.3 Natural *ex vacuo* dilatation of the ventricles as a result of ageing-related cerebral atrophy.

the brain, this *ex vacuo* phenomenon has to be taken into consideration when evaluating for hydrocephalus in the geriatric population. For it to be significant, the ventriculomegaly has to be out of proportion to cerebral atrophy (Figure 56.3).

Lumbar puncture

In many disease conditions, a lumbar puncture (LP) or spinal tap is routinely used to obtain CSF for laboratory studies. Its role is different in NPH; it is not so much for CSF sampling but rather CSF evacuation to see whether removal of CSF from a patient's system results in an improvement of symptoms, primarily gait. The other difference is that larger amounts of CSF evacuation are necessary in the evaluation of NPH as smaller volumes may not be sufficient to uncover potential benefits. It is therefore typically referred to as a high-volume LP to differentiate it from the usual LP where just enough is obtained for cell counts or culture. The amount of CSF removed varies but is usually around 40 ml. Although any competent physician may choose to perform the LP, it is commonly done by the neurologist, and for good reason. Aside from being technically skilled in the procedure itself, neurologists are in the best position to evaluate the character of a patient's gait before and after high-volume LP. For a more accurate comparison, many will videotape the patient walking pre- and post-LP. In patients who show response, there is usually a return to the pre-LP gait disturbance after a few weeks. This further solidifies the diagnosis.

Although CSF may be sent to the laboratory for other tests, it serves no purpose in the diagnosis of NPH. There are ongoing efforts to identify CSF biomarkers that would be helpful in the diagnosis of NPH, but none has been proven to be useful.[24] Measuring CSF pressure for NPH *per se* is also unnecessary since the value of LP is in boosting the diagnosis of NPH and indicating shunt responsiveness if there is subsequent improvement in gait. Several studies have highlighted the high predictive value of a positive lumbar puncture test.[25–27] There are doubts, however, about how well this test identifies candidates for ventriculoperitoneal (VP) shunting, because the amount of CSF removed in this one-time process can be inadequate in producing neurological improvement. One can argue that LP does not closely mimic the continuous drainage of shunting. Some worry that there could be patients who show no gait improvement after this momentary drainage of CSF and potentially lose out on benefiting from a shunt. Hence many still consider or at least discuss the option of shunt placement even if high-volume LP is equivocal or unrevealing, especially if clinical signs and symptoms are typical for NPH. Others would advocate a more detailed and involved test such as a lumbar drain trial (see below). Still, LP continues to be the mainstay in identifying appropriate shunt candidates. It is available anywhere and is logistically simple to administer.

Lumbar drain trial

To mimic better the potential effects of a shunt, many have moved on to performing a lumbar drain (LD) trial rather than just relying on an LP. LD involves performing a lumbar puncture using a large-bore Touhy needle followed by insertion of a small-calibre catheter. The catheter is left in place to drain CSF continuously from the thecal sac for ~4 days. The catheter is connected to an external bag within a closed system that on average drains about 100–150 ml of CSF per day. Unlike LP, this is an in-house procedure and is usually under the care of the neurosurgery service. The patient stays in the hospital for the duration of the LD trial and is checked daily for improvement in gait and cognitive function. Typically, a third-party person such as a physiatrist or neurologist is in charge of the daily assessment so as to minimize bias. The choice between doing an LP or an LD trial varies across institutions not only due to differences in physician beliefs but also for logistical reasons such as bed availability for this type of non-urgent admission. Some patients also do not tolerate LD well. It may need to be aborted if there is significant spinal or low-pressure headache or nerve root irritation by the catheter causing back or leg pain.

LD has been shown to predict the surgical outcome in up to 100% of cases.[28,29] However, most would give an estimate that is closer to 80%. A prospective multicentre study found that a positive lumbar drain test predicted good shunt response in 87% of cases, but cautioned that a negative result in the test is unreliable as the false-negative rate was 64%.[27] Therefore, patients who have a negative lumbar drain test should still be considered for shunting and one should look at the overall clinical picture and the patient's wishes as guides in the decision-making process.

Lumbar or CSF infusion test

The lumbar or CSF infusion test is not a widely used diagnostic tool but has its own advocates. It is a hydrodynamic test that is performed by inserting two cannulas into the lumbar thecal sac, with one cannula attached to an infusion pump and the other to a closed-system pressure monitor. A similar manoeuvre can be done intraventricularly through a surgically placed ventricular access device, but this is less popular as it is more invasive. The test assesses CSF absorption on the premise that the pathology lies in increased resistance to CSF outflow. Normal saline is infused at a constant rate until a steady-state intracranial pressure (ICP) plateau is reached. A value for resistance to CSF outflow, commonly denoted RCSF, is then calculated by dividing the increase in pressure during infusion by the infusion rate.[30] RCSF values below 13 mmHg ml^{-1} min^{-1} are regarded as normal[31] whereas values above 18 mmHg ml^{-1} min^{-1} are abnormal.[32] The positive predictive value has been estimated to be 80% and its false-negative prediction is about 16%.[33] There has been some argument about the details of the equation used to calculate RCSF[34] and also on what absolute value predicts good response to shunting. There are some who feel that the infusion test is of no value in diagnosing NPH.[23] Although the infusion test may be useful, it is not widely employed because it is cumbersome and relatively invasive, with equivalent information that can be obtained with other tests such as the lumbar drain.

Flow within the aqueduct

CSF flow characteristics in the aqueduct of Sylvius can be studied using MRI. Bradley *et al*.[35] found that increased flow void in the aqueduct, as seen on proton density-weighted conventional spin-echo images, was associated with better shunt outcome. Phase-contrast MRI is able to demonstrate CSF movement within the aqueduct during the cardiac cycle. This has been termed aqueductal CSF stroke volume and a finding of hyperdynamic flow correlates well with good response to surgery.[36,37] Although high aqueductal CSF flow is a good predictor of a favourable outcome, a finding of normal velocity should not be interpreted as ruling out NPH.[38] In such instances, further evaluation with other tests needs to be done. It should be mentioned that there have been dissenting opinions on the usefulness of CSF flow rate analysis. One such study showed that measurement of aqueductal CSF flow was not reliable in predicting post-shunt improvement.[39] Likewise, it has been shown that whereas a high CSF flow rate was associated with a good shunt response, the postoperative flow rate was unpredicatable.[40]

ICP monitoring

ICP monitoring has been shown to have some use in NPH. However, it is not the absolute ICP value but rather ICP pulsatility that has clinical significance. A recent study showed that patients who underwent ICP monitoring and were found to have abnormal ICP pulsatility had a 93% response rate to surgery, whereas those who had normal ICP pulsatility had only a 10% surgical response rate.[41] Abnormal ICP pulsatility was defined as an average ICP wave amplitude of >4 mmHg and >5 mmHg in more than 10% of recording time. It also showed that static ICP measurements were not good at predicting surgical outcome. Other investigators have shown that the presence of B waves, which indicate normal mean baseline ICP with transient elevations of mean and pulse pressure, in more than half of the monitoring points to a better outcome with shunting.[42,43]

Neuropsychological testing

Of the clinical triad, the cognitive dimension is probably the most challenging to study. Neuropsychologists, therefore, play an important role in helping complete the clinical picture of an NPH patient. Neuropsychological testing not only assists in the pretreatment diagnosis but is also valuable in outcome assessment and long-term follow-up. It involves a detailed, multifaceted study, but visual attention, verbal recall and motor precision appear to be the most representative tests.[44] Although some have expressed doubts about the value of neuropsychological testing in diagnosing NPH and in outcome prediction, its use has grown and most institutions with formal programmes for NPH employ it to detail the cognitive impairment in NPH. It may even differentiate between signs of NPH and mild Alzheimer's disease.[45]

Other tests

There are other tests that have been used to help in the diagnosis of NPH. In a review of non-invasive biomarkers in NPH, investigators found three diagnostic studies that correlated well with surgical outcomes.[46] These are phase-contrast MR imaging showing CSF flow void (as discussed earlier), magnetic resonance spectroscopy (MRS) and single-photon emission computed tomography (SPECT). An Alzheimer-type pattern on SPECT and a typical *N*-acetylaspartate/choline ratio on MRS were found to predict surgical response with high accuracy. However, these diagnostic modalities have yet to become standard in the workup for NPH as further studies are needed to support their true usefulness. Another diagnostic test that has been described is radionuclide cisternography. However, its results have been found to be poor predictors of response to shunting,[47] Positron emission tomography (PET) has also been investigated. It showed decreased regional glucose metabolism in patients with idiopathic NPH as a group, but there was no significant correlation with shunt outcome.[48] Still, PET has led some to focus attention on the thalamus and basal ganglia,[22] where mean cerebral blood flow has been found to be decreased in NPH patients[49]

Treatment

Patient selection and decision-making

Despite the numerous diagnostic modalities that have become available, patient selection for surgery starts with the recognition of clinical features of NPH coupled with evidence of ventriculomegaly on CT or MRI. The exact criteria for determining which patients to operate on vary from institution to institution. Indeed, it can even vary from one surgeon to the next within the same institution. The establishment of formal NPH programmes has helped reduce some of the variability and the occasional accompanying confusion. At one author's institution, a candidate undergoes neuropsychological evaluation and a large-volume LP. We used to insist on a lumbar drain trial but it became problematic for logistical reasons such as bed availability for these low-priority elective admissions. We have, therefore, relied on response to the LP as an indicator for surgery. When response is equivocal, we still consider a lumbar drain trial for further delineation. At the other institution, the lumbar drain trial is employed to select who will most likely benefit from surgery.

In places where the CSF infusion test is employed, experts recommend a cutoff value of 18 mmHg ml^{-1} min^{-1} on outflow resistance, whereas those with values below 18 mmHg ml^{-1} min^{-1} may also be shunted if their CT shows typical findings of NPH with limited white matter lesions and no significant cerebrovascular disease on history.[50] There are a number of other ancillary tests that may be useful, but these are either not widely accepted or not easily available. Indeed, of all the diagnostic modalities that have been discussed above, no single test can rule out potential response to surgery.[51] This has led some to realize that we may be too rigid and conservative about whom to offer surgery, especially since the procedure involved is relatively low risk. In an interesting study entitled 'Shunts in normal pressure hydrocephalus: do we place too many or too few?', it was calculated that even if half of all shunted patients develop complications, the response rate to shunting would have to be less than 5% for the procedure to do more harm than good.[52] Other studies support advocacy towards a lower threshold for offering shunt placement to patients with suspected NPH in the hope of reducing the number of patients who may miss out on the life-changing benefits of shunt placement.

Ventriculoperitoneal shunting

The mainstay of NPH treatment is CSF diversion in the form of VP shunting. The shunt system has three basic parts: (1) the ventricular catheter, also referred to as the proximal catheter; (2) the valve, which regulates flow and may have an associated reservoir for CSF tapping; and (3) the peritoneal catheter, also known as the distal catheter (Figure 56.4). Basically, the shunting procedure involves inserting the proximal catheter into the lateral ventricle and connecting it to the reservoir-valve unit. This unit, in turn, is connected to the distal catheter which drains into the peritoneal cavity where the CSF is absorbed along its lining. Some wonder whether this will cause the abdomen to bloat, but in reality, unless the peritoneum has a malabsorption problem, the patient will not notice a change because the amount of CSF coming out of the distal tip is actually an intermittent trickle and not a continuous outpour. The

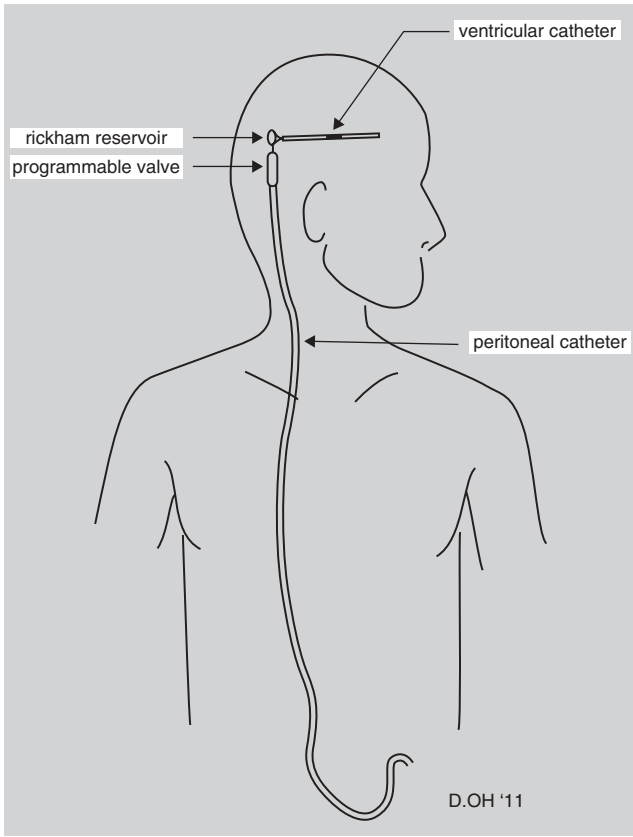

Figure 56.4 Diagram of a ventriculoperitoneal shunt system.

valve and reservoir are implanted in subgaleal space, easily palpable so that the valve can be readily reprogrammed using a hovering magnet and the reservoir can be tapped with a gauge 23 or 25 needle. A CSF or shunt tap is done when CSF samples are needed for studies or the patency of the shunt system needs to be tested.

The ventricular catheter is placed through an occipital or frontal burr hole and the rest of the shunt system is threaded down the side of the neck and anterior chest wall in the subgaleal–subcutaneous layer with the aid of a tunnelling device. The patient is left with two just two small incisions, one in the scalp and another on the abdominal wall. Alternatively, the distal catheter may be implanted into the pleural cavity or the atrium of the heart if the peritoneum is not a viable place for CSF absorption or was a site of previous failure. The operation is done under general anaesthesia and usually lasts about 30–60 min. It commonly entails a one-night stay in the hospital.

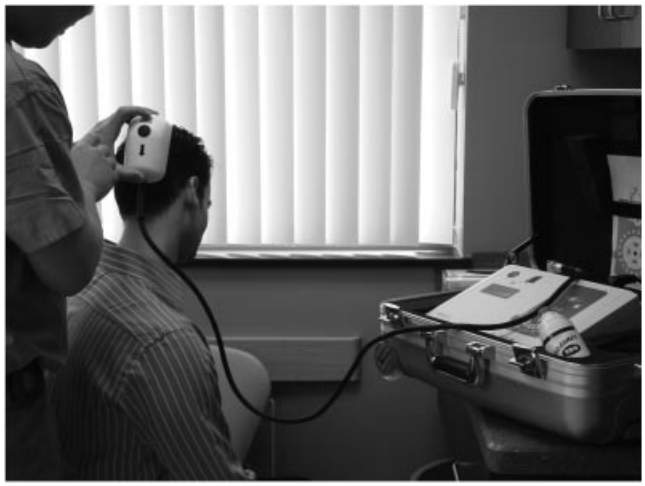
Programmable valves

The catheters used are standard but there is considerable variation in the type of flow-regulating valve. Conventionally, shunt systems employ valves that come with preset opening pressure levels – low, medium and high. Low-pressure valves allow CSF to pass through even at low CSF pressures whereas high-pressure valves allow CSF drainage only when CSF pressures are high enough. In NPH, where the CSF pressure is not typically elevated, patients do well with low- and medium-pressure valves. However, there are times when a higher resistance to drainage is necessary. This is most commonly encountered in cases where overdrainage from the ventricles inside the brain leads to a relative shrinkage of the brain surface away from the dura and causes the formation of subdural effusions or haemorrhage. Patients have had to be taken back to the operating room to change the valve to a high-pressure one to drain less CSF, allow brain re-expansion and make the subdural effusion go away.

It therefore became apparent that finding the right balance between CSF drainage and overdrainage is not something that is best addressed by fixed-pressure valves. Patients also tend to find optimal gait at different valve settings. For this reason, programmable or adjustable shunt valves were developed and have become widely used in the treatment of NPH. As an example, we can look at the most commonly used version, which is the Codman–Hakim programmable valve. It has a pressure setting range of 30–200 mmH_2O and can be adjusted in increments of 10. At the time of surgery, the valve is typically programmed to an initial setting of 120 mmH_2O. Postoperatively and in subsequent clinic visits, the valve setting can be adjusted, according to the patient's progress, by simply holding up a magnetic programmer over the shunt valve (Figure 56.5). It therefore eliminates the need for a reoperation in cases of overdrainage or underdrainage, and allows us to find the optimal pressure setting for a particular patient. As a demonstration of how useful the programmable shunt is, one study showed that about half of shunted patients required adjustments.[53] The reprogramming was downward in 52% of cases for underdrainage (Figure 56.6) and upward in 46% for overdrainage and subdural haematoma formation. The ability to programme and reprogramme the shunt valve is an extremely useful advantage, not only in the immediate postoperative period but also in later years, as a particular patient who does well at a certain pressure level may later require a different setting as his or her intracranial dynamics change over time.

Endoscopic third ventriculostomy

Although VP shunting is the standard treatment for NPH, it is not the only way of diverting CSF from the ventricles. Endoscopic third ventriculostomy (ETV), a well-established procedure for hydrocephalus in children, involves creating a hole in the thin, membranous floor of the third ventricle with the use of a neuroendoscope, which is introduced through a frontal burrhole. It takes advantage of



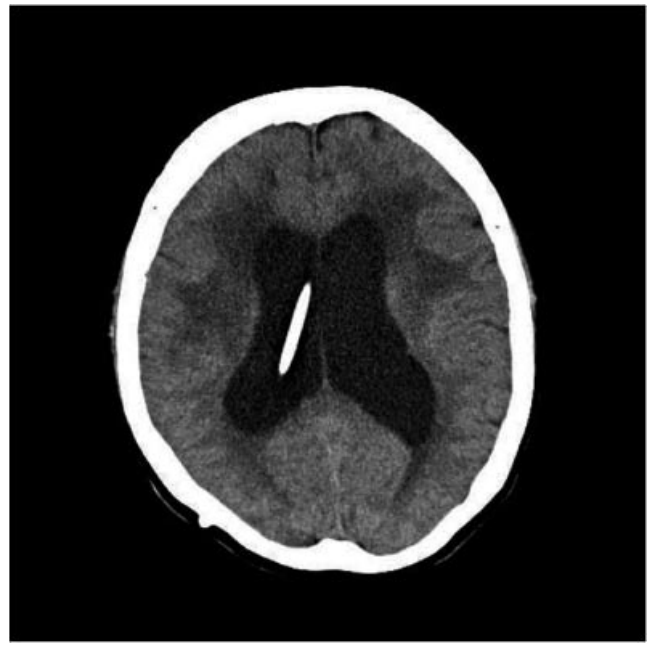
(a)

(b)

Figure 56.5 Valve pressure programming for the Codman–Hakim shunt. The newer version has a built-in ultrasound tip that automatically verifies the new setting which saves having to send the patient for X-ray verification after each adjustment.

an interesting and unique anatomical feature of the CSF pathway, that is, this thin floor is all that separates the CSF being produced in the upper ventricles from the basal subarachnoid space beneath where CSF is eventually absorbed. Hence this allows CSF to bypass the aqueduct of Sylvius, fourth ventricle and the foramina of Magendie and Luschka and gets it straight to arachnoid villi for absorption. It does away with having to leave any hardware in the body and with it shunt-related complications such as malfunction or infection are avoided. It is a safe procedure and is as short as a standard shunt operation.

It is easy to imagine how ETV works well for children with aqueductal stenosis or other forms of obstructive hydrocephalus. Indeed, it has been shown to be useful in NPH especially if aqueductal stenosis is the underlying



(a)

(b)

Figure 56.6 Ventricles do not necessarily get smaller after successful shunting where there is good clinical response. However, a decrease in ventricular size/hydrocephalus and in overall brain 'tightness' can sometimes be demonstrated on imaging. In this figure, the change was seen after lowering the pressure setting of a programmable valve.

cause. However, the question that is raised when applied to idiopathic NPH is whether ETV does any good given that the problem is not an obstruction in the aqueduct, fourth ventricle or foramina; it is a form of communicating hydrocephalus.

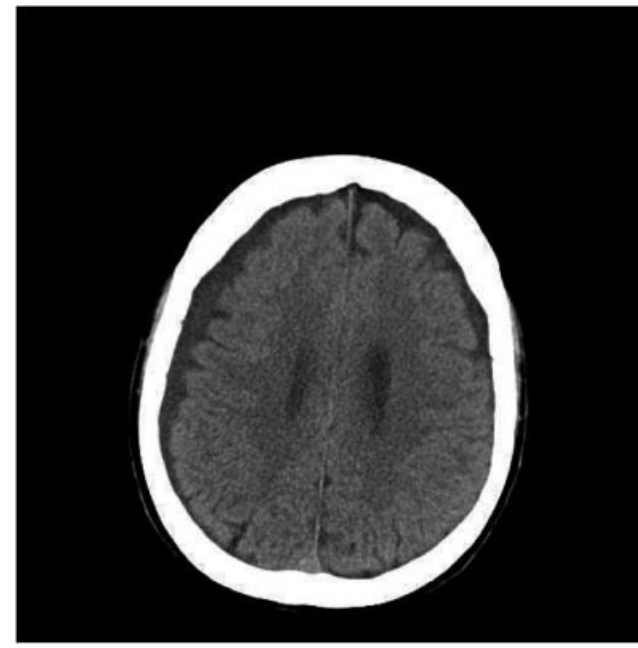
The argument is that the impedance is downstream at the level of the arachnoid villi. However, there is evidence that it can be effective in NPH, with reports suggesting that ETV works by relieving stress along the periventricular tissue and improving local blood flow.[54] Some use ETV in NPH patients whose outflow resistance is increased in the ventricular infusion test but not in the lumbar infusion test, a finding that suggests functional aqueductal stenosis.[55] Recent literature espousing the hydrodynamic theory gives further credence to the effectiveness of ETV in treating NPH, as discussed earlier in this chapter.

Risk and complications

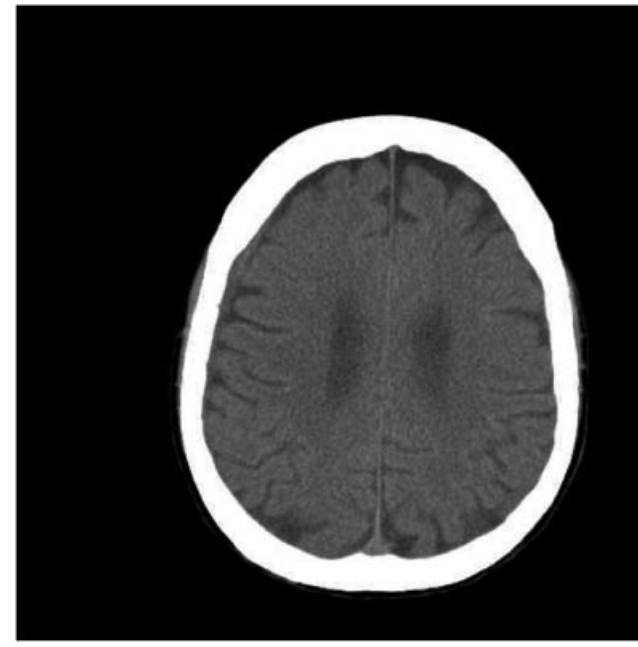
A shunt operation is generally safe, but just as with any operation in the elderly, systemic complications may occur. With reference to the shunt, there is a 1–2% risk of perioperative bleeding or infection. Late shunt complications are also possible. In fact, these are among the most frustrating problems in neurosurgery, although they do not appear to be nearly as common in the adult population as in the paediatric realm. Still, one systematic review of studies on NPH spanning the period 1977–2000 revealed an overall complication rate of 38% and a reoperation rate of 22%.[47] More recent data, however, show lower complication rates of 14–20%,[53,56] reflecting benefits gained through advances in techniques and materials. Furthermore, the advent of programmable valves has made many of these cases readily solvable without having to take the patient back to the operating room.

Shunt infection presents as fever and/or erythema and tenderness along the shunt tract. In severe cases, there can be skin breakdown and discharge of purulent material. It is verified by CSF cell counts and positive cultures obtained through a shunt tap. The optimum treatment for shunt infection is externalization of the distal catheter usually at the level of the clavicle for about 1 week while antibiotics are given to treat the infection. If the patient is not too shunt dependent, it can simply be removed. After the infection clears, the shunt is then re-internalized with a new distal catheter or an entirely new system is installed.

Subdural effusions appear as hypodense collections on CT and T1 hypointense collections on MRI over the cerebral hemispheres. They can sometimes be watched, usually if they are less than 1 cm in thickness. If the shunt is a programmable one, the pressure setting can be raised to obliterate the subdural collection (Figure 56.7). Although not all subdural collections have to be addressed and may actually coexist with improved CSF dynamics and



(a)



(b)

Figure 56.7 Subdural effusion. Note the hypodense collection in the subdural space (a). After increasing the pressure setting of the programmable valve, which decreases the amount of CSF drained from the ventricles and leads to brain re-expansion, subdural effusion is resolved (b).

good clinical response,[57,58] those that are persistent and symptomatic have to be surgically drained.

Shunt obstruction is another complication that may occur, although the rate is again notably lower than in the paediatric shunt population. It is usually due to proteinaceous debris or blood products clogging up the ventricular catheter, valve chamber or distal catheter. This may be checked by doing a shunt tap, as previously mentioned, which allows evaluation of shunt patency. A radionuclide study can also be done to check shunt patency when shunt obstruction is suspected.[59] Any part of the catheter may also fracture or become disconnected for reasons such as trauma or simple wear-and-tear over time. This can be revealed by X-rays that show the entire shunt system, commonly referred to as a *shunt series*. Reoperation involves identifying the malfunctioning component and then either flushing or replacing it.

An intriguing complication is hearing loss. Subjective note of post-shunt hearing loss is not common, but a study actually showed that two-thirds of ears tested showed a loss of more than 10 dB after shunting.[60] Most of it was temporary, however, and recovery was seen within a few months. The cause remains unknown.

ETVs are not without problems. It should be noted that not all neurosurgeons may be comfortable performing it. ETV may be technically challenging for someone who does not perform it routinely. Intraoperative complications include intraventricular haemorrhage and vascular injury in the prepontine cistern upon advancement of the endoscope through the floor of the third ventricle. While shunt-related problems are avoided, ETV may also fail at a later time as the hole in the third ventricular floor can spontaneously close. A repeat ETV may be performed or conversion to a VP shunt may be offered.

Outcome and prognosis

Response rates following VP shunting vary not so much based on the surgical prowess but rather patient selection. It is therefore important that we identify surgical candidates based on predictors of good outcome. These include the presence of the classic clinical features of NPH, an unequivocally positive result on lumbar puncture or lumbar drain trial and the presence of pressure signs on CT or MRI such as periventricular transependymal flow. We also rely on clinical acumen in delineating the character of a patient's gait to see how suggestive it is for NPH. CSF outflow resistance values of more than 20 mmHg ml^{-1} min^{-1} and the absence of dementia have also been correlated with good outcome in patients with late-stage NPH.[61] For patients undergoing continuous ICP monitoring, the presence of B waves in more than 50% of the recording time predict good outcome.[43] Factors that do not appear to affect outcome were patient's age, duration of symptoms, extent of ventricular dilatation and degree of dementia.[56]

The generally accepted success rate of VP shunting for NPH is 80%. In terms of symptom components, improvement is commonly seen in gait and urinary incontinence, but not as consistently in cognitive impairment, particularly short-term memory. Studies estimate that 81–86% of patients improve in gait, 70% in bladder control and 40–44% in cognitive function.[39,56] Sustained long-term improvement is more difficult to measure, as some patients who initially do well after shunting may experience deterioration in later years. However, this problem has been greatly reduced with the use of programmable valves. As the mechanical characteristics and CSF flow dynamics of a patient's brain change over time, reprogramming the valve setting can help in establishing a favourable flow soon after or long after surgery without the need for a reoperation. Shunt devices are designed to last a long time and they usually last a lifetime. Replacement is only necessary when it is clogged, fractured or infected. The survival rate of shunt devices in general is 50% in 5 years whereas for programmable valves it has been estimated to be around 80% in 5 years.[53]

Long-term care and follow-up

Most patients readily recover their functions after surgery. For some, however, rehabilitation is an essential component of the recovery process. Physical therapy can be performed in a rehabilitation centre or at home, depending on how well the patient does after surgery and how much social support is available. As discussed above, there is a period after shunt placement when the shunt valve is reprogrammed based on the patient's clinical performance until the optimal setting is found. Once this has been achieved, the patient is usually followed once per year with a CT scan. Of course, patients are advised to seek immediate attention if any problem occurs in the interim. The CT scan is not so much for monitoring ventricular size, which may or may not change after shunting, but more for checking for formation of subdural collections or other sequelae. The patient may also need to be seen at times when he or she undergoes an MRI for any body part, as being in a strong magnetic field can alter the pressure setting of a programmable shunt valve. We will typically check the valve setting by taking an X-ray of the valve and looking at its dial or simply reprogramme it to the intended setting with ultrasonic confirmation.

Neurologists are typically involved in the initial workup for NPH, but there is now greater recognition of the unique role that they can also play in its long-term management.[18] Their understanding of other similar neurological conditions and how these may overlap or interact with NPH allows for optimal follow-up and guidance of management in partnership with neurosurgeons, geriatricians and other providers.

Key points

- In an older patient with symptoms and signs of gait disturbance, change in mental performance and urinary dysfunction, normal pressure hydrocephalus (NPH) should be considered as a possible diagnosis.
- Imaging via computed tomography (CT) or magnetic resonance imaging (MRI) remains the main diagnostic tool in NPH.
- Ventriculoperitoneal (VP) shunting appears to be successful in about 80% cases of NPH.

CHAPTER 57

Acute stroke care and management of carotid artery stenosis

David Doig and Martin M. Brown
Institute of Neurology, University College London, London UK

Introduction

A stroke is defined as 'rapidly-developed clinical signs of focal or global disturbance of cerebral function, lasting more than 24 h or until earlier death, with no apparent non-vascular cause' by the World Health Organization.[1] A stroke is therefore distinguished from a transient ischaemic attack (TIA), which is defined similarly, except that the focal neurological symptoms must recovery fully within 24 h. The term 'cerebrovascular accident' should be avoided because of its negative connotations. Stroke carries with it a significant personal, community and economic burden. It is estimated that, in the USA alone, around 795 000 patients suffer a stroke each year at a direct and indirect financial cost of over US$70 billion.[2] When considered separately from other cardiovascular diseases, stroke is the third leading cause of death in the Western world, and in the world as a whole it is the second commonest cause of death. It is also the leading cause of disability in survivors. Stroke occurs at all ages from birth onwards, but becomes increasingly common with increasing age and is a major cause of suffering in the elderly population.

The management of acute stroke is evolving and applied evidence from recent randomized controlled trials, along with better management of associated risk factors, has contributed to a relative reduction in age-adjusted morbidity and mortality from the condition in many countries. There now exists a good evidence base for hyperacute and acute interventions, and also for pharmacotherapy with the aim of secondary prevention. Acute stroke will, however, remain an important and common medical presentation as the proportion of the population aged over 65 years increases in many developed countries.

This chapter addresses the aetiology of stroke, the immediate management of the patient presenting with an acute stroke, the initiation of secondary prevention measures and the management of carotid artery stenosis. Intracerebral and subarachnoid haemorrhage are also discussed, as these conditions will also present to the geriatrician or stroke physician with the rapid onset of a focal neurological deficit.

Stroke aetiology

It is important to recognize that the terms 'stroke' and 'TIA' describe the presentation of the patient and are not sufficient as a diagnosis on their own. This requires a description of the underlying pathology (haemorrhage or infarction), anatomy (vessel and territory involved) and aetiology (mechanism). Ischaemic stroke may occur as a result of a number of heterogeneous conditions. The major precipitant of cerebral ischaemia in the elderly population is atherosclerosis. Atheromatous plaque may occlude the artery at the site of buildup, but more commonly plaque rupture with superimposed thrombosis results in occlusion or embolization to a smaller, more distal artery, precipitating cerebral ischaemia. Smaller 'lacunar' infarcts may be caused by microatheroma of the deep penetrating arteries of the brain or by hyaline degenerative disease of the arterioles, which together are known as small-vessel disease. The pathogenesis of atherosclerosis is discussed in more detail later in this chapter. Alternatively, stroke may be caused by intracranial haemorrhage, cerebral venous thrombosis or cardiac embolism.

Cardiac embolism may arise from thrombus formation in the left atrium promoted by arrhythmia (especially atrial fibrillation or flutter), valvular heart disease or valve prosthesis or in myocardial infarction where mural thrombosis may develop on the injured myocardium. An inter-atrial or inter-ventricular septal defect (e.g. patent foramen ovale) may allow the passage of an embolus from the venous circulation to the left side of the heart, with the potential for subsequent paradoxical embolization to the cerebral vessels.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 57.1 Classification of causes of stroke.

Cerebral infarction

Extracranial arterial embolism (internal carotid artery, aorta or vertebral artery)
- Atherosclerosis, arterial dissection, fibromuscular dysplasia, vasculitis, arterial trauma

Cardiac embolism
- Mural thrombus following myocardial infarction, rheumatic heart disease, calcific or prosthetic mitral or aortic valves, endocarditis, atrial fibrillation, atrial myxoma

Paradoxical embolism
- Deep vein thrombosis with atrial septal defect

Trauma
- Fat embolism

Iatrogenic embolism
- Cardiac surgery, cardiac catheterization, cerebral angiography

Intracranial arterial thrombosis
- Large-vessel occlusion – atherosclerosis, vasculitis, dissection, hypercoagulable states, sickle cell disease, Moyamoya disease
- Small-vessel occlusion – hypertensive arteriosclerosis, diabetes, CADASIL, vasculitis

Vasospasm
- Subarachnoid haemorrhage

Haemodynamic ischaemia
- Internal carotid artery occlusion, tandem stenoses, bilateral vertebral arterial occlusion, systemic hypotension (e.g. cardiac arrest), severe stenoses with poor collateral supply

Cerebral venous thrombosis
- Hypercoagulable states, puerperium, intracranial sepsis, malignancy

Intracranial haemorrhage

Subarachnoid haemorrhage
- Aneurysm, arteriovenous malformation, bleeding disorders, vascular malignancies, vasculitis, illegal drug use

Intracerebral haemorrhage
- Cerebral amyloid angiopathy, cavernous angioma, hypertensive small-vessel disease, cerebral venous thrombosis, venous anomalies and other causes as for subarachnoid haemorrhage

A number of other conditions may either cause ischaemic stroke or mimic its signs and symptoms and should be considered in the differential diagnosis. Information from history, examination and investigation pointing to an alternative cause should be pursued vigorously, as the appropriate and timely management of the underlying pathology may alter the chance of recurrent disease (Table 57.1).

Stroke mimics

Conditions that may mimic stroke but that are not of vascular origin include space-occupying lesions (e.g. subdural haematoma, tumour or abscess), hypoglycaemia, functional disorders and epilepsy, especially post-ictal paresis (Table 57.2).

Table 57.2 Differential diagnosis – stroke 'mimics'.

Traumatic
- Subdural haematoma
- Head injury

Metabolic
- Metabolic encephalopathy
- Toxic encephalopathy
- Hypertensive encephalopathy
- Hypoglycaemia

Structural
- Cerebral tumour
- Arteriovenous malformation

Infective
- Focal encephalitis
- Cerebral abscess

Functional

Genetic disorders
- Familial periodic paralyses
- Mitochondrial encephalopathy
- Porphyria

Disorders of neural and neuromuscular function
- Epileptic seizure and post-ictal neurological deficit
- Multiple sclerosis
- Central pontine myelinolysis
- Acute polyneuropathy
- Myasthenia gravis
- Motor neurone disease

Prognosis of stroke

The mortality following first ischaemic stroke may be as high as 41% after 5 years,[3] with vascular causes of death (stroke and myocardial infarction) most common during the first few weeks following the event.[3] The risk of recurrent stroke is highest in this acute period. When patients are divided into groups depending on the aetiology of their stroke, those with significant large-artery (carotid) atherosclerosis are at highest risk of recurrence within the first month. Recurrence is least likely in those with small-vessel disease as a cause of their stroke.

Clinical evaluation and stroke syndromes

Evaluation of the patient should begin with a detailed history. In the case of the aphasic, obtunded or confused patient, a witness history should be obtained from the ambulance staff, relative, friend or carer. It is important to establish the exact time of onset of symptoms, the

progression or regression of a deficit over time and any associated features such as headache, loss of consciousness or possible seizure. Important details from past medical history will be the presence of other cardiovascular, neurological or haematological disease, medications taken, family history and ascertainment of risk factors. It is important to establish the patient's baseline social function with respect to activities of daily living to plan future treatment, including resuscitation status, and also rehabilitation.

Examination should focus on establishing the nature and severity of the neurological deficit to aid in confirming the clinical diagnosis of stroke and establishing the likely site and size of cerebral lesion. Examination of other systems, especially the heart, may give clues to an underlying cause or prompt further investigation.

The severity of neurological deficit should be assessed using a formal tool such as the National Institutes for Health (NIH) Stroke Severity (NIHSS) Score.[4] This examination should be performed at the time of presentation and grades the patient response in a number of domains, which comprise level of consciousness, gaze and vision, motor power, ataxia, language and speech and extinction and inattention, using specific validated techniques of examination. Higher scores are associated with more profound deficit and worse outcome, although the prominence of language domains in the score may underestimate the severity of the impact of right hemispheric syndromes. The NIHSS score is used to select patients for thrombolysis (see below) and monitor their early progress. Other scales, including the Barthel Index[5] and modified Rankin score[6] (Tables 57.3 and 57.4), grade disability and handicap and are used to guide rehabilitation and measure the progress or outcome of treatment.

Identifying the likely size and location of the arterial territory involved from the symptoms and signs is an important aid to determining the mechanism and prognosis of stroke. The commonest arterial syndromes are described in the next section. Occlusion and rupture of vessels (i.e. infarction or haemorrhage) result in similar syndromes, which are indistinguishable clinically. However, in the next section, the description concentrates on ischaemic stroke for simplicity.

Table 57.3 The Barthel Index.[5]

	Bowels
0	Incontinent (or needs to be given enemata)
1	Occasional accident (once per week)
2	Continent
	Bladder
0	Incontinent or catheterized and unable to manage
1	Occasional accident (maximum once per 24 h)
2	Continent (for over 7 days)
	Grooming
0	Needs help with personal care
1	Independent face/hair/teeth/shaving (implements provided)
	Toilet use
0	Dependent
1	Needs some help, but can do something alone
2	Independent (on and off, dressing, wiping)
	Feeding
0	Unable
1	Needs help cutting, spreading butter, etc.
2	Independent (food provided within reach)
	Transfer
0	Unable – no sitting balance
1	Major help (one or two people, physical), can sit
2	Minor help (verbal or physical)
3	Independent
	Mobility
0	Immobile
1	Wheel chair independent including corners, etc.
2	Walks with help of one person (verbal or physical)
3	Independent (but may use any aid, e.g. stick)
	Dressing
0	Dependent
1	Needs help, but can do about half unaided
2	Independent (including buttons, zips, laces, etc.)
	Stairs
0	Unable
1	Needs help (verbal, physical, carrying aid)
2	Independent up and down
	Bathing
0	Dependent
1	Independent (or in shower)
Total	(0–20)

Total middle cerebral artery (MCA) syndromes

Occlusion of the trunk of the middle cerebral artery (MCA) carries the gravest prognosis and may cause infarction of a large area of brain tissue supplied by its superficial cortical branches and the deep lenticular branches supplying basal ganglia and internal capsular white matter. There is cortical dysfunction (such as a speech or spatial disorder depending on the hemisphere involved), motor and/or sensory deficit of the face and arm or arm and leg and homonymous visual field defect. There may also be a decreased level of consciousness secondary to oedema and brainstem compression, which usually develops over the course of the first 24–48 h after onset. Total MCA territory infarction is frequently fatal, with a 1 year mortality of up to 40%, depending partly on the care provided.[7]

Table 57.4 The Modified Rankin Score.[6]

Grade[a]	Description
0	No symptoms at all
1	No significant disability despite symptoms: able to carry out all usual duties and activities
2	Slight disability: unable to carry out all previous activities but able to look after own affairs without assistance
3	Moderate disability: requiring some help, but able to walk without assistance
4	Moderately severe disability: unable to walk without assistance and unable to attend to own bodily needs without assistance
5	Severe disability: bedridden, incontinent and requiring constant nursing care and attention

[a] In clinical trials, a grade of 6 is often added to record patients who have died.

Partial MCA syndromes

Branch occlusions of the MCA are heterogeneous in their presentation. If the upper division of the MCA is affected, then typically there is no visual field defect. If the lower division of the MCA is affected, then typically there is a reduced motor or sensory component to symptoms and signs. Branch occlusion is more commonly caused by embolism than local thrombus. Prognosis is variable, with a 1 year mortality of up to 16%, but 55% of patients are independent at 1 year.[7]

Lacunar syndromes

Occlusion of small perforating arterioles supplying the basal ganglia, external or internal capsule and the pons results in small infarcts known as lacunes. These have been defined on brain imaging as deep subcortical infarcts less than 15 mm in maximum diameter. They are caused by occlusion of the smaller perforating arteries either secondary to microatheroma at the vessel origin or secondary to more distal lipohyalinosis in which degenerative pathological changes occur in the tunica media and adventitia of the vessels. These two pathologies are difficult to distinguish clinically or radiologically and together are often known as *small-vessel disease*. This term is also frequently used by radiologists to describe the appearances of patchy or confluent low attenuation on computed tomographic (CT) or high signal on T_2 and fluid-attenuated inversion–recovery (FLAIR) magnetic resonance imaging (MRI) scans, in the periventricular deep white matter. These changes are also known as leukoaraiosis and are thought to be another manifestation of lipohyalinosis, as are microhaemorrhages seen on gradient echo (T_2*) MRI. Leukoaraiosis, lacunes and microhaemorrhages are independently associated with cognitive impairment. Hypertension is a major risk factor for lacunar infarction, leukoaraiosis and microhaemorrhages. The last are also associated with cerebral amyloid angiopathy.

Four common presentations of lacunar infarction, known as lacunar syndromes, are described. Pure motor stroke presents with unilateral face, arm and leg weakness. The weakness may not involve all three sites, but should involve at least two contiguous sites, that is, face and arm or arm and leg. Pure sensory stroke gives rise to hemisensory loss on the contralateral side. A larger infarct may give rise to a mixed motor/sensory stroke, but the characteristic feature of lacunar infarction remains, which is that there is no disturbance of higher (cortical) function and no visual field deficit. The fourth common type of lacunar stroke, ataxic hemiparesis, describes limb ataxia in combination with a hemiparesis and/or dysarthria. These syndromes arise from lacunar infarction (or occasionally small haemorrhages) in either the internal capsule or the pons and imaging is required to distinguish these sites. Numerous rarer lacunar syndromes are described, including unilateral chorea and hemiballismus from lacunes in the basal ganglia.

Lacunar stroke carries a good prognosis for survival, with a 1 year mortality of about 10%, but 50% of survivors remain dependent.[7]

Posterior circulation syndromes

Vertebrobasilar (or posterior) circulation syndromes result from ischaemia of the brainstem, cerebellum and/or occipital lobes, and therefore the symptoms experienced are varied depending on the vessels and territories affected. Brainstem infarction from basilar artery or perforating vessel occlusion can result in cranial nerve dysfunction, eye movement disorders and/or nystagmus, with or without bilateral motor and/or sensory deficit. Pontine infarction secondary to basilar artery thrombosis may cause the 'locked-in' syndrome. This produces quadriplegia, but with preservation of eye movements and blinking which may facilitate communication. Occlusion of one of the posterior cerebral arteries results in hemianopia, while occlusion of both posterior cerebral arteries results in cortical blindness. In some patients, the posterior cerebral artery supplies the median temporal lobe, in which case the visual field defect may be accompanied by mild or, if bilateral, severe memory impairment (amnesia). In about 5% of individuals, the posterior cerebral artery is supplied by the ipsilateral internal carotid artery via a dominant posterior communicating artery. In such cases, occipital infarction and hemianopia may result from carotid disease.

Cerebellar infarction may result in gait ataxia, but not necessarily any other cerebellar signs. Occlusion of the posterior inferior cerebellar artery (PICA) may produce the characteristic lateral medullary (Wallenberg) syndrome.

This comprises vestibular dysfunction, ataxia, ipsilateral loss of pain and temperature sensation from the face, ipsilateral Horner syndrome and contralateral loss of pain and temperature sensation in the arm and leg. Dysarthria and dysphagia are not specific for brainstem lesions and can occur with any motor syndrome.

In contrast to anterior circulation syndromes, thrombosis of the basilar artery may be responsible for a higher proportion of strokes than embolism from a distant site. The 1 year mortality for posterior circulation infarction is 19%, with 62% of patients independent at 1 year.[7]

Thalamic syndromes

The blood supply of the thalamus is carried by branches of the vertebrobasilar system and also the tuberothalamic artery that arises from the posterior communicating artery. Thalamic nuclei participate in sensory and motor function, language, cognitive function, alertness, memory, mood and motivation.[8] Hence the clinical syndrome that results from thalamic infarction depends on the specific nuclei involved. Unilateral infarction may cause memory loss or confusion, language disturbance when the dominant hemisphere is affected and spatial deficit when the non-dominant hemisphere is affected. The *thalamic syndrome* describes the combination of contralateral sensory loss and hemiparesis associated with the development of distressing post-stroke pain in the affected limbs. Bilateral infarction of the thalamus may result in coma with subsequent severe amnesia.[8]

Prehospital care

In many countries where hyperacute stroke treatments such as thrombolysis are available, the spotlight of public health has fallen on the early recognition of stroke by both the general public and allied health professionals.

Validated clinical tools such as the FAST ('Face, Arm, Speech Test') screening test[9] allow paramedics and the public to identify symptoms of stroke and can allow triage to the correct facility with early warning of the patient's arrival. FAST instructs the user to evaluate facial movement, upper limb power and speech to identify a neurological deficit and paramedic findings on examination correlate well with subsequent examination findings by a trained physician. It may, however, be less sensitive for the detection of posterior circulation events,[9] which has led to the development of the ROSIER ('Recognition of Stroke in the Emergency Room') Scale, which incorporated a measure of hemianopia and may be more suitable for use by physicians in the emergency department. Prospective validation of this scale in 173 patients referred with suspicion of stroke showed sensitivity of 93% (95% CI, 89–97%) and specificity of 83% (95% CI, 77–89%) for the diagnosis of stroke.[10]

A number of other, similar, screening tools in Melbourne (MASS), Cincinnati (CPSS) and Los Angeles (LAPSS) have also been described in the literature.

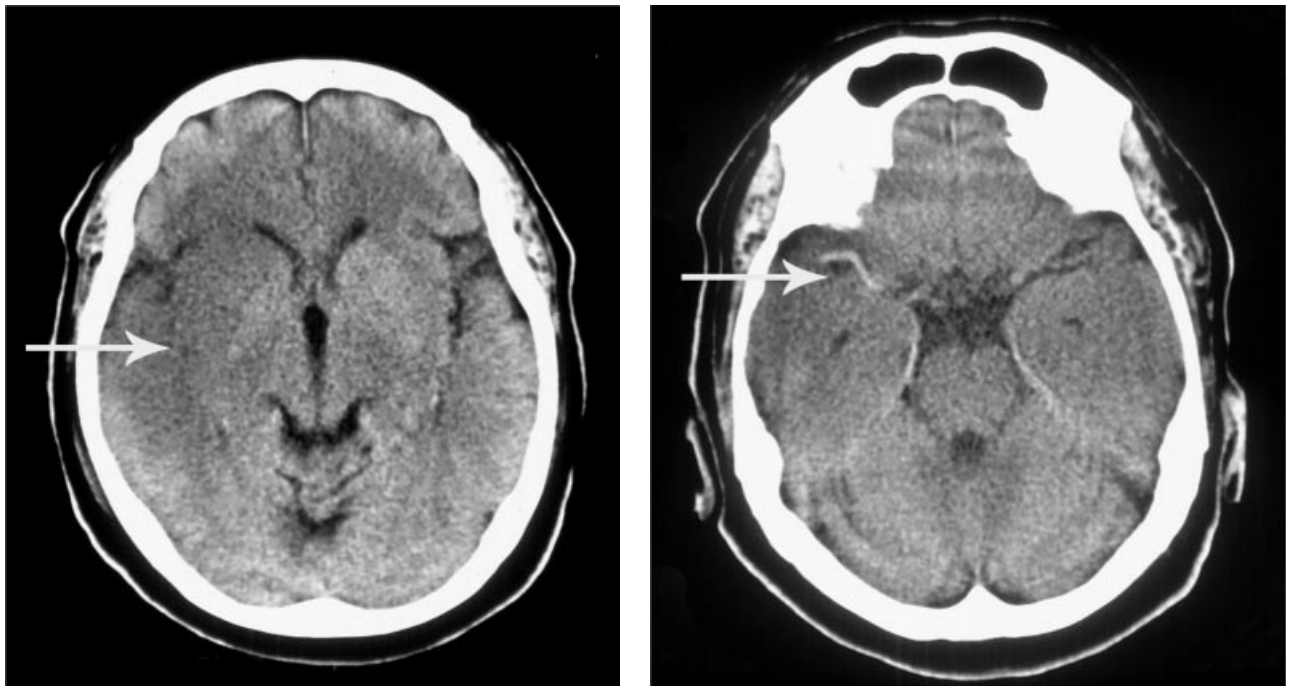
Initial investigations and imaging

The investigation of stroke and transient ischaemic attack are similar and are designed to establish the pathology, anatomy and mechanisms of symptoms and plan treatment. All patients should have urea, electrolytes, creatinine, full blood count, clotting screen, serum glucose and erythrocyte sedimentation rate carried out when they are first seen. A fasting glucose and fasting cholesterol should be done as soon as possible to exclude hypercholesterolaemia and diabetes. Electrocardiography will confirm the clinical assessment of heart rhythm or document evidence of ischaemia or acute myocardial infarction. If symptoms or clinical signs suggest respiratory involvement, such as heart failure or aspiration pneumonia, a chest X-ray should be added to these investigations. Further biochemical investigation of rarer causes of ischaemic stroke or stroke mimics will be directed by the clinical picture.

The immediate concern in acute stroke is the rapid differentiation of ischaemic from haemorrhagic stroke, which is most quickly and reliably demonstrated by non-contrast CT imaging. CT is sensitive and specific for haemorrhage within the first 8 days after stroke,[11] after which time reliability of detection decreases. MRI as an alternative is discussed below. All patients admitted with suspected stroke should undergo cranial imaging as soon as possible after admission and definitely within 24 h.[11,12] An immediate emergency scan is required for patients being considered for thrombolytic therapy or for those at risk of intracerebral haemorrhage by virtue of their presentation, including reduced conscious level, sudden onset of severe headache, a history of trauma, known coagulopathy or therapeutic anticoagulation.

Early signs of ischaemic stroke on CT include hyperdensity of a cerebral artery (showing thrombus *in situ*), slight hypodensity of the brain parenchyma leading to loss of the clear definition of the insular ribbon and lentiform nucleus, sulcal effacement reflecting tissue swelling and mass effect from more pronounced oedema (Figure 57.1).[13] A large hypodense area seen on CT reflects a poor prognosis and is sometimes used as a contraindication to thrombolysis because the risk of subsequent haemorrhage may be increased. This is because hypodensity reflects increased water content of the tissue and suggests both established infarction and the breakdown of the blood–brain barrier in this region. If the hypodensity is clearly delineated, this indicates that the infarction is well established and not hyperacute.

CT angiography (CTA) may be carried in the same session as non-contrast CT to visualize acute intracranial vessel



(a) (b)

Figure 57.1 (a) Early changes of right MCA territory infarction on CT scan. (b) MCA hyperdensity in the same patient.

occlusion, and also extravascular and intravascular stenosis or dissection. Acute CT perfusion imaging may also have a role in the future, allowing assessment of the extent of hypoperfusion in an arterial territory.

CT has the limitation that it is normal within the first few hours after onset in 30–40% of patients.[13] MRI is much better at detecting early changes of infarction and small infarcts, especially in the posterior fossa. MRI is also the technique of choice to identify haemorrhage if the scan is performed more than 8 days after onset. Several MRI sequences can be combined in one examination, termed 'multi-modal MRI', to produce a variety of clinically useful images. T_2 sequences provide good anatomical definition and show established infarction well, but are not very sensitive to early changes. Diffusion-weighted imaging (DWI) is much more sensitive than CT to the early and chronic changes of infarction. DWI becomes abnormal within a few minutes of onset of infarction and shows areas of restricted extracellular movement of water molecules, secondary to ischaemic membrane pump failure and cell swelling from excessive intracellular water, as bright areas. When the infarction is complete and cell lysis has occurred, usually between 7 and 14 days after onset, diffusion of water is facilitated and DWI will then show infarcts as dark areas. However, DWI may also show older infarcts as bright areas because of the phenomenon of 'T2 shine through'. The same MR sequences are therefore used to generate apparent diffusion coefficient (ADC) maps, which show acute infarction as dark and older infarcts as brighter areas.[14] Gradient echo imaging (GRE or T2*) is very sensitive to new and old haemorrhage. FLAIR imaging is highly sensitive to areas of gliosis secondary to established infarction and periventricular small-vessel disease (Figure 57.2). Magnetic resonance angiography (MRA) provides an alternative to CTA for vascular imaging. MR perfusion imaging can show areas of impaired blood flow secondary to arterial occlusion or severe stenosis.

Thus MRI has considerable advantages over CT, in addition to avoiding ionizing radiation. If available in the emergency situation, MRI with DWI can replace CT or may be used as an additional investigation. It should be considered a routine investigation in stroke patients in whom CT has failed to establish the diagnosis and is the investigation of choice after TIA. Limitations of MRI include patient tolerability, increased cost compared with CT and the requirement to exclude patients with metallic foreign bodies or implants.

In-hospital care

As with any acutely unwell patient presenting to hospital, the standard initial assessment and resuscitation of a patient with suspected stroke begin with attention to the airway, breathing and circulation.

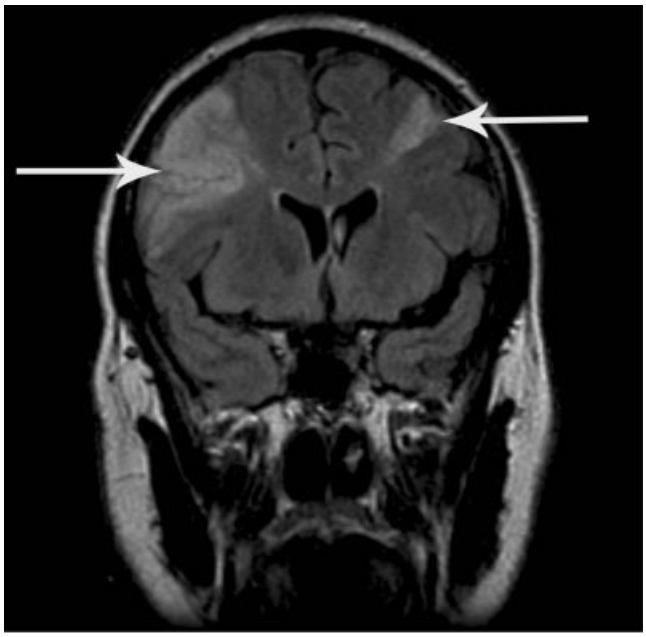


Figure 57.2 Multiple areas of cerebral infarction on FLAIR MR imaging.

Airway

The airway in a stroke patient may be obstructed secondary to a reduced level of consciousness or a buildup of secretions that cannot be effectively swallowed. Simple airway manoeuvres – for example, chin lift or jaw thrust – may be sufficient to clear the airway, or the use of an airway adjunct may be required. Patients with ongoing airway problems may warrant consideration of the involvement of an anaesthetist as an airway specialist.

Breathing

Effective breathing, and therefore effective oxygenation of the blood and brain, may be compromised by a number of mechanisms. A stroke affecting the respiratory centres of the brainstem may cause apnoea or bradypnoea. Problems with swallowing may precipitate aspiration pneumonia. In addition, hypoxaemia may arise through an associated condition such as heart failure or pulmonary embolism. Initial management is directed at treatment of the underlying cause, although guidelines recommend the application of inhaled oxygen only where a new desaturation below 92–95% exists on pulse oximetry.[12]

Circulation

In ascertaining the heart rhythm and blood pressure, some of the risk factors for stroke are being assessed. A finding of an elevated blood pressure is almost universal in patients within 48 h of stroke onset. This may occur either secondary to the stroke itself or reflect pre-existing hypertension. The management of high blood pressure in acute stroke is discussed later in this chapter.

Less common is the finding of hypotension. This may reflect severe dehydration, blood loss or cardiac failure and should lead to a search for the underlying cause, in addition to immediate treatment aimed at restoring the mean arterial blood pressure. The aim is to minimize secondary damage to the ischaemic penumbra in the brain and in the presence of a fixed intracranial pressure the cerebral perfusion pressure is dependent on the mean arterial blood pressure.

Blood sugar

Hypoglycaemia should be excluded – and treated if present – in all patients with neurological deficit, as it is an easily reversible cause of symptoms that mimic stroke. Hyperglycaemia following ischaemic infarction is associated with increase in infarct size and poor outcome. Raised blood glucose is a common finding at the time of presentation and severe hyperglycaemia is a contraindication to recombinant tissue plasminogen (rt-PA) administration. However, the benefit of early correction of blood glucose in stroke patients at the time of presentation remains uncertain. Preliminary investigation of the effects of 'tight' control of blood sugar levels in a stroke patient population has highlighted the high incidence of unintended hypoglycaemia as a consequence,[15] a factor which may offset any potential benefit of the treatment. Control may be achieved by the administration of an insulin infusion or by the administration of subcutaneous insulin, but close monitoring of blood glucose is mandated. It has been suggested that non-diabetic patients receive less intensive correction of blood glucose levels, since hyperglycaemia at the time of presentation may not reflect underlying insulin deficiency or resistance and may be a transient state with a return to baseline levels.[15]

Environment

Fever, defined as a core temperature of $>37.5^{\circ}C$, should prompt a search for a source, as fever carries increased mortality and worse neurological outcome and may indicate an underlying aetiology for the stroke, such as endocarditis. Lower respiratory tract infection and urinary tract infection are common complications of stroke. Antibiotic prescription should be considered, but the effect on clinical outcome of active lowering of the temperature with antipyretics is not clear.

Early attention should also be paid to nutrition and hydration. For those patients in whom a swallowing disorder is suspected, it is appropriate to provide nutrition via a

nasogastric tube and request a formal specialist assessment of swallowing. Regardless of the mode of administration of nutrition, normal hydration should be maintained.[12]

Thrombolysis and recanalization

The introduction of intravenous alteplase (an rt-PA) as treatment for acute ischaemic stroke has transformed stroke care. However, its benefits in acute stroke are tempered by the risk of precipitating intracranial haemorrhage and the strict licensing conditions that govern its safe use. The NINDS (National Institute of Neurological Disorders and Stroke) rt-PA Stroke Study[16] included patients under the age of 80 years with a carotid arterial or vertebrobasilar arterial distribution stroke, not in coma, who could start treatment within a 3 h time window and randomized patients to receive either intravenous thrombolysis with alteplase or placebo. Impairment was measured using the NIH Stroke Score. Intracranial haemorrhage occurred in 6.4% of thrombolysed patients within the first 36 h, compared with 0.6% of those randomized to placebo. However, patients treated with t-PA were around 30% more likely to have minimal or no disability at 3 months.[16] Pooled analysis of the NINDS trial with several other trials of thrombolytic therapy confirmed that, when given within 3 h, intravenous thrombolysis significantly reduces the risk of death or dependency, with a linear relationship between time from stroke onset to treatment and degree of benefit, perhaps extending beyond 3 h.[17] The ECASS-3 trial subsequently confirmed that intravenous alteplase can be given safely to patients under the age of 80 years between 3 and 4.5 h after onset, with a small overall benefit.[18]

Contraindications to thrombolysis include the presence of intracranial haemorrhage, seizure at the time of onset of neurological deficit, recent major surgery or major trauma, severe hypoglycaemia or hyperglycaemia, pancreatitis or pericarditis, recent gastrointestinal or urinary tract bleeding, concurrent anticoagulation with raised INR, severe thrombocytopenia and recent myocardial infarction (Table 57.5). Very severe, mild deficit or rapidly resolving symptoms may also be contraindications. Hypertension, with blood pressure >180/110 mmHg, should be treated cautiously before the administration of thrombolytics. Aspirin is contraindicated within the first 24 h after t-PA administration because of an increased risk of death.[19] If intracranial haemorrhage should result, management guidelines vary, but the discontinuation of ongoing infusion of thrombolytic agent is mandatory. Blood samples should be analysed to provide an up-to-date clotting profile and consideration should be given to the administration of reversal agents (for example, cryoprecipitate). In the event of a severe haemorrhage, neurosurgical consultation may be necessary.

Table 57.5 Contraindications to thrombolysis with tPA.

1	Symptoms only minor or rapidly improving
2	Haemorrhage on pretreatment CT (or MRI)
3	Visible changes pretreatment CT (or MRI) of infarction >one-third of MCA territory
4	Suspected subarachnoid haemorrhage
5	Active bleeding from any site
6	Recent gastrointestinal or urinary tract haemorrhage within 21 days
7	Platelet count less than $100 \times 10^9\ l^{-1}$
8	Recent treatment with heparin and APTT above normal
9	Recent treatment with warfarin and INR elevated
10	Recent major surgery or trauma within the previous 14 days
11	Recent post-myocardial infarction pericarditis
12	Neurosurgery, serious head trauma or previous stroke within 3 months
13	History of intracranial haemorrhage (ever)
14	Known arteriovenous malformation or aneurysm
15	Recent arterial puncture at non-compressible site
16	Recent lumbar puncture
17	Blood pressure consistently above 185 mmHg systolic or 110 mmHg diastolic
18	Abnormal blood glucose (<3 or >20 mmol l^{-1})
19	Suspected or known pregnancy
20	Active pancreatitis
21	Epileptic seizure at stroke onset

Source: adapted from the NINDS protocol.[16]

The ongoing Third International Stroke Trial (IST-3) seeks to determine whether thrombolysis provides benefit up to 6 h from the onset of symptoms and the effectiveness of this therapy in patients over the age of 80 years, who were not included in previous trials.

Providing access to thrombolysis for stroke requires the provision of hyperacute stroke units (HASUs) and well-developed pathways organized to deliver urgent access to brain imaging and stroke expertise, with the aim of achieving door-to-needle time from arrival of the patient to the start of alteplase infusion of less than 30 min, with facilities to monitor patients appropriately following administration of alteplase.

Newer modalities of treatment, such as endovascular mechanical dissolution of thrombus, intra-arterial thrombolysis and acute angioplasty to recanalize an occluded vessel, continue to undergo evaluation and are not yet part of the routine treatment of acute stroke. These treatments require the involvement of an interventional neuroradiology service.

Neuroprotective drugs

The ischaemic penumbra, an under-perfused area of brain surrounding an area of infarcted tissue which is potentially salvageable, offers a target for therapeutic intervention.[20] In

general, it is thought that the higher the residual perfusion of an area, the longer ischaemia may be tolerated before leading to cessation of neuronal electrical activity, failure of ion homeostasis and cell death. In addition to thrombolysis to restore perfusion of this area, a number of 'neuroprotective' agents have been trialled, with disappointing results. Biochemically or physiologically logical treatments, for example using calcium channel inhibitors to reduce vasogenic oedema, have not translated into a clinical improvement. Included in the definition of neuroprotection is therapeutic hypothermia, which remains an experimental procedure. However, tight control of physiological parameters as described above, for example, prevention of hypoxia, is likely to have an important role in limiting secondary damage after ischaemia.

Neurosurgery for ischaemic stroke

Neurosurgical intervention in ischaemic stroke is generally considered in two circumstances. In large middle cerebral artery territory infarction, cerebral oedema develops over the immediate days following the event as brain cells swell, and lyse and may result in midline shift and increased intracranial pressure, sometimes referred to as *'malignant MCA infarction'*. Should cerebral oedema be severe, transtentorial herniation may result in death from brainstem compression. Neurosurgery in patients at imminent risk of brain herniation consists of a duraplasty and the formation of a large bone flap to allow room for swelling of the cranial contents.

A pooled analysis of three randomized controlled trials of craniectomy for malignant MCA infarction (DECIMAL, DESTINY and HAMLET)[21] showed a significantly improved outcome, as measured by the Modified Rankin Scale (mRS), which records disability and death on a scale of 0–6 (where 0 is no symptoms and 6 is death), in the surgical groups versus standard medical treatment. Neuroimaging criteria used in the trials differed, but all aimed to quantify the volume of brain tissue involved as either an absolute volume ($>145\,cm^3$) or a relative volume (more than two-thirds of the MCA territory). These are patients with a poor prognosis and mortality in this group is high. The primary endpoint of the analysis was death or disability. The absolute risk reduction of a bad outcome (mRS $\leq$4) in the surgical group versus the control group was 51% (95% CI, 34–69%) and more patients survived in the surgical group (78% versus 29%).[21] The authors concluded that this represented a number-needed-to-treat (NNT) of 2 for both mRS $\leq$4 and to prevent one death. Only patients younger than 60 years benefited from decompression, with patients over the age of 50 years suffering a higher rate of death or severe disability after surgery compared with those aged under 50 years.

Posterior fossa infarction may also warrant consideration of neurosurgery. The volume of the posterior fossa is small compared with that of the rest of the cranium and oedema secondary to a large cerebellar infarct is tolerated poorly, with the potential for brainstem compression and obstruction of the fourth ventricle and resultant hydrocephalus.

Palliative care

Unfortunately, there are patients who suffer a stroke that is so extensive that they will not recover. In these circumstances, treatment is directed at the relief of pain or other distressing symptoms such as restlessness, mood disturbance or confusion. For those who survive the first few days, spasticity, pressure areas and incontinence, among other neurological consequences, may need specific attention. An open discussion with family members about prognosis and continuing communication is essential. Good communication with ward staff and clear documentation in the notes may prevent unnecessary investigation or intervention. Involvement of local inpatient palliative care services may be beneficial, but there is relatively little published research or guidance in this area.

Stroke units

Care of the patient with stroke has been revolutionized with the introduction of specialized stroke units, which seek to standardize management and coordinate a multidisciplinary team of experts. Features of stroke unit care include early mobilization, medical, nursing and allied professional staff specialized in stroke care and specific investigation such as assessment of swallowing.[22] In a stroke unit, there should also be regular monitoring of physiological variables such as oxygen saturation, blood pressure and temperature. It is unknown exactly which of these interventions is most responsible for an improvement in outcome and there are additional unmeasurable factors, such as the professional dedication and continuing education of ward staff, that may also contribute. There is also specific attention given to the modification of risk factors for recurrent stroke, such as blood pressure management and antithrombotic therapy. However, it is clear that the majority of benefit relates to early intervention and therefore current NICE guidelines in the UK recommend that all stroke patients should be admitted without delay directly to an acute stroke unit.[12]

Systematic review of smaller stroke unit studies in 1997 suggested an overall benefit for stroke unit care and paved the way for the widespread implementation of stroke units. At the conclusion of follow-up, the combined odds ratio of death in a stroke unit versus conventional care was 0.82 (95% CI, 0.69–0.98). The odds ratio of death or dependency was 0.71 (95% CI, 0.61–0.84).[22] There was no

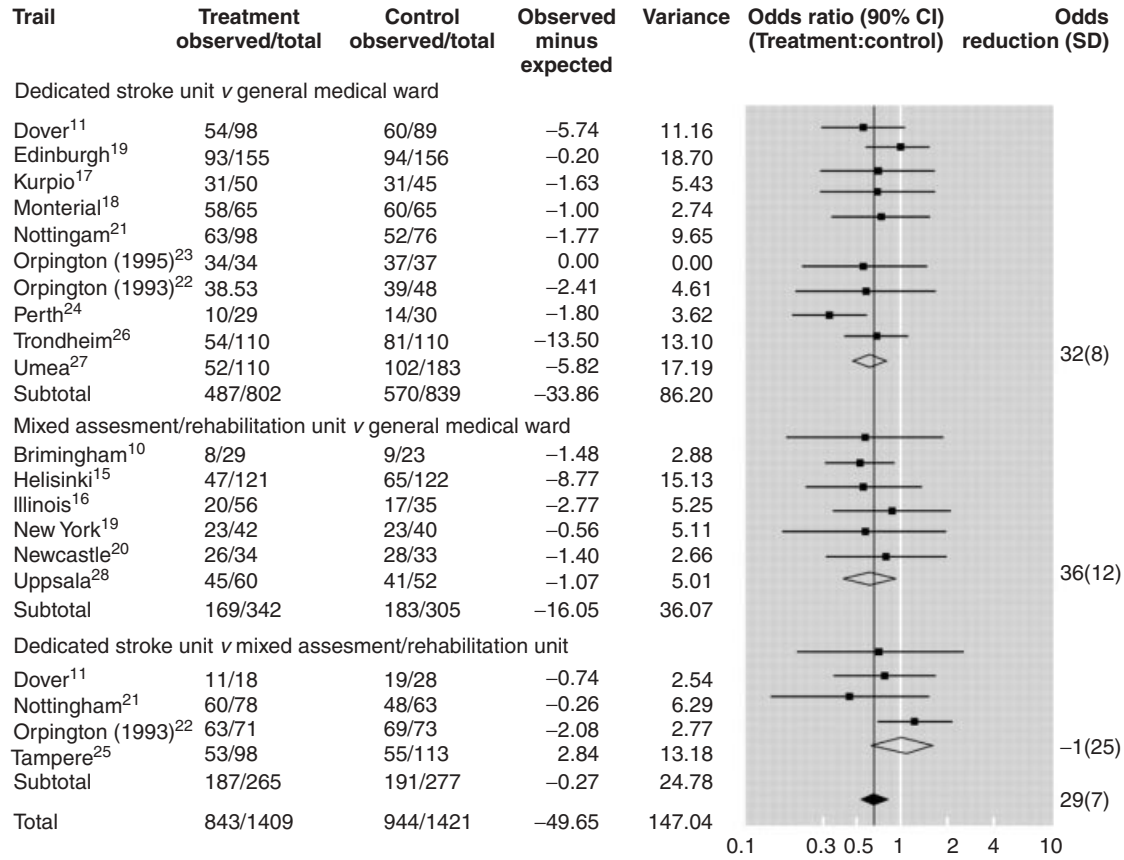

Figure 57.3 Systematic review of randomised trials of organized inpatient care after stroke: odds ratio (95% confidence interval) of death or requiring institutional care at the end of scheduled follow-up in patients receiving stroke unit compared with conventional care. Please note that references given in this figure relate to citations in the original article. statistically significant difference in the calculated length of stay of patients in either group and subgroup analysis did not reveal a difference in groups of different gender, age or stroke severity, leading to the conclusion that stroke unit care is effective and that it should be offered to all stroke patients regardless of individual characteristics (Figure 57.3). Subsequent updated reviews have found similar results.

Secondary prevention

Patients who present with minor stroke or TIA have a high risk of early recurrence. Without treatment, as many as 10% of patients may experience a further event. Certain clinical features predict a high early risk and a number of scores have been developed to predict those at highest risk. The ABCD2 score is the one most commonly used in the UK[23] (Table 57.6). Patients with ABCD2 score of ≥4 should undergo further investigations and initiation of secondary prevention measures should be organized within 24 h of onset. Rapid access clinics are therefore an essential component of a comprehensive stroke service.

Antiplatelet therapy

The benefit of early aspirin administration, after exclusion of haemorrhagic stroke, was demonstrated by the International Stroke Trial (IST).[24] This study compared aspirin with subcutaneous heparin and therapy combining both aspirin and heparin, given within 48 h of onset in 19 435 patients, with a control group receiving neither aspirin nor heparin. In the analysis of aspirin versus no-aspirin groups, those patients allocated aspirin experienced a significantly lower risk of recurrent stroke at 14 days than patients not allocated aspirin (2.8% versus 3.9%).[24] There is therefore a small but significant benefit to early treatment with aspirin, a low-cost intervention. Typically, an initial dose of 300 mg is given, followed by the initiation of long-term therapy with 75 mg daily.

Subsequent work has aimed to identify whether the addition of further therapy, in the form of dipyridamole

Table 57.6 ABCD2 score.[23]

Feature		ABCD2 score
Age	≥60 years	1
	<60 years	0
Blood pressure	SBP >140 or DBP >90 mmHg	1
	SBP <140 and DBP <90 mmHg	0
Clinical features	Unilateral weakness	2
	Speech disturbed without weakness	1

Duration	≥60 min	2
	10–59 min	1
	<10 min	0
Diabetes	Diabetic	1
	Not known to be diabetic	0
Total		Range 0–7

Table 57.7 NICE guidelines for early management and investigation of TIA.[12]

- Start daily aspirin (300 mg) immediately
- Introduce measures for secondary prevention as soon as the diagnosis is confirmed, including discussion of individual risk factors
- Specialist assessment within 24 h of onset, including decision on brain imaging, for patients at high risk of stroke (ABCD2 score of ≥4 crescendo TIA)
- Specialist assessment within 1 week of symptom onset, including decision on brain imaging, for patients at lower risk of stroke (ABCD2 score of ≤3 or presenting more than 1 week after symptoms have resolved)
- Use diffusion-weighted MRI for brain imaging, except where contraindicated. For these people, use CT scanning
- If the person is identified as a candidate for carotid endarterectomy on specialist assessment, perform carotid imaging within 1 week of symptom onset
- Make sure that carotid imaging reports state clearly which criteria (ECST or NASCET) were used when measuring the extent of carotid stenosis

or clopidogrel, offers any increased benefit in longer term secondary prevention after ischaemic stroke or TIA. Aspirin combined with modified-release dipyridamole in the ESPRIT study produced an absolute risk reduction of 1% (95% CI, 0.1–1.8%) compared with aspirin alone for the primary outcome of death from stroke, myocardial infarction or other vascular conditions, without an increase in the risk of haemorrhage.[25] The risk ratio for the primary outcome was similar when the trial results were compared with previous studies in a meta-analysis. At higher doses given acutely, dipyridamole exhibits vasodilatory properties and therefore caution is advised in patients who are known to have a coronary arterial disease. The principal side effect limiting the tolerability of dipyridamole is headache.

Clopidogrel has also been investigated as an alternative to the combination of aspirin and dipyridamole. The PRoFESS Study[26] reported a similar rate of recurrent stroke in patients randomized to treatment with clopidogrel or treatment with aspirin and extended-release dipyridamole, with similar rates of major haemorrhage. A previous study had demonstrated an increased risk of bleeding with the combination of clopidogrel and aspirin in long-term use compared with clopidogrel alone, hence the use of clopidogrel monotherapy in the PRoFESS Study.[27] Therefore, clopidogrel as monotherapy provides an alternative to the combination of aspirin and dipyridamole for secondary prevention of stroke and is the antiplatelet of choice for patients who cannot tolerate aspirin or dipyridamole in combination.

Secondary prevention after stroke requires appropriate management of vascular risk factors and treatment focused on identification of the likely cause of the TIA or stroke. Thorough investigation of patients presenting as stroke or TIA is an important component of secondary prevention measures (Table 57.7).

Blood pressure management

There is good evidence that lowering blood pressure reduces the risk of recurrent stroke, whatever the initial level of blood pressure. Secondary prevention with an antihypertensive drug is typically initiated 7–14 days after stroke onset, when any acute, transient, blood pressure elevation will have settled. The benefits and risks of acute blood pressure lowering in the hypertensive patient presenting acutely with stroke are less certain. Lowering of blood pressure levels initially within the normal range, and also good control of hypertension, with the combination of a diuretic and an angiotensin-converting enzyme (ACE) inhibitor drug, reduced the long-term risk of recurrent stroke by 40% in the PROGRESS trial.[28] An ACE inhibitor alone is not nearly as effective, probably because the benefit depends on how far blood pressure is lowered.

Physiological changes in the cerebral circulation occur at the time of stroke and cerebral autoregulation may be impaired. In an acute stroke, lowering mean arterial blood pressure may reduce the cerebral perfusion pressure and, in areas with critically reduced blood flow (the ischaemic penumbra), this may lead to infarction. However, in patients with evidence of cardiac dysfunction or acute myocardial infarction, the balance of risks may be altered to favour hypotensive therapy. Severe hypertension (systolic blood pressure >180 mmHg or diastolic blood pressure >105 mmHg) is a contraindication to thrombolytic therapy. If blood pressure is therapeutically lowered in acute stroke,

reductions in blood pressure should be closely monitored and rapid falls avoided.

Cholesterol management

The finding of an elevated fasting cholesterol level should prompt the involvement of a dietician or nutritionist.There is good evidence that lowering serum cholesterol levels of $>3.5 mmol l^{-1}$ with, for example, simvastatin 40 mg nocte results in a substantial reduction in the long-term risk of recurrent stroke and myocardial infarction of about one-third.[29,30]

Diabetes management

Management of prolonged fasting hyperglycaemia is in accordance with guidelines for the standard management of diabetes. The evidence suggests that tight control of blood sugar levels over the long term in diabetes has more of an effect on reducing rates of myocardial infarction than stroke rates, whereas the opposite is the case for hypertension. The blood pressure readings in diabetic patients during follow-up after stroke should therefore be maintained at or below the target of 130/80 mmHg.

Anticoagulation

In acute stroke, unfractionated heparin, given subcutaneously, reduces the rate of recurrent stroke and pulmonary embolism, but at the expense of an increase in cerebral haemorrhage of similar magnitude that offsets potential benefit.[24] There is also a significant increase in extracranial bleeding. Low molecular weight heparin (LMWH) has similarly failed to demonstrate a therapeutic benefit at treatment dose. The balance of evidence, therefore, does not favour heparin use in acute stroke. Anticoagulation is therefore reserved for the patient with atrial fibrillation at risk of stroke or for those in whom another indication exists (e.g. prosthetic heart valve or pulmonary embolism).

The only situation where anticoagulation with warfarin has been found to be more effective than antiplatelet therapy is in the prevention of stroke recurrence after TIA or ischaemic stroke associated with atrial fibrillation. Randomized trials have shown that any benefit in the first 2 weeks after onset of stroke is offset by an increase in cerebral haemorrhage. Initiation of warfarin should therefore be delayed until after 2 weeks, except after TIA and minor stroke, when it is logical to start immediately. Warfarin reduces the risk of recurrent stroke in suitable patients with atrial fibrillation by about 70%.[31] Aspirin and other antiplatelet agents are much less effective in preventing recurrent stroke in patients with atrial fibrillation, but provide an alternative for those who cannot or will not take warfarin. There is an assumption that has not been tested in randomized trials that other causes of cardioembolic stroke will also benefit from anticoagulation, including patients with recent myocardial infarction, congestive valvular heart disease and cardiomyopathies. Safe anticoagulation will require patient participation, monitoring and adjustment of therapy and an acceptably low risk of falls.

Carotid artery stenosis

Carotid artery stenosis is responsible for 20–30% of cases of anterior circulation ischaemic stroke and TIA and between 5 and 10% will need endarterectomy (or stenting) to prevent recurrence. The arterial narrowing is usually caused by atherosclerosis, which becomes more prevalent with age and is accelerated by risk factors. Dissection is an important cause in younger patients.

Atherosclerosis

Atherosclerosis is the commonest arterial disorder in developed countries and, when complicated by thrombosis and embolism, may result in ischaemic stroke, myocardial infarction and also peripheral arterial disease. The process of atheroma formation occurs over many years, beginning with low-density lipoprotein (LDL) cholesterol moving into the subendothelium, often at sites of endothelial injury or haemodynamic stress. In the cerebral circulation this occurs at sites of arterial branching, especially the bifurcation of the common carotid artery into the internal carotid artery (ICA) and external carotid artery (ECA). The LDL is oxidized by macrophages and smooth muscle cells. Production of growth factors and cytokines attracting more immune cells, foam cell accumulation and smooth muscle proliferation all result in the growth of an atherosclerotic plaque.[32] Risk factors that accelerate the formation of atherosclerosis include cigarette smoking, diabetes mellitus, age, dyslipidaemia and hypertension. Genetic predisposition may also play a role.

Plaques with a fatty core and a fibrous cap then spread along and around the arterial wall, encroaching on the media and ultimately leading to narrowing of the vessel lumen and stiffening of the arterial wall. A defect in the fibrous cap, due to rupture or erosion, predisposes to thrombosis at that site. Platelets adhere to the vessel wall and are activated, initiating blood coagulation. This is the site of action for antiplatelet agents used in the secondary prevention of stroke. Thrombosis may initially be incorporated into the plaque, but as the plaque grows, the lumen of the vessel may become obstructed, causing a narrowing or stenosis. The atherothrombotic plaque may completely occlude the artery or embolization from the plaque may cause either transient or permanent obstruction of a smaller distal artery, resulting in cerebral or ocular symptoms. Most strokes and TIAs secondary to carotid stenosis occur as a result of

thromboembolism. Hypoperfusion of arterial territories is a relatively rare cause of symptoms compared with other sites, because of collateral supply via the circle of Willis.

Arterial dissection

A rare cause of carotid artery stenosis in the elderly population, dissection may be spontaneous, traumatic or associated with underlying connective tissue disease (such as Marfan syndrome or Ehlers–Danlos syndrome). Most commonly, dissection occurs following minor neck or head trauma associated with sudden rotation of the neck. The ICA is torn against the second cervical vertebra and a haematoma forms in the arterial wall, which can narrow the vessel lumen, leading to thrombosis. Alternatively, an intimal free flap may promote thromboembolism. There may be a delay of up to several days between the event and symptoms in the territory of the anterior cerebral circulation. Diagnostic clues suggesting dissection include a Horner syndrome resulting from compression or ischaemia of the sympathetic chain which surrounds the carotid artery in the neck. Cross-sectional MRI with fat-suppressed sequences is the investigation of choice, revealing a characteristic crescent-shaped haematoma in the carotid arterial wall (Figure 57.4).

Subsequent management is controversial, with most centres anticoagulating patients with heparin and subsequently warfarin, but there is no good evidence of benefit in preventing recurrent stroke compared with aspirin. Stenting may be an option for some patients resistant to medical treatment.

Investigations

Carotid artery atheroma may be found after investigating a neurological event, be sought on imaging after clinical examination reveals a carotid bruit or may be an incidental finding during preoperative workup for procedures such as cardiac bypass surgery. Auscultation for carotid bruit, however, is not a reliable screening test for significant carotid stenosis. A localized bruit is indeed usually caused by a narrowing of the artery, but the extent and significance of the stenosis cannot be predicted by the presence of a bruit. A very tight stenosis, for example, may not cause a bruit or an ECA stenosis of little clinical significance may cause a loud bruit.

The level where the carotid artery divides into ICA and ECA branches varies, but in most patients it is possible to examine the common carotid artery, bifurcation and proximal portions of the ICA and ECA with ultrasound. B-mode duplex ultrasound with Doppler measurement of flow velocities in these arteries is therefore commonly used to screen for ICA stenosis. Although the artery itself may be visualized using plain ultrasound, estimation of the degree of stenosis with accuracy is difficult. Indirect evidence is therefore gathered through measurement of the velocity of flow in the longitudinal direction.[33] As the systolic pulse passes a stenosis, the velocity of blood will tend to increase and it is the absolute velocity of flow both distal to the stenosis and prior to the stenosis that are assessed (Table 57.8). Grading of stenosis for a given examination varies according to the method used. It is important to note which method is being applied.

Table 57.8 Derived figures for Doppler ultrasound criteria for grading ICA diameter reduction.[33]

Diameter reduction (%)	Peak systolic velocity ($cm\ s^{-1}$)	End diastolic velocity ($cm\ s^{-1}$)	PSV_{ICA}/PSV_{CCA}[a]
0–29	<100	<40	<3.2
30–49	110–130	<40	<3.2
50–59	>130	<40	<3.2
60–69	>130	40–110	3.2–4.0
70–79	>230	110–140	>4.0
80–95	>230	>140	>4.0
96–99		'String flow'	
100		'No flow'	

[a]ICA = internal carotid artery; CCA = common carotid artery, PSV_{ICA}/PSV_{CCA} = ratio of the velocities.

It is also possible to derive measurement of the intimal–medial thickness of the carotid artery from B-mode ultrasound, which can be used to measure plaque thickness or progress and to visualize portions of the vertebral arteries in some subjects, but the clinical utility of the latter is limited by the superiority of other contrast methods.[33]

Ultrasound is a safe, non-invasive and relatively inexpensive technique, but its utility remains limited by the requirement of a high degree of operator skill. Results are subject to interobserver variation and technical limitations of the procedure include acoustic shadowing caused by calcified plaque and difficulty in studying a tortuous vessel where flow velocities may appear increased.[33]

Because of these limitations, most units confirm abnormal findings on ultrasound with a second non-invasive imaging modality before considering surgery or stenting for carotid stenosis. Catheter angiography may be required if the non-invasive investigations are discordant or difficult to interpret.

MRA, with or without intravenous contrast, was the first alternative non-invasive technique used for the investigation of arterial pathology in the neck and head to confirm the presence of carotid artery stenosis (Figure 57.5) in patients who have undergone preliminary ultrasound investigation, but MRA may also be used as a screening investigation. The limitations of MRA include patient tolerability and

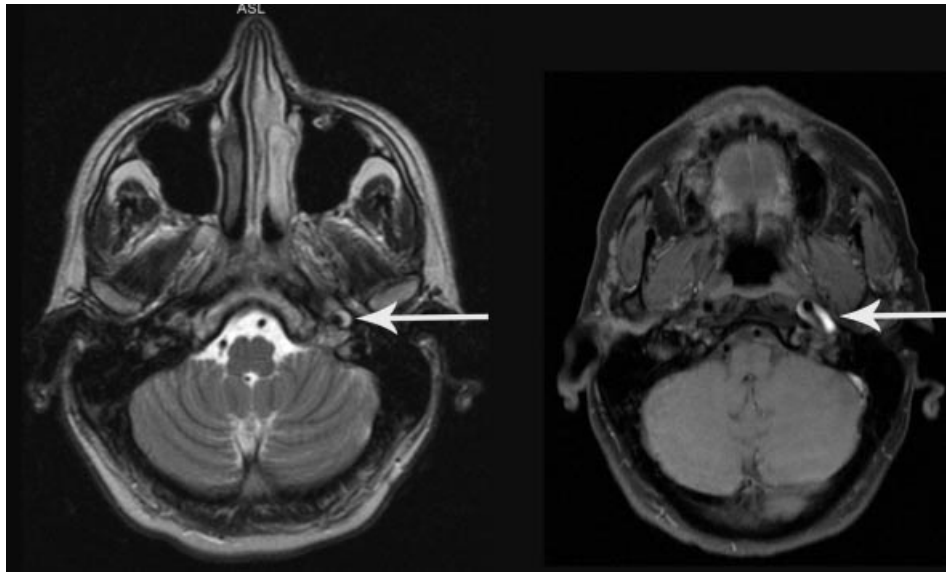

Figure 57.4 Carotid artery dissection on MR imaging – there is left carotid dissection from the high cervical to at least the laceral segment.

Figure 57.5 Carotid artery stenosis.

safety with metallic implants. Technical limitations include misinterpretation of swallowing artefact or turbulent flow as stenosis. MRA and/or duplex ultrasound are increasingly being replaced by CTA with intravenous contrast because it is often combined with CT in the initial evaluation of stroke.

The limitations of CTA include contrast toxicity (including renal impairment), contrast allergy and poor visualization of stenosis if there is heavy plaque calcification.

Catheter angiography is the 'gold standard' investigation for carotid artery stenosis, but this procedure carries with it a significant risk of stroke or TIA of between 0.5 and 2%, depending on indications. The catheter may dislodge atheromatous plaque, dissect the arterial wall or thrombus may form on the catheter. The intravenous contrast administered carries the same risks as for other indications, namely headache, nausea, bradycardia and renal failure. For these reasons, angiography is normally preceded by non-invasive investigation and should only be performed in experienced neurovascular units.

Carotid endarterectomy

The case for intervention

To warrant intervention, the risk of stroke that accompanies carotid endarterectomy (CEA) must be less than the natural risk of stroke in the patient receiving best medical management, and the benefit of surgery must be sufficient to justify the costs to healthcare providers and risks to the patient.

Symptomatic patients

Large randomized clinical trials have demonstrated a benefit of CEA for severe symptomatic carotid artery stenosis compared with medical treatment alone. In the European Carotid Surgery Trial (ECST),[34] over 3000 patients with any degree of carotid stenosis who had a TIA or minor stroke in the 6 months prior to randomization were

randomized to receive CEA or best medical management alone. Concurrently, the North American Symptomatic Carotid Endarterectomy Trial (NASCET)[35] randomized over 2800 patients with >30% carotid stenosis who had symptoms within 3 months of randomization to CEA or best medical management. A meta-analysis of these trials indicates a clear advantage of CEA over medical management for the patients with more severe stenosis, provided that the perioperative risk of stroke or death is no more than 5%.[36] NICE guidelines for the management of carotid stenosis are given in Table 57.9.

ECST and NASCET used different denominators to measure the severity of stenosis, but the NASCET method in which the diameter of the stenosis is compared with the diameter of the distal ICA has become the standard method. The absolute risk reduction of ipsilateral ischaemic stroke or death in those patients with 70–99% NASCET stenosis undergoing CEA was 16% ($p < 0.001$)[36] (Figure 57.6). Patients with 50–69% NASCET stenosis also achieved a risk reduction, but the margin of benefit was slimmer. Below this stenosis threshold, there was evidence of overall harm. In subgroup analyses, male gender, advancing age and recent symptoms were identified as factors conferring additional benefit to the procedure.

Table 57.9 NICE guidelines for the management of carotid stenosis.[12]

- All people with suspected non-disabling stroke or TIA who after specialist assessment are considered as candidates for carotid endarterectomy should have carotid imaging within 1 week of onset of symptoms
- People who present more than 1 week after their last symptom of TIA has resolved should be managed using the lower risk pathway
- People with stable neurological symptoms from acute non-disabling stroke or TIA who have symptomatic carotid stenosis of 50–99% according to the NASCET (North American Symptomatic Carotid Endarterectomy Trial) criteria or 70–99% according to the ECST (European Carotid Surgery Trialists' Collaborative Group) criteria should:
  - be assessed and referred for carotid endarterectomy within 1 week of onset of stroke or TIA symptoms
  - undergo surgery within a maximum of 2 weeks of onset of stroke or TIA symptoms
  - receive best medical treatment (control of blood pressure, antiplatelet agents, cholesterol lowering through diet and drugs, lifestyle advice)
- People with stable neurological symptoms from acute non-disabling stroke or TIA who have symptomatic carotid stenosis of <50% according to the NASCET criteria or <70% according to the ECST criteria should:
  - not undergo surgery
  - receive best medical treatment (control of blood pressure, antiplatelet agents, cholesterol lowering through diet and drugs, lifestyle advice)
- Carotid imaging reports should clearly state which criteria (ECST or NASCET) were used when measuring the extent of carotid stenosis

Asymptomatic patients

The benefits of surgery for asymptomatic carotid stenosis and symptomatic stenosis with more than 6 months since last symptoms are less clear-cut than for symptomatic stenosis. Two large randomized controlled trials have addressed this issue.[37,38]

In the Asymptomatic Carotid Atherosclerosis Study (ACAS), over 1600 patients with asymptomatic carotid stenosis of 60% or more were randomized to receive CEA or best medical treatment. The results showed that surgery significantly reduced the overall 5 year risk of ipsilateral stroke or any perioperative stroke or death from 11 to 5.1% ($p = 0.004$), but not the risk of major stroke. The complication rate in the surgical arm approached 3% at 30 days when preoperative angiography was included in the analysis.[37]

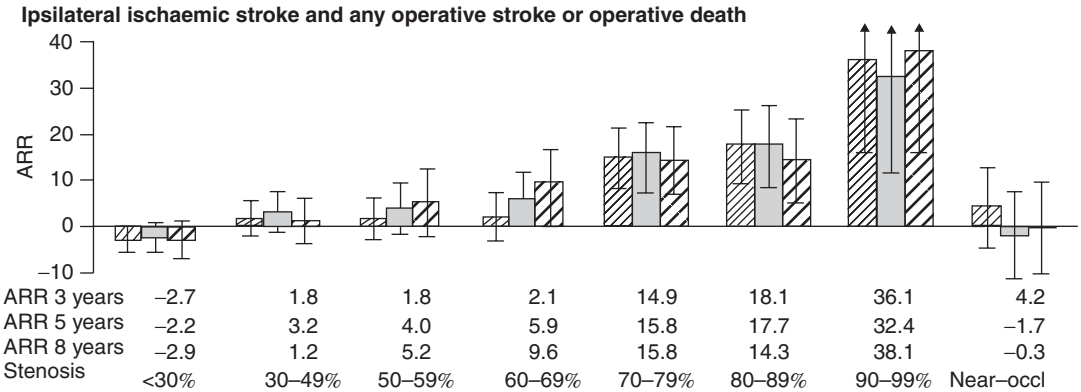

Figure 57.6 Effect of surgery on absolute risk of main trial outcomes at 3, 5 and 8 years' follow-up by degree of symptomatic carotid stenosis, in analysis of pooled data from ECST and NASCET. Reprinted from Rothwell *et al.* (2003),[36] Copyright 2003, with permission from Elsevier.

The Asymptomatic Carotid Surgery Trial (ASCT) randomized over 3000 patients to a policy of immediate or deferred carotid endarterectomy (until surgery seemed to be more clearly indicated, for example in the presence of related symptoms), for asymptomatic 60–99% stenosis. The results showed a benefit to immediate surgery in terms of reducing the 5 year risk of all strokes and perioperative death from 11.8 to 6.4% ($p < 0.0001$). However, subgroup analysis showed no evidence of benefit in patients older than 75 years or in women after taking into account the risks of surgery. There was a less marked benefit in terms of reducing the risk of fatal or disabling stroke. The 30 day rates of stroke or death after CEA in both trials were similar at around 3%.[38]

The results from these trials suggest that although surgery for asymptomatic surgery may be less risky than in symptomatic disease, the benefits of reducing the risk of major stroke or death are less certain. In particular, the rate of stroke in patients with asymptomatic carotid stenosis treated medically in the trials was very low at around only 2% per annum and in order to provide a net benefit with surgery an experienced surgeon working in a centre with low complication rates was necessary. The trials were conducted several years ago at a time when statins were not in widespread use, blood pressure was less well controlled and dual antiplatelet therapy was not used routinely. It is therefore likely that with better medical management, the rates of ipsilateral stroke associated with asymptomatic carotid stenosis will be even lower than recorded in the trials, which could negate any potential benefit of surgery.

These results together suggest that patients with asymptomatic stenosis aged over 75 years or those with less than 60% stenosis should not be offered surgery. Those who otherwise meet inclusion criteria may be offered surgery, but in the knowledge that their risk of stroke with best medical treatment is low. If patients and their neurologists and surgeons opt for medical management, then they should be educated about the symptoms of TIA and stroke and urged to present to a doctor should these occur.

Carotid artery stenting

Carotid artery stenting has developed as an alternative to the more established procedure of CEA. In theory, there are several potential benefits to the patient of this approach. This procedure is normally carried out under local anaesthesia, avoiding the risks of a general anaesthetic. Patients may recover faster from a procedure performed under local anaesthesia, thereby reducing the length of hospital stay. The other major advantage of an endovascular approach is that there is no need for an incision in the neck and the incidence of haematoma, infection and cutaneous or cranial nerve injury is reduced. Complications at the site of endovascular access in the groin are rare.

However, there are few interventionists with extensive experience of angioplasty and stenting in the carotid artery, although experience with endovascular surgery elsewhere in the body is increasing. Endovascular treatment of carotid stenosis may lead to distal embolization of thrombus to the brain during the passage of the catheter through a tight stenosis, and simple balloon angioplasty has been replaced with stenting and the use of cerebral protection devices (either filters or occlusion devices) to try to mitigate this problem. Stents are thought to cause less arterial dissection than balloon angioplasty, but transcranial Doppler studies have shown that embolization frequently occurs during deployment of the stent and during post-stent dilation. The utility of cerebral protection devices is debated and research in this area has not always shown an improved outcome with the use of a protection device.

Although the recovery time following successful endovascular intervention is short, the cost benefits of a reduced length of inpatient stay may be overshadowed by the higher costs of the stent and protection device equipment. Another problem with endovascular treatment is the greater potential for restenosis of the treated artery compared with surgery, although the clinical significance of this is not clear.

The carotid stenting versus carotid endarterectomy trials have consistently shown an excess rate of stroke after stenting for recently symptomatic stenosis compared with endarterectomy. In a pooled analysis of the European-based trials, the overall risk of stroke or death within 30 days of stenting was 7.7% compared with 4.4% after endarterectomy (risk ratio 1.74; 95% CI, 1.32–2.30).[39] However, there is a small excess of myocardial infarction after endarterectomy (risk <1%) and cranial nerve injury.

However, in symptomatic patients, the risks of stroke or death associated with the procedure were identical after stenting and endarterectomy in patients younger than 70 years, while all the excess risk of stroke appeared to be associated with older age. A more recent North American trial, CREST, showed very similar results. Hence stenting may be an option for younger patients. However, although the long-term effectiveness of stenting at preventing stroke recurrence appears similar to that of endarterectomy, there is an increased risk of restenosis after stenting and more long-term data are required to determine how often this leads to symptoms. Trials are examining the role of stenting for asymptomatic carotid stenosis. Stenting is also an option for treatment of symptomatic carotid stenosis in patients not suitable for endarterectomy, for example, stenosis secondary to radiotherapy, fibromuscular dysplasia, dissection and high cervical lesions not amenable to surgery.

Vertebral and intracranial arterial stenting

Surgical access to the vertebral artery origin is difficult and procedures carry high morbidity. Stenting therefore provides a preferable option for the treatment of symptomatic extracranial vertebral arterial stenosis, which most commonly occurs at the vertebral artery origin.[40] Stenting of intracranial arteries, for example basilar or middle cerebral artery, carries a risk of vessel dissection or rupture in addition to the risk of embolization of fragments of plaque. Stenting of these vessels is therefore usually reserved for patients with recurrent symptoms despite medical therapy. However, the benefits are uncertain and randomized trials are needed to establish the benefit of endovascular intervention for vertebral and intracranial stenosis.

Intracranial and subarachnoid haemorrhage

Spontaneous intracerebral haemorrhage

A typical history is given of sudden onset of severe headache, with the subsequent rapid development of focal neurological deficit. However, headache may be absent and in some cases the deficit progresses more slowly, sometimes over several days, especially when the haemorrhage is associated with anticoagulation or a coagulopathy. Intracerebral haemorrhage may also present as collapse. No one clinical feature reliably differentiates haemorrhage from infarction and imaging is essential to distinguish between the two.

Spontaneous intracerebral haemorrhage (ICH) may be divided into those occurring in the absence (primary) or presence (secondary) of an identified underlying structural abnormality. ICH is also associated with oral anticoagulant therapy. In this situation, tissue damage is limited by rapid identification of the condition and reversal of anticoagulation, although treatment dilemmas arise when the patient is anticoagulated for a high-risk condition such as acute pulmonary embolism or prosthetic heart valve. Consideration may have to be given to the eventual reintroduction of anticoagulation despite haemorrhagic risk or alternative strategies such as the placement of an inferior vena caval filter for DVT.

The initial management of cerebral haemorrhage is broadly similar to that of ischaemic stroke, apart from decisions regarding antiplatelet and anticoagulant therapy, which are clearly contraindicated. However, further investigation, including some form of angiography, should be undertaken in selected patients to exclude an underlying vascular abnormality which may require surgical or neuroradiological intervention to reduce the chances of a recurrent bleed. An intracranial aneurysm or arteriovenous malformation (AVM) should be particularly suspected in the younger patient with cerebral haemorrhage. Risk factors such as hypertension promote bleeding from aneurysms and AVMs and therefore should not necessarily influence the decisions about further investigation. The latter should be made after discussion with a neurovascular team at the local neuroscience centre.

Poor prognosis is conferred by a large volume of blood, intraventricular extension or reduced level of consciousness at the time of presentation. However, patients are often referred to neurosurgical colleagues for consideration of intervention and evidence has been sought in randomized controlled trials for this aggressive approach. The STICH trial recruited 1033 patients from neurosurgical centres with supratentorial intracerebral haematoma over 2 cm in diameter, occurring within the previous 72 h and randomized to early surgery or initial conservative (medical) management.[41] The results showed that 26% of the surgical group had a favourable outcome (good recovery or moderate disability on the Glasgow Outcomes Scale) compared with 24% of the conservative treatment group. This small difference between the groups did not reach statistical significance. However, there was a suggestion that patients with haematomas 1 cm or less from the cortical surface were likely to have a favourable outcome and these patients are being included in the second STICH trial.[41]

Cerebellar haemorrhage may present with occipital headache, truncal ataxia and conjugate gaze palsy, followed after an interval by impairment of consciousness and subsequent neurological deterioration as an expanding haematoma compromises the ventricular system, causing hydrocephalus and brain herniation. Surgical evacuation of a cerebellar haematoma is a life-saving measure.

Subarachnoid haemorrhage

The incidence of subarachnoid haemorrhage (SAH) is ~ 6 per 100 000 per year.[42] Bleeding into the subarachnoid space is often the result of rupture of an intracranial aneurysm. There may be a familial component to aneurysm development, but hypertension and smoking are the predominant risk factors for aneurysmal rupture. As in intracerebral haemorrhage, presentation is typically with sudden onset of severe headache, which may be accompanied by nausea and vomiting, neck stiffness, visual disturbance, altered conscious level and collapse. Subarachnoid bleeding may also be the result of trauma, dural fistula, arteriovenous malformations (AVMs) or cerebral venous thrombosis, or no clear cause may be found.

SAH is frequently fatal, with mortality rates in many series around 35–65%.[42] A significant proportion of the survivors remain dependent and complications such as delayed cerebral ischaemia secondary to vasospasm, rebleeding of the affected vessel and the development

of hydrocephalus may lead to a poorer outcome. At the time of presentation, outcome appears to be predicted by Glasgow Coma Scale score, age and the volume of intracranial blood. However, non-aneurysmal perimesencephalic haemorrhage, in which the bleeding is confined to the basal cisterns around the midbrain and there is no extension of the haemorrhage to the lateral Sylvian fissures or to the anterior part of the interhemispheric fissure, is associated with a good outcome. The cause is uncertain.

CT of the head is the preferred initial investigation and the pattern of bleeding may suggest a site of origin. CT angiogram may be added to this to localize the site of bleeding and identify a target for acute intervention. In the well patient, if clinical suspicion for SAH remains despite the lack of evidence on brain imaging, then lumbar puncture should be undertaken to look for xanthochromia. Lysis of the red blood cells in the cerebrospinal fluid (CSF) produces oxyhaemoglobin and bilirubin, giving a yellow colour to the CSF after centrifugation between 12 h and 14 days after SAH. MRI imaging with gradient echo T2 sequences or the FLAIR technique can also demonstrate SAH accurately. MRI is most useful in the setting of delayed presentation, with negative CT but positive lumbar puncture where a site of bleeding is sought.[42]

Management of SAH should be discussed with the neurovascular team at the local neuroscience centre and consists of treatment to secure the aneurysm or other source of bleeding and the prevention of secondary cerebral damage. Neurosurgery may be considered for those patients with an intracerebral haematoma secondary to SAH or surgical ventricular drainage for those who develop hydrocephalus. Surgical solutions to prevent rebleeding include operative clipping of the aneurysm, but there is increasing use of endovascular exclusion of the aneurysm using platinum coils. The ISAT study demonstrated lower morbidity and mortality after endovascular coiling compared with neurosurgical clipping for aneurysms suitable for both treatments.[43] The only agent shown in a randomized trial to prevent cerebral ischaemia after SAH is nimodipine, a calcium channel antagonist, continued for 3 weeks.[44] The oral or nasosgastric enteral route is preferred over intravenous administration to avoid precipitating hypotension. Its effect in reducing cerebral vasospasm may be the mechanism for the reduction in risk of a poor outcome.

Discussion

Acute stroke can be a devastating disease and the safe and effective evidence-based management of this condition and its consequences is fundamental to the practice of the geriatrician. Stroke is a medical emergency and early presentation of symptoms with prompt recognition by healthcare providers will allow the patient to be considered for treatments that limit disability or improve outcome, such as intravenous thrombolysis. Subsequent multidisciplinary care in a stroke unit will allow access to the best medical management of risk factors, reducing the risk of recurrent stroke, allowing timely further investigation and permitting better access to rehabilitation therapies. Rare causes of stroke, such as cerebral venous thrombosis, should always be kept in mind because they may need different management.

If, during investigation, a tight carotid artery stenosis is discovered, there is good evidence to guide the patient's further management. Selected symptomatic patients benefit from carotid endarterectomy. Carotid artery stenting provides an alternative for patients considered at high peri-procedural risk of stroke from endarterectomy. All patients with TIA or stroke who might be suitable for surgical or endovascular treatment should therefore be investigated for carotid stenosis, initially with non-invasive methods.

Intracranial haemorrhage, including subarachnoid and cerebral haemorrhage, is likewise a threat to life. Those patients who survive an intracranial haemorrhage without major disability may need further investigation to determine the presence of a treatable aneurysm or AVM.

NICE stroke guidelines with key priorities for implementation are given in Table 57.10.

Table 57.10 NICE stroke guidelines – key priorities for implementation.[10]

- In people with sudden onset of neurological symptoms, a validated tool, such as FAST (Face, Arm, Speech Test), should be used outside hospital to screen for a diagnosis of stroke or TIA
- All people with suspected stroke should be admitted directly to a specialist acute stroke unit following initial assessment, either from the community or from the A&E department
- Brain imaging should be performed immediately for people with acute stroke if any of the following apply:
  - indications for thrombolysis or early anticoagulation treatment
  - on anticoagulant treatment
  - a known bleeding tendency
  - a depressed level of consciousness (Glasgow Coma Score <13)
  - unexplained progressive or fluctuating symptoms
  - papilloedema, neck stiffness or fever
  - severe headache at onset of stroke symptoms
- On admission, people with acute stroke should have their swallowing screened by an appropriately trained healthcare professional before being given any oral food, fluid or medication

Key points

- Acute stroke is a major cause of death and disability in the older population.

- Selected patients benefit from thrombolysis after early brain imaging to distinguish between infarct and haemorrhage.
- Multidisciplinary care in a stroke unit improves outcome.
- Early treatment of severe carotid artery stenosis may prevent recurrent stroke.
- Patients with stroke and TIA should be managed as emergencies by a specialized stroke service to prevent early brain damage and recurrent stroke.

CHAPTER 58

Stroke and stroke rehabilitation

Lalit Kalra
King's College, London, UK

Introduction

Stroke is the leading cause of severe disability in most of the developed world. The World Health Organization (WHO) estimated that in 2002, 15.3 million people had a stroke worldwide, with more than one-third, 5.5 million, resulting in death.[1] Population projections for Europe suggest that the proportion of the population aged 65 years and over will increase from 20% to 35% by 2050, and this demographic shift will increase the number of acute stroke episodes from 1.1 million to more than 1.5 million per year by 2025.[2] In addition to a high mortality, stroke is also associated with significant disability amongst survivors. Nearly 40% of stroke survivors had severe and 20% had moderate disability, which consumed nearly one-third of all healthcare resources in a large community study in patients over 80 years of age.[3] Stroke is also an expensive disease. The estimated average cost of a stroke varies between countries and the average ranged from US$468 to $146 149 in a review of 120 studies across the world.[4] The average cost of stroke varied between $2822 in Eastern Europe and $12 883 in Japan to $22 377 in the UK, $24 548 in Sweden and $28 253 in the USA.[5] These costs do not take informal costs of care into account; when such costs are included, the total cost of stroke nearly doubles.[6] An estimation of total costs of stroke using a long-running community-based South London Stroke Register estimated that stroke costs in the UK totalled £9 billion per year with productivity losses due to morbidity and mortality accounting for £1.3 billion.[7]

Recent years have seen several developments to improve the management of stroke patients and reduce mortality, disability and costs associated with this disease. These range from advances in imaging techniques which improve diagnostic capabilities[8] and acute interventions aimed at reducing the size of brain injury[9] to improved acute care[10] and organized rehabilitation aimed at reducing residual dependence.[11] Despite the proven efficacy of thrombolysis and optimism about physiological manipulations in the acute phase of stroke, these interventions will have only a modest impact on eventual outcome in most stroke patients because of the limitations on their use.[12] On the other hand, over 300 randomized controlled trials provide a sound foundation for evidence-based practice in stroke rehabilitation, supplementing and often confirming decades of clinical experience.[13] Hence early and planned multidisciplinary rehabilitation remains the cornerstone of stroke management in the foreseeable future because it is applicable to most stroke survivors and has a strong evidence base for effectiveness in all patients, regardless of stroke severity.

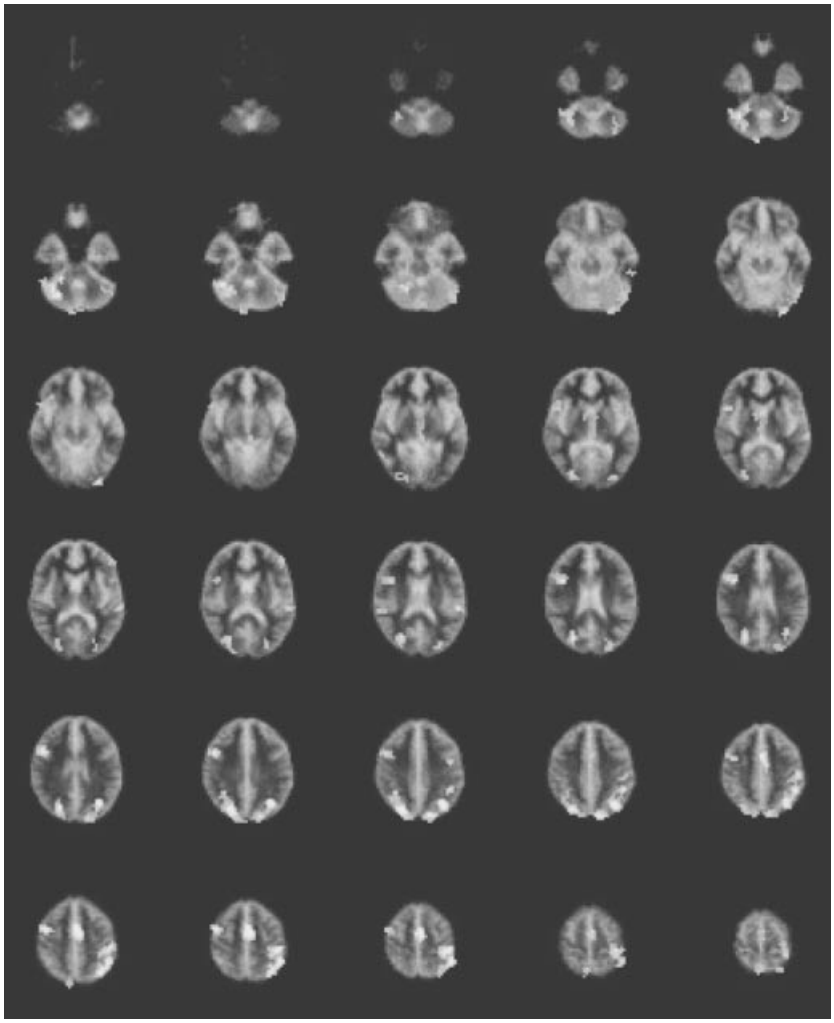
The neurological basis of recovery

The principle that underlies all rehabilitation is that the brain has an inherent capacity to recover lost function after stroke.[14] This is based on observations that most survivors regain some or many of the functions initially lost as a result of the stroke. Recovery is of two types: intrinsic, which involves neuronal regeneration and setting up of new axonal connections, and adaptive, in which alternative strategies, usually behavioural changes, are used to overcome disability.[15] The majority of patients show both intrinsic and adaptive recovery, the proportion of each being dependent upon factors such as age, severity of stroke, cognitive abilities and rehabilitation input after stroke. Intrinsic mechanisms consist of restitution, which includes repair of partially damaged pathways, and strengthening of existing pathways, mediated by local changes in blood flow, neurogenesis and cell migration, growth factor release, metabolism or neurotransmitter concentrations. Diaschisis or substitution is the development of new, but functionally related, pathways in the unaffected areas of the brain to take over the lost function. Studies in experimental models have shown a number of cellular and histological changes, such as axonal sprouting and formation of new dendritic connections, in the unaffected hemisphere of chronic stroke models, which probably are responsible for long-term recovery in these animals.[16] The

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

degree of recovery due to intrinsic mechanisms is variable and may be incomplete in a significant number of patients. In these circumstances, re-education in compensatory techniques, either by changed use of the affected side or retraining of the unaffected side, becomes an important behavioural adaptation to improve function and reduce the level of disability posed by the impairment.[17]

The development of advanced neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (MRI), has helped to demonstrate the processes of reorganization of neural activity after stroke in human subjects.[18] These studies have shown that unilateral motor tasks are associated with activation (increased metabolic activity) primarily in the contralateral sensorimotor cortex and the ipsilateral cerebellum in healthy subjects (Figure 58.1). The contralateral premotor cortex, ipsilateral somatosensory cortex and bilateral supplementary motor areas also participate in hand and finger motor tasks, particularly when the task increases in complexity. In recovered stroke patients, activation on these tasks is seen in the peri-infarct cortex and supplementary areas of the affected side (Figure 58.2) and also in additional regions including the ipsilateral sensorimotor and premotor cortex (Figure 58.3). The cerebellum, thalamus and prefrontal areas play an important part in restoration of function. The process of reorganization is dynamic, there is an evolution of changes with time and several different patterns have been



Group brain activation map in 5 subjects showing activation of the cerebellum,superior temporal gyrus, prefrontal cortex, SMA, PMC, lateral premotor cortex and somatosensory cortex on performance of the CRT

Figure 58.1 Activation on functional MRI during a choice reaction task (CRT) in a normal subject.

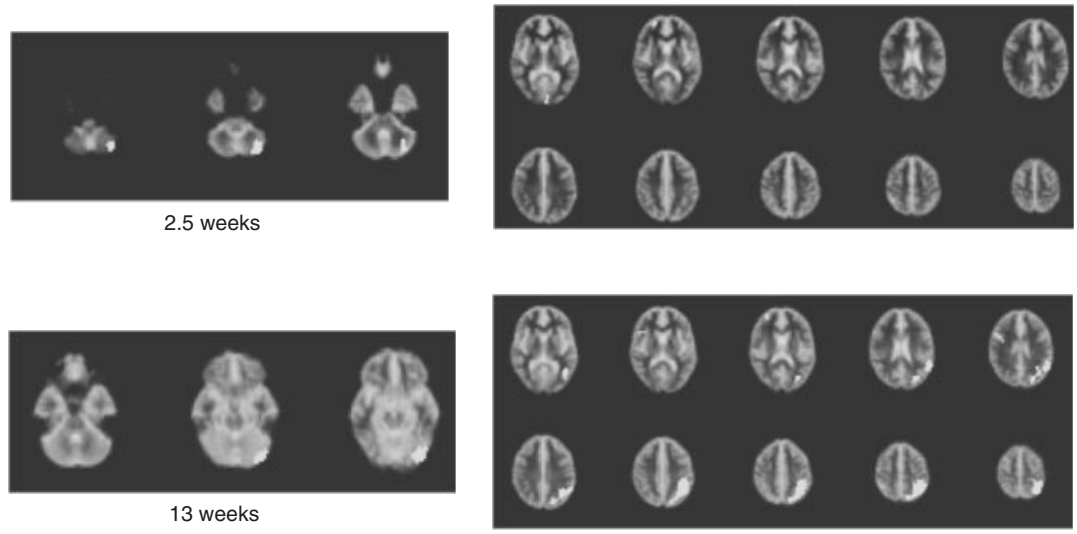


Figure 58.2 FMRI on CRT using affected hand in a patient with small lacunar infarct in the left internal capsule.

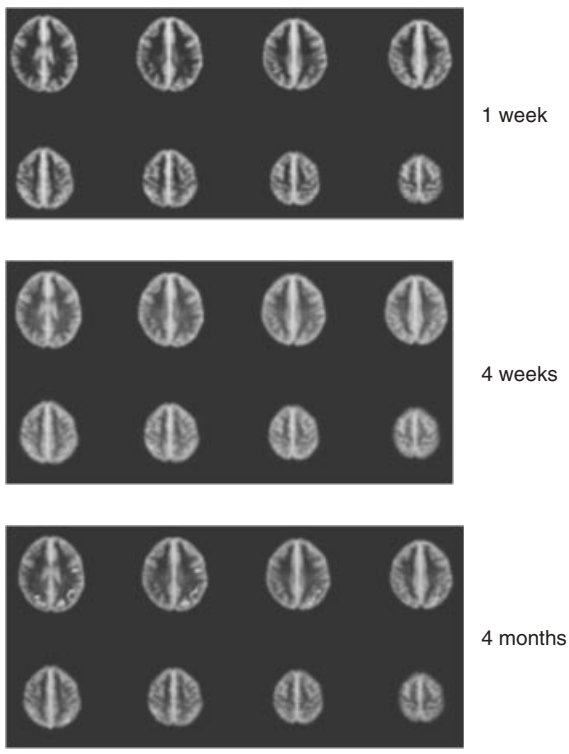

Figure 58.3 FMRI on CRT using affected hand in a patient with cortical infarct in the right hemisphere.

described. These include activation, and later extinction, of bilateral cerebellar and prefrontal areas, an initial increase followed by a decrease in activation of motor areas and progression from early contralesion activity to late ipsilateral activity.[19–22] All these changes appear to be associated with recovery, although their exact significance and relevance to recovery remain a subject of debate. It is now clear that there are multiple motor circuits in the brain which serve similar functions. Conventional pathways dominate in healthy subjects and inhibit the activity of alternative pathways in other areas of the brain. Disruption of traditional pathways in cerebral ischaemia reduces or eliminates the inhibition normally exerted by these pathways and allows activation of alternative pathways in the premotor areas of the affected side and primary motor areas on the unaffected side. Hence the paradigm for function has shifted from strict cerebral localization to that of interactive functioning of diverse cortical areas activated by the constantly changing balance of inhibitory and excitatory impulses.

New evidence suggests that neurogenesis represents a key factor in plasticity of the normal brain in response to environmental stimuli and that newly generated nerve cells form synaptic contacts which become fully integrated into existing neuronal circuitry.[15,23] Stroke-induced neurogenesis takes place in the subventricular zone and ischaemic boundary of adult human brains and has been demonstrated even in elderly patients up to 90 years of age.[24] Ischaemic injury to the brain sets up orchestrated waves of cellular and molecular events characterized by a

reduction in growth-inhibitory molecules and activation of growth-promoting genes by neurons. Angiogenesis appears to be the first step in regeneration, closely followed by the production and migration of neural progenitors.[25] Neural progenitors interact with other cells such as the astrocytes and oligodendrocytes and other growth factors, creating a microenvironment which promotes neurite outgrowth that repair damaged connections or establish new signalling pathways.[25]

An important concept in rehabilitation is that of 'brain plasticity', which implies that it is possible to modulate or facilitate reorganization of cerebral processes by external inputs.[23,26] This concept is supported by studies which show that activation can be facilitated by sensory stimulation, repetitive movement of the affected limbs or the use of drugs which modify neurotransmitter release.[27–29] Absence of adequate external inputs may have a negative effect – primate studies have shown that lack of afferent stimulation because of loss of voluntary activity impedes recovery in function after induced ischaemic injury to the brain.[30,31] The timing and intensity of intervention may also be important. Although some studies have suggested that very early attempts at intensive movement training in experimental models result in an increase in the size of the cortical lesion,[32] the bulk of evidence supports the benefits of early initiation of rehabilitation in animal models.[33] This emerging picture fits in well with theoretical concepts about motor learning, which emphasizes the importance of repetition, attention and goal-directed activity.

The observations made in animal experiments provide increasing support for some of the basic underpinnings of stroke rehabilitation, that is, that the earlier rehabilitation is started the better the recovery is, that greater intensity of treatment translates into greater recovery and that improvement can continue for some time after discharge from hospital or rehabilitation centre.[34] Feys *et al*., using a randomized controlled design, showed that adding an early, repetitive and targeted stimulation to the arm during the acute phase after a stroke resulted in a clinically meaningful and long-lasting effect on motor function in patients, even after 5 years of observation.[35] A meta-analysis of the effects of augmented exercise therapy after stroke has shown that such treatment has a small but favourable effect on activities of daily living (ADLs) within the first 6 months after stroke.[36] Intensive language training has been shown to improve language functioning significantly and this correlated with cortical perilesional reorganization or plasticity.[37] In an observational study, Bode *et al*.[38] investigated the importance of therapy content and intensity after controlling for stroke severity and found that content and amount of therapy are important predictors of greater than expected gains in self-care and cognition. A small functional MRI study demonstrated that drugs can modify reactivation and recovery; a single dose of fluoxetine resulted in significantly greater activation in the ipsilesional primary motor cortex and significantly improved motor skills on the affected side in patients with pure motor hemiparesis.[39]

To summarize, advances in basic sciences and clinical research are beginning to merge and show that the human brain is capable of significant recovery after stroke, provided that the appropriate treatments and stimuli are applied in adequate amounts and at the right time. There is also evidence to suggest that advances in pharmacotherapeutics and robotic assistive technology can further enhance and hasten the process of recovery, and will change the focus of rehabilitation from intuitive methods employed at present to new strategies firmly rooted in the neuroscience of recovery.

Patterns of recovery

Recovery is fastest in the first few weeks after stroke, with a further 5–10% occurring between 6 months and 1 year. About 30% of survivors are independent within 3 weeks and by 6 months this proportion rises to 50%.[40] Late neurophysiological recovery can continue for several years but is at a much slower rate and seldom results in dramatic changes in overall functional ability.[41] Completeness of recovery depends largely on the severity of the initial deficit. The more severe the initial deficit, the less likely is it that complete recovery will occur. The pattern of recovery is not uniform and shows considerable variation between individuals and also between different deficits in the same individual. There is currently no validated method for predicting the precise mode or degree of recovery for a given individual. In addition, there can be considerable variation in day-to-day progress of individual patients, which may mask overall recovery or at times give rise to false optimism. This problem can be overcome by monitoring patients over time, as overall trends are more important than 'one-off' assessments. Recovery may be affected adversely by the development of stroke-related complications. Comorbidity in elderly patients is another variable that affects overall recovery and rehabilitation.

The rate of recovery varies for different impairments and disabilities. Some problems, such as homonymous hemianopia, dysphagia and sitting balance, resolve very quickly in stroke survivors, whereas arm paralysis and language impairment recover more slowly and less completely. Perceptual problems may persist or take a very long time to recover. If all stroke survivors are considered, 62% are independent in self-care at 3 months and 66% at the end of 1 year, despite the persistence of neurological deficit in some patients.[42]

Objectives of rehabilitation

Rehabilitation in stroke is not simply a matter of being treated by a therapist or a group of therapists but involves a whole range of approaches to managing disability, provided by a coordinated multidisciplinary team and tailored to restore patients to their fullest possible physical, mental and social capability.[43] The goals of rehabilitation are to:

- maximize patients' role fulfillment and independence in their environment within the limitations imposed by underlying impairment and availability of resources;
- make the best possible physical, psychological and social adaptation to any difference between the roles desired and the roles achieved following stroke;
- ensure the long term wellbeing and quality of life of stroke survivors and their families by providing the necessary knowledge, skills and support using a range of health, social and voluntary services resources.

An important objective of the rehabilitation process is to monitor the relevance, quality and effectiveness of the services provided in order to ensure that they meet the expectations of patients and their families and obtain the best possible value for the money and effort being expended.

The revised WHO International Classification of Impairments, Disabilities and Handicaps (ICIDH) provides a conceptual model for stroke rehabilitation.[44] In this model, the terms disability and handicap have been replaced by limitations in activities and restriction in participation. The focus of attention shifts from pathology to handicap and from patient to environment during the course of rehabilitation.[45] The key areas that rehabilitation impacts upon are limitation of activity (disability) and restriction of participation (handicap). Disability is the lack of ability to perform an activity in the manner, or within the range, that the person was able to accomplish prior to the stroke and relates to function. In this context, the ability to undertake basic activities of self-care is fundamental to any physical rehabilitation programme. Handicap is the social consequence of disability and constitutes the limitations faced by stroke patients in fulfilling their normal role in society. It is not always possible to differentiate handicap from disability and most pragmatic approaches tend to combine these two dimensions, referring to them as social disability.

Rehabilitation in stroke is essentially a multidisciplinary activity, which has been described as a problem-solving educational process focusing on disability and intended to reduce handicap.[46] The basic principles that should be applied throughout rehabilitation of stroke patients are:

- documentation of impairments, disabilities and handicaps and, where possible, measuring them using simple, valid scales;
- maximization of independence and minimization of learned dependency;
- adopting a holistic approach to patients that takes into account their physical and psychosocial background, support mechanisms and environment;
- supporting caregivers and helping them to develop physical and psychological skills to provide long-term, sustainable support to stroke patients.

Process of rehabilitation

Rehabilitation has four important components: assessment, planning, intervention and evaluation.

Asessment

Assessment is fundamental to ascertain the precise nature and severity of deficits and define treatment goals prior to commencement of a rehabilitation programme because it provides a logical basis for treatment and management of stroke patients. The major reasons for undertaking assessments in stroke patients are to:

- define the type of patient, the extent of disability and the potential for recovery and/or responding to intervention (prognostication);
- identify main areas of difficulty and their underlying causes and also the expectations of the patient and the family;
- monitor the process of rehabilitation (evaluation) and assess the degree of recovery or residual disability at the end of the rehabilitation process (outcome).

A large number of neurological, physical and functional assessments are currently available and can be divided into global assessments (which determine the overall impact of stroke) and specific assessments (which deal with a single level or domain of impairment or disability). Composite scores for global disease severity are unreliable because of the dominance of speech and language function over other indexes and because, when very different disabilities are combined into one score, much specific information is lost.[47] Most scores also mix a variety of impairments and disabilities without considering their interactions.

The importance of knowing what information is wanted and why, that is, the purpose of a measure, is central to choosing any measure in rehabilitation. It is also important to decide on the least amount of information needed to achieve this purpose. The necessary characteristics of suitable measures are validity, reliability, sensitivity, simplicity and communicability. It is best to use existing measures wherever possible provided that they are valid for the purpose in mind, reliable in the circumstances proposed and relevant to the objectives of intervention. Moreover, the use of established measures makes communication and interpretation of data easier.

Predicting when a stroke patient has reached their full potential for recovery and may not benefit from further

therapy inputs is an imprecise science. Estimation of the functional capacity for recovery is particularly important for chronic stroke patients (more than 1 year after stroke), especially as these are the patients most likely to be denied further rehabilitation inputs. Unfortunately imaging and electrophysiological techniques to aid such predictions have generally proven to be expensive and unhelpful in clinical practice. However, it may be possible to combine these modalities to develop algorithms for patient selection for both research and clinical programmes. A recent example of this is the combined use of transcranial magnetic stimulation (TMS) and MRI to determine the integrity of corticospinal tracts and predict functional recovery potential.[48] The study showed that motor evoked potentials to TMS in the affected limb in the presence of little or no asymmetry in the fractional anisotropy map of the internal capsule on MRI (indicative of minimal long tract damage) was associated with a potential for improvement up to 3 years after stroke.

Planning

Planning is the process of goal setting based on identification of aims, objectives and targets.[49] Goals can be set at different levels; most patients will have immediate goals which relate to basic personal ADLs such as achievement of sitting balance, independent transfers and independence in toiletting activities. As patients continue to improve, goals need to be set for higher levels of function which incorporate not only independence in household activities but also the ability to undertake social, leisure and occupational pursuits. The ultimate goal of the rehabilitation programme is to improve overall wellbeing and participation, but many rehabilitation programmes often stop once patients have achieved independence in personal ADLs. It is important that planning takes into account not only the immediate needs of the patients but also their potential needs when they return to their own environment. This often involves adapting rehabilitation to the home setting and addressing the needs of caregivers, many of whom will play an important role in providing ongoing support and management of disability at home.[50] The areas of practical importance in goal setting are:

- *Accommodation*: Where will the patient live and what physical adaptations will be needed?
- *Personal support*: What is the level of support available for existing caregivers and what extra help will be essential for the patient?
- *Life satisfaction*: What roles will the patient be fulfilling within their social setting and how will they be occupying their time?

Many difficulties arise in stroke rehabilitation because the goals of intervention are not set in advance or because these goals have not been discussed and agreed on by all relevant parties. Goals of rehabilitation vary according to the expectations of those involved. The goal of hospitals may be to discharge patients as soon as possible, whereas the goal of patients may be to return to their previous functional status even if this is unattainable. The goal of caregivers may be to minimize the level of input that they need to provide even at the cost of institutionalization. Many of the difficulties ultimately faced in managing patients and in evaluating the effectiveness of interventions can be traced back to conflicts between the goals and objectives of different parties. An essential function of the whole rehabilitation team is to identify and modify unrealistically high (and sometimes unjustifiably low) expectations of patients and their families by making them more aware of the nature of residual deficit and expected prognosis as soon as these are reasonably clear. The two major problems that arise in goal setting include failure to use a common language in communication between various professionals or between professionals and patients and, second, failure to agree on a time frame within which the rehabilitation process must be accomplished.

Intervention

The minimum requirement of any stroke intervention is to provide care necessary to maintain the status quo and prevent deterioration of the patient's condition or functional ability due to poor management or complications. Further intervention should be aimed at facilitating recovery and improving outcome by minimizing disability and preventing handicap. Although large amounts of time and resources are devoted to various therapy interventions after stroke, evidence suggests that these resources are not used optimally in many settings and many of the potential gains of therapy input are not realized because of organization and systems limitations.[51,52] There is also limited evidence on individual interventions because despite the large number of studies available, most of them have small and heterogeneous samples, small amounts of formal therapy have been given in any trial and the interventions most often become a comparison between different intensities of treatment. In addition, there is considerable diversity of outcome measures used in these studies and limited comparability of study designs.[53]

At present, there are many rehabilitation techniques available, some with more robust evidence than others in trial conditions, but none that have been shown to be superior to any other in the major areas of physical therapy or in speech and language function in clinical practice. A summary list of current approaches is given in Table 58.1 and some of the more commonly used approaches are summarized.

Table 58.1 A summary of rehabilitation techniques in stroke.[54]

- **Early mobilization**
  - Key strategy associated with good functional outcomes
  - Meta-analyses over 55 years: no positive independent benefit
  - Not harmful for most stroke patients
- **Restoration of motor function**
  - Balance and motor therapy ± sensory feedback effective for function and mobility
  - CIMT clinically relevant improvements in arm motor function
  - Robotic devices
- **Neuromuscular stimulation**
  - rTMS associated with function recover in motor deficit, visuospatial neglect or aphasia
- **Motor imagery**
  - Positive effect arm function, promise for leg function
  - Virtual environments and tasks
  - Effects greater when combined with conventional therapy
- **Spatial Neglect**
  - Spatial techniques have limited success (prism adaptation)
  - Generalized attention enhancing techniques may be better

Early mobilization

Early mobilization is a key rehabilitation strategy associated with good functional outcomes in several observational and controlled studies.[55] Despite this, mobilization protocols remain poorly defined and vary across units and across patients. A review which combined data from observational studies and meta-analyses was not able to find any positive, unequivocal benefit associated with early mobilization, independent of other aspects of stroke care,[56] but concluded that early mobilization after stroke was not harmful for most stroke patients and may contribute as part of the routine stroke unit in achieving good long-term outcome in stroke patients.

Restoration of motor function

Restoration of motor function is a primary objective of stroke rehabilitation and there are several pooled data analyses of studies on various strategies for improving motor performance in stroke patients.[57] A prospective meta-analysis of the effectiveness of bilateral movement training in post-stroke motor rehabilitation showed that bilateral movements alone or in combination with auxiliary sensory feedback were effective in improving functional and mobility outcomes in stroke patients.[58]

Treadmill training has been shown to improve gait and walking speeds significantly in hemiparetic patients when used as an adjunct to conventional treatment. There are many approaches to gait training, but the most effective combination of training parameters, such as amount and timing of body support during the gait cycle, belt speed and acceleration, remains unknown.[59] The applicability of treadmill training in clinical practice is limited by the availability of specialist equipment and the technique may be suitable for only a small proportion of young stroke patients with relatively modest impairments.

Constraint-induced movement therapy (CIMT) has been one of the most important and well researched therapeutic approaches to restoring motor function. CIMT is based on the assumption that immobilization of the unaffected side to prevent learned 'non-use' and promote use of the affected limb results in faster (and more complete) recovery. The most convincing evidence for CIMT comes from the Extremity Constraint-Induced Therapy Evaluation (EXCITE) Trial.[60] The study showed that CIMT intervention in stroke patients was associated with statistically significant and clinically relevant improvements in arm motor function that persisted for at least 1 year. Despite this successful demonstration in a clinical trial, there continue to be doubts on the extent to which individualized CIMT is practical or cost-effective.[61] A meta-analysis has also suggested that recovery with CIMT is proportional to the amount of exercise given to the affected limb and it may be possible to achieve comparable benefits by less hazardous and less frustrating conventional therapy methods.[62]

Neuromuscular stimulation

Peripheral neuromuscular electrostimulation techniques appear to improve aspects of functional motor ability, motor impairment and normality of movement in recovering stroke patients.[63] A review of the use of repetitive transcranial magnetic stimulation (rTMS) in patients with post-stroke motor deficit, visuospatial neglect or aphasia showed that low-frequency rTMS to restore inhibition applied over the unaffected hemisphere or high-frequency rTMS to reactivate hypoactive regions applied over the affected hemisphere were associated with functional recovery.[64] There was great variation regarding the number of rTMS sessions required for a sustained effect and the timing of rTMS application after stroke.

Motor imagery

In recent years there have been several small clinical studies exploring the concept of motor imagery in stroke rehabilitation.[65] Most tasks involved mentally rehearsing movements of the arm and intervention periods varied from 2 to 6 weeks. The meta-analysis of these studies shows that mental practice has a positive effect on recovery of arm function and may have promise for improving leg function after stroke. The effects of motor imagery training appear even greater when combined with a conventional stroke rehabilitation programme in subacute stroke patients.[66]

Spatial neglect

A major advance in neglect rehabilitation is the shift of the conceptual paradigm from a spatial lack of awareness to a more generalized reduction in attentional abilities.[67] Non-spatial attention training has been shown to be associated with improvements in neglect, underpinned by changes in cortical activation pattern areas known to be associated with attention.[68] The clinical implications are that it may be possible to overcome spatial neglect in stroke patients by interventions that improve generalized or sustained attention. The expectation is that these techniques may prove to be more effective and have a more sustained effect compared with conventional spatially oriented methods which did not result in sustained improvements in neglect that could be transferred to functional tasks.

Organized (stroke unit) care

Evidence suggests that organized care, such as that provided in stroke units, both facilitates neurological recovery and expedites discharges.[69] The conceptual rationale for organized stroke care is the awareness that stroke affects several domains of human performance and results in multiple impairments, many of which have significant interactions in determining the level of disability.[46] It is also clear that no single discipline has all the skills, resources and expertise required to manage all aspects of recovery from stroke. Facilitation of recovery is further compounded by the different speeds at which impairments recover, as discussed previously, demanding a staged approach to interventions and therapy inputs. Rehabilitation goals are also shaped by personal needs of stroke patients, the environment they will return to and the personal support available after discharge. Hence the complex interdisciplinary process of stroke rehabilitation requires a multidisciplinary approach and collaborative policy of coordinated delivery of treatments based on comprehensive assessments and delivered by staff trained in stroke management in consultation with patients and their caregivers. This level of coordination of care is another argument to support the development of organized stroke services.[70]

The last two decades have seen a number of randomized controlled trials that suggested that organized care offered advantages to patients with stroke. However, many of these studies were too small to demonstrate a robust statistical benefit. Hence the Stroke Unit Trialists' Collaboration (SUTC) was set up to pool data from these and other ongoing studies from Australia, North America and Europe.[71] Despite the variations methods of organized care and patient selection criteria, the meta-analysis of pooled data from 29 trials which include 6536 patients shows odds reductions in mortality of 0.86 (95% CI, 0.71–0.94), death or dependence of 0.78 (95% CI, 0.68–0.89) and death or institution of 0.80 (95% CI, 0.71–0.90) at 1 year associated with organized care, which are independent of age and gender.[72] More importantly, and in contrast with thrombolysis for acute stroke, these benefits are seen for all stroke patients regardless of stroke aetiology or the duration between stroke onset and intervention. This expectation of the translation of trial efficacy into clinical effectiveness in mainstream practice has been further demonstrated in longitudinal studies.[73,74]

One of the difficulties faced in the interpretation of the evidence is that organized stroke care, especially stroke units, may mean different things to different people.[71] Definitions vary from 'a team of specialists who are knowledgeable about the care of stroke patients and who consult throughout a hospital or the community wherever a patient may be' to 'a geographic location within the hospital designated for stroke and stroke-like patients who are in need of medical and rehabilitation services and the skilled professional care that such an unit can provide'. There is also considerable controversy about the number and diversity of disciplines that need to be involved in stroke care and differences in staff composition between different settings have limited the generalization of findings in individual settings.

There are also difficulties in assessing the independent benefits of different types of organization of stroke care, mainly because the comparators for organized care in different studies range from general medical wards to different types of organized care. This heterogeneity of comparisons makes it difficult to determine if one type of stroke care organization is superior to other methods of organizing stroke care, as there is no common yardstick against which the benefits of different strategies of stroke care can be measured. Langhorne has shown that there is a definite benefit associated with comprehensive and rehabilitation stroke units and mixed rehabilitation units, all of which show an odds ratio (OR) of 0.85–0.89 in favour of organized care.[75] There may also be a possible benefit with acute (semi-intensive) units, although this just failed to achieve statistical significance (OR 0.88; 95% CI, 0.76–1.01). Mobile stroke teams were associated with no benefit in this analysis (OR 0.98; 95% CI, 0.95–1.05). There are no trials of acute intensive care, so this strategy of organizing stroke care remains untested. However, a review of the data suggests that emphasis on acute intensive care alone may not be adequate to change overall outcomes and that continuity of care is needed to realise the full potential of organized stroke unit care.

The amount of formal therapy received by stroke patients is small even in specialist stroke units. An important paper reported that patients spend more than 50% of their time in bed, 28% sitting out of bed and 13% in therapeutic activities and are alone for 60% of the time during the therapeutic day, even in a stroke unit.[76] The impact of a rehabilitation culture

on therapy input was elegantly illustrated in the CERISE study, a comparison of stroke rehabilitation units across four settings in Europe.[77,78] The study showed that motor recovery outcomes after stroke varied significantly across Europe and were not proportional to the therapy resources allocated to stroke but determined by the actual amount of treatment provided to stroke patients. For example, although the greatest amount of therapy resources being committed to stroke rehabilitation in the UK compared with other centres (70 h per week), stroke patients received the least amount of therapy input (1 h per day) compared with others. Stroke patients in the UK spent nearly 65% of the therapeutic day sitting, lying or sleeping and had greater contact with visitors compared with therapists. In contrast, therapy input in Germany was structured and strictly timed, resulting in significantly more time being spent with patients and with the best outcomes in Europe.

To summarize, there is consensus that well-organized and well-planned rehabilitation guided by well-defined goals based on adequate assessment and sensitive negotiation with patients and caregivers and provided on a specialist unit reduces disability and long-term institutionalization. There is, however, little evidence supporting any specific treatment technique for stroke patients. A pragmatic functional approach individualized for each patient's needs is recommended and strict adherence to theories with little scientific basis or clinical evidence of effectiveness should be discouraged. There is evidence suggesting that early, intensive intervention by therapists may speed recovery and hasten discharge from the hospital without increasing the total amount of therapeutic input. However, observational studies suggest that therapy time may not always be optimally deployed and rehabilitation can be made more effective and efficient by addressing issues around the process of rehabilitation.

Evaluation

Evaluation is the process of monitoring a patient's progress (or lack of it) and assessing the effectiveness of the rehabilitation process itself. Objective assessment of effectiveness of stroke rehabilitation has proven difficult for several reasons. These include the confounding effect of spontaneous recovery from stroke and difficulty in defining the extent of need and perceptions of good outcome, which may vary with the perspective of different observers. The wide variety of impairments and disabilities associated with stroke, and alsos the large number of instruments available to measure each impairment and disability, have also contributed significantly to the lack of a common assessment for outcome in stroke rehabilitation. A sensible approach is to use simple assessments more frequently during the rehabilitation process to monitor and adjust the treatment programme. A review of studies on stroke rehabilitation has shown the predominance of (ADL scales in monitoring rehabilitation.[79] This may be because the level of independence in ADL is not only the basis for more complete recovery but is also important in determining the care needs of, and resource use by, patients who continue to be dependent. Widespread use of ADL scales is further supported by the general agreement on the core ADL components (bladder and bowel function, feeding, cleanliness, dressing and mobility), high inter-rater reliability in clinical settings which is not influenced by the method of data collection and communicability within multidisciplinary teams. On the other hand, ADL scales blur the distinction between impairment and disability, have a low ceiling effect and cannot identify the reasons why patients fail to achieve goals.

There is little consensus on the most relevant outcome, the method of measurement or the most appropriate timing of such assessment in stroke patients.[45] The perception of a favourable outcome may vary depending upon professional, patient or carer perspectives and how long after stroke it is assessed. Although it has been recommended that outcomes should be measured at different levels within the ICIDH framework, patients will value their ability to undertake desired activities or to participate in social roles more than improvements in specific areas of performance. Even within the ICIDH framework, the rate and extent of change may vary between the different levels and continue over months. Consequently, it is important to consider the timing of any assessments and the influence of factors known to affect the chosen outcome measures. Measures at the level of activities (disability) are widely used for outcome and have the advantage of objectivity, reliability and sensitivity besides being simple and relevant to the patient. Measurement of participation and quality of life, however, may be more relevant and appropriate over the longer term. Appropriate timing of assessments is important and the natural history of recovery from stroke must be considered when selecting the time of assessment. Spontaneous recovery, especially in patients with greater severity of stroke, may not plateau until 6 months after the event. Most experts agree that 6 months is the most appropriate time point at which to measure neurological and functional outcome. Wider interactions with environment and society become important after this stage and measurement of participation, life satisfaction and emotionality should preferably take place at a time when the patient's social condition has stabilized.

Common problems in stroke rehabilitation

Stroke-related disorders that are important during rehabilitation include visual problems (hemianopia or inattention), dysphagia with the risk of aspiration and infection,

communication problems, venous thrombotic disease, urinary and bowel problems, spasticity and contractures, pressure sores, shoulder pain, associated reactions, cold hemiplegic arm and oedema of the limbs. The main neurological complications include depression, seizures, behavioural changes and central pain. Stroke patients are also at a higher risk of falls, which, in association with osteoporotic bone changes in the hemiplegic limb, often result in fractures on the stroke side. Various studies have shown that complications occur in about 60% of stroke patients undergoing rehabilitation and are more frequent in patients with severe disability.[80]

Dysphagia

Dysphagia is a common complication of stroke; recent reviews show that its incidence ranges from 21 to 55% based on clinical tests and from 44 to 78% based on videofluoroscopy.[81] Although aspiration and dysphagia are not synonymous, many of the problems associated with dysphagia in stroke patients are because of aspiration and their close relationship means that there is considerable overlap between the assessment and management of these two conditions. In addition, a substantial number of patients have silent aspiration (aspiration without cough or any outward sign of difficulty) and are at an increased risk of developing complications because clinical swallowing assessments underdiagnose the problem and appropriate preventive strategies are not applied.[82] Dysphagia is associated with significantly higher mortality and morbidity in stroke patients, longer hospital stays, increased demands on feeding resources and higher admissions to nursing homes.[83] Evidence indicates that detection of aspiration and institution of appropriate management strategies reduce pneumonia, mortality, length of hospital stay and overall healthcare expenditure.[81] Dysphagia is also associated with malnutrition, poor participation in rehabilitation and worse functional outcome in survivors.[84,85] Although acute dysphagia improves in 80% of survivors, data from a 5 year follow-up of 1288 stroke patients in the South London Stroke Register showed that dysphagia at stroke onset was associated with a 3–5-fold increase in institutionalization at 5 years.[86] The prolonged duration of hospital stay, higher institutionalization and increased need for statutory support after discharge associated with dysphagia are estimated to cost the NHS £200 million per year.[87]

Videofluoroscopy is the gold standard for assessment of dysphagia[88] but is not a feasible screening option in clinical settings.[82] The water swallowing test is routinely used in clinical practice but its diagnostic accuracy has been questioned.[82] However, it is likely to remain the mainstay of bedside screening because it is safe, relatively straightforward and easily repeated.[89] Decreases in blood oxygenation during swallowing and reduced ability to clear airways of aspirate have been observed in dysphagic patients, suggesting that oximetry may help in the diagnosis of aspiration.[90] Direct flexible endoscopy of the vocal cords and aspiration is another technique available to clinicians but requires expertise and validation in larger clinical studies.[91]

Current management options for dysphagia are limited.[2,14] Compensatory techniques and dietary modifications under the supervision of speech and language therapists and dieticians remain the mainstay of treatment of dysphagia in stroke patients. Patients with persistent dysphagia require alternative means of nutrition [e.g. nasogastric tubes, percutaneous endoscopic gastrostomy (PEG)]. Other measures to alleviate swallowing problems include stimulation of the pharynx by mechanical or thermal means, cortical stimulation with magnetic fields to stimulate the swallowing reflex and insertion of artificial electrical pacemakers to trigger laryngeal elevation.

Dysphasia

Dysphasia is a defect in language function manifesting as impairment in speech production, comprehension, reading or writing in the absence of motor disturbances of voice production or writing, visual or auditory deficits and intellectual or cognitive impairment. Impaired ability to understand speech is common in dysphasic patients. The difficulty in comprehension increases with increasing linguistic complexity of the speech presented and length of sentences used. The extent to which a dysphasic patient can understand what is being said is frequently overestimated, which can result in misunderstandings between patients and their families or professionals involved in patient care. It is important that communication problems are identified early in stroke patients because many therapy interventions are dependent on this function.

The more severe forms of dysphasia are often easy to diagnose on clinical examination in most stroke patients. The diagnosis of mild dysphasia may be more difficult, especially if the patient has a high-level language deficit. It is also important to differentiate dysphasia from confusion secondary to cognitive impairment. Enquiries about the patient's language background (native language, profession, social and educational status), previous speech problems and hand dominance should be part of the examination. Problems in comprehension are particularly difficult to assess. A bedside measure can be obtained by assessing the patient's ability to respond to commands of increasing complexity, either in content or in linguistic structure. It should be remembered that in some patients errors may occur because of dyspraxia or memory problems. All patients suspected of having dysphasia should be assessed by speech and language therapists regardless of the severity of the impairment. Appropriate treatment

of dysphasic patients consists of individualized therapy programmes supervised by speech and language therapists, development of simple communication strategies to allow multidisciplinary rehabilitation and educating caregivers in communication techniques appropriate to the patient's level of impairment.

Perception

Perception is an important but neglected aspect of stroke management. The outcome of rehabilitation frequently depends on effective management of perceptual problems rather than on motor recovery alone. Despite this, perceptual problems are poorly understood and difficult to assess objectively because of the paucity of valid assessment instruments. Their management is equally difficult and a subject of great controversy. Perceptual problems after stroke can be divided into (i) neglect, which is the disregard ofm and failure to attend to, one half of external space; (ii) agnosias, which comprise problems with interpreting sensory data from the environment or the body (visual, tactile, autotopagnosia); and (iii) apraxias, the collection of problems involving formulating, initiating or sequencing motor activity. Visuospatial dysfunction can be particularly disabling in stroke patients, as it affects their ability to judge distances and relationships between objects or between self and objects in a three-dimensional setting, causing severe restrictions in daily living activities. Patients with anosognosia are also difficult to rehabilitate because of the lack of awareness of any problems.

It is not known whether these deficits respond to general stimulation or to specific remedial measures. Recent research suggests that neglect may be amenable to therapeutic interventions such as prism correction, electrical stimulation and increasing attentional activities, but further studies are required to confirm these findings. Although visuospatial problems delay or compromise functional recovery in most patients, some individuals eventually make a full functional recovery despite residual impairments. There is no effective treatment for apraxia. Management currently focuses on increasing the patient's awareness of the condition and its effects. This requires early recognition of the problem and teaching of adaptive skills and coping strategies to patients and their relatives.

Tone and spasticity

The management of muscle tone is an integral part of therapy input in stroke patients. Muscle tone as a dynamic, complex process that is part of an overall pattern of posture and movement which plays a vital role in recovery from stroke. Appropriate management of tone is one of the fundamental principles of the Bobath method of facilitative physiotherapy, which gives priority to normalization of tone and improving symmetry even at the cost of postponing standing or walking. However, this preoccupation with normalization of tone is not supported by evidence and there are several other approaches which combine early mobilization with active muscle tone management during rehabilitation.[92]

The management of abnormal tone and spasticity is difficult, as it depends on achieving the right balance between hypo- and hypertonia between different muscle groups. The problem is compounded by the fact that spasticity varies between different groups of muscles, times of day, emotional state of the patient, activity being undertaken and posture of the limb. Inappropriate exercise can result in inappropriate tone patterns to the ultimate detriment of the patient. If not managed correctly, spasticity leads to bad gait patterns, contractures and loss of function. Management of spasticity should be undertaken jointly by doctors and physiotherapists. Spasticity should be considered in relation to other impairments and in the context of therapy goals because interventions directed solely at reduction of spasticity are unlikely to result in significant functional gains.

Treatment of abnormal tone is initiated by physiotherapists, who can offer a range of interventions, including physical therapy, attention to posture and seating and conventional orthoses. Drug therapy can be used in conjunction with physical manoeuvres and adjusted to achieve optimum effects. Its main drawback is its lack of selectivity; since all muscle groups are affected equally, there may be undesirable hypotonia in some muscle groups (e.g. drugs for reducing spasticity in arm muscles may affect walking). In general, improvements in localized treatment of spasticity which can be administered selectively to specific muscle groups without major adverse effects have resulted in options such as baclofen and dantrolene being replaced by botulinum therapy.[93]

The focal injection of botulinum toxin inhibits the release of acetylcholine into the synaptic cleft, resulting in a reversible paresis of the muscles relevant for the spastic deformity. It has proven effective and well tolerated in several placebo-controlled trials for the treatment of focal upper and lower limb spasticity, although it has not been shown to improve motor function.[93] In a systematic review of 11 double-blind randomized placebo-controlled trials that included 782 patients, botulinum toxin reduced upper limb spasticity in patients post-stroke, but the improvement in functional ability was not established.[94] There were insufficient data to establish botulinum efficacy on lower limb spasticity.

Electrical stimulation techniques are a useful adjunct to other treatments, particularly for treating spastic equinus deformities. In some cases, phenol nerve blocks can produce good results, especially when standard treatments fail or botulinum toxin produces beneficial short-term

effects. In patients refractory to medical treatments, surgical interventions such as abalation of peripheral nerves, tenotomies or reconstruction of tendons and joints may be required.

The hemiplegic shoulder

Shoulder pain, restriction of movement and subluxation of the shoulder joint are common problems in stroke patients. In hypotonic patients, the loss of muscle strength around the shoulder joint and the weight of the paralyzed arm may result in malalignment of the humeral head in the shallow glenoid cavity, predisposing to inferior subluxation of the shoulder. There is considerable variation in the reported incidence of subluxation in stroke patients, but it is estimated that one in every five patients is affected. Shoulder pain is more common and inconsistently related to subluxation. It is encountered in rehabilitation settings with disconcerting frequency and may be a result of spasticity in the shoulder muscles, glenohumeral subluxation, reflex sympathetic dystrophy (the shoulder–hand syndrome) or orthopaedic causes such as rotator cuff injury, arthritis or adhesive capsulitis made worse by immobility. Contributory factors include careless handling of patients and incorrect position of the hemiplegic arm. Management should be undertaken in collaboration with physiotherapists and includes measures such as proper positioning of the arm during periods of inactivity, avoidance of abnormal arm movements which cause excessive strain on the shoulder joint or inappropriate pulling of the hemiplegic arm during transfers and early passive exercise to prevent joint stiffness and contractures. Treatment with analgesics, strapping, non-steroidal anti-infammatory drugs and steroid injections may help in some patients.

Depression

Estimates of depression in stroke vary widely and it is estimated that between 30 and 60% of stroke patients have clinically significant depression, the highest prevalence and severity occurring in the first 2 years after stroke.[95] Diagnosis of mood disorders in patients with acute stroke is difficult because changes in appetite, sleep or interest (all indicative of depression) may be a normal adjustment response to physical disability and changed roles. The diagnosis of depression in stroke is further hampered by the presence of dysphasia and impairments in attention or concentration which make assessment difficult. A pooled estimate from population-based studies of individuals who have had a stroke indicated a prevalence of depression of about 33% at any time during follow-up.[96] There are no precise estimates on severity of depression after stroke, although most patients seem to have minor symptoms of depression. Women, younger patients and those with greater disabilities are at a higher risk of developing post-stroke depression.[97] Post-stroke depression also appears to be more common in patients with a family or personal premorbid history of depression.

Post-stroke depression may last for 7–8 months or more without treatment and is highly correlated with failure to resume premorbid social and physical activities. Depression also has a negative effect on functional and cognitive recovery, integration into the family environment and caregiver stress in stroke patients.[98] There is growing evidence suggesting that early recognition of depression in stroke and early treatment with appropriate antidepressants can facilitate recovery.[99] Specific treatment strategies, including counselling, cognitive behavioural therapy and treatment with antidepressants, have been used for treating post-stroke depression with variable results. A systematic analysis involving 1655 patients with stroke who underwent treatment for depression after stroke showed some effect of pharmacotherapy (i.e. tricyclic antidepressants, selective serotonin reuptake inhibitors, monoamine oxidase inhibitors and others such as flupentixol/melitracen, reboxetine and trazodone) in improving mood but no effect on cognitive functions, ADLs or reducing disability.[100] Psychotherapy was ineffective in improving mood or overall functioning in patients with stroke and depression and had no effect on ADLs or social functioning.

Pain

Pain assessment in stroke patients can be difficult, but a population-based study has shown that nearly one-third of stroke patients have moderate to severe pain in the first few months after stroke.[101] Although pain improves spontaneously in most cases, it can interfere with physical therapy, interrupt sleep and contribute to depression. Post-stroke pain can be caused by pre-existing arthritis, decreased mobility, changes in gait and abnormal body posture. Patients with spino-thalamic involvement may develop a central post-stroke pain syndrome, which is often associated with sensory loss.[102] Central post-stroke pain syndrome can be difficult to treat but may respond to amitriptyline or gabapentin.

Fatigue

Many patients suffer from fatigue after a stroke, which can be long lasting and cause functional limitations. Although post-stroke fatigue has been attributed to depression, physical deconditioning, associated medical ailments and effects of medications are likely to be contributory factors.[103] Treatment of post-stroke fatigue involves treatment of underlying causes; no specific treatment has been shown to have any benefit.[104]

Psychosocial aspects

Stroke is a major life event which presents major difficulties for patients, their partners and their families. It not only may result in physical dependence but also requires a wide range of emotional and social adjustments within families, often leading to role reversals and establishment of new hierarchies.[105] The post-stroke phase is a period of considerable turmoil during which patients and their families need to be supported in order to achieve good outcomes. The reaction to stroke is akin to breavement; a phase of shock and despondency is followed by a period of positive thinking and optimism as patients focus on the activities of the rehabilitation team. Many patients and caregivers harbour unrealistic hopes of recovery and it becomes important for the clinician to prevent unrealistic expectations and pave the way to more successful adaptation to the reality of residual disability. People who were very active and independent prior to stroke feel distressed when they need to rely on others for even the most basic personal tasks. This loss of esteem may lead to apathy and even depression and is more likely to happen in the paternalistic environment of hospitals. The attitude and approach of the medical team are crucial in enabling the patient to maintain dignity. Esteem plummets when patients are not given much attention on hospital rounds or are depersonalized by staff who refer to them as 'CVAs' or 'hemis' rather than considering them to be unique individuals. Stroke patients may need counselling in addition to practical support to cope with the fears of disfigurement, loss of physical function, falls, poverty and an uncertain future after returning home. Alterations in personality may occur after stroke and are a source of great distress to partners and caregivers of stroke patients.

Conclusion

Stroke is a devastating illness and causes long-term disability which dramatically and irreversibly changes the lives of patients and their families. Although there is great optimism that improvements in preventive care and acute interventions will reduce the burden of stroke, their potential remains to be realized. Meanwhile, organized coordinated rehabilitation provided by specialists and in partnership with patients and their caregivers offers the only realistic hope of reducing disability and handicap after stroke. Despite its proven effectiveness, specialist stroke rehabilitation is not available to the majority of stroke patients who stand to gain from this input. Part of the problem is the lack of infrastucture, resources, staff and training to provide specialist care. This is compounded by the lack of awareness of the special needs of stroke patients and the benefits of dedicated rehabilitation among some professionals. Increased resources may be difficult to achieve in the short term, but improving the level of awareness amongst health professionals may prove a quicker, simpler and effective way of improving stroke outcome.

Key points

- Stroke is the leading cause of severe physical disability in adults.
- The brain is capable of significant recovery after stroke, provided that appropriate treatments are applied in adequate amounts and at the right time.
- Early and planned multidisciplinary rehabilitation remains the cornerstone of stroke management.
- Rehabilitation is a multidisciplinary problem-solving, educational process focusing on disability and intended to reduce handicap.
- Objectives of rehabilitation should include supporting and training caregivers in disability management.

CHAPTER 59

Communication disorders and dysphagia

Pamela M. Enderby
University of Sheffield, Sheffield, UK

Communication

Effective communication allows an individual to convey successfully a message or meaning to another person and for that meaning to be correctly interpreted. Communication is one of the most fundamental characteristics of higher cognitive functioning and is dependent upon symbolic encoding, either in sounds, script or gesture. These complex acts are supported by virtually every aspect of brain function, with the afferent sensory stimuli being processed through associated regions, being integrated with stored memories and emotions along with immediate factors relating to attention, arousal and motivation which can stimulate a verbal or gestural response governed by different environmental and behavioural conditioning.

In its simplest form, communication requires one individual to be able to receive a message from another, either auditorily or visually, to interpret this message and to generate an appropriate response which is encoded into sounds, gestures or written letters in order to respond. Thus, the term 'language' refers to a code used to represent and communicate ideas and feelings. Language may be verbal or non-verbal, for example, written words, sign language, gestures. However, all modes are governed by rules shared within cultures. Speech is the verbal expression of language which comprises of the meaning (semantics) and sounds (phonology). Language can also be expressed through writing using symbols (as in letters) or agreed body movements for signs (e.g. sign language or gestures).

Ageing and communication

There is evidence that language is an inherent capacity and that the neural basis for language is not only a dynamic process but prewired biologically.[1] Researchers have investigated the capacity for language in different animal species and although some animals, particularly apes, can be taught to use symbols, humans appear to be specifically, physically and neurologically adapted for the integrated neurocognitive requirements for complex speech and language. Much work has been done on the development of language from birth during its rapid acquisition stage. Less work has been conducted examining the effects of ageing on communication processes later in life.[2] However, it is clear that changes in vision and hearing, laryngeal function and cognitive function impact upon the effectiveness of communication. For example, less cognitive agility may reduce the facility to make inferences when complex language structures are used; the use of stereotypical phrases to fill in language when original vocabulary is less easily accessed and a slight deepening and huskiness in the voice may all be associated with normal communication changes associated with age. Many of these will be subtle and will not be evident in casual conversation.[3]

The impact of age-associated changes on the sensory systems is likely to have a profound effect on communication, but it is difficult to define exactly when the normal deterioration in hearing and eyesight becomes pathological and affects communication more extremely.[4]

Hearing

The prevalence of hearing impairment depends upon the criteria used to define it. However, many studies have indicated that between 30 and 40% of older people (over the age of 70 years) have a hearing loss of 25 dB hearing level. This level would affect the ability to hear normal conversation. Although men are more likely to have more severe hearing level loss than women, increasing age is by far the major determinant in predicting who is likely to have a hearing difficulty. A decrease in overall hearing acuity is often accompanied by disproportionate difficulty in discriminating higher frequency sounds and a lowering of the threshold at which sounds cause discomfort. These age-related changes are called *presbycusis*. Distortions of the speech signal result in misinterpretation and misunderstanding, which have implications for easy and effective communication and also cognition and mood.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Hearing loss can be profoundly isolating and reduce enjoyment in many activities, and is frequently associated with depression.[5] For many elderly individuals, communication problems and related psychosocial difficulties resulting from hearing impairments could be reduced significantly by the use of hearing aids.[6] However, a high proportion of those provided with hearing aids do not use them. One study indicated that only 21% of hearing-impaired elderly individuals provided with a hearing aid used them. Improved usage is associated with an education programme accompanied by the provision of a hearing aid. This should include information on how physically to manipulate the aid itself in addition to giving encouragement to develop the necessary tolerance in order to become accustomed to the different auditory input provided through a hearing aid. Thus, provision of a hearing aid is not an end in itself and is unlikely to lead to successful improvement in communication.[7]

Vision

This chapter would be incomplete without mentioning the contribution of vision to communication but, as this is less central, only an outline is given. Visual changes occur with age and affect depth perception, colour sensitivity, the ability to focus and the ability to adapt to changes in lighting. In addition, a number of visual impairments, such as cataract, glaucoma and macular degeneration, are associated with increasing age. Vision obviously affects reading and writing, but reduced ability to see gestures and facial expressions or to recognize people can impair the communication process in a more subtle manner.[8] One of the concerns to speech and language therapists is that visual and hearing impairments can profoundly affect an individual's response to rehabilitation of acquired dysphasia or dysarthria. Detailed speech and language assessments usually require reasonable vision and hearing; hence patients with defects in these may be more difficult not only to treat but also to evaluate and diagnose.

Cognition

Age-related cognitive decline is examined in depth elsewhere in this book.

There is a close relationship between thought and language and it has been suggested that various types of cognitive decline, including specific dementia types, lead to fundamentally different communicative symptoms. However, with cognitive decline, pragmatic dysfunction leading to incompetence in communicative processes is more frequently evident than linguistic difficulty. Thus, a person may have appropriate language structure, but may use the language in a way that does not communicate effectively, either by ignoring the context, lacking coherence or showing difficulty in sticking to a topic.

Studies have indicated that certain cognitive abilities, such as accessing vocabulary, may be insensitive to age-related changes until the age of 75–85 years.[9] The main difficulty in normal ageing is associated with slowing of processing time and less resistance to distraction.[10] However the prevalence of dementia increases with age, rising from around 1% at age 65 years to 35% at 85 years. The rate of increase for both genders is marked throughout ageing.[11] It is estimated that 30% of those with dementia do not get a diagnosis, particularly in the young onset group (aged under 65 years) who are usually diagnosed late in the course of their dementia.[12]

Dementia can be seen as going through three stages, progressing from mild, through moderate to severe loss of function. Language can be affected at each stage, causing difficulties in understanding and expression and may, along with memory problems, be an early indicator of the condition. Individuals may demonstrate word-finding difficulties, particularly for objects and people's names, and use empty phrases (i.e. without meaning). Additionally, the individual has difficulty in focusing on a topic of conversation and may start in the middle of a topic, with no reference to the listener's knowledge or understanding of the subject. This difficulty in providing relevant information for the listener causes communication to break down and is frequently misunderstood by the communication partner.[13,14]

Persons with age-related cognitive disorders affecting communication can be assisted by speech and language therapists. The therapist will undertake a differential communication assessment and advise the patient and carers on strategies to improve effectiveness of interaction. These strategies include reducing the use of pronouns such as 'he' or 'she' and referring to people or things by name; avoiding open-ended questions, for example, giving definite options; encouraging gesture and using communication prompts such as pictures and charts.[15]

A review of recent research indicates that multi-modality intervention that included physical exercise, volunteer work and exercises to help memory and language can have beneficial effects provided that participants are physically able to complete the intervention. The training of caregivers of patients with Alzheimer's disease about the disease, communication strategies and the use of memory books and wallets can help to improve their communication interactions with patients with Alzheimer's disease.

Motor speech

The power and range of movement may be affected by age; this can subtly change respiration, phonation and articulation, allowing the listener frequently to identify a

speaker that they cannot see as being older or younger. The voice becomes less robust with the onset of tremulous, frail or a thinned quality. It is possible that these changes are associated with some adaptation of the laryngeal cartilages, thickening of the vocal folds and reduction in respiratory support.

Depression

There is a high prevalence of depression in older people and this has been found to be higher than that of dementia.[16] It has an impact on communication, leading to reduced communication, less interest in the communication of others and a general withdrawal from social groups. Depression has been associated with grieving over loss of functions (such as hearing and physical dependence), loss of autonomy and control over life, loneliness and anxiety about the future. Depression can be so profound that it can mimic a cognitive dysfunction or aphasia and in all cases will mean that rehabilitation of another specific communication disorder will be rendered more difficult. Identifying whether depression is a component of the communicative disorder is essential as its treatment can assist with general management of other physical deficits.

Diagnosis and assessment of communication disorders

The specific communication disorders associated with age-related pathologies, such as stroke, progressive neurological disease or dementia, are dysphasia, dysarthria and dyspraxia. Dysphasia is commonly a consequence of left-hemisphere stroke which can also give rise to dyspraxia. Dysarthria is more commonly a symptom with bilateral hemisphere damage or damage to the cerebellum or extrapyramidal system as a consequence of head injury, brain tumour or progressive neurological diseases such as Parkinson's disease.

Dysphasia

Dysphasia is a disorder of language which affects the ability to understand or to express oneself in speech or writing. While the term 'aphasia' denotes a greater severity, the terms are now frequently used interchangeably. Dysphasia is usually of sudden onset and results from focal brain damage. One-third of stroke survivors are affected by aphasia and between 30 and 43% of those affected will remain severely affected in the long term.[17]

Traditionally, aphasia has been classified according to localization theory. Wernicke aphasia is correlated with damage to the left posterior region of the perisylvan cortex or primary language area. A lesion in this area frequently produces disturbances of auditory comprehension, inability to repeat and name objects, but with the preservation of verbal fluency. Paraphasic errors and indefinite pronouns pervade expressive language of Wernicke aphasic patients, who often retain inappropriate, but rich, intonation. In contrast, Broca aphasia is classically associated with lesions localized to the left anterior region of the perisylvan cortex. Broca aphasia is associated with less disordered comprehension, severe word-finding problems and marked impairment of fluency. Thus, the patient will give the appearance of struggling for speech. Studies have indicated that the more profound, debilitating aphasia (Wernicke) is associated with increasing age. Thus, a high proportion of stroke patients over the age of 80 years will have Wernicke aphasia profoundly affecting their comprehension ability. One of the hypotheses for this age-related shift in aphasia type is that cerebral damage has a more posterior focus with advancing age, which could be associated with aetiological changes.

More recently, speech and language therapists have adopted a cognitive neuropsychological model for diagnosing and managing dysphasia as this approach is of more direct assistance in planning and targeting therapeutic intervention. This model is based on the assumption that the language system is organized in an integrated and modular manner and that this can be selectively impaired by brain damage. Thus, once the particular modules have been identified by assessment, then treatment can either stimulate the use of this linguistic deficit or teach strategies to overcome or bypass that aspect of the system. Much research, most of which is based on single case studies, has identified particular patterns of language associated with disruptions to the neurolinguistic structure and has reported varying degrees of success in focusing therapeutic intervention.[18–20]

There is no universally accepted treatment which can be applied to every aphasic person.[21] This is due to the great variation of persons with aphasia, in terms of symptoms and their severity, and in individual differences in lifestyle needs and preferences. A Cochrane review by Greener *et al*.[22] emphasized the importance of functional approaches to therapy, stating that 'The aim of rehabilitation in aphasia is primarily to maximise successful communication in day-to-day interactions' (p. 35).

In general, aphasia therapy strives to improve an individual's ability to communicate through multiple strategies by aiming to

- help the person to use remaining abilities;
- restore language abilities as much as possible by developing strategies;
- compensate for language problems;
- learn other methods of communicating;
- coach others (family, health and social care staff) to learn effective communication skills to maximize the aphasic patient's competence.

About half of recovery from stroke occurs within the first month, but it can continue up to 6 months post-stroke (according to Wade, 1997, cited by Greener *et al*.[22]) and beyond. Single and group case studies have demonstrated improvements in language recovery after many years post-stroke.[18,23,24] There is evidence for the potential of neuroplasticity in the brain, that is, the ability of the brain to use other regions for functions where the original region has been damaged and that early, intense treatment can enhance this.[17]

It is important for all healthcare professionals to be able to have a good understanding of the communicative ability of a patient with aphasia – particularly confidence in the level of comprehension, in order that the patient is engaged in decisions and engaged in giving informed consent appropriately. There are several bedside screening tests which can assist with identifying the level and nature of dysphasia, for example, the Frenchay Aphasia Screening Test.[25] The more formal speech and language therapy assessments provide a detailed description of the neurolinguistic and functional aspects of the aphasia which would inform speech therapy intervention, for example, the Comprehensive Aphasia Test.[26]

A review of recent research indicates that when all other factors (e.g. health, education and social status) are held constant, chronological age alone is not a good predictor of either severity or prognosis in aphasia, with some very elderly patients improving and recovering remarkably well. However, the risk of concomitant problems is greater with increasing age and these may well contribute to a less good outcome. For example, patients who have aphasia alongside age-related memory problems or hearing loss provide more challenges to rehabilitation.

A recent Cochrane review of the impact of speech and language therapy for persons with dysphasia[27] along with two meta-analyses[28,29] indicate that speech language therapy is effective for people with aphasia. There are features of therapy that may make treatment more successful, for example, timing, intensity and involvement of family and friends. More intense therapy of longer duration results in greater gains for aphasic individuals. There seems to be little difference between different types of aphasia therapy. Family and volunteer involvement is successful and results in better outcomes for individuals with aphasia. Laypersons can be effectively trained to deliver some aphasia therapies. Novel computer-based therapies can reduce therapist time, are acceptable to patients and effective. Augmentative and alternative communication (AAC) devices can be successfully used with aphasic individuals, some of whom may be more suited to the use of such devices. It is important to remember that the effectiveness of therapy relies strongly on patient participation and motivation.

The use of computers to deliver therapy to people with aphasia is growing in popularity. Many studies indicate that language treatment can be made accessible for frequent practice and can be adapted to address different deficits and language styles and can implement structured approaches to neurolinguistic learning. Single case and group studies using both qualitative and quantitative methodologies indicate encouraging progress with computer-delivered treatment.[30] Additionally, there is growing recognition relating to the social consequences of aphasia to the patient and the family and increasing evidence that a holistic life-long approach to support a person with aphasia improves the quality of life, preventing isolation, depression and withdrawal from society.[31]

Assessment of mental competence and comprehension is important in some cases where the need for informed consent, power of attorney or testamentary capacity is being considered. While observation and subjective opinion may lead to a particular conclusion, it is essential to support and/or test this with objective tests and consider other influences, for example, social pressures, perseveration, fatigue and poor attention span which may affect ability.[15]

Dyspraxia of speech

Dyspraxia of speech refers to the inability to carry out fine voluntary movements necessary for speech, while voluntary and automatic movements of the same muscles often remain intact. Thus, a patient may be unable to stick their tongue out on command but can lick their lips to remove a crumb (oral dyspraxia). Muscular weakness may be absent or insufficient to account for the speech difficulty and the patient may produce expletives or automatic speech (as in counting) clearly but is unable to imitate sounds and words (verbal dyspraxia). Speech is characterized by effortful groping and patients have difficulty in imitating and repeating sounds and words. Patients with dyspraxia frequently do not have difficulty with other oral motor tasks such as controlling saliva or swallowing, and this can help distinguish dyspraxia from dysarthria where those functions are frequently abnormal. Dyspraxia rarely exists without some degree of dysphasia and may lead to individuals being thought of as having more language impairment than is the case; it is primarily associated with cortical damage.

Dysarthria

Speech requires accurate motor programming, initiation and control of fine movements of the lips, tongue, palate and larynx, which act in harmony with timing of inspiration and expiration. This results in the precise articulation, pitch and tonal quality, resonance and phrasing which are associated with normal speech.[32] Impairment of the central peripheral nervous system can affect this choreography and produce a motor speech disorder termed *dysarthria*. Again,

Table 59.1 Speech symptoms associated with underlying pathology.

Type	Features
Spastic	Strained and hoarse voice, hypernasality and slow, imprecise articulation (Aronson, 1993, cited in Palmer *et al.*[33]). Often accompanied by swallowing and drooling difficulties[33]
Flaccid	Isolated areas of involvement depending on which motor neurone is affected (Enderby, 1983, cited in Palmer *et al.*[33])
Ataxic	Excess loudness, tremor and irregular articulatory breakdowns (Aronson, 1993, cited in Palmer *et al.*[33]). Intonation, pitch and volume can also be affected (Enderby, 1983, cited in Palmer *et al.*[33]), in addition to difficulty with alternate tongue movements
Hypokinetic	Breathy monotone voice with reduced loudness (Enderby, 1983, cited in Palmer *et al.*[33]) and articulation tends to be accelerated and imprecise (Yorkston *et al.*, 1999, cited in Palmer *et al.*[33])
Hyperkinetic	Features strained hoarseness and voice arrests
Mixed	Similar symptoms to spastic dysarthria and tends to be accompanied by a wet-sounding voice with rapid tremor, poor laryngeal and tongue movements and poor control of lips (Enderby, 1983, and Aronson, 1993, cited in Palmer *et al.*[33])

the term anarthria usually indicates a more severe form of the disorder.

The different types of abnormal speech can indicate the level of underlying neurobiological dysfunction (see Table 59.1).

Traditionally, speech and language therapists have managed dysarthria by assisting in differential diagnosis, treating the speech problem and preventing secondary complications by facilitating participation in normal activities (Yorkston, 1996, cited in Sellars *et al.*[34]). Evaluation of speech and language therapy of this kind of group has been deeply problematic given the heterogeneous nature of the underlying impairments, making single case studies the most usual method for evaluation. Frequently people with dysarthria benefit from augmentative or alternative communication methods.

Augmented and alternative communication

Augmentative and alternative communication (AAC) refers to any system of communication that is used to supplement or replace speech, to help people with oral communication impairments to communicate. For individuals with aphasia or dysarthria, this could range from 'low-tech' aids such as drawing and writing or communication books, to 'high-tech' aids such as computerized voice output communication aids.

The objectives of introducing AAC to a patient with an acquired communication problem is to maximize their communicative function in the areas of life that are seen as a priority by the patient and to continually review the changing needs of the patient. It is necessary to[35]

- identify participation and communication needs;
- assess capabilities in order to determine appropriate options;
- assess external constraints;
- find strategies for evaluating the success of interventions.

To ensure appropriate access to the range of resources available, individuals who may benefit from communication aids should have access to an AAC specialist or team, who are skilled in assessment, planning, intervention and continuing support in this area.

Swallowing

The normal swallow

Swallowing involves a process of transporting saliva, food and drink from the mouth to the stomach and it involves the protection of the respiratory system from being entered by anything other than air. Normal swallowing is easy, quick and unconsciously performed, but it is a highly complex process carried out more than 1000 times per day in normal adults just to clear saliva from the mouth to the oesophagus. In the one second that it takes to swallow to clear the mouth of saliva, over 40 paired muscles are used.[36] The mouth, nose and pharynx are passages for food and air in addition to being involved in speech. The mechanisms for using these pathways appropriately can be affected by central and peripheral neural or structural damage. Swallowing necessitates cessation of respiration with closure of the airway, while the pharynx is being used to transport saliva, liquids or foodstuff. Alterations in tone, pressure or timing can cause aspiration, that is, the leakage of food or fluid into the airway. This will commonly cause coughing or choking as the system acts in a coordinated fashion to expel the foreign material and return it to the pharynx. However, silent aspiration can occur where food or liquid does not stimulate coughing or choking and penetration of the material is unimpeded.

Oral phase

Swallowing is frequently described as having three phases, the oral phase, the pharyngeal phase and the oesophageal phase. In the oral phase, sometimes termed the preparatory phase, food is taken into the mouth, chewed and moved back to the opening of the pharynx. The lips seal the

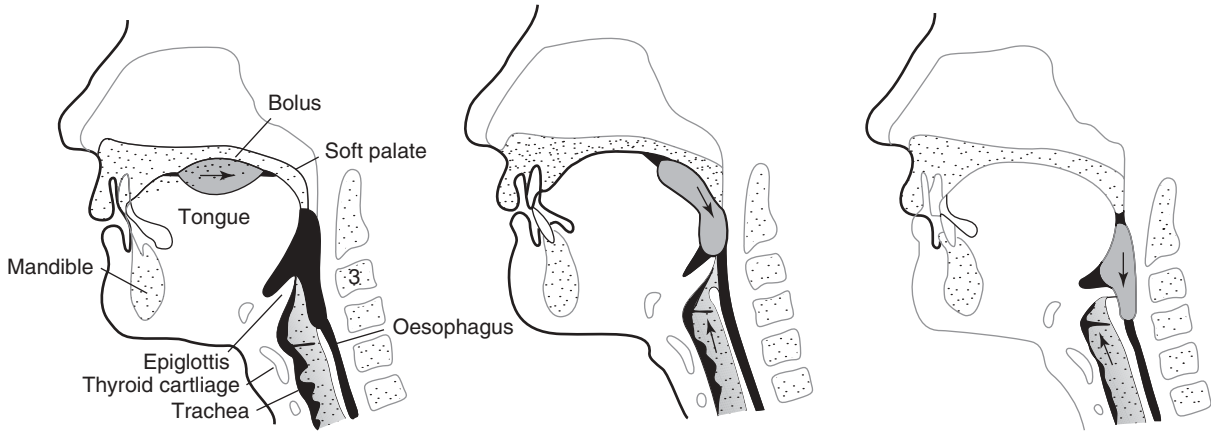

Figure 59.1 Normal swallowing process.

oral cavity and the hyoid rises. At the start of the oral propulsion phase, the soft palate will seal off the nose prior to the tongue propelling the bolus into the pharynx. The oral phase is mainly under voluntary control and can be disturbed if the lips are affected and unable to make a good seal – this delays the initiation of the swallow. Facial palsy can lead to some of the bolus being deposited within the buccal sulcus and poor tongue movements will result in poor bolus control (Figure 59.1).

Pharyngeal/oesophageal phases

The pharyngeal phase is considered to start when the bolus touches the posterior pharyngeal wall. The nasal pharynx is sealed more tightly through the raising of the soft palate and the laryngeal inlet is sealed through raising the larynx, closure of the vocal folds and tilting of the epiglottis. Descending movements of the pharyngeal constrictor muscles squeeze the bolus down. The oesophageal phase is seen as the last phase of swallowing; it is the involuntary transport of the bolus through the oesophagus to reach the stomach. Anatomically, the oesophagus starts at the upper oesophageal sphincter; this sphincter is frequently called the PE (pharyngoesophageal) segment or is otherwise known as the *cricopharyngeal sphincter*. This sphincter at rest is contracted and the bolus alone will not stimulate its release. It relaxes in concert with the pharyngeal bolus transport and opens in unison with the anterior movement of the larynx. This protects the pharynx from regurgitated food and prevents air from entering the oesophagus during breathing. The timing of the opening and closure of this sphincter can be problematic in many neurological diseases. If this sphincter is not released in a timely fashion, patients will complain that they have difficulty in pushing food down into their throat or they may have overspill aspiration with the bolus not clearing through the pharynx into the oesophagus before the airway becomes patent. The ageing process alone affects deglutition with an increase in chewing movements in order to form a bolus and to initiate swallowing, a slowed swallowing propulsion time and a reduction in pharyngeal and oesophageal peristalsis. There is evidence that, with increasing age, the normal elderly aspirate increasingly, but this may not give rise to any symptoms. The mechanisms for tolerating increasing aspiration are not fully understood. However, targeted assistance for those with dysphagia can reduce symptoms and improve weight gain and quality of life.[37]

Dysphagia

The broad term 'dysphagia' can encompass problems at the oral, pharyngeal or oesophageal stages of swallowing and should not be confused with difficulties with feeding or eating, which may be associated with anorexia, depression or other psychological problems or difficulties in transporting food from the plate to the mouth. Symptoms associated with dysphagia include choking during eating or drinking, difficulty in swallowing certain food types, an inability to swallow saliva, nasal regurgitation of food or drink and discomfort during swallowing. While dysphagia should not be defined by the presence or absence of aspiration, patients with feeding or swallowing problems need to be assessed in order to identify the risk of aspiration, as this is particularly associated with increased chest infections, pneumonia and mortality.

Persons with dysphagia are more at risk of malnutrition and dehydration along with aspiration that can lead to aspiration pneumonia. All of these complications can lead to poor outcome and can ultimately be the cause of death, but additionally there are profound social and psychological effects of swallowing disorders. Coughing and choking can be frightening for both the patient and carers. Dribbling/drooling can be socially offensive and embarrassing and have a severe effect on the quality of life of the patient.

Box 59.1 Bedside swallow assessment.

Risk indicators

- Weak, husky voice (dysphonia)
- Inability to cough voluntarily
- Weak cough – no effective expulsion
- Pooling of food or saliva in mouth/cheek
- Frequent coughing/choking even on saliva
- History of recent chest infection
- Complaints of difficulty with swallowing
- Reports having to gulp/or abnormal sensation
- Reports difficulty with some types of food

Observation

Try teaspoons of water, and if successful try teaspoons soft purée, and then if successful try foods with more substance

Observe:

- Patient reports negative sensation
- Poor lip closure/degree of leakage
- Untimely or absent elevation of larynx
- Residue in mouth following swallow
- Lack of clarity of voice, following swallow
- Choking/coughing before, during or after swallow

Clinically, dysphagia is common with 78% of people having had a stroke initially presenting with this symptom and a high percentage of those with dementia and progressive neurological disease also having dysphagia. It presents a 'major diagnostic and therapeutic challenge'.[38] Interdisciplinary management of dysphagia is advocated[39]; the aim of this management is to protect the patient from complications of dysphagia, maintain adequate nutrition and ensure that patients and carers are fully aware of the nature of deficit and methods of managing the problems.

Assessment will in the first instance be done at the bedside (see Box 59.1) and will take account of the oral and laryngeal structures and movements, dental state, cognition, posture and other issues which can contribute to the safety of the patient to progress with oral feeding. It is important to note that the absence of the gag reflex does not automatically indicate a major swallowing problem, just as the presence of the gag does not indicate safe swallowing. Other factors, such as the bolus control, clarity of the voice (is it wet and gurgly after a test swallow?) and the effectiveness of the cough (is the cough firm and effective?) are all important. A therapist will frequently give different trial swallows of food substances (semisolid, firm, etc.) and liquid. Certain food substances may be more easily and safely transported and, therefore, there could be recommendations on the consistency of oral intake. If it is clear from the bedside assessment that there is a danger of aspiration, it may be necessary to request further assessment in a videofluoroscopy clinic which can determine more objectively the type and nature of the aspiration and whether positioning the patient or changing the consistency of the bolus can moderate such risk. However, there are certain guidelines that can assist with the management of any person with dysphagia. It is important to remember that it is very difficult to swallow safely if one is not fully conscious and aware. Furthermore, if a patient is unable to sit upright or cough purposefully, the likelihood of aspiration is increased. Any of above would indicate a necessity for more in-depth dysphagia assessment.

Videofluoroscopy to assess swallowing is not infallible. The procedure can produce both false positives and false negatives. For example, the trial swallows may not produce, at the time of recording, evidence of dysphagia which in some patients occurs only with fatigue after several mouthfuls – a false negative. However, on other occasions, aspiration may be observed, which is asymptomatic or induced by the tension of the situation or unpleasantness of the radiopaque material – a false positive. The indications from videofluoroscopy must be placed in the context of the history of the patient.

Some patients are able to eat certain food textures more efficiently and safely. For example, persons with either reduced oral sensation, buccal control or inadequate laryngeal lift may aspirate more on fluids rather than on semisolids. Fluids do not stimulate the swallow reflex so rapidly, cannot be formed into a bolus, overflow into the pharynx and larynx without needing propulsion and leak into larynx more readily. Therefore, some patients may be advised to avoid liquids, but may manage a soft puréed diet. Other patients may have difficulty in manoeuvring or forming a bolus due primarily to the involvement of tongue, lips and jaw and these patients may need to avoid foods that require chewing.

Problems with communication and/or swallowing are profoundly disabling to the patient and cause great anxiety to relatives. While some of these components may not resolve spontaneously or with treatment, they all deserve appropriate assessment and intervention aimed at improving the management of the symptoms, improving the quality of life by maximizing function and reducing secondary sequelae.

Key points

- Communication and swallowing impairments are profoundly disabling and impact upon the quality of life.
- Discriminating between dysphasia, dysarthria and dyspraxia is important for neurological diagnosis and therapeutic intervention.

- Patients need their level of comprehension to be assessed objectively by the speech and language therapist as it is frequently not what it seems.
- There is evidence that some patients continue to improve communication skills and swallowing function with therapy beyond the period of spontaneous recovery.
- Appropriate identification and management of dysphagia reduces mortality and morbidity.

CHAPTER 60

Acute and chronic subdural haematoma

Eric Schmidt and Emmanuel Moyse
Service de Neurochirurgie, Hôpital Purpan, Toulouse, France

Introduction

When Virchow first described '*pachymeningitis haemorrhagica interna*', subdural haematoma (SDH) was considered as a fatal disorder. Over the past 150 years, a dramatic improvement has been achieved due to better understanding of its pathophysiology, new imaging methods and refinement of operating techniques. However, the morbidity and mortality are still relatively high, especially in the elderly population.

The subdural space lies between the inside of the skull with the periosteal/meningeal dura and the arachnoid layer. That layer contains the cerebrospinal fluid (CSF) and the bridging veins, and surrounds the pia of the brain. This potential subdural space becomes a real subdural space when the dural border cell layer cleaves away from the inner meningeal layer.[1] Subsequently a subdural, or more precisely intradural, haematoma may evolve in that space. As the brain atrophies and pulls away from the skull, the strain placed on the meninges is relieved by a splitting open of the weak layer at the dura–arachnoid junction. Figure 60.1 is a magnified schematic representation of a subdural haematoma. The creation of such meningeal spaces in elderly individuals explains, in part, what sometimes appear to be spontaneous haematomas in this area of the meninges in this patient population.

Haematoma in that space can be either acute or chronic. To fill this potential space and cause pressure on the brain, a mass requires that the pressure applied is greater than the intracranial pressure (ICP), that is, >17 mmHg. Acute SDHs are mainly post-traumatic and of arterial or arteriolar origin. There are two common causes of acute SDH: parenchymal laceration and bridging vessel rupture. Parenchymal laceration represents a severe primary injury and the acute SDH worsens the clinical condition. Surface or bridging vessels might be ruptured during cerebral acceleration–deceleration due to violent head motion. Once the initial bleed has been initiated, the acute SDH becomes subacute and then can turn into chronic SDH. The difference between acute and chronic SDH was defined by McKissock *et al*. in 1960.[2] He denoted 'acute' those cases presenting urgent symptoms within 3 days of trauma, 'subacute' those presenting within 4–20 days and 'chronic' those presenting after 20 days.

In the elderly population, acute SDH has a high morbidity and mortality rate. However, although chronic SDH is common and treacherous, it is potentially treatable. Indeed, the drainage of a chronic SDH is one of the most rewarding and least demanding neurosurgical procedures.

Acute subdural haematoma

Acute SDH is a serious, life-threatening condition and its management is complex, especially in the elderly. Acute SDHs are mainly post-traumatic, but can also be spontaneous in the context of coagulopathy. According to McKissock *et al*.,[2] an acute SDH is diagnosed within 1–3 days after trauma. In severe acute SDH, neurological deficit occurs immediately. The mechanism of injury and also the outcome differ between age groups. In younger patients, most acute SDHs are caused by motor vehicle accidents and in older patients by falls.[3] It has also been shown that older patients have a higher mortality rate and that it is likely that age causes an alteration in the pathophysiological response of the central nervous system to severe trauma.[4] Because of the frequent association of acute SDH with parenchymal injury, surgical management decisions should take into consideration the recommendations for both lesion types. Spontaneous or non-traumatic acute SDHs in the elderly represent a specific clinical entity related mainly to coagulopathy, anticoagulants or antiplatelet therapy. This coagulopathy-associated acute SDH is prevalent in a particular group of patients in which the risk is associated with coagulopathy of one sort or of another.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

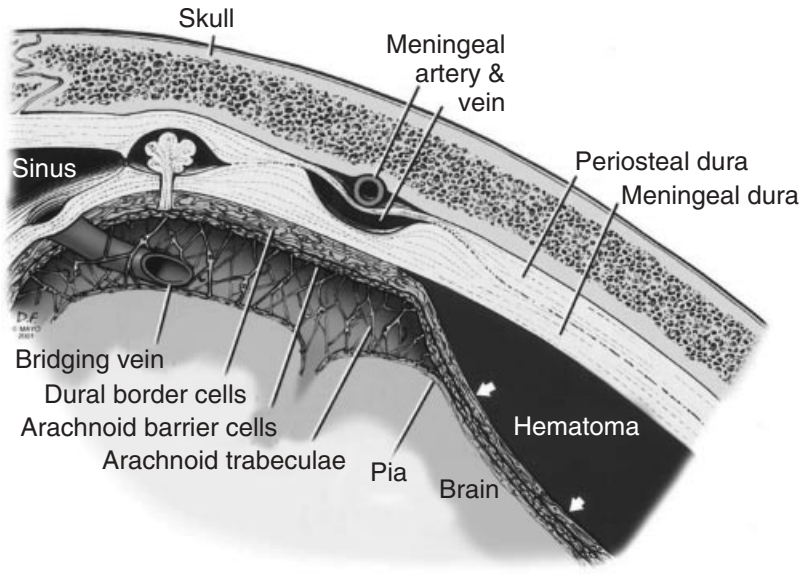

Figure 60.1 Schematic and magnified representation of a subdural haematoma. The dura has two layers: the periosteal dura located on the inner side of the skull and the meningeal dura towards the meninges. Underneath, the arachnoid layer with its trabeculae contains the CSF and the bridging veins. Between the arachnoid and the meningeal dura there is a dural border cell layer. The potential subdural space becomes a real subdural space when the dural border cell layer cleaves away from the inner meningeal layer. Subsequently, a subdural or more precisely intradural haematoma may evolve in that space. (Reproduced from Atkinson *et al. Journal of Magnetic Resonance Imaging* 2003;**17**:484–6, with permission from Wiley-Blackwell.)

Pathophysiology

There are various abnormalities predisposing a cortical artery to rupture: avulsion of an arterial twig branching at a right-angle from the parent artery, rupture of a small artery traversing the subdural space and connecting a cortical artery to the dura mater, termed 'bridging artery', or adhesions between a cortical artery and the dura mater or arachnoid.[5] An acute SDH is related to an arterial bleed in the subdural space. It has been shown that global cerebral blood flow is reduced after acute SDH, leading to a critical ionic imbalance with oedema and widespread cell death. Local pressure causes focal ischaemia, which leads to increased energy metabolism and reduced tissue oxygenation, which can cause infarction a few hours after acute SDH. Even after rapid decompression and haematoma evacuation (<4 h), many patients die. The majority of patients with chronic SDH must, at some time, have had an acute spontaneous SDH. Therefore, probably, many of the so-called spontaneous cases may have been the result of a brisk head movement not severe enough to be considered trauma or of an unrecognized or forgotten trauma. The recognition of spontaneous acute SDH as a clinical entity is important, since many of these patients may subsequently go on to develop chronic SDH.

Epidemiology

Studies conducted after the introduction of computed tomographic (CT) scanning have reported an incidence of acute SDH between 10 and 30% in patients admitted with severe traumatic brain injury. When including mild, moderate and severe head injuries, 11% present with acute SDH.[3] More than one-third of cases of acute SDH are in patients over 60 years old. Similarly, about one-third of cases of admitted head injuries in the elderly population will have an acute SDH.[6] Only 30–40% of acute SDHs requiring surgery are isolated lesions. In the majority of cases, an acute SDH is associated with other intracranial and extracranial injuries. Associated intra- and extracranial lesions have been reported in larger series to occur in 50% of patients presenting with head trauma and in 70% of patients with Glasgow coma scale (GCS) <10.[3]

Clinical presentation

Patients with acute SDH are most of the time comatose: 40–80% of patients had a GCS score of 8 or less.[3] A lucid interval has been described in 10–40% of patients before admission but there is no conclusive evidence that this correlates with outcome. Pupillary abnormalities are observed in 30–50% of patients on admission or before surgery. Acute subdural haematoma may be located along the falx, between the two cerebral hemispheres with the 'falx syndrome': paresis or focal seizures contralateral to the haematoma.

Investigation

CT scanning is the method of choice. On a CT scan, acute blood collection with a haematocrit >23% has a higher density than the brain parenchyma, that is, >80 Hounsfield units. Acute SDHs are classically hyperdense and crescent-shaped, with a concave surface away from the skull. However, they can have a convex appearance, especially in the early stage of bleeding. Subdural blood can also be seen as a layering density along the tentorium cerebelli and the falx. It is also important to identify the

Figure 60.2 CT scan of a left acute subdural haematoma in an elderly patient. The hyperdensity is crescent-shaped with a concave surface away from the skull. Midline shift is inferior to the thickness of the haematoma.

brain parenchyma lesion such as intracerebral haematoma and contusion, subarachnoid haemorrhage, midline shift, brain swelling and skull fractures. An example of a left acute SDH is displayed Figure 60.2.

Management

Observation for a small acute SDH is usual. Surgery should be considered for progressive neurological deterioration. The main difficulty in the elderly population with acute SDH is to decide whether or not an old patient in a coma with an acute SDH should be operated on or not, as the morbidity and the mortality are known to be very high.

Small SDHs often do not require evacuation, as surgery may increase the brain injury if there is a hemispheric swelling with herniation risk through the craniotomy. Patients in a coma, that is, with a GCS score of 3–8, on initial presentation were found to be significantly associated with increased mortality and a poor outcome. Initial pupillary reaction was also shown to be a very important prognostic factor for outcome. For elderly patients with both pupils dilated and non-reactive to light an unfavourable outcome was predicted (death rate almost 100%).[3,7,8] Concomitant parenchymal brain lesions and traumatic subarachnoid haemorrhage were also predictive of a worse outcome, due to an increased intracranial pressure.[9] Studies also showed an increase in mortality with large haematoma; the survival rate dropped below 50% when the acute SDH thickness exceeded 18 mm. A midline shift of more than 10 mm was found also to be correlated with a high mortality. However, it is possible that patients older than 65 years tolerate a greater midline shift because of brain atrophy. The difference between the subdural haematoma thickness and the midline shift seems to be a very strong prognostic factor. In fact, a striking decline in the survival rate was found when the midline shift was greater than the haematoma thickness. When the midline shift was greater than the thickness of the SDH, that is, more brain swelling than SDH, the survival rate was less than 25%.[4] It has been suggested that all patients with acute SDH in a coma (GCS score <9) should undergo intracranial pressure (ICP) monitoring. Surgery is indicated only when ICP values are <40 mmHg owing to the poor outcome of elderly patients with high ICP monitoring.[3] In patients with acute SDH and indications for surgery, surgical evacuation should be performed as soon as possible,[3] but recent studies failed to show any significant difference in outcomes between patients undergoing early (<4 h) or delayed (>4 h) surgery.[4] The haematoma is usually evacuated with a craniotomy and subdural drainage or by decompressive craniectomy. A large craniotomy flap is often required to evacuate the thick coagulum and to gain access to possible bleeding sites. The actual bleeding site is often not identified at the time of surgery. Nevertheless, there is no statistically significant difference in the number of re-operations, irrespective of the chosen operative method (large versus simple craniectomy).

A management algorithm was developed based on clinical and CT parameters to predict the outcome of older patients with acute SDH and to indicate whether surgical haematoma evacuation should be performed.[4] This algorithm is represented schematically in Figure 60.3.

Trauma and emergency department clinicians encounter an increasing number of older patients with head injuries on premorbid antithrombotic therapies. These patients are at increased risk of acute brain lesions. In the setting of minor head injury, patients may not exhibit signs of overt bleed. Therefore, clinicians must weigh the risks and benefits of completing a head CT to rule out a subclinical haemorrhage. Currently, no studies have addressed the efficacy or utility of reversing anti platelet therapy in traumatic head injury with exogenous platelet administration. However, in warfarin-treated patients presenting with traumatic head injuries, clinicians should have a low threshold for obtaining a head CT to rule out acute intracerebral bleeding. Rapid reversal of anticoagulation to a near-normal profile may be warranted in CT-documented acute haematoma.[10] In these patients, the mortality is closely

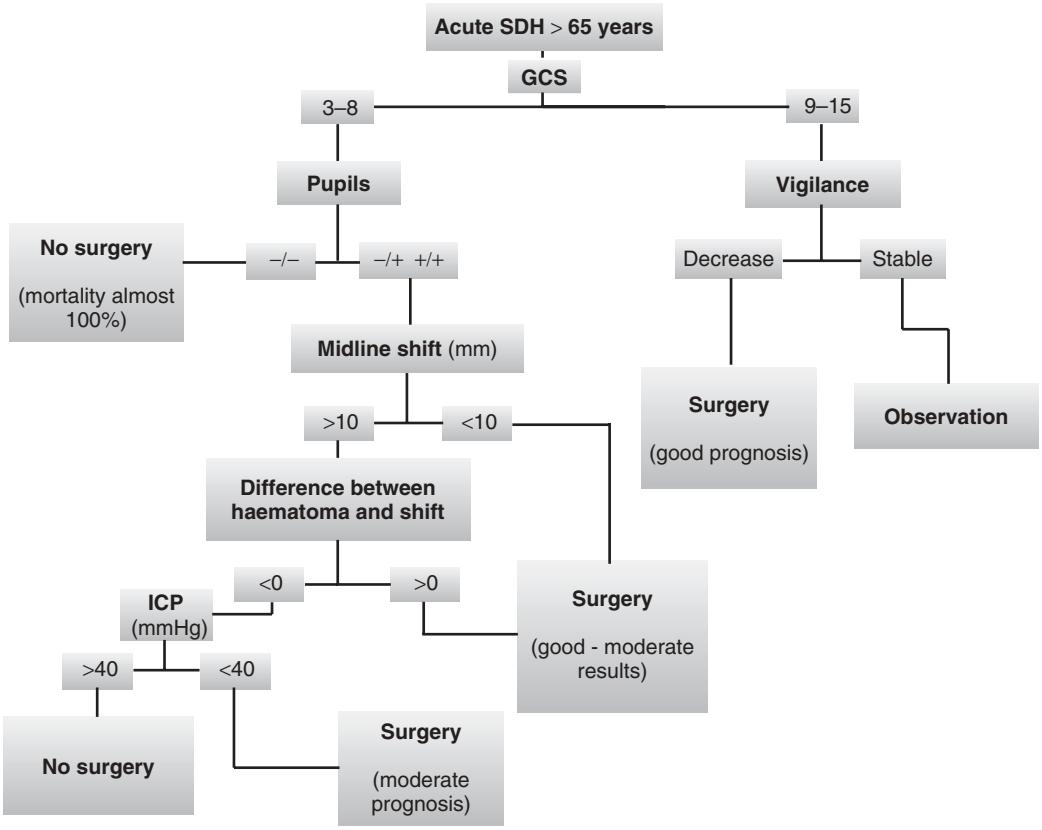

Figure 60.3 Acute subdural haematoma management algorithm, based on Petridis *et al*.[4] See the section on management of acute SDH for details.

linked to the extension of intracranial bleeding. In patients treated with anticoagulants and suffering from severe head injury, antagonism has to be started as soon as possible after admission. A specific early management protocol for patients exposed to intracranial haemorrhage might reduce the mortality rate.[11]

Association between mechanical cardiac valves and traumatic head injury is not unusual in the elderly population. There is no significant increase in vital risk if anticoagulants are temporarily stopped for 1–2 weeks. In contrast, mortality and morbidity in antiplatelet drug-treated patients are mainly related to a premorbid condition. In patients presenting with head injuries and acute SDH, prophylactic anticoagulation should be started 72 h after the trauma.[12]

Outcome

Increasing age is a strong independent factor in prognosis for severe traumatic brain injury, with a significant increase in poor outcome in patients older than 65 years of age. Among patients with acute SDH, there is a relationship between poor outcome and age, low GCS and signs of herniation, but it is not possible to predict death with certainty on the basis of old age and poor GCS.

Chronic subdural haematoma

Chronic SDH is a common but puzzling disease. This disease is fairly frequent in the very young but is found mainly in the elderly and those with prior brain atrophy. Although frequent, chronic SDH is treacherous condition: the elderly population with chronic SDH has a demonstrated increased risk of morbidity and mortality.[2,13] Chronic SDH is also a puzzling condition as the mechanism of constitution and expansion is still not fully understood. The presentation and pathophysiology of chronic SDH are different from those of acute SDH. For chronic SDH, neurological symptoms and brain dysfunction are purely the results of brain compression, as there is rarely a trauma severe enough to cause significant primary injury or initiating secondary injury. However, we must emphasize the *continuum* between acute and chronic SDH. Differentiating acute and chronic conditions is appropriate in a taxonomic approach, but SDH should be considered as a very dynamic process. The main characteristic of a chronic SDH is its resolution with sometimes little therapeutic intervention. This suggests that this condition may sometimes be asymptomatic throughout the population and undergo spontaneous resolution without treatment in a number of cases.

A stated above, chronic SDH is a common condition with increasing age, but also a mysterious condition. Indeed, the mechanism by which the initial clot becomes large enough to compress the underlying brain is not fully understood. Even stranger is the fact that resolution of chronic SDH occurs in most cases merely from a solitary drainage, leaving intact the membranes deemed to be the cause of the expanding nature of the chronic SDH.

Epidemiology

The mean age at diagnosis is 56–63 years and men outnumber women by 3:1. Although it is not exclusively a disease of old age, chronic SDH is much more common in the elderly. As the elderly population of the Western world has increased, chronic SDH has become a more frequent neurological problem. Its incidence in individuals younger than 65 years of age has been reported to be 3.4 per 100 000 people, whereas in those older than 65 years of age estimates range between 8 and 58 per 100 000.[14] Throughout the world, at present almost one in 10 people are over 60 years old, and by 2050 the figure will be higher than one in five. In 2009, individuals >65 years of age accounted for 39.5 million people in the USA and 85.1 million in Europe (12.8% and 17.3% of the respective populations). By 2030, the population older than 65 yeas is expected to double worldwide, and is projected to climb to 20% of the population in the USA and 25% in Europe. Based on the increase in the ageing population alone, the incidence of chronic SDH is expected to double worldwide in the next 25 years. This known increased risk has to be anticipated in terms of prevention, management and therapeutic intervention in order to lessen its effect on a fragile population, especially in terms of dependency.

Various conditions are prone to the development of chronic SDH. Brain atrophy is the most important predisposing factor as it provides a potential space for haematoma expansion. This explains the high mortality and morbidity of chronic SDH. Atrophy is a predictor of poor outcome after chronic SDH.[15,16] Haematoma thickness also tends to be larger in older patients. Major dehydration is a less commonly associated condition and is found concurrently in only 2% of patients. Fall is an important risk factor as it is related to dementia and brain atrophy. Hence the patient is trapped in a vicious circle: cognitive and gait impairment, fall, minor and repeated brain trauma, micro bleed, chronic SDH, brain function impairment, cognitive and gait decline, fall, . . . and so on. Other risk factors have been identified: alcohol abuse, seizures, CSF shunts, cardiovascular disease (hypertension, arteriosclerosis), thrombocytopenia, diabetes and coagulopathies including therapeutic anticoagulation. The number of patients who receive antiplatelet and/or anticoagulant drugs is increasing, especially in the aged population. In a recent paper, the use of antiplatelet and/or anticoagulant drugs was demonstrated to be over-represented among patients with non-traumatic chronic SDH compared with patients with a history of head trauma.[17] There was, however, no significant association between medication with antiplatelet and/or anticoagulant drugs and recurrence of chronic SDH. Considering the increased use of antiplatelet and anticoagulant drugs in modern cardiovascular and neurovascular medicine, attention should be drawn to the possible risks of intracranial bleeding complications and the benefit-to-risk ratio of these drugs has been addressed. However, in comparison with the powerful stroke prevention action of antiplatelet and anticoagulant drugs, the side effect of chronic SDH remains small.

Pathophysiology

Many chronic SDHs start out as acute subdural. The haematoma results from tearing of a bridging vein. The tendency for bridging veins to be disrupted in the subdural rather than the subarachnoid space is thought to be due to the lack of outer reinforcement of the bridging vein there. In the subdural space, the veins lack the support of the arachnoids' trabeculae and are thus more fragile. The initial SDH is small in most cases and, owing to the venous origin of the haematoma, is not usually associated with a sudden or steep increase in intracranial pressure. In addition, the wide sulci and the atrophic brain allow for dome enlargement before the onset of significant neurological symptoms. In acute SDH, displacement of the brain resulting in a midline shift >10 mm is usually associated with elevated ICP, often greater than 40 mmHg. In patients suffering from chronic SDH, however, normal pressure has been observed in the presence of a midline shift as large as 20 mm. Owing to the slow expansion of the haematoma, the period of spatial compensation of the haematoma is probably long enough to cause considerable distortion of the brain before there is a significant rise in intracranial pressure.

Membrane formation around the haematoma is a characteristic feature of chronic SDH. Such membranes are thought to be due to a non-specific inflammatory response of the highly vascular inner layer to the presence of blood products, fibrin and fibrin degradation products in the subdural cavity.[18] The avascular arachnoid has a much lower reaction potential than the inner dural layer in which blood evokes an inflammation response. Within days, fibroblasts invade the clot and form neomembranes on the inner (cortical) and outer (dural) surface. This is followed by in-growth of neocapillaries, enzymatic fibrinolysis and liquefaction of the blood clot. Fibrin degradation products are reincorporated into the new clots and inhibit haemostasis.[19] Whereas acute SDH shows a thick, reddish clot, chronic SDH usually produces a much darker brownish fluid similar to motor oil.

Secondary enlargement of chronic SDH is common. It has been hypothesized[20] that the membrane around the haematoma acts as an osmotic membrane, with CSF diffusing into the hyperosmotic haematoma. Repeated microhaemorrhage from the neocapillary network in the outer membrane or abnormally high vascular permeability are thought to be responsible for haematoma enlargement. Therefore, the course of enlargement is determined by the balance of plasma effusion and/or rebleeding from the neomembranes on the one hand and reabsorption of fluid on the other.

Clinical presentation

A subdural haematoma is considered chronic when it is discovered 3 weeks or more after the initiating injury. However, the trauma is minimal or even unrecognized in one-third of cases.[21]

The classic presentation of a post-traumatic chronic SDH includes two phases. The first phase is the traumatic event, which is usually minor. After its dissipation and a silent period of various lengths, the second phase begins with the onset of delayed clinical manifestations. The time elapsed between the first and second phases is deemed to represent the formation and maturation of haematoma membranes. The clinical manifestation usually consists of non-specific headaches, drowsiness or unsteadiness, decline in mental function, confusion and language or motor deficits. Focal deficits with hemiparesis and dysphasia may present in dominant hemisphere collection. From time to time, the patient may complain of recurrent symptoms like transient ischaemic attack, or they may develop varying degrees of coma or seizures, either focal or less often generalized. The three main complaints are gait disturbance or fall, mental disorientation and limb weakness.[22] Owing to the protean presentation of chronic SDH, the diagnosis is often unexpected prior to the imaging. Due to the progressive, subacute degree of neurological failure, the diagnosis of chronic SDH is difficult. In older patients, a slow decline within weeks or few months can be related to a chronic SDH. Coagulopathy and anticoagulant therapy may accelerate this presentation in many cases.

There are many other neurological conditions that yield very similar clinical presentations of a slow decline: stroke, tumour, hydrocephalus and primary neurodegenerative disorders represent differential diagnosis.

Investigation

CT scanning is the method of choice for investigation: scanning is easily accessible, quick, efficient and cheap. The CT scan shows the location, size and age of the SDH and also the alteration of the brain parenchyma. On a CT scan, subdural haematomas are classically described as delineated fluid collections that are crescent-shaped, with the concave surface away from the skull. They are fairly easily identified, located and measured in size.

The attenuation pattern of subdural blood changes over time. X-ray attenuation of a fresh clot is dependent on haemoglobin. Every acute blood collection with a haematocrit >23% has a higher density than the brain parenchyma: 80 Hounsfield units for the clot in comparison with 30 Hounsfield units for the normal brain. Therefore, the acute SDH is hyperdense with respect to the normal brain. This hyperdense pattern of the clot last only 1–3 days. After the acute phase, the SDH becomes less dense due to haemoglobin clearance and becomes more fluid due to inflammation, oedema and CSF diffusion. Between 4 days and 2 weeks, the subacute SDH is isodense with the brain parenchyma (~30 Hounsfield units). Between 2 weeks and 3 months, thanks to haemoglobin clearance and fluid formation, chronic SDH has a density slightly higher than that of water (~10 Hounsfield units), that is, a lower density than the brain, termed hypodense. Over 3 months, SDH either spontaneously resolves or turns into fluid collection, also known as hygroma, with a density almost identical with CSF (~0 Hounsfield units by definition). In most cases, the presentation of a mature chronic SDH has a mixed density with acute bleeding. The diagnosis of chronic SDH is fairly easy on CT imaging. However, subacute SDH is sometimes difficult to identify owing to its isodensity with the brain. In such cases, subtle signs of bleeding such as effacement of sulci or medial displacement of the junction between grey and white matter should be sought. It is important to delineate the underlying brain alteration. One should gauge the mass effect on the brain parenchyma: displacement and distortion of anatomical structures, midline shift, ventricles effacement or oedema. The underlying brain atrophy is difficult to identify in the early phase. The extent of atrophy is sometimes difficult to determine in preoperative CT scans, especially in the presence of midline shift and contralateral ventricular dilation. An example of bilateral chronic SDH is displayed in Figure 60.4.

Magnetic resonance imaging (MRI) is less often used to identify and manage chronic SDH. Although MRI is more efficient at analysing isodense haematoma and fluid, this examination is costly and time consuming. Haemosiderin, which is a constant feature of parenchymal haematomas, is rarely seen in chronic SDHs. The MRI signal of a chronic SDH is mainly defined by the concentration of methaemoglobin. However, this concentration is very dynamic due to dilution, absorption and/or degradation. In general, chronic SDH displayed more hyperintensity than normal brain in both T1 and T2 weighted MR images.[23,24] This technique is also useful for distinguishing chronic SDH from hygroma. A chronic SDH older than 30 days gives a low or isointense signal on T1 and a high

Figure 60.4 CT scan of a bilateral chronic subdural haematoma in an elderly patient with significant atrophy. On the left side, note the heterogeneous pattern of the SDH: chronic hypointense ventrally, acute hyperdense dorsally and subacute isodense in between.

signal on T2 weighted images which are similar to the CSF signal.

Angiograms are sometimes considered for non-traumatic, non-coagulopathy-associated acute SDHs as micro-arteriovenous malformation or aneurysms might produce acute bleeding in the subdural space. Out of the context of unexplained acute SDH, chronic SDH does not require an angiogram.

Management

As mentioned earlier, chronic SDH is an unusual disease: sometimes asymptomatic and resolving spontaneously without treatment or healing with little therapeutic intervention. Medical management is sometimes proposed, but most of the time a symptomatic chronic SDH is operated on and drained. However, the surgical procedure is prone to complications.

The *medical management* of chronic SDH is controversial. Non-operative measures, such as, hypertonic or hyperosmolar solutions and systemic glucocorticoids have been proposed to treat or more precisely to reverse the vicious circle of fibrinolysis in chronic SDH. Noticeably, the literature concerning these therapies is encouraging with favourable results but consists of small case series and very few clinical observations.[25] However, dexamethazone (e.g. 8 mg every 8 hours) should be in the armamentarium to heal a chronic pauci symptomatic chronic SDH.

The *surgical treatment* is the reference treatment. The neurosurgical evacuation of the haematoma results in a great improvement in neurological condition. Three techniques are most often used: twist-drill craniostomy, burr-hole craniostomy and craniotomy. Twist-drill craniostomy[26] consists in drilling a small hole of diameter <5 mm in the skull to drain the haematoma and if necessary insert a drain. This technique is very simple but does not permit any visual control of the intracranial procedure. Burr-hole craniostomy[15] involves a larger hole (5–30 mm) that allows the visual control of the dura and the cortex which can be coagulated prior to incision. This latter technique permits proper drain insertion, but does not result in the optimal drainage as membranes are intact. Craniotomy involves surgical opening of the skull. This is a much more aggressive technique with a large bone flap and direct access to the brain, the haematoma and the membranes. It allows substantial evacuation of the haematoma, rinsing and even membranectomy. Markwalder's review on chronic subdural haematoma was an important step in minimizing the invasiveness of the surgical treatment.[15] A meta-analysis[13] comparing all three techniques concluded that they have about the same mortality (2–4%). Craniotomy is associated with a much higher morbidity than is craniostomy (12.3 versus 3–4%) and recurrence with twist-drill craniostomy is much higher than with burr-hole craniostomy (33 versus 12.1%) and craniotomy (33 versus 10.8%). Burr-hole craniostomy, with evacuation via one or two burr-holes drilled over the site of the haematoma, is the most popular surgical technique worldwide. However, recurrence after the initial drainage procedure ranges from about 5 to 30%.[13] Whether a drain should be left in place after burr-hole craniostomy has been much debated until recently. A recent and well-performed randomized trial clearly found the benefit of postoperative drainage in the management of chronic subdural haematoma after burr-hole evacuation.[22] Recurrence occurred in 9% of the patients with drain and 24% for those treated with a single burr-hole without drain. At 6 months mortality was 8% in the drain group and 18% in the no-drain group, but medical and surgical complications were much the same between the groups.

Complications after surgical evacuation of a chronic SDH are not rare and potentially lethal. Because of old age and the frailty of most patients with the condition, an overall complication rate of 21% has been reported.[25] Wound infection, subdural empyema, tension pneumocephalus, seizures, brain contusion, subdural or epidural haematoma, intracerebral or intraventricular haemorrhage, catheter penetration of the brain and even death may occur after surgery. The mechanisms underlying this event remain unclear,

especially within the ventricular system. The need for a slow and gradual decompression of haematoma is essential. The recurrence of the haematoma is fairly frequent and can be significantly reduced by placing a drain after evacuation of the SDH. By means of an artificial neural network for outcome prediction of chronic SDH, various conditions have been identified as risk factors for postoperative recurrence: postoperative intracranial air, high-density haematomas and low Glasgow coma scale on admission. Other risk factors for recurrence include history of seizure, alcohol abuse and CSF shunts.[27] The role of antiplatelet and/or anticoagulant drugs in chronic SDH has also been examined in various studies. They failed to demonstrate an increased risk of recurrence of chronic SDH.[17] The only independent factor for recurrence seems to be bilateral chronic SDH.[28] However, it seems that the substitution of coagulation factors has to be considered.

Outcome

There is a clinical improvement when the subdural pressure is reduced to close to zero, which usually occurs after 20% of the collection has been removed. Patients who have high subdural fluid pressure tend to have more rapid brain expansion and clinical improvement than patients with low-pressure chronic SDH. Clinical improvement does not require complete resolution of the fluid collection. CT scans showed persistent fluid in 78% of cases at 10 days and 15% at 40 days.[15] A simple drainage procedure is sufficient to treat successfully almost 80% of patients and 90% with two procedures. Overall mortality with surgical treatment of chronic SDH is in between 5 and 10%.[13] Outcome is also related to the clinical condition at the time of treatment; worsening of neurological status following drainage occurs in 4% of cases.

Subdural hygroma

Subdural hygromas involve accumulation of CSF in the subdural space.[29] They are more common in men, usually located in the frontal region and may be uni- or bilateral. They usually occur after head injury, but have also been described after meningitis, craniotomy, shunt and venous thrombosis. They may also be spontaneous or a traumatic complication of arachnoid cysts. The development of hygroma into chronic SDH is not uncommon; however, the mechanism by which this transition occurs is not fully understood.

Pathophysiology

A trivial trauma can cause a separation of the dura–arachnoid interface, which is the basic requirement for the development of a subdural hygroma. If the brain shrinks due to brain atrophy, excessive dehydration or decreased intracranial pressure, fluid collection may develop by a passive effusion. The mechanism of formation of hygroma is probably a tear in the arachnoid membrane with resultant CSF leakage into the subdural compartment. Hygroma fluid contains prealbumin, which is also found in CSF but not in subdural haematomas. Hygromas may be under high pressure and may increase in size due to a possible flap-valve mechanism. The resulting mass effect exerts a pressure on the brain with the possibility of significant morbidity. Persistent traumatic hygroma usually results in haemorrhage into the subdural fluid owing to the tearing of bridging veins or bleeding from the neomembrane. Between the brownish 'motor oil' of a chronic SDH and the crystal clear fluid of hygroma, there is a variety of subdural collections, either blood tinged or xanthochromic under variable pressure regimens. Mild to severe ventricular dilations were observed in some patients. Ventricular dilation that occurs late after trauma when subdural hygromas reduce, probably does so by an *ex vacuum* compensatory effect. In these cases, the sulci and fissures are evident by localized or diffuse atrophy. However, not all ventricular dilations can be explained by an atrophic process. Some of them could be a result of disturbance in CSF absorption bridging subdural hygroma and external hydrocephalus.

Clinical presentation

There is no specific sign attributed to subdural hygroma, because its clinical aspects are overlapped by other traumatic lesions. The diagnosis of subdural hygroma almost always is discovered by evolution CT scan about 2 weeks after trauma; however, some studies have found subdural effusions as early as 24 h before hygroma formation. Many patients present without focal findings and there is no specific symptomatology attributed to hygromas. Complex hygromas usually present more acutely and require more urgent treatment. Elderly patients with marked age-related brain atrophy and a widened CSF space can cause confusion on differential diagnosis.

Investigation

On CT scan, the density of a hygroma is similar to that of CSF (~0 Hounsfield units by definition). MRI is more efficient in differentiating proper hygroma from late chronic SDH. CSF fluid has a specific MRI pattern with a low signal on T1 and a high signal on T2 weighted images. Residues of blood, especially methaemoglobin, can also be identified with MR techniques.[30] The mass effect of a subdural hygroma on the cortex has to be considered, as it might indicate a pressurized fluid collection.

Management

Since the majority of patients with a subdural hygroma do not show a mass effect, surgery is rarely required. Outcome is closely related to the primary head injury and not to the hygroma itself. The complexity of subdural hygroma depends on various factors, including the dynamics of absorption and expansion, duration of observation and indication of surgery. Among the variety of the primary head injury with respect to types and severity, subdural hygroma is a common epiphenomenon of head injury. Most hygromas resolve when the brain is well expanded. However, a few hygromas become chronic SDH. Asymptomatic hygromas do not require treatment. In rare instances, a hygroma may be large causing a mass effect on the brain and requires surgical treatment. Simple burr-hole drainage is then proposed.

Key points

- Acute SDH is a devastating disease in the elderly.
- Acute SDH mandates reversal of anticoagulation as soon as possible.
- Surgery has to be considered in the elderly according to a management algorithm.
- Every slow decline within weeks or a few months can be related to a chronic SDH.
- CT scan is the method of choice to show, measure and date chronic SDH.
- Evacuation of a chronic SDH with a burr-hole and drain improves 80% of patients.
- After surgery, the complication rate is 20% and the overall mortality is 10%.
- Antiplatelet and/or anticoagulant drugs increase the risk of non-traumatic chronic SDH.
- The powerful stroke prevention of antiplatelet and anticoagulant drugs renders chronic SDH a small side effect.

CHAPTER 61

Epilepsy

Pamela M. Crawford
York Hospital, York, UK

Introduction

Epilepsy is the third most common neurological diagnosis in old people after dementia and stroke. The peak ages of onset of epilepsy are in childhood and old age (Table 61.1).[1] About 25% of newly diagnosed patients and 23% of people with epilepsy in the community are over the age of 60 years. However, little epilepsy research has been undertaken in elderly subjects and there have been only three double-blind randomized trials of antiepileptic drugs (AEDs) in the elderly.[2] Epilepsy is defined as the tendency to recurrent seizures, excluding febrile convulsions. A single seizure is not considered as 'epilepsy', although studies have suggested that up to 75% of people go on to have a second seizure and in the elderly this may be as high as 90%.[3]

A seizure results from a paroxysmal abnormal synchronous electrical discharge in the brain. A diagnosis of epilepsy is not an endpoint diagnosis – it should automatically lead to investigations for classifying the type of seizure (compare making a diagnosis of jaundice) as epilepsy is the result of many diverse neurochemical, neuropathological and neurophysiological abnormalities. Epilepsy is a clinical diagnosis based on an eyewitness description of an episode. At least 10% of people with a diagnosis of 'epilepsy' do not have the disorder. One of the commonest misdiagnoses is reflex anoxic seizures. These occur when someone feels faint and is kept upright, a few muscle jerks occur and a diagnosis of an 'epileptic' seizure is made. As epilepsy has such serious consequences with regard to activities of daily living, in particular driving, it is a diagnosis which should not be made lightly. If there is doubt, it is better to await clear evidence. An electroencephalogram (EEG) does not make the diagnosis of epilepsy as many trivial abnormalities are often overinterpreted. An EEG simply helps classify the kind of epilepsy – localization-related or generalized.

Aetiology

In the majority of elderly patients who develop epilepsy, it will be presumed to be secondary to cerebrovascular disease (Table 61.2).[4] Although the majority of patients are worried that they have an underlying brain tumour, this is rare. Neurodegenerative diseases such as Alzheimer's disease account for a significant percentage of those developing epilepsy. With the advent of MRI scanning, it is likely that in a higher proportion of patients an aetiological factor will be found in a higher proportion of elderly patients.

Dementia

Epileptic seizures are common in demented patients, especially in the later stages of the disease. A study in Dundee suggested that 9% of patients had had an epileptic seizure; 92% of reported seizures were tonic–clonic. As complex partial seizures are generally more common than tonic–clonic seizures, this would suggest that many partial seizures probably go unrecognized. Patients developing epilepsy were significantly younger and more severely demented. On the whole, the epilepsy appeared to be reasonably well controlled.[5] Another study found that the mean onset of epilepsy was 6.5 years (range 2–15 years) after the onset of the dementia. There was a threefold increase in the incidence of epilepsy compared with a reference population.[6] A study of 446 autopsy-proven cases of Alzheimer's disease found that 17% were documented as having seizures during their lifetime. However, two-thirds of patients had less than three seizures, suggesting that on the whole the seizure disorder was mild.[7]

Cerebrovascular disease

Cerebrovascular disease is the commonest cause of seizures in the elderly. Cerebrovascular disease increases the risk of

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 61.1 Incidence of epilepsy at different ages.

Age (years)	Incidence
0–10	60:10^5
20–40	40:10^5
60–69	101:10^5
70–79	150:10^5
80–89	190:10^5

an epileptic seizure by a factor of 20 and is the commonest cause of seizures in the elderly. There is an increased risk of developing epilepsy in the first year after a cerebrovascular accident by a factor of 17 compared with the risk in age-matched patients in the general population.[8] The overall incidence of seizures after a cerebrovascular accident varies between 4.4 and 12.5%, depending on the population studied and the methods used. Studies looking at the risk factors for the subsequent development of epilepsy have suggested that patients with haemorrhagic strokes, embolic stroke, cortical lesions, hippocampal involvement or lesions involving more than one lobe are at greater risk of developing epilepsy. Early seizures within 2 weeks of a cerebrovascular accident (2–8%) are due to acute biochemical abnormalities, and late seizures (after 2 weeks) are secondary to chronic processes such as removal of inhibition and formation of new synaptic connections. Epileptic seizures in old age are often the first signs of cerebrovascular disease and therefore people presenting with a first seizure should be evaluated for risk factors for vascular disease as they have a 2.8–9 greater risk [95% confidence interval (CI) 2.45–3.40] of having a stroke within 5 years.[2,9] A post-ictal Todd's paresis is often misdiagnosed as a stroke recurrence and if the patient has a seizure with a weakness then this alternative diagnosis needs to be considered.

Diagnosis

The diagnosis of epilepsy is the same in elderly as in younger patients. It is a clinical diagnosis based on eyewitness description of the episodes. One of the major problems in diagnosing epilepsy in the elderly is that they may be unable to give a description of what is actually happening to them before or after an attack and, as they often live on their own, an episode may not have been witnessed. A classical tonic–clonic seizure is relatively easy to diagnose from eyewitness descriptions. Minor attacks such as absence or complex partial seizures are much more difficult to diagnose. Often they may consist of staring episodes where the person is not responsive for a few seconds. These can be followed by automatisms or confusion, often short-lived. An EEG is useful for the classification of seizure type. Only rarely can it be used to make a diagnosis, that is, if a seizure occurs while an EEG is being performed or specific diagnostic EEG changes occur. In addition, the post-ictal period can be longer in the elderly, lasting from hours to days, leading to the incorrect diagnosis of dementia.[10] In more than 50% of elderly patients who were finally diagnosed with epilepsy, epilepsy was not the initial suspected diagnosis.[11] In the elderly, after the first seizure the risk of recurrent seizures is very high, greater than 90%.[3] Suggestions have been made that elderly patients should be treated with AEDs after the first seizure.

Differential diagnosis

Transient ischaemic attacks (TIAs)

A TIA is a vascular event lasting less than 24 h. It tends to be associated with negative phenomena such as weakness or sensory loss. Conversely, epilepsy tends to have positive phenomena such as paraesthesias or jerking of a limb. However, at times it is difficult to differentiate simple partial seizures from TIAs. If consciousness is lost, it is very unlikely to be a TIA. It also has to be remembered that cerebrovascular disease is an important aetiological factor in the development of epilepsy.

Transient global amnesia

This is not an uncommon disorder occurring in later life, when a person has no memory for a significant period of between a few hours and a day or so. Eyewitnesses say that the person appeared normal and was able to perform complex tasks. On closer questioning, the person often was repeating the same questions such as 'what time is it?' A person tends to have only a single episode, so if repeated the diagnosis needs to be reconsidered. The symptoms are due to a defect in memory for events of the present and recent

past. During the episode, consciousness is retained and there is no impairment in intellectual functioning. Studies have suggested that there is no increase in risk factors for vascular disease and no subsequent increase in cerebrovascular disease. There is, however, an increased incidence of migraine. Transient global amnesia is an important diagnosis to make in that, unlike epilepsy, people in the UK with this condition, after reporting to the Driving Vehicle Licensing Authority (DVLA), are allowed to continue driving.

Cardiac arrhythmias

These are very important in the differential diagnosis of epilepsy in the elderly. If the brain is starved of oxygen, for whatever reason, a tonic–clonic seizure will result. Both tachy- and bradyarrhythmias can result in tonic–clonic seizures. Clues to the fact that the seizure may be a secondary phenomenon may be found in the prodrome. A history of feeling faint or palpitations should make a clinician suspect a cardiac cause for the episodes of loss of consciousness. A 24 h EEG with an ECG lead, videotelemetry and reveal devices can be useful in trying to differentiate between a cardiac and an epileptic episode. If the episode is cardiac in nature, the arrhythmia will begin before the abnormal electrical activity in the brain by a significant time lapse. It has to be remembered that during a seizure it is not uncommon for a cardiac arrhythmia to occur, but it will begin at about the same time as the abnormal electrical activity in the brain.

Syncope

If a person is kept upright during a vasovagal attack, it is not uncommon for a few myoclonic jerks to occur and in susceptible people a tonic–clonic seizure can result. The events leading up to the episode of loss of consciousness and also eyewitness descriptions are very important. The feeling of faintness, dizziness and the need to get fresh air preceding the episode make it likely that the episode was syncopal rather than epileptic in nature. The person is usually upright during the episode. They feel dizzy, queasy and giddy and often things recede or go black. Pallor is noted and often a cold perspiration. Nausea and vomiting occasionally accompany these symptoms. After falling to the ground, consciousness is regained very fast, and if the person lies down the episode can often be aborted. A few myoclonic jerks can occur, as can incontinence if the bladder is full. Micturition syncope, especially in men having to get up during the night, is a relatively common cause of loss of consciousness; so too is cough syncope. The elderly are more prone to syncope as they may have impaired cardiovascular reflexes or be on vasodilating drugs such as glyceryl trinitrate (GTN) or have carotid sinus hypersensitivity.

Psychogenic epileptic attacks

Psychogenic epileptic attacks are thought to be rare beginning in the elderly but are commonly misdiagnosed as people often have underlying organic problems.

Panic attacks

It is rare for these to present *de novo* in the elderly as usually there is a life-long history. The person feels that something is going to happen. He/she feels the need to take deep breaths, becomes dizzy and light-headed, develops paraesthesias in the limbs and around the mouth and the legs become heavy. Symptoms can be reproduced by getting the person to hyperventilate. The initial precipitant was often a faint and panic attacks develop subsequently because of a fear of a further episode.

Drop attacks

These are episodes of unknown aetiology where a middle-aged or older person, usually a woman, will suddenly drop to the ground. There is no preceding warning and consciousness is not lost. There is often bruising to face, hands and knees. After the episode, the person can get up immediately. The EEG is normal, even during a fall. There is no treatment.

Hypoglycaemia

Hypoglycaemia is a rare cause of tonic–clonic seizures. It obviously needs excluding in diabetic patients on treatment. Rarely an insulinoma can produce tonic–clonic seizures. Other metabolic causes such as hypocalcaemia can precipitate seizures.

Alcohol and drugs

Alcohol abuse and withdrawal can precipitate seizures and it is important to take an alcohol history, even in the elderly. Many drugs, particularly tricyclic antidepressants, antimalarials, phenothiazines and butyrophenones, lower the seizure threshold and can precipitate seizures. The withdrawal of benzodiazepines occasionally can produce seizures.

Sleep disorders

Seizures during sleep need to be differentiated from parasomnias, but usually epilepsy can be diagnosed by taking a good history from the patient and obtaining an eye-witness description of the episode. A REM (rapid eye movement) sleep behaviour disorder occurs when somebody

acts out their dreams. Periodic limb movement disorders are characterized by periodic movements occurring during non-REM sleep. Most commonly people dorsiflex their ankles and flex their knees and hips every 20–40 s and this can be associated, in about 30% of patients, with restless legs syndrome. Hypnic jerks are a normal phenomenon occurring in about 70% of the population and consist of brief myoclonic jerks at sleep onset.

Seizure classification

Epilepsy is classified in two ways. There is classification of the seizure itself (Table 61.3)[12] and then there is syndromic classification.[13] Epilepsy is divided into two main groups. The generalized epilepsies are when the abnormal electrical activity rises from both hemispheres together (generalized spike wave). Localization-related epilepsy is when the abnormal electrical activity arises in one place in the brain and then spreads.

Generalized epilepsies

The generalized epilepsies are divided into two broad categories, primary and secondary.

Primary generalized epilepsy is probably a channelopathy that manifests itself in various syndromes such as childhood absence epilepsy and juvenile myoclonic epilepsy. Various types of seizures can occur, such as absence seizures, myoclonic and tonic–clonic seizures in association with generalized spike wave (three per second) on the EEG. These syndromes tend to occur in people of normal intelligence and begin in childhood or early adult life, although occasionally new-onset cases have been seen in the elderly or the diagnosis has been missed. Minor seizures beginning for the first time in the elderly are not absence seizures or *petit mal*. They are likely to be complex partial seizures. Primary generalized epilepsy responds best to treatment with sodium valproate or lamotrigine or levetiracetam as second-line therapy. The outlook for total seizure control is excellent. The majority of children with childhood absence epilepsy will be seizure free and off treatment by adult life. Most patients with juvenile myoclonic epilepsy become seizure free but will relapse if treatment is stopped even if the patient is elderly. Many elderly people with a long-standing seizure disorder will never have had their epilepsy classified. In particular, the diagnosis of juvenile myoclonic epilepsy is commonly missed. Changing someone on to a more effective AED such as valproate can render them seizure free even in extreme old age.

Symptomatic *secondary generalized epilepsy* is more commonly seen in people with learning disabilities.

Table 61.3 Classification of seizures.[12]

- **I** *Partial seizures*
  - A Simple partial seizures
  - B Complex partial seizures
    - 1 With impairment of consciousness at onset
    - 2 Simple partial onset followed by impairment of consciousness
  - C Partial seizures evolving to generalized tonic–clonic convulsions
    - 1 Simple evolving to generalized tonic–clonic convulsion
    - 2 Complex evolving to generalized tonic–clonic convulsion (including those with simple partial onset)
- **II** *Generalized seizures*
  - A Absence seizures
    - 1 Typical absence seizures
    - 2 Atypical absence seizures
  - B Myoclonic seizures
  - C Clonic seizures
  - D Tonic seizures
  - E Tonic–clonic seizures
  - F Atonic seizures
- **III** *Unclassified seizures*

Localization-related epilepsy

In localization-related seizure disorders, the abnormal electrical activity begins in one area of the brain and spreads. The seizure manifestations depend on the site of onset of the abnormal electrical activity and the rate of involvement and spread to other areas of the brain. For example, abnormal electrical activity arising in the temporal lobe may begin with a feeling of fear or *déjà vu* or an abnormal taste or smell. This is a simple partial seizure, which is rarer in the elderly than younger patients with epilepsy.[14] As the abnormal electrical activity spreads, it involves more of the temporal lobe and consciousness is lost – a complex partial seizure. The person may be seen to stare or gulp or swallow or perform repetitive movements or automatisms. If the abnormal electrical activity spreads to the other side of the brain, a tonic–clonic seizure results. Therefore, tonic–clonic seizures occur in both generalized and localization-related epilepsies. This is the type of epilepsy that usually begins in late adult life. Tonic–clonic seizures are usually readily recognized as being due to epilepsy but are rare in the elderly (26%) compared with younger patients (65%).[14]

Investigations (Table 61.4)

EEG (Table 61.5)[15]

The diagnosis of epilepsy is based on an eyewitness description of a seizure, plus the exclusion of other causes. An EEG is useful in trying to classify the type of seizure disorder and occasionally in diagnosis if seizure activity is captured. Many patients without epilepsy will have minor

Table 61.4 Investigation of epilepsy in the elderly.

EEG	**Routine**

CT scan/MRI	

Table 61.5 Types of EEGs.

Routine EEG (20 min)
- To try to confirm the diagnosis of epilepsy
- Classification of epilepsy syndrome
- To determine presence/absence of photosensitivity

Sleep/sleep-deprived EEG (if original EEG is normal),
To help make diagnosis of epilepsy
To classify the seizure disorder

Ambulatory EEG
- Detection/quantification of generalized spike wave discharges

Video-EEG telemetry
- Diagnosis of undiagnosed paroxysmal attacks (need to occur at least weekly)
- Suitability for epilepsy surgery

abnormalities in the EEG, particularly in the elderly because of cerebrovascular disease. Between seizures, a person with epilepsy can have a normal EEG, so an EEG is not an appropriate tool to diagnose epilepsy. A referral to a cardiologist may be indicated. If an ordinary EEG is normal, a *sleep deprivation EEG*, performed after a night without sleep, can sometimes be helpful. *Ambulatory ECGs* and *videotelemetry* can be useful in the diagnosis of odd episodes of loss of consciousness. A 24 h ambulatory EEG is portable but only records from a few scalp electrodes. An ECG lead should be recorded at the same time. When the person feels an event coming on or it has happened, an event button is pressed. The episode can be reviewed for both the cardiac rhythm preceding and during the event and the EEG activity. However, it must be realized that epileptic episodes may be missed or misinterpreted because of the placement of electrodes or movement artefact. Videotelemetry is a more sophisticated monitoring technique that is only available at specialist neurological centres. A standard EEG and ECG are recorded at the same time as the patient is videoed. This means that the episode can be observed as well as looking at the EEG. Neither of these investigations is likely to be of value unless the patient is having at least weekly episodes.

ECG

A routine ECG can either demonstrate a cardiac arrhythmia or suggest that a patient may be prone to a brady- or tachyarrhythmia, for example, heart block or an supraventricular tachycardia (SVT). If cardiac causes are suspected, a 24 h ECG is mandatory. Occasionally a REVEAL device may be indicated.

CT scan/MRI

A form of imaging is valuable in trying to determine the aetiology of the seizure disorder, especially as neurosurgeons will consider operations on older patients. If seizures are focal in origin, an MRI scan is the most sensitive investigation to look for underlying pathological changes. A normal CT scan will exclude any major underlying pathology, although a small low-grade glioma may not be visible. A change in seizure frequency or the development of neurological signs is an indication for rescanning. Other investigations such as basic haematology, biochemistry and an ECG are usually performed. Various other investigations may be indicated, depending on the likely aetiology of the seizures.

Treatments

The aim of treatment is to suppress seizures totally with the lowest possible dose of one AED. This can be achieved in over 80% of elderly people developing epilepsy[16] and the majority are on monotherapy. The choice of drug depends on the type of seizure disorder and various factors such as other medical conditions and therapies. The elderly are also more prone to AED side effects and interactions partly because of concomitant diseases and medications. Long-term antiepileptic treatment also predisposes towards osteoporosis. It is estimated that AED treatment for over 5 years doubles the risk of osteoporotic fractures in the elderly.[17] In primary and symptomatic generalized epilepsy, the drug treatment of choice is sodium valproate, levetiracetam or lamotrigine. In people with localization-related epilepsy, all the first-line drugs are equally effective; they just differ in side effects. It is therefore advisable to choose a drug with a low side effect profile such as carbamazepine, sodium valproate, lamotrigine or levetiracetam. Barbiturates (phenobarbitone, mysoline) have little place in today's treatment of epilepsy. Phenytoin, although an effective drug, is difficult to use. Second-line therapies include gabapentin, topiramate, zonisamide, lacosamide and tiagabine. Clobazam can be useful for predictable

seizures or when they occur in clusters. A study looking at AED usage in the elderly showed that the mean dose of AED was lower than in younger patients. Even so, 27% of these patients felt that they had side effects from their medication.[18] Several studies have shown that a greater proportion of drugs such as phenytoin, sodium valproate and benzodiazepines are present in the free state in plasma in the elderly, which implies a higher brain concentration. There is an alteration in the half-life and clearance of the commonly used AEDs, suggesting reduced dosage requirements. Clinical studies have shown that lamotrigine and gabapentin are better tolerated than carbamazepine in the elderly but the difference disappears if carbamazepine (controlled release) is used and increased slowly.[19–21] The majority of clinical decisions about antiepileptic treatment in the elderly are based on data for younger patients' experience and principles of pharmacotherapy in the elderly.[2] A study of 622 patients showed that 64% of patients over the age of 60 years had to stop taking an AED because of side effects compared with 33% of younger adults.[22] Elderly patients are more sensitive to central and systemic side effects of AEDs, particularly cognitive side effects. If one of the commonly used monotherapy drugs fails to control seizures adequately then a referral to a neurologist or specialist epilepsy clinic may be helpful.

Antiepileptic drugs (Tables 61.6 and 61.7)

Phenobarbitone

Phenobarbitone is an effective AED but its use is accompanied by an unacceptably high incidence of behavioural problems and sedation. There are many new drugs that are just as effective, but produce a much lower incidence of side effects.

Primidone

Primidone is a compound that is converted in the body to phenobarbitone. It has an even higher incidence of side effects than phenobarbitone and should no longer be used.[22]

Phenytoin

Phenytoin is an effective AED but appears to have a higher side effect profile than some of the newer agents. It is a difficult drug to use because of its many interactions and saturable metabolism. Phenytoin has a narrow therapeutic range and non-linear pharmacokinetics, so small increases in dosage can precipitate toxicity. A comparative study of phenytoin and sodium valproate suggests that they are both equally effective in controlling seizures in the elderly, while having similar effects on cognitive function.[23]

Carbamazepine

Carbamazepine is one of the first-line drugs for the treatment of partial seizures. It can have a positive effect on behaviour. It is a hepatic microsomal enzyme inducer and therefore speeds up the metabolism of other drugs such as warfarin, phenytoin, phenobarbitone and lamotrigine, in addition to inducing its own metabolism. Its main side effect is a rash, which occurs in about 10% of people. If it is given in high dosages, people are likely to complain of double vision and drowsiness. If this occurs after a dosage increase, it is worth waiting for a week to see if symptoms resolve as hepatic enzyme induction occurs and blood levels fall. Maximum tolerated monotherapy dosages tend to be between 800 and 1200 mg per day. The retard formulation tends to be associated with a lower incidence of peak dose side effects.

Sodium valproate

Sodium valproate is the other first-line drug for localization-related epilepsies and the treatment of choice for the

Table 61.6 Antiepileptic drug summary: useful management pointers – treatment of localization-related epilepsies.

Carbamazepine
Benefits: a commonly used, very effective AED
Caution: Interactions with other drugs metabolized by cytochrome P450 including warfarin
Side effects. rash/Stevens–Johnson syndrome. Those at greatest risk are those who have had previous rash with phenytoin/phenobarbitone/lamotrigine or are of Han Chinese or Thai origin. Hyponatraemia. Low white-cell count. Osteomalacia
Contraindications: AV conduction abnormalities, bone-marrow depression

Oxcarbazepine/Eslicarbazepine
Similar to above. Lower incidence of sedation/rash. Possible increased incidence of hyponatraemia

Gabapentin
Benefits: no interactions. Excreted unchanged by the body. Effective in neuropathic pain
Caution: reduced dose in renal failure
Side effects: dizziness, peripheral oedema, weight gain

Pregabalin
Benefits: Related to gabapentin but more powerful. No interactions. Also licensed for generalized anxiety, neuropathic pain
Caution: reduced dose in renal failure
Side effects: weight gain, sedation, dizziness, peripheral oedema

Phenytoin
Benefits: once daily dosage, does not need titration
Caution: very easy to precipitate toxicity. Interactions with other drugs metabolized by cytochrome P450 including warfarin
Side effects: rash, gingival hypertrophy, hirsutism, ataxia, blood disorders, osteomalacia

Lacosamide
Little experience in the elderly
Contraindications: cardiac conduction problems
Side effects: nausea and vomiting, drowsiness, prolonged PR interval

Table 61.7 Antiepileptic drug summary: useful management pointers – treatment of localization-related and generalised epilepsies (i.e. broad-spectrum AEDs).

Valproate
Benefits: most effective AED for generalized epilepsies
Caution: encephalopathy, parkinsonism
Side effects: weight gain, thrombocytopenia, osteoporosis

Lamotrigine
Benefits: possibly the most effective AED for localization-related epilepsy
Caution: interaction with other AEDs
Side effects: rash, Stevens–Johnson syndrome, insomnia

Levetiracetam
Benefits: no interactions with other drugs
Caution: renal impairment
Side effects: irritability, depression

Topiramate
Benefits: Also effective as migraine prophylaxis
Caution: ensure adequate hydration
Side effects: cognitive impairment, mental slowing, paraesthesias, renal calculi, weight loss

Zonisamide
Benefits: once daily dosage
Caution: ensure adequate hydration
Side effects: irritability, weight loss, sedation, depression, cognitive impairment, renal calculi

Clobazam/Clonazepam (benzodiazepines)
Benefits: quick action, good at terminating seizures
Caution/contraindications: respiratory depression, sleep apnoea, neuromuscular respiratory weakness
Side effects: drowsiness, tolerance
Note: often used as a PRN medication

Phenobarbitone
Advantages: once daily
Side effects: sedation, rash, osteomalacia

generalized epilepsies. The main side effects of sodium valproate are weight gain, tremor and hair loss at higher doses. About 60 cases of acute fatal hepatic failure have been reported with valproate therapy, the majority being children under the age of 2 years with developmental delay. These problems should be differentiated from the benign elevation in liver enzymes that occurs in about 30% of patients treated with valproate. Parkinsonism with cognitive decline has been reported and was found in about 2% of the elderly receiving sodium valproate.[24] Sodium valproate can also predispose towards osteoporosis. The elderly may be slightly more at risk of a low platelet count compared with younger patients.

Gabapentin
Gabapentin is an AED that is structurally related to GABA. It is an effective AED in partial seizures but does not appear to work in absence seizures and may exacerbate some symptomatic generalized seizure disorders. It is also licensed for chronic pain. It has a low side effect profile. The main side effects reported are dizziness, drowsiness and light-headedness. Its benefits are its ease of use and lack of interaction with drugs including other AEDs, apart from a minor interaction with cimetidine. Gabapentin is excreted unchanged in the urine; therefore, doses do need to be reduced in renal failure. It has been evaluated after stroke in the elderly.[25]

Pregabalin
Pregabalin is structurally related to gabapentin. Clinical studies have shown it to be effective as add-on therapy in resistant partial seizures. It has not been evaluated in the elderly. It is also licensed for neuropathic pain and generalized anxiety. It is effective and well tolerated in the elderly. Pregabalin does not have any major interactions with other drugs and is excreted unchanged by the kidneys. Its main side effects are dizziness, somnolence and weight gain.

Lamotrigine
Lamotrigine is a broad-spectrum AED like sodium valproate and is active against both generalized and partial epilepsies. It is well tolerated with a low side effect profile. Its main problems are rash and interactions with other AEDs. This has meant that differing dosage schedules and maximum doses are used according to concomitant AEDs. Its half-life varies from 15 h when used in combination with enzyme inducers such as phenytoin or carbamazepine to 30 h when used as monotherapy and 72 h when combined with sodium valproate. Studies in elderly patients suggest that it is well tolerated[26] and often only low doses are needed to suppress seizures.

Topiramate
Topiramate appears to be an effective AED but does have a high side effect profile, including mental slowing and difficulties in concentration. Studies in the elderly showed it to be well tolerated and effective.[27] It can cause significant weight loss and there is a risk of renal calculi.

Clobazam
Clobazam is a 1,5-benzodiazapine specifically licensed for the treatment of epilepsy. It is used in a dose of between 10 and 30 mg at night. Its main problem is that, if used daily, tolerance tends to develop in 30–70% of people. It is very useful for predictable seizures or if seizures cluster. It can be used to terminate episodes of minor status.

Clonazepam

Clonazepam tends to be used for generalized epilepsies. Again it has the problem of tolerance and appears to be more sedative than clobazam.

Diazepam/midazolam

Rectal diazepam is of considerable value in terminating episodes of convulsive and non-convulsive status epilepticus. It can be used in the community and the need for hospital admission may be avoided. There is a video available from the manufacturers to teach carers in the use of rectal diazepam. A more acceptable alternative (although not licensed or evaluated in the elderly) is buccal midazolam (10 mg). It and rectal diazepam can be used to stop prolonged seizures or status epilepticus in the community.

Ethosuximide

Ethosuximide decreases absence and atypical absence seizures (generalized epilepsies). It is of no value in complex partial seizures and so has little use in the elderly.

Levetiracetam

Levetiracetam is a broad-spectrum AED. Subanalyses of studies have suggested that it is effective and well tolerated in the elderly.[28] Levetiracetam has a highly favourable pharmacokinetic profile in that it does not bind to protein and is excreted unchanged in the urine, so it should be used with caution in those with impaired renal function. A study in the elderly developing epilepsy after a cerebrovascular accident showed that it was effective and well tolerated.[29] Levetiracetam does not induce liver hepatic microsomal enzymes; it can be titrated rapidly and an effective dose can be initiated on starting therapy. About 7% of elderly people develop psychiatric problems or irritability.[28]

Tiagabine

Tiagabine is a GABA reuptake inhibitor that appears effective in people with complex partial seizures, particularly those who have responded to vigabatrin. At present it appears from clinical trials to have a lower side effect profile than vigabatrin and may provide a useful alternative to vigabatrin. It has not been evaluated in the elderly and is not commonly used.

Oxcarbazepine/eslicarbazepine

These are analogues of carbamazepine. They have advantages over the parent compound in that they appear to be less sedative with a significant lower incidence of side effects, including rash. Oxcarbazepine's main drawback is that there is an increased incidence of hyponatraemia compared with carbamazepine, so it may be of limited use in the elderly.[30] This particularly occurs in those who are on concomitant naturiuretic drugs. Oxcarbazepine and eslicarbazepine are effective against partial seizures. Eslicarbazepine is metabolized to oxcarbazepine.

Lacosamide

Lacosamide is a newly licensed AED for drug-resistant partial seizures. It appears to be well tolerated but there are no data in the elderly.

Antiepileptic drug level monitoring

Antiepileptic drug levels only need to be monitored in those patients who have continuing seizures in order to check compliance, which is one of the commonest reasons for therapy failure. Levels are much more difficult to interpret in the elderly because of an increase in the free state and the lack of a 'therapeutic' range in this age group. People are their own *in vivo* drug assays. If someone is seizure free, they are receiving the correct dosage of AED and no alterations in dose are indicated. If seizures continue without side effects, then the dose can be increased. If dose-related side effects occur, the dosage is too high. There is no bottom limit to the so-called therapeutic range and many people are able to tolerate plasma levels in excess of the 'upper limit'. Anticonvulsant levels occasionally are helpful for drugs such as phenytoin which have difficult pharmacokinetics and can give an idea of the scope for dose increments in someone with continuing seizures. Sodium valproate levels are of little value as there are wide fluctuations in measured concentrations throughout the day. Blood level monitoring is not needed for any of the recently licensed AEDs. A study in elderly patients suggested that the majority of samples taken for AED concentrations were taken for no specific reasons and there was a limited response to the results obtained.

Management of drug-resistant epilepsies

If seizures have failed to respond to a first-line AED, various questions need to be asked:

1. Is this epilepsy?
2. Is this the best AED for the seizure type?
3. Is it being given in an adequate dosage?
4. Is the person actually taking the drug?

If someone has genuinely failed to respond, alternative therapies need to be considered. If seizures are predictable, intermittent clobazam is a useful adjunctive therapy. If not, another drug needs to be added and the dosage increased until a response is obtained or side effects develop. If the second drug is ineffective, then it should be stopped before another therapy is considered. If it is effective, then the first drug gradually needs to be withdrawn, as the aim of treatment is someone seizure free on monotherapy.

Anticonvulsant withdrawal

The Medical Research Council (MRC) Antiepileptic Drug Withdrawal Study showed that in patients who have been seizure free, at least 40% were able successfully to withdraw from therapy. The longer the seizure-free period, the greater was the likelihood of success. Successful withdrawal was also associated with few seizures before becoming seizure free and the use of a single AED. Patients who had juvenile myoclonic had a >95% chance of relapse even if they had been seizure free for many years. This is the only group of people that needs to be on treatment for life.[31] Many elderly people would be able to stop AED therapy satisfactorily but are reluctant to decrease therapy because of the driving regulations. The DVLA in the UK suggests that a person does not drive while treatment is being reduced nor for 6 months after stopping treatment. If a person has a seizure on trying to come off therapy or afterwards, they need to inform the DVLA and may not drive for 1 year.

Status epilepticus

Status epilepticus is a major neurological and medical emergency associated with a high morbidity and mortality. It is defined as a condition in which epileptic activity persists for 30 min or more; this covers a wide spectrum of clinical symptoms and with a highly variable pathophysiological, anatomical and Aetiological basis. The elderly give rise to the largest number of status epilepticus cases per annum even though the incidence is higher in childhood. In patients with established epilepsy, tonic–clonic status epilepticus rarely occurs without warning. It is usually preceded by a phase in which seizures become increasingly frequent and severe. Urgent treatment with a benzodiazepine (such as clobazam, diazepam or buccal midazolam) or paraldehyde will often prevent the evolution into true status epilepticus. Once status epilepticus has developed, the patient needs to be admitted to hospital and i.v. lorazepam (4 mg bolus i.v.) or diazepam (10 mg at a rate of 2–5 mg min^{-1}) needs to be administered. If intravenous access is not possible, intramuscular (i.m.) or rectal paraldehyde is a useful alternative. If seizures continue, then an infusion of phenytoin (18 mg kg^{-1} at a rate of 50 mg min^{-1}, e.g. 1000 mg in about 20 min) with diazepam 10–20 mg over 5–10 min if not already given or phenobarbitone (10 mg kg^{-1} at a rate of 10 mg min^{-1}, e.g. 700 mg over 7 min) should be administered. If seizures continue for longer than 30–60 min, admission to an ITU is indicated, as treatment with a general anaesthetic using either propofol or thiopentone is needed. Anaesthesia should continue for 12–24 h after the last clinical or electrical seizure and then the dose should be tapered down/off. The clinical features of complex partial status are highly variable, reflecting the diverse underlying pathophysiology. Episodes frequently last for many hours. They are characterized by confusion that can fluctuate. They can often be precipitated by a tonic–clonic seizure, and can vary from a profound stupor to mild mental slowing. Characteristically, language may be sparse and answers to questions, although appropriate, are often delayed. There can also be motor manifestations and psychotic symptoms can occur. An EEG will be diagnostic.[32]

Driving

After a first seizure, in the UK the DVLA needs to be informed and usually driving will need to cease for 6 months. People with epilepsy who have been free of all types of seizures for 12 months or more may reapply for their licence. For those who continue to experience their seizures only during sleep, they may drive if that has been the only manifestation of their epilepsy for over 3 years.

Key points

- Epilepsy is the third most common neurological disorder in the elderly.
- It is important to make an accurate definite diagnosis.
- Epilepsy in the elderly is usually easy to treat.
- Use an appropriate AED (taking into consideration pre-existing disorders and medication) in the lowest possible dose.
- Long-term AED therapy predisposes toward osteoporosis.

CHAPTER 62

Syncope and non-epileptic attacks[1]

Richard C. Roberts
University of Dundee, Dundee, UK

Introduction

Presentation with a 'collapse', 'blackout' or 'funny turn', with or without impairment of awareness and responsiveness, is common in older people and there is a wide differential diagnosis (Table 62.1). The commonest a etiologies are epileptic seizures, the various types of syncope and cerebral vascular disease. Epileptic seizures and cerebral vascular disease are discussed in other chapters; this chapter deals with syncope and some of the less common a etiologies, such as psychogenic non-epileptic attacks.

The information required to reach the correct diagnosis is usually contained within the history from the patient and from witnesses, and an adequate history will often obviate the need for extensive investigations. Difficulties arise most commonly when no witness account is available. When an attack has been witnessed, attempts should be made to contact a witness, even if he/she was a bystander not previously known to the patient. If a witness has not accompanied the patient to the consultation, a witness account can usually be obtained by making use of that important investigative tool, the telephone, and ringing the relative, friend, care assistant, shop assistant and so on, involved. General practitioners or ambulance personnel called to attend a patient who has collapsed can provide crucial diagnostic evidence, as they are in a position to interview witnesses while the features of the episode are fresh in their minds.

Diagnosis can sometimes be difficult. Pending clarification by the occurrence of further attacks, diagnostic uncertainties may persist even after specialist referral and investigation. It is usually better to accept this diagnostic uncertainty, explaining it to the patient and relatives, than to plunge for a specific diagnosis which may be incorrect and lead to inappropriate treatment and management. In particular, problems arise when non-epileptic attacks are labelled as epileptic. The patient then has to come to terms with an erroneous diagnosis to which significant stigma is still attached, and receives unnecessary antiepileptic drug treatment, possibly with adverse effects.

[1]This chapter is as in the Fourth Edition.

Syncope

Syncope can be defined as loss of consciousness due to transient impairment in blood flow to the brain. The term 'presyncope' can be used to describe symptoms of impending syncope. It is impaired flow to the brainstem and thalamus that is most likely to result in loss of consciousness, and thus adequacy of flow in the posterior (vertebrobasilar) circulation usually determines whether syncope will occur. The impairment in blood flow can occur for a variety of reasons, and it is important to recognize this since the different causes of syncope have differing symptoms and signs. A classification of syncope is given in Table 62.2. The incidence of the different causes of syncope changes with age. In the older patients, areflexic syncope, cardiac syncope and carotid sinus syndrome become increasingly frequent. It is a common problem, accounting for 0.77% of A&E department attendances, with admission rates increasing with age (Sun *et al*., 2004). A specialist syncope and falls service will improve the diagnosis and outcome (Kenny *et al*., 2002).

Mechanisms underlying syncope

A sudden fall in blood pressure and syncope can occur due to the following:

1 'Reflex syncope', when there is a reflex response of an intact autonomic nervous system to a trigger (e.g. vasovagal syncope, carotid sinus syndrome).

2 'Areflexic (paralytic) syncope', when an erect posture is adopted and there is postural hypotension due to a dysfunctional autonomic nervous system (e.g. autonomic neuropathy).

3 'Cardiac syncope', when there is a sudden reduction in cardiac output due to a cardiac disorder (e.g. bradyarrhythmia, tachyarrhythmia).

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 62.1 Differential diagnosis of blackouts and funny turns.

Syncope
Epilepsy
Transient ischaemic attacks
Panic attacks
Hyperventilation attacks
Other psychogenic non-epileptic attacks ('non-epileptic attack disorder')
Sleep phenomena
Hypoglycaemia
Migraine
Transient global amnesia
Cataplexy
Paroxysmal movement disorders
Paroxysmal symptoms in multiple sclerosis

Table 62.2 Classification of syncope.

Reflex	Vasovagal	Psychological (fear, trauma, pain)
	Carotid sinus	Low venous pressure (standing, haemorrhage)
	Micturition	Anoxia
	IXth and Xth cranial nerve disease	Neck pressure
	Oculocardiac	Micturition
		Glossopharyngeal neuralgia
		Neck tumours
		Ocular pressure (children)
Areflexic	Autonomic neuropathy	Upright posture
	Spinal cord disease	Upright posture
	Drugs	Upright posture
	Old age	Upright posture
Cardiac	Dysrhythmias	Exertion
	Ventricular outflow obstruction	
Respiratory		Coughing
		Trumpeting
		Weight lifting
		Hyperventilation
Cerebrovascular	Vertebrobasilar TIAs	

Syncope can also occur due to transiently reduced perfusion of the brain in 'respiratory syncope', when there is a transient increase in intrathoracic and intracranial pressure (e.g. cough syncope). Finally, a transient reduction in perfusion of the brainstem may also occur in cerebrovascular disease and occasionally present as syncope, for example, vertebrobasilar transient ischaemic attacks (TIAs). In elderly patients, there may be a combination of these mechanisms.

In reflex syncope a fall in blood pressure occurs due to (1) bradycardia and a reduced cardiac output (cardioinhibitory response), (2) vasodilatation in muscle and a reduced peripheral resistance (vasodepressor response), or (3) a combination of these mechanisms (mixed response) (Barcroft *et al*., 1944; Brigden *et al*., 1950). In vasovagal syncope, these responses can be distinguished by tilt testing, and in the elderly vasodepressor responses are much more frequent than in younger patients (Galetta *et al*., 2004). Recognition of this is important as insertion of a cardiac pacemaker is not likely to prevent attacks in patients with vasodepressor responses. In vasovagal syncope there is also reflex vasoconstriction in skin, causing pallor and reflex sweating. The trigger for these reflex responses is usually either 'psychological' (e.g. a response to fear, sight of trauma, pain) (Roddie, 1977) or low venous pressure detected by mechanoreceptors in the great veins and heart (e.g. prolonged standing, haemorrhage) (Abboud, 1989). Anoxia can be a trigger, and it is important in the context of anaesthesia and air travel (Sharpey-Schafer, 1956; Bourne, 1957). Non-massive pulmonary embolism may present as syncope, probably by triggering a vasovagal reflex (Castelli *et al*., 2003). In the carotid sinus syndrome syncope is thought to be triggered by activation of a 'hypersensitive' carotid sinus, and can be provoked by carotid sinus massage; again cardioinhibitory, vasodepressor and mixed responses occur. In micturition syncope, the trigger is the sudden loss of the pressor stimulus of a distended bladder (Taylor, 1963), occurring usually when the patient has got up to micturate at night, the skin is vasodilated, and the upright posture has just been assumed (contrary to common belief, 'straining' is not an important factor).

In areflexic syncope, the loss of the baroreceptor reflexes that normally keep the blood pressure stable despite changes in posture can occur for a wide variety of causes. These include autonomic neuropathy (in diabetes, Shy–Drager syndrome, Guillain–Barré syndrome, etc.) and spinal cord disease (in particular, traumatic cervical cord lesions) (Bannister, 1988). The baroreceptor responses tend to become more 'sluggish' in the elderly, causing an increased tendency to postural syncope with age. This can be exacerbated by a large range of medications, by dehydration, and by some conditions affecting the central nervous system (e.g. Parkinson's disease). Caird *et al*. (1973) found a postural fall in blood pressure of more than 20 mmHg in about 30% of a large elderly population, and a fall of more than 40 mmHg in 10%. Drugs implicated included ganglion blockers, diuretics, phenothiazines, antihistamines, antidepressants, benzodiazepines, barbiturates and antiparkinsonian drugs. Davidson *et al*. (1989) emphasized the role of drugs given for cardiovascular disease in causing syncope, in particular, nitrates, β-blockers and nifedipine. Donepezil may increase the risk of syncope. Orthostatic hypotension and syncope are common in the elderly following haemodialysis.

Cardiac syncope occurs in association with complete heart block (Stokes–Adams attacks), but also with other severe bradyarrhythmias, asystole, and paroxysmal

tachyarrhythmias (e.g. ventricular tachycardia). The commonest underlying condition is sinoatrial node dysfunction (sick sinus syndrome), with intermittent sinus arrest or sinus node exit block. If it is associated with atrioventricular block, paroxysmal tachycardia may also occur (tachy–brady syndrome). In the older patient, the arrhythmias will occur most commonly in the context of ischaemic heart disease. Cardiac syncope also occurs with ventricular outflow tract obstruction due to aortic stenosis or hypertrophic cardiomyopathy and may be associated with exertion.

A number of different mechanisms contribute to respiratory syncope (Sharpey-Schafer, 1953; McIntosh *et al*., 1956; De Maria *et al*., 1984). The rise in intrathoracic pressure associated with coughing, playing a wind instrument, weight lifting, or performing the Valsalva manoeuvre will be associated with a decrease in venous return to the heart, reduced cardiac output and fall in blood pressure. With cough syncope, which can occur after just one or several paroxysms of coughing, this will be only a brief response. Two additional mechanisms are of probable importance. First, the very high intrathoracic pressure transient is transmitted via the carotid artery to the baroreceptors, causing a more prolonged reflex fall in blood pressure. Second, the very high pressure transients are also transmitted via the venous system to the intracranial cavity, reducing cerebral perfusion pressure. Yet another mechanism is likely to contribute to syncope associated with hyperventilation; the fall in carbon dioxide partial pressure causes vasodilatation in muscle and reduced peripheral resistance.

Vertebrobasilar ischaemia may occasionally present as syncope, but there will usually be additional neurological symptoms. The underlying a etiology might either be embolic or related to critical changes in flow distal to atheromatous disease. With the latter the symptoms may be related to changes in posture.

Clinical manifestations of syncope

The usual image of a syncopal attack is of a subject feeling dizzy, going pale, falling with loss of awareness and then recovering rapidly within about 30 s. This sequence of events certainly occurs, but the variety of other manifestations of syncope of different types needs to be emphasized. The motor manifestations are particularly prone to cause diagnostic error and will be discussed first, followed by the other clinical features. In the elderly, presentation may be with a history of falls or drop attacks with no recall of loss of consciousness (Kenny *et al*., 2001).

Motor manifestations

A detailed study of vasovagal syncope in normal young volunteers led to important insights into the variety of clinical manifestations of syncope, which is relevant to the differential diagnosis of blackouts at any age. Lempert *et al*. (1994) induced vasovagal syncope in 56 of 59 volunteer medical students, by asking them to hyperventilate while squatting, and then to stand up performing the Valsalva manoeuvre. They carefully documented the manifestations with video recording. It was only a minority of subjects that lay still after falling, 90% having some asynchronous myoclonic jerks of the limbs. In a few, the jerks were quite vigorous for several seconds, such that the attack might be mistaken for a generalized clonic seizure. Some displayed other motor activity, such as limb-posturing, head-turning, complex movements, eye deviation and eyelid flicker, that might be misinterpreted as manifestations of partial epileptic seizures. Vocalization was frequent.

Similar findings of a very high frequency of myoclonic movements in syncope have also been reported in cardiac syncope (Aminoff *et al*., 1988). The opportunity to make these observations of the features of cardiac syncope has arisen with patients with recurrent ventricular arrhythmias treated with implantation of an automatic defibrillator, in whom syncope has been deliberately induced by induction of the arrhythmia to test the defibrillator. Simultaneous electroencephalogram (EEG) recording has shown no evidence of associated epileptiform activity. The variety of clinical manifestations of syncopal attacks has also been documented in attacks induced by use of a tilt table (Passman *et al*., 2003).

In vasovagal and cardiac syncope, therefore, the classic image of the patient falling, lying still for some seconds and then coming round is unusual, and much more often there are jerks and other motor manifestations. In these types of syncope it can be argued that the fall in blood pressure was very sudden and marked, and that this may have predisposed to the myoclonus. There is anecdotal evidence that the patient who faints, and who is propped up on falling rather than falling flat on the ground, is more likely to have myoclonic movements, presumably associated with a more prolonged and severe fall in blood pressure, and rarely the hypoxia may provoke an epileptic seizure. It may be that myoclonic movements are less common in patients with areflexic syncope and postural hypotension, in whom the presyncopal symptoms will often permit preventive measures, the fall in blood pressure is less catastrophic and the blood pressure will be immediately restored once they have fallen.

Other clinical features

The various trigger factors for the different types of syncope have been described in the preceeding text, and their importance will be discussed further in the section on diagnosis.

Warning symptoms, before loss of awareness, are common with reflex and areflexic syncope, but are absent in some patients (or not recalled). The symptoms of lightheadedness, dizziness and blurring of vision are familiar to most people on standing up from a hot bath too suddenly.

Additionally, there may be nausea, 'hot and cold' feelings, feelings of depersonalization or distance from the surroundings and buzzing in the ears. In the Lempert *et al*. (1994) study, described earlier, the students often described having had visual and auditory disturbances. Palpitations, dyspnoea and chest pain may occur (Graham and Kenny, 2001). Warning symptoms in cardiac syncope are less frequent and can consist just of a brief premonition as well as better-defined dizziness. A history of palpitations is usually sought, but positive responses are often difficult to interpret and negative responses are not diagnostically useful.

Marked pallor and clamminess are prominent features of vasovagal syncope due to the reflex vasoconstriction in skin and reflex sweating. In contrast, patients with areflexic syncope and postural hypotension may have relatively little colour change in association with their attacks, there is no sweating and the skin remains warm. Patients with cardiac syncope become pale owing to the marked reduction in cardiac output, and sometimes there is subsequent flushing when the output is restored (but this sequence is not sufficiently consistent or specific to be diagnostically very helpful).

If the opportunity arises to feel the pulse early in vasovagal and other causes of reflex syncope, it will be weak and there will be a reflex bradycardia. In contrast, in areflexic syncope there will be no change in heart rate. In cardiac syncope the heart rhythm changes could, of course, be diagnostic, but it is rare for a chance to arise to feel the pulse in an attack.

Not all syncopal attacks are associated with complete loss of either responsiveness or awareness. In the Lempert *et al*. (1994) study, 13 of the 56 subjects had a fall associated with only partial loss of awareness, and sometimes with confused behaviour that might be mistaken for a partial epileptic seizure. These phenomena are also well recognized in patients with postural hypotension and areflexic syncope.

Incontinence may occur with syncope of any type, and is not useful in differential diagnosis. Tongue biting is extremely rare, but has been reported as a consequence of the fall.

Syncopal attacks of any type are necessarily brief, with responsiveness returning in less than a minute and often much sooner. Marked reduction of cerebral perfusion for significantly longer periods would clearly result in ischaemic brain damage or death. Patients with reflex and with areflexic syncope usually recover very rapidly without confusion once supine, unless there has been a complicating factor such as head injury. Even patients with cardiac syncope and a transient severe reduction in cerebral perfusion recover rapidly. Following ventricular tachycardia or ventricular fibrillation, Aminoff *et al*. (1988) described recovery of consciousness within 20 s of restoration of the circulation, and subsequent confusion lasted no more than 30 s.

Diagnosis and investigation of syncope

The diagnosis of 'blackouts' is critically dependent on adequate patient and witness accounts of the attacks. In diagnosing syncope correctly, emphasis should be placed on potential trigger factors and the short duration of attacks. Thus, areflexic syncope is likely when there has been a clear relationship between the attacks and changes in posture, irrespective of a description of 'some jerking', other motor features, incontinence and injury in some attacks. Vasovagal attacks and other causes of reflex syncope are likely when potentially syncopal attacks have been associated with characteristic trigger factors and much less likely if they have not, in which case cardiac syncope should be seriously considered. The presence of underlying cardiac disease increases the probability of a cardiac cause. Cough syncope should be considered in patients with chronic obstructive pulmonary disease, emphysema and chronic cough, and an adequate witness account should be obtained, since some patients fail to recall the bout of coughing that triggers an attack. Syncope as a manifestation of cerebral vascular disease is unlikely in the absence of additional symptoms suggestive of posterior circulation transient ischaemic attacks.

In the last 15 years, increasing use has been made of tilt testing to obtain evidence to support a suspected diagnosis of vasovagal syncope and to investigate the underlying mechanisms (Grubb *et al*., 1991; Smith *et al*., 1994; Patel *et al*., 1993; Sutton *et al*., 1992). It has proved to be safe in the elderly (Gieroba *et al*., 2004; Galetta *et al*., 2004). The proportion of positive tilt tests is increased following the administration of glyceryl trinitrate. One of the difficulties in interpretation of the results, however, is the occurrence of positive tests in a significant minority of control subjects, which limits the positive predictive value. Nevertheless, provocation of a habitual attack is diagnostically very suggestive.

The work of Kenny has suggested that carotid sinus syndrome is a common cause of syncope in the elderly, and is not just confined to those with a history of fainting, following neck movement when wearing a collar (Kenny *et al*., 2001). Other groups have also reported a high incidence of syncope provoked by carotid sinus massage in patients with otherwise unexplained syncope (Freitas *et al*., 2004; Kumar *et al*., 2003). Carotid sinus massage appears to carry a very low risk of complications, despite potential underlying atheroma, but should not be carried out if there is a carotid bruit unless ultrasound examination has excluded severe carotid stenosis (Richardson *et al*., 2002).

When cardiac syncope is suspected, routine 12 lead electrocardiogram (ECG) recording will occasionally

demonstrate an arrhythmia, or abnormalities that predispose to arrhythmias. Twenty-four-hour ECG tapes can be diagnostic if an attack is recorded, but the yield of diagnostic recordings is very small unless the attacks are very frequent. Moreover, interpretation of the significance of asymptomatic rhythm disturbances can be difficult. In an older population, minor asymptomatic cardiac dysrhythmias are common and may be an incidental finding unrelated to a patient's attacks. When cardiac syncope is suspected, specialist cardiac referral will usually be indicated for further assessment, non-invasive investigation, and intracardiac electrophysiology in selected cases. In the last few years, implantable loop recorders have emerged as important tools in the diagnosis of cardiac syncope, permitting recordings of cardiac rhythm during attacks, even when the attacks are infrequent (Solano *et al*., 2004; Armstrong *et al*., 2003). The yield of positive recordings is greater in an elderly population (Brignole *et al*., 2005). Although the recorders are expensive, they can be cost-effective as there is a relatively high chance of capturing an attack and answering the clinical question (Krahn *et al*., 2003).

In areflexic syncope, the diagnosis is likely to be supported by finding a postural fall in blood pressure on examination that may or may not be symptomatic. The size of fall that is clinically significant varies between patients. A fall of at least 20 mmHg is usually defined as abnormal, but in some patients a fall of 10 mmHg is symptomatic, whereas in others with a higher supine blood pressure a fall of 40 mmHg might be asymptomatic. The blood pressure should be measured supine, immediately after standing and after standing for 1–2 min. Failure of the baroreceptor reflex responses can be confirmed by observing the heart rate changes in response to the Valsalva manoeuvre, standing and deep breathing.

There are a number of features of syncope that can cause diagnostic confusion with epileptic seizures. The jerky myoclonic movements might be interpreted as a generalized tonic–clonic seizure, but in the context of syncope these movements are brief, usually lasting only a few seconds and no more than 10 s. Other motor manifestations, a warning feeling of depersonalization, auditory and visual hallucinations and confused behaviour risk being misinterpreted as features of partial epileptic seizures. Pallor and clamminess are important features of vasovagal syncope but are not specific and such autonomic manifestations can occur in some partial epileptic seizures. Misdiagnosis of syncopal attacks as epilepsy can have tragic consequences when they are due to potentially fatal, but treatable, cardiac arrhythmias. Although most patients will have one type of attack, epilepsy and syncope can coexist. Rarely, patients have been described in whom an epileptic seizure has been triggered by a syncopal event and, conversely, significant cardiac arrhythmias (and potentially syncope) can occasionally be induced by epileptic seizures.

When a confident clinical diagnosis of syncope has been made, the temptation to request an EEG 'just in case it's epilepsy' must be resisted. If EEGs are done in a population of patients in which the prevalence of epilepsy is very low, then they have a very low positive predictive value (Scottish Intercollegiate Guidelines Network, 2003). Even if epileptiform abnormalities are found, the patient may still be more likely to have had a syncopal than epileptic attack. A request for EEG should be reserved for cases in which there is diagnostic uncertainty, and in which it is felt that epilepsy is a reasonably likely diagnostic possibility. It should be remembered that note should only be taken of definite epileptiform features and that non-specific slow-wave abnormalities are not diagnostically helpful.

Although the differentiation of syncope and epilepsy can be difficult, syncope is less likely to be confused with the other attack disorders listed in Table 62.1, which have characteristic clinical features or tend to cause attacks that are more prolonged.

Management of syncope

Vasovagal syncope is usually managed by avoiding provocative factors, and only a small proportion of patients need other interventions; many pharmacological treatments have been advocated, but are of no or uncertain efficacy, and pacemaker insertion may be ineffective (Brignole, 2003; Kaufmann and Freeman 2004; Connolly *et al*., 2003). Tilt training has been suggested, but is poorly tolerated and of uncertain benefit. In carotid sinus syncope the role of drug treatment is again uncertain; insertion of a cardiac pacemaker may need to be considered, if there is a significant cardioinhibitory component to the response to carotid sinus massage (Brignole, 2003; Healey *et al*., 2004). Surgical denervation of the carotid sinus is a possibility in severe cases. Micturition syncope can usually be avoided by micturating sitting down. Cardiac syncope requires appropriate specialist treatment with antiarrhythmic medication, pacing or insertion of an implantable defibrillator as appropriate; timely and effective treatment may be life saving. In cough syncope, treatment has to be directed at the underlying chest condition.

In older patients with syncope, areflexic syncope with postural hypotension is a common management challenge. Attention should first be directed to factors that may be causing or exacerbating the problem. The patient's medication should be reviewed, but it is not always possible to discontinue relevant drugs. For instance, in Parkinson's disease the effect of dopaminergic drugs in aggravating a postural fall in blood pressure may have to be balanced against their beneficial therapeutic effects. Treatable conditions such as Addison's disease should be excluded. Factors causing vasodilatation should be avoided, such as high

temperatures, marked exertion and alcohol. Small, frequent meals should be eaten rather than large meals. Dehydration should be avoided. When sitting up or standing, the changes in posture should be made slowly and reversed temporarily if postural symptoms supervene. Crossing the legs, tensing the calf muscles and abdominal compression can sometimes transiently ameliorate postural symptoms (Wieling *et al*., 1993).

Elastic compression stockings can make a significant contribution, although patients may need help in putting them on and they are difficult to tolerate in the summer. Sleeping with slight head-up tilt may help, possibly by expanding plasma volume, but a tilt of more than about 10° is difficult to tolerate. Chronic exposure to low blood pressure seems to improve cerebral autoregulation, so patients should be encouraged to remain as active as possible.

If these measures are not adequate in controlling symptoms of postural hypotension, drug treatment may be commenced. Most drugs are used without their licence and benefits may be limited. Fludrocortisone 100–200μg at night is usually commenced first and causes salt and water retention (and potentially hypokalaemia). Ephedrine, a sympathomimetic, can be added (15 mg t.i.d., increasing if necessary to 30 mg t.i.d.). Higher doses may cause tremor, tachycardia and agitation. A number of other drugs, including midodrine, have been used (Jankovic *et al*., 1993; Hoeldtke and Streeten, 1993; Mathias *et al*., 1986). With drug treatment supine hypertension is a risk. Pacing does not help (Sahul *et al*., 2004).

In an elderly population, the risks of serious injury and complications from falls are very high. It is important that the patient with syncope recognizes these risks, and understands the need to take precautions to avoid syncopal attacks, if at all possible.

Other non-epileptic attack disorders

Panic attacks and hyperventilation attacks

The clinical diagnosis of panic attacks in the context of an anxiety syndrome is usually straightforward, but fear and anxiety can of course be features of partial epileptic seizures. Treatment is directed toward the underlying anxiety disorder.

Hyperventilation may or may not be a component of panic attacks and, conversely, hyperventilation attacks may or may not be associated with panic. Classically, hyperventilation is associated with dizziness, paraesthesia in the hands and around the mouth and a paradoxical feeling of breathlessness. Feelings of unreality or depersonalization can occur, and may lead to a misdiagnosis of partial epileptic seizures, particularly when there is impaired consciousness, tetany or tremor. The hyperventilation can be subtle and not always obvious, even to an experienced witness. The paraesthesia and tetany are probably related to a reduction of extracellular ionized calcium induced by the respiratory alkalosis. The cerebral symptoms are ascribed to reduction of cerebral blood flow, and are associated with EEG slowing (Gotoh *et al*., 1965). Occasionally, loss of consciousness occurs in hyperventilation attacks, and this may be due to syncope caused by vasodilatation in muscle. It has been reported, however, that loss of consciousness can also occur without a fall in blood pressure, and it has been suggested that this is due to the severity of cerebral vasoconstriction (Naschitz *et al*., 1997). In the diagnosis of hyperventilation attacks, an attempt to induce symptoms by hyperventilation in the clinic or laboratory can be useful. Attacks may be aborted by rebreathing ('paper bag treatment'). Training in breath control and anxiety management by physiotherapists and/or clinical psychologists is indicated when the attacks are troublesome.

Psychogenic non-epileptic attacks

Psychogenic non-epileptic attacks ('non-epileptic attack disorder', pseudoseizures, functional seizures) present for the first time most frequently in teenage or young adult females, but there is increasing recognition that they also present in elderly patients. They are a common diagnosis in elderly patients undergoing assessment with long-term EEG and video monitoring in specialist epilepsy units (Kellinghaus *et al*., 2004). A significant number of patients with psychogenic non-epileptic seizures are misdiagnosed, in particular, as having epilepsy, and are treated inappropriately. Between 6 and 15% of patients investigated for apparently uncontrolled epileptic seizures have psychogenic non-epileptic seizures. When attacks persist despite treatment, a diagnosis of epilepsy should always be reviewed, and some patients with misdiagnosed psychogenic non-epileptic attacks will be identified. The correct identification of pseudostatus epilepticus is also very important.

A wide range of psychiatric labels have been attached to different patients with psychogenic non-epileptic attacks, in particular, conversion disorder and somatization disorder, but also anxiety, depression, post-traumatic stress disorder, episodic dyscontrol, and malingering. This suggests a variety of often ill-understood underlying mechanisms. With the exception of malingering, which is a very rare cause of an attack disorder, the attacks appear to occur without the conscious mediation of the patient. Often the attacks occur without any apparent trigger. One exception is episodic dyscontrol, in which rage attacks are triggered by irksome events and control of temper is inappropriately lost. In making a diagnosis of psychogenic attacks, it is usually important to take into account the 'whole picture' and not just one aspect of the patient's problems. As with other attack disorders, the diagnosis is critically dependent on adequate descriptions of the attacks but even with video recording, this may not, by itself, provide adequate

information. In a study in which neurologists attempted to make a diagnosis of epileptic or non-epileptic attacks on the basis of video recordings alone, they were correct in only 71% of epileptic seizures and in 73% of psychogenic non-epileptic seizures (King *et al*., 1982). In addition, account needs to be taken of the timing and circumstances of attacks, the detailed past medical and psychiatric history, current psychiatric, neurological and other symptoms and examination findings, bearing in mind that psychiatric symptoms are common in patients with epilepsy as well as in those with non-epileptic attacks. Other factors may be interictal and ictal EEG, the relationship of attacks to medication and measurements of serum prolactin.

The attacks tend to fall clinically into two main groups, those in which the patient collapses with impaired or absent responsiveness and little movement, and those with prominent motor activity (Meierkord *et al*., 1991). Betts and Boden (1992a) suggested an additional category of 'abreactive' attacks with hyperventilation, stiffening, breath-holding, gasping, incoordinate jerking and pelvic thrusting, and sometimes screaming, spitting and retching. In non-epileptic seizures, injury and incontinence are not uncommon, but tongue biting and cyanosis are very rare. In generalized tonic–clonic epileptic seizures, limb movements are in-phase, whereas in nonepileptic seizures with generalized limb movements they are usually out-of-phase (Gates *et al*., 1985). Some frontal lobe epileptic seizures can, however, also be associated with brief prominent out-of-phase limb movements (e.g. bicycling movements). Some attacks are easy to diagnose. For instance, episodes of collapse and unresponsiveness that are prolonged (e.g. 30 min) are most unlikely to be epileptic. Attacks with wild movements of all limbs and some degree of retained responsiveness are also unlikely to be epileptic. However, other attacks can be difficult to classify and require specialist referral.

Long-term video and EEG monitoring and the recording of attacks will usually, but not always, lead to a diagnosis. They are expensive. Even when attacks are relatively infrequent they can be worthwhile, as patients with psychogenic non-epileptic seizures tend to have more attacks than expected during monitoring. Indeed, short-term video EEG recordings on outpatients have been shown to have a high diagnostic yield when combined with suggestion that an attack will be provoked by hyperventilation or photic stimulation (McGonigal *et al*., 2004). The absence of epileptiform abnormalities during an attack does not exclude epilepsy, as many simple partial and rare complex partial seizures are not associated with scalp EEG changes. Prolactin level measurements have only a limited role. About 20 min after a generalized tonic–clonic seizure there is usually a marked rise in serum prolactin above 1000 mUl^{-1}, which is not seen in psychogenic non-epileptic seizures, but can occur following syncope (Trimble, 1978). The rise should be confirmed by measuring a baseline level or the level at least 1 h after the seizure. In practice, however, it is unusual to have much diagnostic difficulty with attacks that might be generalized tonic–clonic epileptic seizures and, with the more difficult diagnosis of attacks that might be partial seizures, the rise in serum prolactin is less marked and reliable. A rise above 500 mUl^{-1} is often seen after complex partial seizures, but not after simple partial seizures (Dana-Haeri *et al*., 1983; Laxer *et al*., 1985). However, such rises have also been reported following psychogenic non-epileptic seizures (Alving, 1998).

Between 10 and 30% of patients with psychogenic non-epileptic seizures also have epilepsy, and sometimes there is an inverse relationship between the frequency of the epileptic and non-epileptic attacks. In managing such patients, it is obviously necessary to distinguish clearly between the types of attack.

The first step in the management of psychogenic non-epileptic seizures is to explain the diagnosis clearly to the patient and his/her family. If the label of epilepsy has previously been attached, it is made clear that this is being removed (except in those with both types of attack). It is explained that a diagnosis of non-epileptic attack disorder is a positive diagnosis, that it is quite common and that the mechanisms underlying the attacks are sometimes not well understood. It is important that there is no hint of a suggestion that the attacks are being 'put on', and it should be made clear that this is not the case (except in the very rare malingerer). Further management will involve withdrawal of antiepileptic drugs, counselling from informed clinicians, nurse specialists or clinical psychologists and treatment of any associated depression or anxiety. It will usually be important to involve the whole family in the treatment programme. If the attacks are diagnosed early and any precipitating issues are dealt with, then the prognosis is good (Betts and Boden, 1992b). In the older patient with a long history of attacks, however, the prognosis for cessation of the attacks will be poor, and management will be aimed at helping the patient cope with them.

Sleep phenomena, hypoglycaemia, migraine, transient global amnesia, cataplexy, paroxysmal movement disorders and paroxysmal symptoms in multiple sclerosis

It is beyond the scope of this chapter to describe these remaining disorders in detail.

Episodic events during sleep can be due to normal physiological phenomena (e.g. hypnic jerks, periodic movements) and sleep disorders (e.g. myoclonus, restless legs syndrome, non-REM and REM parasomnias, sleep apnoea) as well as due to partial or generalized epileptic seizures. Periodic movements become increasingly frequent with age and are very common in an elderly population. They may disturb the sleep of the patient as well as that of the partner. They occur at a regular interval of 10–60 s and

usually consist of transient flexion movements of one or both legs lasting a few seconds. The restless legs syndrome also becomes more frequent with age and is associated with periodic movements of sleep. REM parasomnias occur characteristically in elderly males, last up to a few minutes and involve thrashing about and calling out in response to vivid dreams. Injury to a partner in the same bed is a risk. They can be confused with frontal lobe seizures and may respond to clonazepam.

Hypoglycaemia can cause a variety of manifestations. Attacks usually begin with autonomic disturbances such as sweating, palpitations, nausea and hunger. Symptoms related to cerebral dysfunction may then ensue, including paraesthesia, visual disturbance, weakness, tremor, dizziness, confusion and aphasia, as well as coma and epileptic seizures. Sometimes there are bizarre prolonged episodes of altered behaviour that might suggest a fugue state or partial status epilepticus. Most attacks occur in the context of diabetes, liver disease, alcohol abuse or in clear relationship to meals (reactive hypoglycaemia). Insulin-secreting tumours are very rare, and often diagnosed late.

The focal sensory, motor and psychic symptoms that can occur in migraine attacks may be mistaken as epileptic phenomena or ascribed to transient ischaemic attacks. The duration of migrainous symptoms tends to be longer (usually between 5 and 60 min) than the duration of epileptic symptoms (usually between a few seconds and 2 min). Associated headache, photophobia, nausea and vomiting will usually make a diagnosis of migraine clear. The loss of consciousness that can occur in vertebrobasilar migraine can cause diagnostic difficulty.

The diagnosis of transient global amnesia is usually immediately apparent from the history if a witness account is available to describe the profound amnesia (retrograde and anterograde) lasting usually between one and a few hours. There is often repetitive questioning with failure to recall the replies. The cause of the attacks remains uncertain and there is no specific treatment. It is important to distinguish them from prolonged postictal confusional states with amnesia that may follow partial epileptic seizures, and from ictal amnesia.

Cataplexy, paroxysmal movement disorders and paroxysmal symptoms in multiple sclerosis are unlikely to present for the first time in older patients. In all these conditions there is no impairment of consciousness, and responsiveness is only transiently impaired in cataplexy due to the transient weakness.

Key points

- In attack disorders a detailed account from the patient and witnesses is often crucial in reaching an accurate diagnosis.
- Motor manifestations lasting a few seconds (jerks, twitches, posturing) are common in syncopal attacks.
- Cardiac syncope, carotid sinus syndrome and areflexic syncope (with postural hypotension) become increasingly common in the elderly.
- Carotid sinus massage, tilt testing and cardiac loop recorders are playing an increasing role in the differential diagnosis of syncope.
- Psychogenic non-epileptic (functional) seizures can occur in older as well as younger patients, and are commonly misdiagnosed.

CHAPTER 63

Parkinson's disease

Joël Belmin

Groupe Hospitalier Pitié-Salpétrière-Charles Foix and Université Pierre et Marie Curie (Paris 6), Ivry-sur-Seine, France

Introduction

Parkinson's disease (PD) is the second most common neurodegenerative disease after Alzheimer's disease. Despite progress in understanding the neurochemical mechanisms, the exact cause of PD remains undetermined. The main pathological findings are loss of neurons in the substantia nigra and a profound depletion of dopamine in areas of projection pathways from the substantia nigra as in the striatum. In addition, a protein, α-synuclein, bound to ubiquitin accumulates in damaged neurons and contributes to form Lewy bodies, another hallmark of the disease found in cells of the substantia nigra and other brain areas. Several genetic factors, in particular about 10 gene mutations, have been identified in familial cases of PD, but they are observed mainly in early-onset PD and are infrequently involved in late-onset PD.

The prevalence of PD is ~1% in subjects aged over 65 years. The median age at diagnosis is 60 years, so less than about 40% of cases begin after age 60 years. Usually late-onset PD is defined by first symptoms occurring after the age of 60 years. Hence very late-onset PD, beginning after the age of 75 years, is not frequently observed. The incidence of PD rises with age until 80 years, but seems to decrease in the ninth decade. The mean duration of the disease from diagnosis to death is 15 years. Therefore, owing to age factors and referral bias, most PD patients seen in geriatric settings have a longstanding PD with impaired independence of other complications.

Risk factors for PD have been extensively studied. The existence of a family history of PD is found in 6–10% of cases. Weak associations have been found between PD and head injuries, rural living, obesity and exposure to herbicides or pesticides. Male gender is a controversial risk factor, depending on the population studied. Cigarette smoking and coffee consumption seem to be protective factors.

Signs and symptoms of very late-onset Parkinson's disease

Many symptoms can be caused by PD or other parkinsonian syndromes. Some of them are motor symptoms such as tremor, difficulties in moving, writing and walking, falls and changes in gait and posture. Others are non-motor symptoms such as bradyphrenia (slowness of mental function), depression, memory problems and dementia, constipation, bladder dysfunction and autonomic dysfunction (gastrointestinal, sexual, cardiovascular). Physical examination shows extrapyramidal signs which can suggest PD to the geriatrician (Table 63.1).

PD usually starts in an insidious manner and progresses slowly. Cardinal extrapyramidal signs do not appear at the same time and tremor can precede bradykinesia and rigidity for several months or years. PD signs are usually asymmetric or even unilateral at the beginning and become bilateral and/or symmetrical as the disease progresses.

Other signs are frequent in PD, especially as the disease progresses. *Abnormal posture* with flexion of limbs and trunk is observed when standing, and walking shows a decrease in step length and height and reduced swing of the arms. *Neuropsychiatric symptoms* are dominated by anxiety and depressive syndrome. Anxiety disorders encountered in PD are mainly generalized anxiety disorder and obsessive–compulsive disorder. Major depression episodes are frequent in PD and about 50% of patients might be affected during the course of the disease. The diagnosis of depression is often difficult because symptoms such as fatigue, sleep disorders and lack of interest may be encountered in PD in the absence of overt depression. *Cognitive symptoms* might be encountered is PD patients, but cognitive impairment (defined by an abnormally low performance in cognitive testing) is never a sign of early PD and is observed in PD only after several years of evolution (PD-related dementia).

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 63.1 Cardinal signs of Parkinson's disease.

Sign	Characteristics in PD	Conditions other than PD that should be considered
Tremor	At rest, 4–6 s^{-1}, asymmetric at the beginning, regular, increased by emotion, decreased by posture	Postural tremor: essential tremor, hyperthyroidism, drug-induced tremor, exaggerated physiological tremor, dystonia tremor Intentional tremor: cerebellar disorders
Bradykinesia and akinesia	Slowness and/or poverty of movements and speech, loss of facial expressions	Depression, dementia, hypothyroidism, drug-induced (sedatives), encephalopathy, parkinsonism other than PD
Rigidity	Found on passive movements, asymmetric at the beginning, lead-pipe type at examination	Pyramidal rigidity: abnormalities of reflexes and other neurological signs Oppositional rigidity: not permanent Extrapyramidal rigidity other than PD: axial or symmetrical at the beginning

Autonomic disorders are dominated by orthostatic hypotension and constipation. *Orthostatic hypotension*, frequently found in PD, is directly related to autonomic dysfunction and is often worsened by antiparkinsonian drugs. Orthostatic hypotension is often asymptomatic but can cause discomfort or fainting syncope. Orthostatic hypotension is defined by a decrease in systolic blood pressure by 20 mmHg (or diastolic BP by 10 mmHg) within 3 min following the passage from supine to standing. Repeated search of orthostatic hypotension is a part of the monitoring of any parkinsonism patient. *Constipation* is found in about 50% of PD patients and is related to bowel motility impairment, sphincter dysfunction and poor physical activity. Autonomic symptoms also include *sweating*, *drooping*, *sexual dysfunction* and *urinary symptoms*, such as urinary frequency, urgency and dysuria, whose links with PD can be established after having rejected the role of urinary infection, bladder or prostate diseases and/or anticholinergic drugs.

Differential diagnosis of Parkinson's disease

Tremor

PD may begin with isolated tremor. Other causes of tremor are listed in Table 63.1. Intention tremor which is increased by voluntary movement orients towards cerebellar diseases, and also other components of cerebellar syndrome (dysmetria, hypotonia, dysdiadokinesia, dysarthria) if present.

Postural tremor is increased by maintaining posture. Hyperthyroidism is easily recognized by other signs and blood determination of thyroid-stimulating hormone (TSH). Essential tremor is the main differential diagnosis. Family history of tremor and involvement of the head and voice are very suggestive of essential tremor. In difficult cases, brain single-photon emission computed tomography (SPECT) using a transporter of dopamine, ioflupane (DaTSCAN), shows a normal pattern in essential tremor and abnormalities in PD and other parkinsonian syndromes (except neuroleptic-induced parkinsonism). Drugs that might induce tremor include amiodarone, lithium, bronchodilators, metoclopropamide, neuroleptics, valproate and theophylline.

Extrapyramidal syndromes other than Parkinson's disease

Extrapyramidal syndromes can be observed in several conditions other than idiopathic PD. Especially in very late-onset parkinsonism, the relative frequency of extrapyramidal syndromes other than PD is greater than in early-onset parkinsonism, accounting for 20–40% of new parkinsonism cases in the elderly. The main causes of extrapyramidal syndrome are given in Table 63.2. In most cases, medical history and physical examination allow their identification. Parkinsonian syndrome other than PD responds poorly to L-dopa. This can be recognized by medical history if the patient was given L-dopa. In difficult cases, the response to L-dopa can also be clinically assessed (Box 63.1).

Drug-induced parkinsonism is very frequent in older patients. Neuroleptics, including those used as antiemetics, are the major cause of drug-induced parkinsonism. New antipsychotics (i.e. atypical antipsychotics, such as risperidone, olanzapine and quetiapine) also provoke parkinsonism even if this adverse effect in less frequent than with classical neuroleptics. Some other drugs infrequently induce parkinsonism, such as certain calcium channel blockers (cinnarizine, flunarizine), valproate and amiodarone. Cases with fluoxetine and other serotonin reuptake inhibitors have also been reported, but evidence is poor. Risk factors for drug-induced parkinsonism are advanced age and female gender. In about 50% of cases, extrapyramidal signs occurs within the first month after starting the drug, but might appear later.

Box 63.1 Response to L-dopa.

Response to L-dopa is sometimes useful to differentiate PD from other extrapyramidal syndromes. This is not formally a diagnosis test for PD but rather an indicator of dopaminergic response. If the patient has been previously treated with L-dopa for several weeks or longer, medical history helps assess the response to L-dopa. If the patient has not been treated before, this response can be assessed by administering to a fasting patient 150–250 mg of L-dopa associated with a dopa decarboxylase inhibitor. Tremor, rigidity and akinesia of members should be assessed every 30 min for 2–3 h. L-Dopa is not considered to improve non-motor symptoms or signs, and also posture and gait.

Extrapyramidal signs are usually bilateral and symmetrical. They comprise akinesia, bradykinesia and rigidity, but tremor is very unusual. By contrast, tardive dyskinesia, another movement disorder, is frequently associated in persons with neuroleptic-induced parkinsonism; it comprises involuntary movements of the lips, tongue and mouth, but could also involve other parts of the body. When the offending drug is stopped, signs of parkinsonism often alleviate, but this occur very slowly, over periods as long as several weeks or months. In about 20% of the patients, some extrapyramidal signs persist, which suggests that these people had PD or another neurodegenerative parkinsonism that was precipitated by the drug challenge. Tardive dyskinesia is often permanent in many patients, even after stopping the drug. There is no satisfactory treatment for drug-induced parkinsonism. Stopping the drug responsible is the best option and in elderly patients this is often possible since neuroleptics are mainly used to control behavioural complications of dementia, a condition for which they are ineffective. In elderly patients with severe psychosis, the switch from classical neuroleptic to low-dose atypical antipsychotic drugs should be tried. Anticholinergic drugs which are used in younger psychiatric patients treated with neuroleptics should be avoided in the elderly because they often induce delirium and other adverse effects. Prevention of drug-induced parkinsonism is a crucial issue in geriatric care and can be achieved by avoiding prescribing neuroleptics in elderly patients, especially in those with dementia.

Lewy body dementia and *Alzheimer's disease*, which are two frequent diseases causing dementia in older people, could be responsible for extrapyramidal syndrome. Lewy body dementia is strongly related to PD, since the two diseases share some physiopathological processes such as cellular Lewy bodies and α-synuclein metabolism abnormalities. Lewy body dementia is characterized by (i) cognitive dysfunction fulfilling the criteria of dementia, with insidious

Table 63.2 Causes of extrapyramidal syndrome other than Parkinson's disease.

Causes of extrapyramidal syndrome	Characteristics
Frequently observed as very late-onset parkinsonism	
Drug-induced parkinsonism	Exposure to neuroleptics (or other drugs) before the onset of parkinsonism. Dyskinesia is frequent. No tremor. Ioflurane SPECT normal pattern
Lewy body dementia	Dementia occurring a few months before or after the onset of parkinsonism, hallucinations, severe adverse reactions to neuroleptics
Alzheimer's disease	Parkinsonism is infrequent in Alzheimer's disease and is observed at moderate or severe stages. Hippocampal atrophy on MRI. Ioflurane SPECT normal pattern
Progressive supranuclear palsy	Postural instability and repeated falls occurring early in the course of the disease, axial rigidity, limitation of vertical gaze, neck dystonia, impaired saccades on ocular electrophysiology. No tremor. MRI: midbrain atrophy
Cerebrovascular disease	Parkinsonism associated with several cerebral infarctions on MRI and worsening of parkinsonism signs after infarctions. Usually with multilacunar state, pseudobulbar syndrome, emotional lability, pyramidal signs and/or vascular dementia
Normal pressure hydrocephalus	Gait disturbances, urinary incontinence, cognitive slowness. Cerebral imaging: marked enlargement of brain ventricles not explained by brain atrophy
Very rarely observed as very late-onset parkinsonism	
Multiple systemic atrophy	Severe dysautonomia (orthostatic hypotension, urinary disorder, sexual dysfunction, gastrointestinal symptoms) early in the course of parkinsonism. Pyramidal or cerebellar syndrome
Corticobasal degeneration	Dystonia, myoclonus and sensory disorders, foreign hand syndrome
Huntington's disease	Chorea, familial cases
Wilson's disease	Liver disease, complex neurological signs including parkinsonism, psychiatric symptoms, familial cases, Kayser–Fleischer ring around the iris
Miscellaneous	Toxic, post-encephalitis, repeated skull trauma

onset and progressive evolution, and (ii) association with one or several of the following features: hallucinations, extrapyramidal syndrome, fluctuation course, falls and poor tolerance to neuroleptics. The extrapyramidal syndrome might be present at the diagnosis of Lewy body dementia or might occur as the disease progresses. In some cases, the extrapyramidal syndrome might precede the onset of cognitive dysfunction for several months and often the diagnosis of PD is first considered; the occurrence of dementia in the few months after the diagnosis of extrapyramidal syndrome leads to the identification of Lewy body dementia. By contrast, PD-related dementia occurs in advanced stages of PD, after progression for several years. About 15% of patients with Alzheimer's disease are reported to experience extrapyramidal syndrome. Usually, extrapyramidal signs are mild and are recognized by physical examination. In many cases, the extrapyramidal syndrome might result from actual or past exposure to neuroleptics, which should be searched for carefully by interviewing patients, proxies, physicians and pharmacists. Extrapyramidal signs could also be observed in neuroleptic-free Alzheimer's disease patients. In these cases, the diagnosis of Lewy body dementia should also be considered. SPECT imaging of the brain using dopamine receptor radioligand helps to distinguish Alzheimer's disease from Lewy body dementia. The presence of extrapyramidal signs at the diagnosis of Alzheimer's disease is a reliable predictor of a more rapid decline.

Progressive supranuclear palsy is a neurodegenerative disorder which is frequently misdiagnosed as PD. The disease is characterized by an extrapyramidal syndrome associated with complex eye movement dysfunction. Tremor is infrequent and rigidity predominates at the spine. Posture and gait abnormalities are frequent at the early stage and lead to repeated falls, also favoured by attention and visual problems. Eye movement problems comprise the inability to shift the gaze downwards voluntarily, impaired saccades and difficulty in controlling the eyelids. Motor symptoms are unresponsive to L-dopa. As the disease progresses, changes in personality, dementia and swallowing problems are common. A typical pattern of MRI imaging has been described in progressive supranuclear palsy and relates to midbrain atrophy (Figure 63.1). Ocular electrophysiology also helps in recognizing supranuclear palsy and the disease.

Cerebrovascular diseases could also provoke extrapyramidal syndrome. This can be observed in patients with several brain infarctions, mainly a multilacunar status, in association with subcortical dementia and a pseudobulbar state. Posture and gait abnormalities are frequent and also swallowing problems. Tremor is infrequent and response to L-dopa is poor. The onset or the worsening of extrapyramidal signs within 1 month after a stroke strongly supports the diagnosis of cerebrovascular parkinsonism. Cerebral MRI documents vascular lesions of the brain as multiple lacunae and/or severe leukoaraiosis.

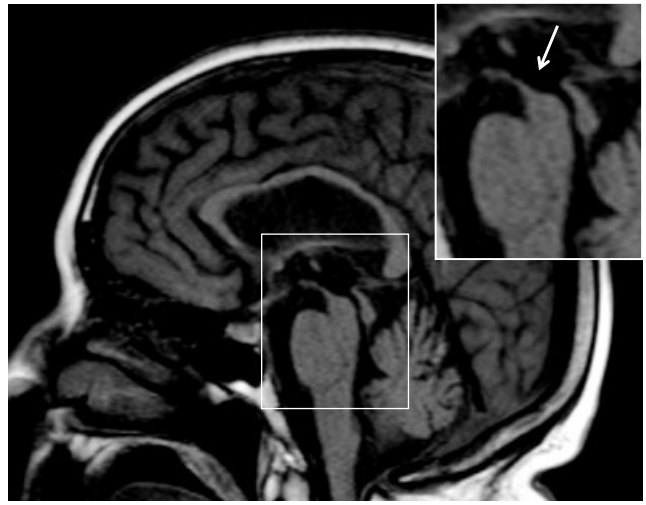

Figure 63.1 MRI showing convex aspect of the midbrain, indicating atrophy (arrow) typically observed in progressive supranuclear palsy (the normal midbrain aspect is concave).

Normal pressure hydrocephalus is a rare condition characterized by gait disturbance, dementia and urinary incontinence. Gait abnormalities could mimic those observed in PD with short steps, shuffling, slowness, stooped trunk and lower limb flexion, but there is no tremor or rigidity. Cerebral imaging shows marked enlargement of ventricles contrasting with the absence of cortical atrophy and small sulci and also periventricular high signals in the T2 sequence.

Other extrapyramidal syndromes are very infrequently observed in elderly people (Table 63.2).

To diagnose PD appropriately in an older individual, it is important to consider all other causes of parkinsonism and to examine whether criteria for PD are fulfilled (Table 63.3). In some cases, the diagnosis remains uncertain and follow-up usually clarifies it with the onset of new signs and symptoms.

Advanced Parkinson's disease

After 10–15 years of progression, PD is usually responsible for severe disability. Motor impairment could be major and alters several activities of daily living. Akinesia is often severe, whereas tremor and rigidity are less marked. The face is expressionless. Freezing problems are frequent. Posture and gait abnormalities are major and many patients experience repeated falls and fractures. Many patients are wheelchair bound. Patients often experience insomnia, pain, sweats, orthostatic hypotension, dysphagia, dysarthria, drooling of saliva, urinary

Table 63.3 Diagnosis criteria for Parkinson's disease of the Queen Square Brain Bank.

Step 1: Diagnosis of parkinsonian syndrome
- Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude or repetitive actions)

And at least one of the following:
- Muscular rigidity
- 4–6 Hz rest tremor

Postural instability not caused by primary visual, vestibular, cerebellar or proprioceptive dysfunction

Step 3: Supportive prospective positive criteria of Parkinson's disease

Three or more of the following required for diagnosis of definite Parkinson's disease:
- Rest tremor present
- Progressive disorder
- Persistent asymmetry affecting the side onset most
- Excellent response (70–100%) to L-dopa
- Severe L-dopa-induced chorea
- L-dopa response for 5 years or more
- Clinical course of 10 years or more
- Hyposmia
- Visual hallucination

Step 2: Exclusion criteria for Parkinson's disease
- History of repeated strokes with stepwise progression of parkinsonian features
- History of repeated head injury
- History of definite encephalitis
- Oculogyric crises
- Neuroleptic treatment at onset of symptoms
- More than one affected relative
- Sustained remission
- Strictly unilateral features after 3 years
- Supranuclear gaze palsy
- Cerebellar signs
- Early severe autonomic involvement
- Early severe dementia with disturbances of memory, language and praxis
- Babinski signs
- Presence of a cerebral tumour or communicating hydrocephalus on CT scan
- Negative response to large doses of L-dopa (if malabsorption excluded)
- MPTP exposure

dysfunction and cognitive/psychiatric disorders such as depression, anxiety, visual hallucinations and/or dementia. Fluctuations and motor dyskinesia are very frequent and remain a challenge for the treatment.

Management of Parkinson's disease in the elderly

Pharmacological treatment

L-Dopa is the main and often only treatment for PD in the elderly. L-Dopa is a precursor of dopamine that crosses the blood–brain barrier and is used in combination with a peripheral decarboxylase inhibitor to lessen its systemic effects. The drugs used are Madopar (L-dopa + benserazide) and Sinemet (carbidopa + L-dopa). L-Dopa is effective in tremor, bradykinesia and rigidity of PD.

L-Dopa exists in several forms, distinguished by their absorption rates. Standard L-dopa is usually given the drug within 3–4 times daily, preferably 30 min before meals. In the first years of PD, most patients are controlled with 300–600 mg per day. L-Dopa should be started at low doses which can be increased very gradually until the appropriate effect is obtained. The dispersible form (dispersible Madopar) achieves peak plasma concentrations faster and can be used in early morning akinesia, in order to achieve an effect more quickly. It allows the first dose of standard L-dopa to be taken at the same time. As the disease progresses, the dose of L-dopa should be progressively increased and adverse effects are frequent. The main side effects of L-dopa are nausea and vomiting, hypotension and psychiatric disorders (hallucinations, delusions, delirium). Sedation, nightmares, vivid dreams and hallucinations could also occur as dose-related side effects. After several years of use, motor fluctuations can occur with the on–off phenomenon. Fluctuations include a delayed effect of L-dopa and wearing off between the doses. In addition, involuntary movements such as chorea, athetosis and dystonia could occur. These complications lead to revision of the timing of L-dopa administration.

Several antiparkinsonian drugs are not used in the elderly. Direct *dopamine agonists* act directly on dopamine D2 receptors. They include apomorphine, piribedil, ropinirole, lisuride and pergolide mesylate. They can be used in young persons with PD in order to delay the introduction of L-dopa, but they are not used in older persons with PD. Adverse effects are numerous and could be severe. *Anticholinergic drugs* proposed in PD to improve tremor (e.g. trihexyphenidyl and tropatepine) are never used in older persons with PD. *Selegiline* and *rasagiline* are type B monoamine oxidase inhibitors which have been proposed for neuroprotective effects in early PD.

Catechol-O-methyl transferase inhibitors (COMT-I) (entacapone and tolcapone) decrease the degradation of dopamine in the brain and increase and prolong the effect of L-dopa. They are useful in older patients with motor fluctuations and/or L-dopa-induced dyskinesia. A single tablet combining L-dopa, carbidopa and entacapone has been marketed (Stalevo) with three doses of L-dopa/carbidopa (50/12.5, 100/25, 150/37.5 mg) and fixed-dose entacapone

Table 63.4 Methods for treating non-motor symptoms and complications in Parkinson's disease; each of them should be considered after adjusting L-dopa therapy.

Condition	Treatment
Nausea, vomiting	Domperidone
Depression, generalized anxiety disorder	Selective serotonin reuptake inhibitor, psychotherapy
Hallucinations, delusions	Clozapine, quetiapine
Dementia	Rivastigmine
Orthostatic hypotension	Midodrine, droxidopa, elastic venous compression
Insomnia	Sleep hygiene, clonazepam
Constipation	Fibre intake, hydration, osmotic laxatives (macrogol)
Drooling	If severe, botulinum toxin injections in salivary glands
Urinary urgency	Anticholinergic drugs with low penetration in brain

(200 mg per tablet). This association is so far indicated in patients with PD with motor fluctuations with end dose not stabilized by L-dopa–dopa decarboxylase inhibitor. Amantadine (200–400 mg per day) was shown to be effective in lessening peak-dose dyskinesia. The dose should be adjusted in patients with renal impairment and adverse effects such as delirium are frequent in old patients.

Some other drugs might also be useful in controlling non-motor symptoms or complications (Table 63.4).

Non-pharmacological treatments

Functional neurosurgery

Bilateral deep brain stimulation of the subthalamic nucleus or globus pallidus interna produces sustained improvement in motor function, especially for symptoms that respond to L-dopa therapy, and reduces drug-induced involuntary movements. This treatment is proposed to patients who are cognitively intact and with a severe disability related to motor complications refractory to best fit treatment. Severe comorbidities are also a limitation. Hence deep brain stimulation is not currently used in elderly people with PD. Adverse effects are related to the intracranial procedure and there are some concerns about long-term safety with risks of depression and suicide. Follow-up of stimulated patients has revealed that disability progresses with time, probably in relation to neurodegeneration.

Rehabilitation and help with loss of independence

Functional rehabilitation should be started early in the disease as it helps preserve motor function. Rehabilitation sessions should preferably be held at the time of the peak effect of L-dopa. It combines specific exercises intended to sustain the maintenance of joint flexibility, walking, lifting, posture and balance, turns and drills aimed at fighting against attitudes in flexion. Speech therapy is helpful in patients with dysarthria or drooling at a later stage, and trouble with swallowing.

Loss of independence implies that human help should be organized for activities of daily living at home. In most cases, loss of independence due to motor problems can be managed at home, but professional help, caregiver involvement, meals-on-wheels and other help may be necessary. PD is not a frequent cause of admission to geriatric institutions except when severe cognitive and behavioural complications occur. PD is a chronic disease that benefits from improved coverage by national health insurance in France and in other EU countries.

Psychological support and patient education

Psychological support and patients' and caregivers' education help increase acceptance and understanding of disease and treatment and could optimize the utilization of health resources. Association of patients and caregivers could also help.

Key points

- Parkinson's disease is the second most common neurodegenerative disease after Alzheimer's disease, but the exact cause remains undetermined.
- Symptoms include motor symptoms such as tremor, motion difficulties, falls and changes in gait and posture, and non-motor symptoms such as bradyphrenia, memory problems and dementia, constipation and bladder and autonomic dysfunction.
- Symptoms increase as the disease progresses.
- Parkinson's disease is responsible for severe disability after 10–15 years of progression.
- Management includes pharmacological treatment, especially with L-dopa, non-pharmacological treatment, such as functional neurosurgery, rehabilitation and help with loss of independence.

CHAPTER 64

Non-parkinsonian movement disorders

Katie Kompoliti and Cynthia L. Comella
Rush University Medical Center, Chicago, IL, USA

Introduction

Non-parkinsonian movement disorders that tend to affect primarily the elderly include chorea, restless legs and periodic leg movements during sleep and while awake, dystonia and tremor (Table 64.1).

Chorea

Chorea, derived from the Greek word for 'dance', is a continuous, random sequence of irregular, unpredictable movements that flit from one body part to another. A variety of choreatic disorders begin during childhood or early adulthood. Those that are important in the elderly include Huntington's disease (HD), senile chorea and tardive dyskinesia.

Huntington's disease

HD is an autosomal dominant neurodegenerative disorder characterized by abnormal involuntary movements, progressive dementia and psychiatric manifestations. In 1993, the specific mutation in HD was identified as an expansion of the unstable CAG trinucleotide repeat in the IT15 gene in chromosome 4p (Kremer *et al*., 1994; Hersch *et al*., 1994). Individuals with HD have more than 40 CAG repeats. There is an association of age of onset and number of repeats only in the very early and very late-onset HD (Andrew *et al*., 1993). Juvenile onset cases are associated with repeat lengths greater than 52 and paternal transmission. This preponderance of paternal transmission has been reported for cases with onset before age 21 and is due to CAG repeat length expansion during spermatogenesis (Hersch *et al*., 1994). Early onset is associated with the rigid type or Westphal variant of HD. In contrast, late-onset HD, defined as onset at age 50 or later, is associated with less than 42 repeats. Although it is believed that individuals with repeat lengths of 40 and 41 may not exhibit symptoms in their lifetime, it is unclear whether this is due to decreased penetrance among carriers with such lower repeat sizes or the mere fact that they did not live long enough. Approximately 1–2% of at-risk individuals screened for HD will have repeat lengths between 36 and 39. It is difficult to predict which of these individuals will develop symptoms of HD within a normal lifespan (Myers *et al*., 1998).

HD has a subtle, insidious onset in the third and fourth decades of life and gradually worsens over a course of 10–20 years until death. Clinically, the disease usually presents with an involuntary movement disorder characterized by chorea, dystonia, bradykinesia, incoordination and impaired postural reflexes. Oculomotor dysfunction is a frequent early sign and is characterized by slowed, delayed or inaccurate saccades. As HD advances, swallowing and speech may become impaired, eventually disrupting communication and leading to aspiration pneumonias. Intellectual decline or dementia is a uniform feature, although the severity of cognitive impairment varies among patients. Psychiatric features are also common and disabling, appearing as the presenting manifestation in up to one-third of HD patients (Biglan and Shoulson, 2002).

Approximately 25% of persons affected by the disease exhibit initial signs of chorea at age 50 or later, and half of these will not come to medical attention until after age 60. The clinical features of late-onset HD resemble those of midlife onset but the illness is more slowly progressive and less functionally debilitating. In late-onset disease, symptoms may appear to plateau or progress very slowly over several years. The most common symptoms in a series of 25 late-onset cases were mild to moderate chorea and cognitive impairment (100% of cases), dysarthria (88%) and gait disturbance (72%) (Myers *et al*., 1985). The chorea in late-onset HD often allows the patient to stay at home,

This chapter is as in the previous edition, with a list of more recent important references provided and annotated by Professor Alan Sinclair.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 64.1 Definition of movement disorders.

Disorder	Definition
Tremor	Rhythmic oscillation typically about a joint, alternating or simultaneous co-contraction of agonist and antagonist muscle groups
Chorea	Irregular, non-stereotypical quick jerks, randomly distributed
Dystonia	Sustained abnormal postures, often with a twisting character, sometimes overlying repetitive jerks

with minimal nursing support, to remain ambulatory and to maintain activities of daily living for many years.

Pathology and pharmacology

Histological studies of HD have demonstrated diffuse brain atrophy with severe neuronal loss and gliosis occurring selectively in the caudate nucleus and putamen. This neuronal loss in the striatum is largely confined to the GABAergic medium-sized spiny neurons that project to the globus pallidus, and which receive glutamergic input from the cortex and dopaminergic input from the substantia nigra. The severity of neuropathological changes was found to be closely related to the age at onset of the illness. An earlier clinical onset is associated with more severe neuropathological involvement, while older onset cases show a slower rate of progression of neuropathological changes (Myers *et al*., 1988).

The exact mechanisms that lead to the selective neuronal loss in HD are poorly understood. Hypotheses include glutamergic excitotoxicity, mitochondrial bioenergetic dysfunction, apoptosis and transcriptional dysregulation (Biglan and Shoulson, 2002). Huntingtin, the mutant protein product of CAG expansion, undergoes abnormal cleavage in the cytoplasm, resulting in the translocation of the N-terminal fragment in the nucleus and the formation of aggregates in the nucleus. It has been hypothesized that this altered cleavage and subsequent nuclear translocation represent key steps in the pathogenic cascade leading to neuronal dysfunction and cell death (Saudou *et al*., 1998).

Treatment

Currently, there is no effective treatment to slow or reverse the inexorable progression of HD. Neuroprotective strategies have been explored, including coenzyme Q10, remacemide, minocycline, creatine and Huntington's disease advocacy centre (HDAC), but none of these agents has been proven to alter the natural history of the disease, under the specific experimental conditions studied (Biglan and Shoulson, 2002). There are, however, several approaches to control the symptoms. Unfortunately, HD research has had a tendency to concentrate on the motor aspects of the disorder, whereas the major problems are behavioural (e.g. dementia, depression, psychosis) and the chorea is often the least relevant in terms of management. Chorea improves with the use of dopamine receptor-blocking agents (e.g. neuroleptics) or dopamine-depleting agents (e.g. reserpine or tetrabenazine). The newer, atypical neuroleptics, especially olanzapine, have become the drugs of choice, when treatment of chorea is needed (Bonelli *et al*., 2002; Jimenez-Jimenez *et al*., 2002; Paleacu *et al*., 2002). More recently, amantadine, an *N*-methyl-D-aspartate (NMDA) antagonist, has been found to be effective in treating chorea in patients with HD (Verhagen Metman *et al*., 2002). Management of the associated psychiatric disorders with the appropriate administration of psychotropic drugs should also be considered. Depression is managed with selective serotonin reuptake inhibitors (SSRIs) and mirtazapine, and psychosis and behavioural issues are addressed with atypical antipsychotics (Bonelli *et al*., 2004). Dementia is unfortunately the most disabling facet of this disorder and is untreatable. In fact, the most effective approach to HD available today is genetic counselling.

Spontaneous oral dyskinesia and senile chorea

Clinical features

Gowers, at the end of the nineteenth century, described an isolated form of chorea of late life as an entity separate from HD and neuroleptic use (Critchley, 1931). Isolated spontaneous oral dyskinesia (SOD) in the elderly is a clearly defined and fairly common syndrome but is more often recognized as part of other neurological syndromes such as tardive dyskinesia, Huntington's chorea, acquired hepatocerebral degeneration and complication of prolonged levodopa therapy in Parkinson's disease (PD). In some patients, the occurrence of SOD is associated with the edentulous state and the improvement with appropriate dental appliances suggests that the absence of teeth in some individuals causes or makes the clinical syndrome worse (Sutcher *et al*., 1971). In one study, observation was carried out on 1018 non-institutionalized, frail elderly subjects attending day care centres to document the prevalence of SODs. A total of 38 subjects were suspected to have SODs for a prevalence rate of 3.7% and 31 had probable tardive dyskinesia, for a prevalence rate of 3.0%. In a survey covering medical and dental issues in the same population, subjects with suspected SOD reported more frequent ill-fitting dental devices, oral pain and a lower rate of perception of good oral health compared with non-dyskinetics. Individuals with suspected SOD typically presented with mild stereotyped masticatory or labial movements compared with the more complex phenomenology of probable TD (tardive dyskinesia) cases (Blanchet *et al*., 2004).

Pathology and pathophysiology

Recent developments in molecular genetics have provided a reliable test for confirmation of the diagnosis of HD that is highly sensitive and specific. Shinotoh *et al*. (1994) measured CAG trinucleotide repeat expansion in the Huntington's gene in four cases of senile chorea, and found that CAG repetition lengths were normal. They considered this evidence that senile chorea exists as a distinct clinical entity that is nosologically separate from HD.

There is a paucity of pathological reports of senile chorea in the literature. Neuropathological cases of senile chorea reported in the past were before the advent of genetic testing for HD and it is possible that many of them represented mild cases of HD and no cognitive changes.

Treatment

Chorea can be ameliorated with neuroleptic agents. Neuroleptic agents should be initiated at low doses and slowly titrated upward to optimal symptom control. Neuroleptic use in this age group is associated with a higher incidence of TD and drug-induced parkinsonism (see Chapter 63, Parkinson's disease). Thus, the use of newer atypical neuroleptics is preferable. Although the atypical neuroleptics have been advocated to carry a much smaller risk of drug-induced parkinsonism or TD, this has not been the case with some of them. Therefore, physicians should be vigilant for the development of these complications. Amantadine is useful in ameliorating chorea, but it is excreted unchanged in the urine and it can become toxic in elderly people with decreased renal function. Anticholinergic agents and dopamine agonists tend to worsen these movements and should be avoided. Treatment of either senile chorea or SODs is indicated only if the movements are severe enough to cause functional impairment. In edentulous patients, well-fitting dentures may improve the symptoms.

Tardive dyskinesia

TD is defined as abnormal involuntary movements associated with chronic treatment with dopamine receptor-blocking agents. Neuroleptics are the most frequently implicated drugs, although other agents, for example, metoclopramide, have also been associated with the development of TD (Khot *et al*., 1992). The diagnosis of TD requires (1) history of at least 3 months total cumulative (continuous or discontinuous) neuroleptic exposure; (2) the presence of at least 'moderate' abnormal involuntary movements in one or more body areas or at least 'mild' movements in two or more body areas; (3) absence of other causes for the movements (Task Force on late Neurological effects of antipsychotic drugs, 1980). Since the earlier reports of TD, a variety of involuntary movements, in addition to the well known oral–buccal–lingual masticatory movements, have been described, including dystonia, akathisia, tics and myoclonus (Burke, 1992). It has been suggested that the newer, atypical neuroleptics (risperidone, olanzapine, quetiapine, ziprasodone, clozapine) are less likely to cause TD (Jeste, 2004; Dolder and Jeste, 2003). Clozapine and quetiapine are the ones associated with the lowest risk (Tarsy *et al*., 2002).

The typical movements of TD are choreic in speed and amplitude, but usually tend to be more stereotypic and repetitive and less random or unpredictable than chorea of other a etiologies. The orofacial and lingual muscles tend to be involved earlier and more frequently in TD. The disorder is usually only slowly progressive after initial development, and in many patients, especially the elderly, it does not appear to progress at all and may actually gradually improve with age.

Possible risk factors for TD include advanced age, female gender, affective disorder, mental retardation, brain damage, length of neuroleptic exposure, use of anticholinergic drugs, history of acute extrapyramidal side effects, antidepressant drugs, depot neuroleptics, history of drug interruptions or holidays, elevated serum neuroleptic concentrations and late-onset psychosis (Lohr and Bracha, 1988).

Studies evaluating the prevalence and risk factors for TD have been largely confounded by vague diagnostic criteria, biased study samples, lack of matched control populations and concurrent neuroleptic use, which can mask TD. Overall, most studies suggest that the average prevalence of TD is estimated as 15–20% (Khot *et al*., 1992). In one series, 45% of patients had relatively persistent symptoms over the course of 5 years, while 24% had a fluctuating course. Only 11% improved, while 7% got worse. Remissions usually appear within 1–2 years after discontinuation of medication, although they may not occur until 5 years after discontinuation of medication (Bergen *et al*., 1989).

Pathology and pathophysiology

No characteristic pathological abnormalities have been found in TD. The pathophysiology is not clearly understood. The development of dopamine receptor supersensitivity following chronic dopamine receptor blockade is hypothesized to be the mechanism underlying TD. This would explain why, as the neuroleptic agents are withdrawn and receptor blockade reduced, TD may appear for the first time, or pre-existing TD may worsen. Furthermore, exacerbation of the movements by dopaminergic agonists and improvement with increased dopamine receptor blockade or dopamine depletion support the notion that alterations in dopamine receptors are likely to be involved. As a result of the deficiencies in the dopamine supersensitivity hypothesis, attention has also been focused on other neurotransmitters, such as GABA, norepinephrine, acetylcholine and serotonin (Khot *et al*., 1992).

Treatment

Once it occurs, TD is frequently difficult to treat. Therefore, only individuals with defined indications for the use of these agents should be treated, especially among the elderly, who appear to be at a higher risk for developing TD. Although it is not proven, the neuroleptic dose should be maintained at the lowest possible and the drug should be used for the shortest period of time allowed by the patient's psychiatric disease. If the patient's psychiatric disorder is sufficiently severe to require long-term neuroleptic use, an atypical neuroleptic should be considered.

Several medications have been used in the treatment of persistent TD with variable response. These include dopamine depleters (reserpine or tetrabenazine), noradrenergic antagonists (propranolol, clonidine), γ-aminobutyric acid (GABA) agonists (clonazepam, diazepam, valproate, baclofen), botulinum toxin injections and, to a lesser degree, vitamin E, buspirone and calcium channel blockers, which have been used with variable results (Miyasaki and Lang, 1995). When the predominant movement is chorea, anticholinergic agents may worsen the movements; if, on the other hand, dystonia is the primary characteristic, these agents can be beneficial.

Restless Legs Syndrome and Periodic Limb Movements During Sleep and While Awake

Restless legs syndrome (RLS) is a sensorimotor disorder characterized primarily by motor restlessness, which is brought on by rest and accentuated later in the day and during the early night in those with normal circadian rhythms. The urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching. The prevalence of RLS is estimated to be 10–15% in the general population. Symptoms often begin before age 20, but usually become severe enough to seek medical attention in the fourth decade (Walters *et al*., 1996). Periodic limb movement disorder (PLMD) is frequently associated with RLS but may occur independently, especially in the elderly. The prevalence of PLMD increases with advancing age. RLS and PLMD, taken together, are the primary diagnosis in 13.3% of patients complaining of insomnia (see Chapter 54, Sleep apnoea and sleep disorders) and in 6.9% of patients complaining of excessive daytime sleepiness (Montplaisir and Godbout, 1989).

RLS and PLMD have been related to several other medical conditions, including peripheral neuropathy, iron deficiency anaemia and end-stage renal disease (Garcia-Borreguero *et al*., 2004). Selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants and monoamine oxidase inhibitors can induce or aggravate PLMD, as does withdrawal from anticonvulsants, benzodiazepines and barbiturates. Exacerbations of RLS can occur during pregnancy or with iron deficiency anaemia. Finally, PLMD may accompany other sleep disorders, in particular, sleep apnoea or narcolepsy (Montplaisir and Godbout, 1989).

RLS can be diagnosed by the following four clinical criteria: (1) an urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs; (2) the urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting; (3) the urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching; (4) the urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night (Hening *et al*., 2004). Supportive clinical features include a positive family history, positive response to dopaminergic therapy and the presence of periodic limb movements (during wakefulness or sleep) (Hening *et al*., 2004). Family history of RLS can be found in 40–90% of patients with RLS (Montplaisir *et al*., 1997; Winkelmann *et al*., 2000). PLMD occurs in 80% of patients with RLS. The severity of RLS can vary greatly throughout a patient's lifetime but the disease is typically chronic and the course progressive. The sudden remissions, lasting for months or even years, are as difficult to explain as are the relapses, which appear without any apparent reason.

Periodic limb movements of sleep (PLMS), originally called *nocturnal myoclonus*, are best described as rhythmic extensions of the big toe and dorsiflexions of the ankle, sometimes with flexions of the knee and hip, each movement lasting 0.5–5.0 s and occurring every 20–40 s. Standard criteria for PLMS include their occurrence in a series of four or more movements spaced by intervals of 5–90 s (onset to onset) with electromyogram (EMG) burst durations of 0.5–5 s that rise to 1/4 of the EMG biocalibration amplitude (Hening *et al*., 2004). Intense movements may cause numerous arousals, leading to non-restorative sleep. PLMS may be asymptomatic, diagnosed through a bed partner's report or polysomnogram. PLMS occur primarily in stage 2, non-REM (rapid eye movement) sleep, less often in stages 3 and 4, and infrequently during REM sleep.

Fifty percent of patients with RLS have abnormal involuntary movements while awake, called *periodic leg movements during wake* (PLMW), formerly called *dyskinesias while awake*. Like the PLMS, PLMW are discrete, repetitive, stereotyped movements that recur at intervals of seconds, tend to involve primarily the legs and occur almost exclusively at rest and disappear with action. PLMW are longer compared with the leg movements during sleep (shorter than 10 s during wakefulness vs 5 s during sleep).

Differential diagnosis of RLS and PLMS should include hypnic myoclonus, fragmentary myoclonus, painful legs and moving toes syndrome, nocturnal cramps, body

jerks induced by long-term administration of levodopa or akathisia. The symptoms of akathisia are prominent throughout the waking hours of the day or night, whereas the symptoms of RLS are more prominent at night. Akathisia patients manifest the external signs of an inner urge to move, whereas patients with RLS move about to relieve the dysesthetic sensations they have in their legs.

Although our understanding of the pathophysiology and genetics of RLS has advanced considerably, there is currently no recognized objective test for the disorder. Standard sleep measures remain useful in terms of sleep initiation, continuity and sufficiency. These are often combined with measures of PLMS. Recently, the suggested immobilization test (SIT) has been proposed as a possible auxiliary measure, examining the ability of a period of imposed rest to induce subjective and motoric features of RLS. A combination of the SIT conducted in the evening with measurement of sensory discomfort and the presence of frequent PLM during awake epochs of the standard polysomnography (PSG) can provide a high degree of diagnostic accuracy (sensitivity of 82% and specificity of 100%) (Hening *et al*., 2004).

Pathophysiology and pharmacology

Several lines of evidence suggest that RLS results from dysfunction of the central rather than the peripheral nervous system. RLS improves with centrally acting dopamine agonists, and this effect can be antagonized only by centrally acting and not peripherally acting dopamine antagonists (Garcia-Borreguero *et al*., 2004). Nevertheless, the spinal cord may also be involved in the generation of PLM as they have been observed in patients with spinal cord lesions. However, treatment with dopamine agonists produces only mild improvement in the symptoms of these patients, compared with the marked response in patients with RLS (de Mello *et al*., 1996).

Neurophysiological studies, including reflex studies and studies on cortical activity, have failed to elucidate the a etiology of this syndrome. There is evidence though, obtained from functional magnetic resonance imaging (MRI), pointing towards a subcortical site as a location for the dysfunction (Bucher *et al*., 1997). It is possible that the disease arises as a result of subcortical dysfunction with state-dependent reduced spinal and cortical inhibition. In addition, the periodic nature of the PLMS reflects the disinhibition of intrinsic spinal periodic generators (Garcia-Borreguero *et al*., 2004). Functional imaging with positron emission tomography (PET) and single-photon emission computed tomography (SPECT) have only found a modest decrease for the dopamine D2 receptor. Iron deficiency may be associated with RLS, particularly for patients with onset at a later age and family history. Decreased midbrain iron despite normal serum iron has also been demonstrated in RLS. RLS severity correlates with serum ferritin levels and oral administration of iron seems to improve RLS symptoms, especially if pretreatment ferritin levels are lower than 45 $\mu g\,l^{-1}$ (O'Keeffe *et al*., 1993; Sun *et al*., 1998). Several steps in dopaminergic pathways require normal iron levels; therefore, iron deficiency would be expected to result in dopaminergic dysfunction.

Treatment

At present, dopamine receptor agonists are the treatment of choice for RLS, particularly if daily treatment is needed or the condition is severe. This is mainly due to their longer elimination half-life, which results in less long-term complications. Several dopamine agonists have been studied under controlled conditions, showing efficacy for the treatment of the symptoms of RLS. Interestingly, cabergoline, the dopamine agonist with the longest half-life, is the only one to which no cases of augmentation have been linked so far (Garcia-Borreguero *et al*., 2004).

L-Dopa at a daily dose of 50–250 mg, in conjunction with a decarboxylase inhibitor, given as a single dose before bedtime, has been proven to be effective in producing subjective improvement of symptoms and sleep quality, shortening of sleep latency and a reduction in PLMS (Collado-Seidel *et al*., 1999). Yet, in the course of long-term treatment with L-dopa, rebound and augmentation appear. Rebound refers to the reappearance of symptoms at a time coinciding with the end of the half-life period of the drug, usually early in the morning. Augmentation reflects the occurrence of RLS symptoms earlier in the day, an overall increase in symptom severity as a result of long-term dopaminergic treatment. Augmentation frequently represents a serious problem in treating patients with RLS.

Opioids have been found to be effective in treating RLS/PLMS in a subgroup of patients and they are considered second-choice options. The required doses found to be effective are relatively high, often at the higher end of the analgesic range. Although opioids can be useful in a subpopulation of patients, the risk for abuse and the addictive potential of these compounds limit their clinical use.

Anticonvulsants such as gabapentin have been found to exert therapeutic effects. Gabapentin is particularly effective for cases associated with pain or dysaesthesia (Happe *et al*., 2001). Benzodiazepines, such as clonazepam, can be useful in ameliorating some of the symptoms of RLS, but their effects might be mediated by sleep induction rather than direct suppression of RLS symptoms.

In addition to symptomatic medication, it is important to ascertain that the body iron stores are adequate. Oral administration of iron is recommended if serum ferritin levels are lower than 45–50 $\mu g\,l^{-1}$ (O'Keeffe *et al*., 1993).

Dystonia

Dystonia is defined as a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements, or abnormal postures (Fahn, 1990). Dystonia is classified in three ways: by body distribution of the abnormal movements, by a etiology, and by age at onset (Table 64.2). Focal dystonia refers to the involvement of a single body area, segmental to the involvement of contiguous body areas, multifocal to the involvement of noncontiguous body areas, hemidystonia to the involvement of one arm and one leg on the same side and generalized to the involvement of one leg and trunk or two legs and an additional body area (Table 64.3). The a etiological classification divides the causes of dystonia into two major categories: idiopathic (or primary) and symptomatic (or secondary). The idiopathic group is further subdivided into familial and non-familial (sporadic) patterns.

Table 64.2 Classification of dystonia.

By age at onset
Childhood onset, 0–12 years
Adolescent onset, 13–20 years
Adult onset, >20 years
By cause
Idiopathic

Generalized
Hemidystonia

Table 64.3 Classification of dystonia according to distribution.

Focal dystonia: single body part
Blepharospasm: eyelids
Oromandibular dystonia: mouth
Spasmodic dysphonia: larynx
Torticollis: neck
Writer's cramp: arm
Segmental dystonia: two or more contiguous body parts
Meige syndrome: eyes and mouth
Generalized dystonia: one leg and trunk or both legs and another body part
Childhood-onset hereditary torsion dystonia
Multifocal dystonia: two or more noncontiguous body parts
Hemidystonia: ipsilateral arm and leg

Dystonia beginning in childhood usually starts in the legs and progresses to become generalized or multifocal. Early-onset primary torsion dystonia usually starts around age nine and has a genetic background in the great majority of cases. Approximately 80–90% of Ashkenazi Jewish children and 50% of non-Jewish children test positive for the DYT1 defect. The remaining cases are either non-genetic or belong to less common (e.g. DYT6, DYT13) or still unknown genetic causes of dystonia (Ozelius *et al*., 1997). In contrast, adult-onset dystonia is usually sporadic. The onset of dystonic symptoms is usually gradual, with slow progression over the first 5–10 years. Although the dystonia may slowly worsen or spread to an adjacent body area, it seldom generalizes in the adult. Up to 33% of dystonic patients may experience a partial or complete remission, but this is rarely permanent (Greene *et al*., 1995).

The most frequent primary focal dystonia seen in a movement disorder clinic is spasmodic torticollis or cervical dystonia (CD). CD is a focal dystonia affecting the muscles of the neck and upper torso. Depending on the specific pattern of muscles involved, it can produce turning of the head (torticollis), tilting of the head towards the shoulder (laterocollis) and flexion (antecollis) or extension (retrocollis) of the head (Bressman and Greene, 2000).

The second most frequent dystonic syndrome seen in the adult is blepharospasm. Blepharospasm is manifested by increased blinking, clonic eye closure or sustained, tonic eye closure. In some patients, reading, driving or watching a movie may be impossible. The severity of the spasms can be such that can render the patient functionally blind. The association of blepharospasm with lower facial or oromandibular dystonia is referred to as Meige's or Bruegel's syndrome. Oromandibular dystonia involves the muscles of facial expression or the masticatory and other oral muscles. Clinically, patients have involuntary grimacing, puckering, frowning, jaw opening or closing, tongue protrusions and a variety of other movements that may be exacerbated by the use of the muscles. In addition to social embarrassment, it may impair speaking, eating and drinking.

Spasmodic dysphonia is a focal dystonia of the laryngeal muscles resulting in either a strained and choked or quiet and breathy voice, depending on the dystonic position of the vocal cords (adductor or abductor, respectively). Limb dystonia can affect either the upper or lower extremity, and is usually task-specific. The most common form is writer's cramp.

Pathology and pathophysiology

Pathological studies have been carried out on patients with primary torsion dystonia and there are no consistent pathological abnormalities identified by light microscopy (Gibb *et al*., 1988). Studies in symptomatic hemidystonia show lesions of the putamen, the thalamus and the connections of

the basal ganglia with the thalamus and the cortex (Marsden *et al*., 1985). Although autopsy studies have shown variable changes in norepinephrine, there have been no consistent neurochemical changes described in idiopathic dystonia. The lack of sufficient brain specimens has hindered further pathologic studies.

PET using fluorodeoxyglucose (FDG) in 11 patients with unilateral dystonia compared with 11 age-matched controls showed a relative metabolic overactivity of the lentiform nucleus and premotor cortices (Eidelberg *et al*., 1995). Pathophysiological, mechanisms have been suggested by electrophysiological studies. Electomyography shows prolonged co-contracting bursts of activity in agonist and antagonist muscles and frequent spread of activity to distal muscles not normally used in a particular movement. These abnormalities can be explained by a loss of inhibitory control at the segmental (spinal cord, brainstem) or cortical level (Berardelli *et al*., 1998).

The DYT1 gene encodes for a protein, torsin A. In normal adult brain, torsin A is widely distributed, with intense expression in the substantia nigra compacta, cerebellar dentate nucleus, Purkinje cells, basis pontis, locus ceruleus, numerous thalamic nuclei, the pedunculopontine nucleus, the oculomotor nuclei, the hippocampal formation and the frontal cortex. Although the exact function of torsin A remains elusive, speculation on the mechanism the mutant torsin A compromises cellular function includes disrupted processing of normal torsin A or other proteins, interference with membrane trafficking and formation of cytoplasmic inclusions (Walker *et al*., 2002).

Treatment

Treatment of dystonia has had limited success. Pharmacological treatment of dystonia is largely based on empirical, rather than scientific rationale. Anticholinergic medications, such as trihexyphenidyl, have been found to be of benefit in 67% of patients with idiopathic dystonia studied, mean age 18.6 years (Greene *et al*., 1988). In the elderly, the side effects from anticholinergics are frequent and often dose-limiting. These include sedation, mental clouding, dry eyes and mouth, blurred vision, urinary retention and constipation. Other agents reported anecdotally to be of benefit include baclofen, tizanidine, clonazepam, tetrabenazine, reserpine, tegretol, lithium and bromocriptine. Although dopamine receptor-blocking agents have been used, the risk of TD has traditionally precluded routine administration of these agents. The newer, atypical neuroleptics, which carry less of a risk for tardive syndromes, can be an alternative approach. Patients with dopa-responsive dystonia manifested as childhood-onset dystonia with diurnal fluctuations and associated parkinsonism may respond dramatically to low doses of levodopa (Nutt and Nygaard, 2001).

The introduction of botulinum toxin into clinical practice in the late 1980s revolutionized treatment of focal dystonia. Botulinum toxin, when injected locally, blocks acetylcholine release at the neuromuscular junction and, therefore, weakens the muscle. It has been successfully used in the treatment of most forms of focal or segmental dystonia (Comella and Pullman, 2004; Goldman and Comella, 2003), although it does not provide any permanent benefit or change in prognosis.

When drugs are ineffective or have shortcomings, surgical approaches can be considered. The procedure of choice currently is deep brain stimulation (DBS) of the internal segment of the globus pallidum (GPi). Bilateral pallidal lesions can be associated with significant adverse effects including speech difficulties and cognitive disturbances. It is for this reason that neurosurgeons have sought to develop surgical procedures that offer the efficacy of selective pallidal lesions but have a better index of safety. With the introduction of DBS to treat first chronic pain and then PD, it became logical to apply DBS to treat dystonia. There is now increasing experience in the use of DBS to treat various forms of dystonia. The initial results suggest that certain primary dystonias can show a strong improvement with GPi DBS (Lozano and Abosch, 2004).

Tremor

Tremor is a rhythmic, oscillatory movement produced by alternating or synchronous contractions of antagonistic muscles. Tremor is considered the most common movement disorder. Tremors can be classified according to their phenomenology, distribution, frequency or a etiology. Phenomenologically, tremors are categorized as rest, postural, and kinetic tremors (Lang *et al*., 1992) (Table 64.4). Rest tremor is defined as tremor occurring when the affected body part is in complete repose. The classic example of a rest tremor is found in PD. Postural tremor is defined as tremor occurring during maintenance of an antigravity posture. Essential tremor (ET) is the prototype. ET is primarily a postural tremor, although it may be present to a lesser degree during movement, particularly when the

Table 64.4 Tremor classification.

Tremor type	Description	Associated disorder
Rest tremor	Large amplitude; 4–6 Hz	Parkinsonism rubral tremor
Postural tremor	Amplitude varies; 6–12 Hz	Essential tremor
Kinetic tremor	Large amplitude; 3–4 Hz	Cerebellar tremor

movement involves postural adjustments. ET is familial in approximately half of the patients, with an autosomal dominant inheritance pattern. Some studies have suggested that there is an association between ET and dystonia, and between ET and parkinsonism. On the basis of an analysis of 678 patients diagnosed as ET, 6.1% were found to have concomitant PD and 6.9% had coexisting dystonia (Koller *et al*., 1994).

ET is more common in the upper extremities, although legs, head, trunk, face and vocal cords may be affected. Although sometimes referred to as benign, the symptoms result in major disability in up to 15% of those afflicted, with 3% of patients being completely disabled. Over time, it tends to progress slowly with long periods of stable symptoms intervening. Alcohol suppresses the tremor for a few hours in 30–60% of patients (Boecker *et al*., 1996).

Kinetic tremor is seen with voluntary movement, during the initiation (initial tremor) the course of the movement (dynamic tremor) and as the affected part approaches a target. Clinical–anatomical correlations indicate that kinetic tremor is usually associated with lesions of the cerebellum or the cerebellar outflow pathways. Lesions of the cerebellar hemispheres or upper brainstem may cause kinetic tremors with a frequency ranging from 5 to 7 Hz. Caudal brainstem lesions may cause faster tremors, ranging from 8 to 12 Hz (Cole *et al*., 1988).

Task- or position-specific tremors occur either during a specific task, for example, writer's tremor, or while maintaining a position, for example, orthostatic tremor. In 1984, Heilman described a tremor occurring after a few seconds of standing, which would progressively increase unless the patient began to walk, at which time the tremor ceased and the gait was normal (Heilman, 1984). Usually, patients with orthostatic tremor have normal clinical examination except for wide base standing and unsteadiness, which disappear when walking. Arm tremor resembling ET is found present in one-third of cases. Electrophysiological exploration is necessary for diagnosis and shows a regular rapid tremor (frequency around 16 Hz) in the weight-bearing muscles (Sander *et al*., 1998; Mastain *et al*., 1998). Orthostatic tremor cannot be considered as a clinical variant of postural essential tremor. Its pathophysiology is unknown, but the efficacy of clonazepam, primidone barbiturates suggests the impairment of the gabaergic system.

Tremor is widely experienced in neurologically intact individuals undergoing intense anxiety or stress, with the use of drugs (Table 64.5), and with other metabolic derangements. Non-pathological tremor has a low amplitude and a high frequency (Marsden, 1984).

Table 64.5 Non-parkinsonian movement disorders associated with selected drugs.

Disorder	Drug
Tremor	Amphetamines
	Bronchodilators
	Sympathomimetics
	Lithium
	Tricyclic antidepressants
	Selective serotonin reuptake inhibitors
	Valproic acid

	Anticonvulsants
Dystonia	Neuroleptics (acute and tardive)
	Metoclopramide (aute and tardive)
	Levodopa
	Dopamine agonists
	Chloroquine
Tics	Neuroleptics (tardive)
	Metoclopramide (tardive)
	Cocaine
	Amphetamines
	Lamotrigine

Pathophysiology and pharmacology

The mechanism underlying ET is not known. It has been hypothesized that the tremor arises from abnormal spontaneous firing of the inferior olivary nucleus, which drives the cerebellum and its outflow pathways via thalamus to the cerebral cortex and then to the spinal cord. The involvement of the olivo–cerebellar–thalamo–cortical circuitry in ET is supported by changes in the cerebellar blood flow as measured by PET. Using a higher-resolution camera, the investigators were additionally able to demonstrate bilateral midbrain activation in the region of the red nuclei during tremor, without change in the activity of the inferior olive (Wills *et al*., 1995).

The neurochemical abnormality underlying ET may relate to the adrenergic system. This is based on clinical observations of improvement in tremor using β-adrenergic antagonists and tremor induction when using β-adrenergic antagonists (Koller *et al*., 2000a).

Treatment

Treatment of ET is indicated if the symptoms are sufficiently severe to interfere with daily activities or threaten job security. Propanolol is considered the treatment of choice. It is started at a low dose and is gradually increased until clinical benefit, side effects, or a maximal dose of 320 mg

is reached. β-Blockers are contraindicated in patients with broncho-constrictive disorders, peripheral vascular disease and congestive heart failure, and relatively contraindicated in diabetes mellitus. If propanolol is ineffective or contraindicated, primidone may provide symptomatic relief. The starting dose is 25–50 mg once daily with a slowly increasing dose schedule until clinical benefit or side effects occur. The major drawback of primidone is the occurrence of sedation, although small increments in the dose may avoid this side effect. Other drug alternatives include clonazepam, methazolamide, flunarizine, nimodipine and gabapentin. All these have been tried in small numbers of patients with variable results.

Surgical treatment for ET has been used since the early 1950s. The optimal target has been determined to be the ventralis intermedius (VIM) nucleus of the thalamus. Thalamotomy improves contralateral tremor in more than 90% of patients. Long-term studies of thalamotomy indicate that the benefits continue in most patients. Persistent morbidity associated with thalamotomy, which occurs in less than 10% of patients, includes dysarthria, dysequilibrium, weakness and cognitive impairment. Bilateral thalamotomy is associated with substantial morbidity and is usually avoided. Chronic stimulation of the VIM is a safe and effective alternative to thalamotomy. Adverse effects of chronic stimulation include paresthesia, dysarthria, dysequilibrium and localized pain. DBS of the VIM nucleus of the thalamus appears to be safer than thalamotomy and is now the recommended procedure of choice (Koller *et al*., 2000b; Koller *et al*., 2001; Pahwa *et al*., 2000).

Key points

- Chorea in the elderly is a clearly defined and fairly common syndrome but is more often recognized as part of other neurological syndromes such as tardive dyskinesia, Huntington's chorea, acquired hepatocerebral degeneration and complication of prolonged levodopa therapy in PD.
- The clinical features of late-onset HD resemble those of midlife onset, but the illness is more slowly progressive and less functionally debilitating.
- TD is frequently difficult to treat, therefore only individuals with defined indications for the use of these agents should be treated, especially among the elderly, who appear to be at a higher risk for developing TD, and atypical neuroleptics should be the agents of choice.
- RLS is a sensorimotor disorder characterized primarily by motor restlessness, which is brought on by rest and relieved by movement, such as walking or stretching. PLMD is frequently associated with RLS but may occur independently, especially in the elderly. Both RLS and PLMD are treated with dopaminergic agents.
- Dystonia in the elderly appears mostly as focal or segmental dystonia and not generalized. It can be treated with botulinum toxin injections or medications.
- Tremor is a frequent occurrence in the elderly and can be seen as rest tremor, in PD, postural and kinetic tremor, in ET and as a side effect of medications, intention tremor in situations associated with cerebellar lesions, and task or position-specific tremor, in dystonia.

CHAPTER 65

Diabetic neuropathy

Aaron I. Vinik[1] and Elsa S. Strotmeyer[2]

[1]Eastern Virginia Medical School, Norfolk, VA, USA
[2]University of Pittsburgh, Pittsburgh, PA, USA

Introduction

Diabetic neuropathies (DNs) encompass a wide range of nerve abnormalities and prevalence rates reported are between 5 and 100%, depending on diagnostic criteria used.[1–3] DNs affect both peripheral and autonomic nervous systems and cause considerable morbidity and mortality in both type I and type II diabetic patients. DNs account for more hospitalizations than all other diabetic complications combined and are responsible for 50–75% of non-traumatic amputations.[4,5] In older adults who have diabetes, peripheral neuropathies (PNs) are especially troublesome because of their detrimental effects on stability, sensorimotor function, gait and activities of daily living (ADLs).[6–8] The incidence of distal symmetric neuropathy rises dramatically with increasing age after 65 years in both diabetic and non-diabetic men and women, with a higher incidence among older adults with diabetes (32.2, 95% CI 21.7–42.7 versus 5.8, 95% CI 4.3–7.8, per 1000 person-years).[9] Diabetes accounted for 39% of prevalent and 49% of incident cases of neuropathy in older adults,[9] emphasizing diabetes as a critical although not sole risk factor. In the USA for 1999–2000, 28% of adults aged 70–79 years and 35% of adults aged >80 years had PN, based on a simple screen for reduced sensation at the foot.[10] In this chapter, we present and discuss the most recent approaches to the treatment of the common forms of diabetic neuropathy, including symmetric, focal and diffuse neuropathies (Box 65.1, Figure 65.1). We also provide the reader with algorithms for the recognition and management of common pain and entrapment syndromes and a global approach to the recognition of syndromes requiring specialized treatments based upon our improved understanding of their aetiopathogenesis. A comprehensive evaluation of autonomic neuropathy is beyond the scope of this chapter, but the reader is referred to two excellent reviews on this topic.[11,12].

Pathogenic mechanisms

Figure 65.2 shows our current view on the pathogenesis of DPN. The aetiology includes metabolic; vascular; autoimmune; oxidative and nitrosative stress; and neurohormonal growth factor deficiency. Inflammation is more clearly involved in the specific inflammatory neuropathies such as vasculitic and granulomatous disease than in DPN *per se*,[13] although this has not been studied in age-related neuropathies. P- and E-selectin and VCAM-1 activated during the inflammatory process predict the decline in peripheral nerve function among diabetic patients.[14] Impaired blood flow and endoneurial microvasculopathy, mainly thickening of the blood vessel wall or occlusion, play a critical role. Metabolic disturbances in the presence of an underlying genetic predisposition cause reduced nerve perfusion. Both animal and human studies have shown major defects arising from chronic hyperglycaemia and altered lipid metabolism.[15] Oxidative/nitrosative stress-related mechanisms are also important in vascular dysfunction and tend to increase vasoconstriction. Improving nerve blood flow may improve nerve conduction velocity in DPN.[16] Oxidative and nitrosative stress and inflammation are implicated in several neurodegenerative disorders, including Alzheimer's disease and amyotrophic lateral sclerosis (ALS),[17] and in DPN.[18,19] Potentially, similar mechanisms play a role in the peripheral nerve with ageing. As ageing[20] and type 2 diabetes[21–25] are associated with increased levels of subclinical systemic inflammatory markers, such as

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Box 65.1 Classification of diabetic neuropathy[a].

Focal neuropathies
- Mononeuritis
- Entrapment syndromes

Diffuse neuropathies
- Proximal motor (amyotrophy)
  - Coexisting chronic inflammatory demyelinating polyneuropathy (CIPD)
  - Monoclonal gammopathy of undetermined significance (MGUS)
  - Circulating GM1 antibodies and antibodies to neuronal cells
  - Inflammatory vasculitis

Generalized symmetric polyneuropathies
- Acute sensory
- Autonomic
- Chronic sensorimotor distal polyneuropathy (DPN)
  - Large fibre
  - Small fibre

Adapted from Thomas[117] and Vinik.[37]

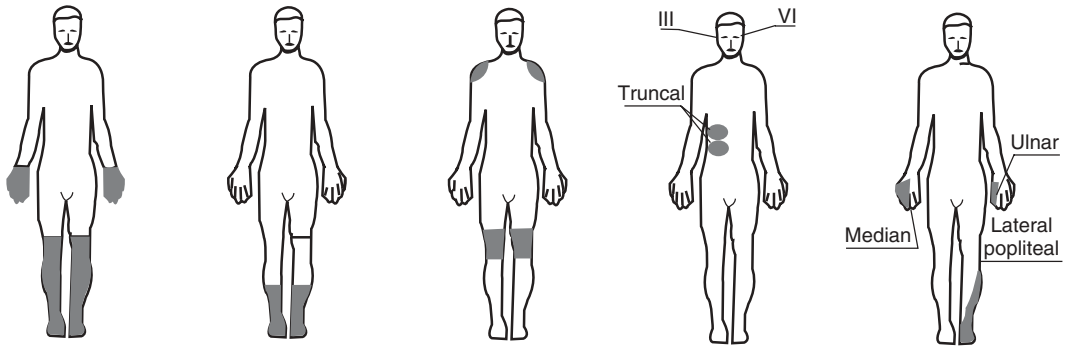
cytokines IL-6 and TNF-α, and acute-phase proteins such as CRP. An Italian population-based study found that high levels of sIL-6R and lower vitamin E were significantly related to lower nerve conduction velocity.[26]

Clinical presentation and diagnosis

Focal neuropathies (mononeuropathies and entrapment syndromes)

Mononeuropathies occur primarily in older adults. Their onset is generally acute and associated with pain and they heal spontaneously, usually within 6–8 weeks. These neuropathies are caused by vascular obstruction, typically in the cranial nerves III, VI and VII, ulnar, median and peroneal. Mononeuropathies must be distinguished from entrapment syndromes, which start slowly, progress and persist without intervention (Table 65.1).

Common entrapment sites in diabetic patients involve the median, ulnar and peroneal nerves, the lateral cutaneous nerve of the thigh and the tibial nerve in the tarsal canal. Their onset is gradual and is usually limited to a single nerve.[27] Carpal tunnel syndrome is the most common entrapment syndrome, affecting one in three diabetic patients.[28] It occurs three times more frequently in patients with diabetes compared with the normal healthy population[29] and may be related to diabetic cheiroarthropathy, repeated undetected trauma, metabolic changes or an accumulation of fluid or oedema within the confined space of the carpal tunnel.[30] Surgical treatment of entrapment syndrome neuropathies is effective, but the decision to proceed with surgery should be based on severity of symptoms, appearance of motor weakness and failure of non-surgical treatment, and there must be electrophysiological evidence of nerve entrapment.



Large fibre neuropathy	Small fibre neuropathy	Proximal motor neuropathy	Acute mono neuropthies	Pressure palsies
Sensory loss: 0 → +++ (touch, vibration) Pain: + → +++ Tendon reflex: N → ↓↓↓ Motor deficit 0 → +++	Sensory loss: 0 → + (thermal, allodynia) Pain: + → +++ Tendon reflex: N → ↓ Motor deficit: 0	Sensory loss: 0 → + Pain: + → +++ Tendon reflex: ↓↓ Proximal motor deficit: + → +++	Sensory loss: 0 → + Pain: + → +++ Tendon reflex: N Motor deficit + → +++	Sensory loss in nerve distribution: + → +++ Pain: + → ++ Tendon reflex: N Motor deficit + → +++

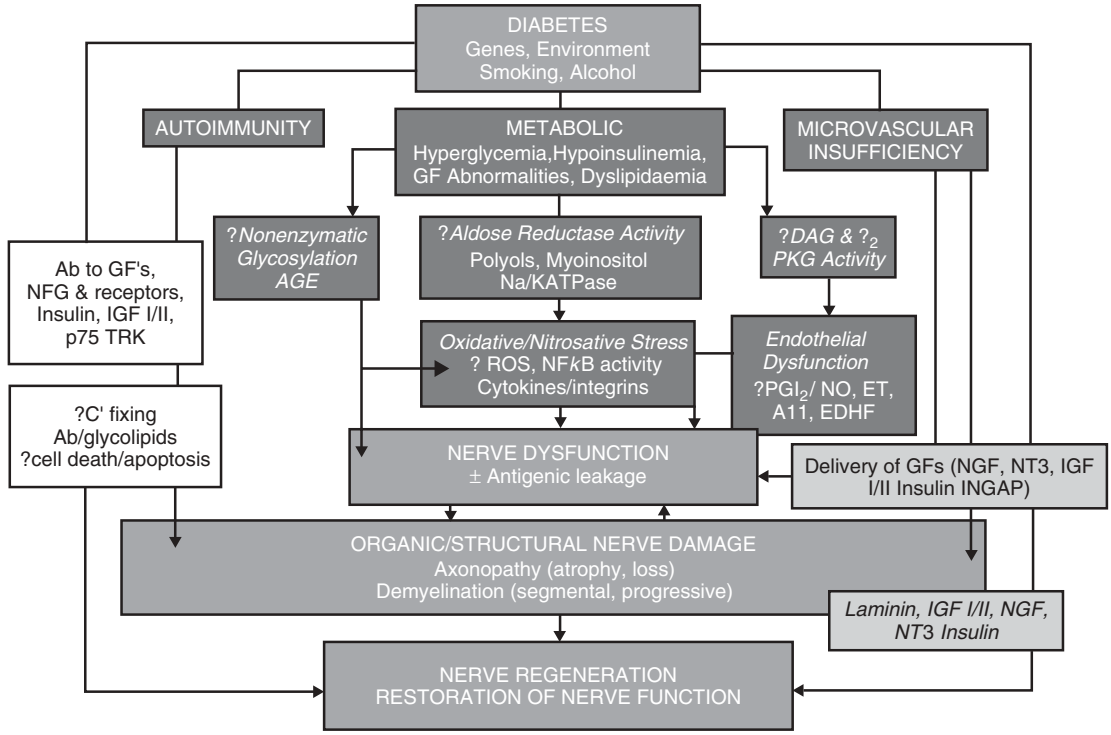

Figure 65.2 Pathogenesis of diabetic neuropathies based upon autoimmunity, metabolic and microvascular insufficiency.[121] Ab, antibody; AGE, advance glycation end products; C′, complement; DAG, diacylglycerol; ET, endothelin; EDHF, endothelium-derived hyperpolarizing factor; GF, growth factor; IGF; insulin-like growth factor; NFkB, nuclear factor κB; NGF, nerve growth factor; NO, nitric oxide; NT3, neurotropin 3; PKC, protein kinase C; PGI2, prostaglandin I2; ROS, reactive oxygen species; TRK, tyrosine kinase.

Table 65.1 Comparison of features of mononeuropathies, entrapment syndromes and distal symmetrical polyneuropathy.

Feature	Mononeuropathy	Entrapment syndrome	Neuropathy
Onset	Sudden	Gradual	Gradual
Pattern	Single nerve but may be multiple	Single nerve exposed to trauma	Distal symmetrical polyneuropathy
Nerves involved	CN III, VI, VII, ulnar, median, perineal	Median, ulnar, peroneal, medial and lateral plantar	Mixed, motor, sensory, autonomic
Natural history	Resolves spontaneously	Progressive	Progressive
Treatment	Symptomatic	Rest, splints, local steroids, diuretics, surgery	Tight glycaemic control, pregabalin, duloxetine, antioxidants, 'nutrinerve', research drugs
Distribution of Sensory loss	Area supplied by the nerve	Area supplied beyond the site of entrapment	Distal and symmetrical. 'glove and stocking' distribution

Reproduced from Vinik A *et al.*,[121] Chapter 35, with permission.

Diffuse neuropathies (proximal motor neuropathies)

Proximal motor neuropathy can be clinically identified based on proximal muscle weakness and muscle wasting. It may be symmetric or asymmetric in distribution and is sometimes associated with pain in the lateral aspect of the thigh. Patients usually present with weakness of the iliopsoas, obturator and adductor muscles, together with relative preservation of the gluteus maximus and minimus and hamstrings.[31,32] Those affected have great difficulty rising out of a chair unaided, although heel or toe standing is surprisingly good. In the classic form of diabetic proximal motor neuropathy, axonal loss is the predominant process and the condition coexists with distal symmetric

polyneuropathy.[33] Electrophysiological evaluation reveals lumbosacral plexopathy.[34] Common features include the following:

- Primarily affects the elderly.
- Onset may be gradual or acute.
- Begins with pain in the thighs and hips or buttocks.
- Pain followed by significant weakness of the proximal muscles of the lower limbs with inability to rise from a sitting position (positive Gower's manoeuvre).
- Begins unilaterally and spreads bilaterally.
- Coexists with DPN.
- Spontaneous muscle fasciculation or provoked by percussion.

Proximal motor neuropathy is now recognized as being secondary to a variety of causes unrelated to diabetes, but which occur more frequently in patients who have diabetes than in the general population. It includes patients who have CIDP, MGUS, circulating GM1 antibodies and antibodies to neuronal cells and inflammatory vasculitis.[35,36] Vinik[37] found that almost half of patients with proximal neuropathies have a vasculitis and all but 9% have CIDP, MGUS or a ganglioside antibody syndrome.[37,38] Sharma *et al*.[39] examined over 1000 patients who had neurological disorders and found that CIDP was 11 times more frequent among diabetic than non-diabetic patients.

In contrast, if demyelination predominates and the motor deficit affects proximal and distal muscle groups, the diagnosis of CIDP should be considered. It is important to divide proximal syndromes into these two subcategories because the CIDP variant responds dramatically to intervention,[37,39,40] with IVIG, plasmapheresis, steroids and immunosuppressive agents,[37] whereas proximal motor neuropathy runs its own course over months to years. Until more evidence is available, we consider them as separate syndromes.

These conditions should be distinguished from spinal stenosis syndromes common in older individuals, which occur because of (1) encroachment on nerve roots as they emerge from the spinal cord, (2) osteophytes that narrow joint space and cause compression, (3) hypertrophy of the ligamentum flavum by ageing, (4) disk dehydration due to ageing and (5) arachnoiditis. If compression occurs at the level of T12 and L1/2, the vascular system may be involved. This often causes claudication during downhill walking and is relieved with spinal flexion. Nerve root compression is more typical at L5/S1 and therefore in difficult cases it may be necessary to obtain an MRI of the lumbosacral spine. Diagnosis is critical because therapy may range from simple physical therapy to surgical decompression if symptoms are severe or if motor paralysis exists.

Chronic sensorimotor distal polyneuropathy

Chronic sensorimotor DPN is the most common and widely recognized form of diabetic neuropathy. The onset is usually insidious, following stress or initiation of therapy for diabetes. DPN may be either sensory or motor and may involve small fibres, large fibres or both.[41] Initial neurological evaluation should focus on detection of the specific part of the nervous system affected by diabetes. Most patients with DPN have a combination of both large and small nerve fibre involvement (Figure 65.3).

Large fibre neuropathies

A majority of neuropathies in older adults involve large fibres. Large fibre neuropathies may involve sensory and/or motor nerves and most patients will present with a 'glove and stocking' distribution of sensory loss.[42] These tend to be the neuropathies of signs rather than symptoms.

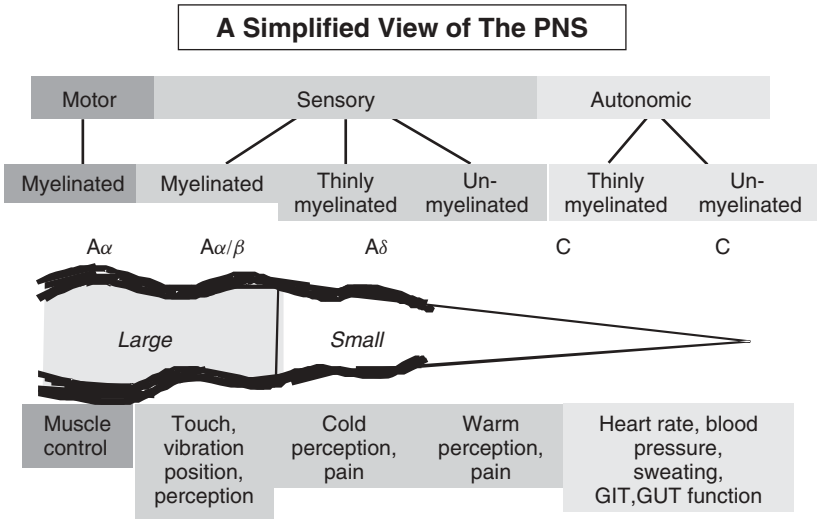

Figure 65.3 Schematic presentation of the physiological function of different nerve fibres.[121] Aα fibres are large myelinated fibres, in charge of motor functions and muscle control. Aα/β fibres are also large myelinated fibres, with sensory functions such as perception to touch, vibration and position. Aδ fibres are small myelinated fibres, in charge of pain stimuli and cold perception. C fibres can be myelinated or unmyelinated and have both sensory (warm perception and pain) and autonomic functions (blood pressure and heart rate regulation, sweating, etc.). GIT, gastrointestinal tract; GUT, genitourinary tract.

Table 65.2 Decline in neurological function between 20 and 80 years of age.

Function	Dysfunction (%)
Vibratory sensation	97
Stability (rombergism)	32
Handwriting speed	30
Handgrip strength	22
Ankle jerk	9
Ataxia (finger–nose test)	8
Pain perception	0

Data from references 118–120.

They are manifested by reduced vibration (often the first objective evidence of neuropathy) and position sense, weakness, muscle wasting and depressed tendon reflexes. Early in the course of the neuropathic process, multifocal sensory loss might also be found (Table 65.2) The symptoms may be minimal, such as a sensation of walking on cotton, floors feeling 'strange', inability to turn the pages of a book or inability to discriminate among coins. In some patients, severe distal muscle weakness can accompany the sensory loss, resulting in an inability to stand on the toes or heels.

Little is known, however, at the clinical and population levels about the role of age-related loss in peripheral nerve function to sarcopenia and loss of strength associated with ageing. Loss of lean mass, or sarcopenia, is thought to account for much of the loss of strength and function in older adults.[43,44] In addition to lower mass, ageing muscle is characterized by loss of muscle fibres, predominantly type 2 fast-twitch fibres and an increase in grouping or 'clustering' of type 1 fibres.[45] These changes are thought to be caused in part by disuse atrophy and in part to drop out of the anterior horn motor neurons at the level of the spinal cord. When the motor neuron is lost with disease (polio, ALS) or ageing, remaining motor neurons can sprout new dendritic connections to 'orphaned' muscle fibres. This reinnervation process may be responsible for the increase in grouping of type 1 fibres and may limit regaining type 2 fibres after loss caused by atrophy. Although the innervation of muscle tissue is essential to its function, very little is known about the relative contribution of peripheral nerve function to muscle function and functional decline in community-dwelling older adults. In diabetes, severe PN is clearly related to muscle atrophy.[46] Recent work in epidemiological cohort studies of older adults indicates that poorer motor nerve function is related to lower calf muscle density[47] and poorer sensory and motor nerve function is related to lower quadriceps and ankle strength, independent of diabetes and peripheral arterial disease status.[48] Given the known atrophy and denervation in the pathophysiological description of muscle ageing, it is remarkable how little is known at the clinical and population levels about the role of age-related loss in nerve function to the age-related loss of muscle mass and strength. This neurogenic process may be a critical link in the pathogenesis of sarcopenia and mobility loss in old age.

Older adults who have large fibre neuropathies have difficulty stabilizing their bodies when walking on irregular surfaces, with concomitant impairment of reaction time and balance.[6] This lack of peripheral sensory input increases the risk of falling and fracture in these patients. In the Women's Health and Ageing study, women with diabetes reported difficulty in performing 14 of 15 daily tasks, which included walking two to three blocks, lifting 10 pounds, using a telephone and bathing.[7] Failure to perform basic ADLs readily compromises an individual's independence and quality of life (QOL), which increases mortality and morbidity in this susceptible population.[49] The Norfolk QOL tool is used to measure patients' perception of the effects of diabetes and diabetic neuropathy.[49]

Epidemiological studies have found that older adults with poor peripheral nerve function have worse physical performance, balance, muscle density and bone density.[22,23,47,50,51] Most of these associations were independent of diabetes status. A twofold higher prospective decline in motor performance exists for older adults who have distal symmetrical neuropathy.[52] Older women with PN have significantly greater step width:length ratio and step-time variability, less efficient gait and lower gait speed compared with controls.[8,53] Clinical consequences of higher fall and fracture rates are also evident in older adults who have peripheral nerve impairments.[54–58]

In recent years, several inexpensive devices have been developed for the assessment of somatosensory function, including vibration, thermal energy and light-touch perception. These instruments allow for the non-invasive assessment of cutaneous sensory functions, which correlate with specific neural fibre function. In addition to the above modalities, quantitative sensory tests (QSTs) are available for the assessment of pain threshold and cutaneous current perception.[41] Clinical manifestations of large fibre neuropathies include the following:

- impaired vibration perception and position sense;
- depressed tendon reflexes;
- dull (like a toothache), crushing or cramp-like pain in the bones of the feet;
- sensory ataxia (waddling like a duck);
- wasting of small muscles of feet with hammertoes and weakness of hands and feet;
- shortening of the Achilles tendon with equinus;
- increased blood flow to the foot (hot foot) with increased risk of Charcot neuroarthropathy.

Small fibre neuropathies

Small nerve fibre dysfunction usually occurs early and is often present without objective signs or electrophysiological evidence of nerve damage.[41] It manifests first in the lower limbs with symptoms of pain and hyperalgesia, followed by a loss of thermal sensitivity and reduced light-touch and pinprick sensation.[59] Small unmyelinated C-fibres control pain sensation, warm thermal perception and autonomic function. A patient who has early damage to these nerves may experience burning, dysesthetic pain, often accompanied by hyperalgesia, and allodynia. This pain is distinct from that of large fibre neuropathy, in which the pain is usually described as deep and 'gnawing'. Because peripheral sympathetic nerve fibres are also comprised of small, unmyelinated C-fibres, it is not surprising that pain is improved with sympathetic blocking agents (e.g. beta-blockers, calcium channel blockers).

It should be noted that dry, cracked skin and impaired skin blood flow in the feet, together with impaired sympathetic regulation of sweat glands and anteriovenous (AV) shunt vessels in the feet, create a favourable environment for bacteria. In the absence of pain, which occurs with the depletion of substance P, patients may be led to believe that their neuropathy has subsided, when in fact it is progressing. These patients may also display decreased thermal pain thresholds, which may be caused in part by the decrease in nerve growth factor (NGF) that maintains small fibre neurons. The clinical manifestations of small fibre neuropathies can be summarized as follows:

- prominent pain: burning and superficial and associated with allodynia; i.e. interpretation of all stimuli as painful (e.g. touch);
- hypoalgesia late in the condition;
- defective autonomic function with decreased sweating, dry skin, impaired vasomotion and blood flow and cold feet;
- intact reflexes, motor strength;
- silent electrophysiology;
- absence of objective signs reduced sensitivity to 1.0 g Semmes–Weinstein monofilament and pricking sensation using the Waardenberg wheel or similar instrument;
- as the condition progresses, abnormal thresholds for warm thermal perception, neurovascular function, pain, quantitative sudorimetry and quantitative autonomic function tests;
- increased risk of foot ulceration and subsequent gangrene.

Differential diagnosis

Diabetes as the cause of neuropathy is diagnosed by exclusion of various other causes of neuropathy. In those patients who have diabetes and neuropathy who present with symptoms of distal symmetric sensorimotor deficit, differential diagnosis should include hereditary sensory neuropathies, vitamin B_{12} and folate deficiency, syphilis, Lyme disease, neuropathy associated with IgM monoclonal gammopathy of undetermined significance (IgM MGUS neuropathy), other paraneoplastic conditions, autoimmune diseases and toxic neuropathies. In patients who have one or more motor neurological syndromes, chronic motor neuropathies, acute inflammatory demyelinating polyneuropathy (AIDP), CIDP and immunoglobulin G (IgG) and IgA MGUS neuropathies should actively be sought (Table 65.3).

Recent evidence supports an autoimmune aetiology for neuropathy in AIDS, Lyme disease, AIDP, CIDP, multifocal motor neuropathy, MGUS neuropathies and even diabetic polyneuropathy.[30,42] Hence an intensive workup for humoral immune mechanisms should be performed. If any of these conditions are found, the appropriate therapeutic regime for the specific disease must be instituted before embarking on a regime of diabetic neuropathy management. It is not always possible to determine the exact cause of neuropathy if monoclonal gammopathy and diabetes coexist in the same patient. A course of intravenous

Table 65.3 Differential diagnosis of distal symmetric polyneuropathy.

Type	Syndrome
Congenital/familial	Charcot–Marie–Tooth
Traumatic	Entrapment syndromes
Inflammatory	Sarcoidosis
	Leprosy
	Lyme disease
	HIV
Neoplastic	Carcinoma – paraneoplastic syndromes
	Myeloma, amyloid
	Reticuloses, leukaemias, lymphomas
Metabolic/endocrine	Diabetes mellitus
	Uraemia
	Pernicious anaemia (vitamin B_{12} deficiency)
	Hypothyroidism
	Porphyria (acute intermittent)
Vascular	Diabetes, vasculitis
Toxic	Alcohol
	Heavy metals (lead, mercury, arsenic)
	Hydrocarbons, chemotherapeutic drugs
Autoimmune	Diabetes
	PLA syndrome
	Chronic inflammatory demyelinating neuropathy
	Multifocal motor neuropathy
	Guillain–Barré syndrome

(i.v.) immunoglobulin or immunosuppression should be attempted, depending on the class of monoclonal antibody.

Nerve tissue biopsy may be helpful for excluding other causes of neuropathy and in the determination of predominant pathological changes in patients who have complex clinical findings as a means of dictating choice of treatment.[40,60] The authors' laboratory performs nerve biopsies only when non-invasive neurological procedures fail to provide an answer or when extensive evaluation is necessary for scientific purposes.[60] We expect a further increase in our dependence on histopathological and ultrastructural examination of nerve tissue for differentiation of neuropathic syndromes as our knowledge of pathophysiological and clinical complexity among diabetic neuropathic variants increases. Figure 65.4 depicts a diagnostic algorithm for the assessment of neurological deficit and classification of neuropathic syndromes.

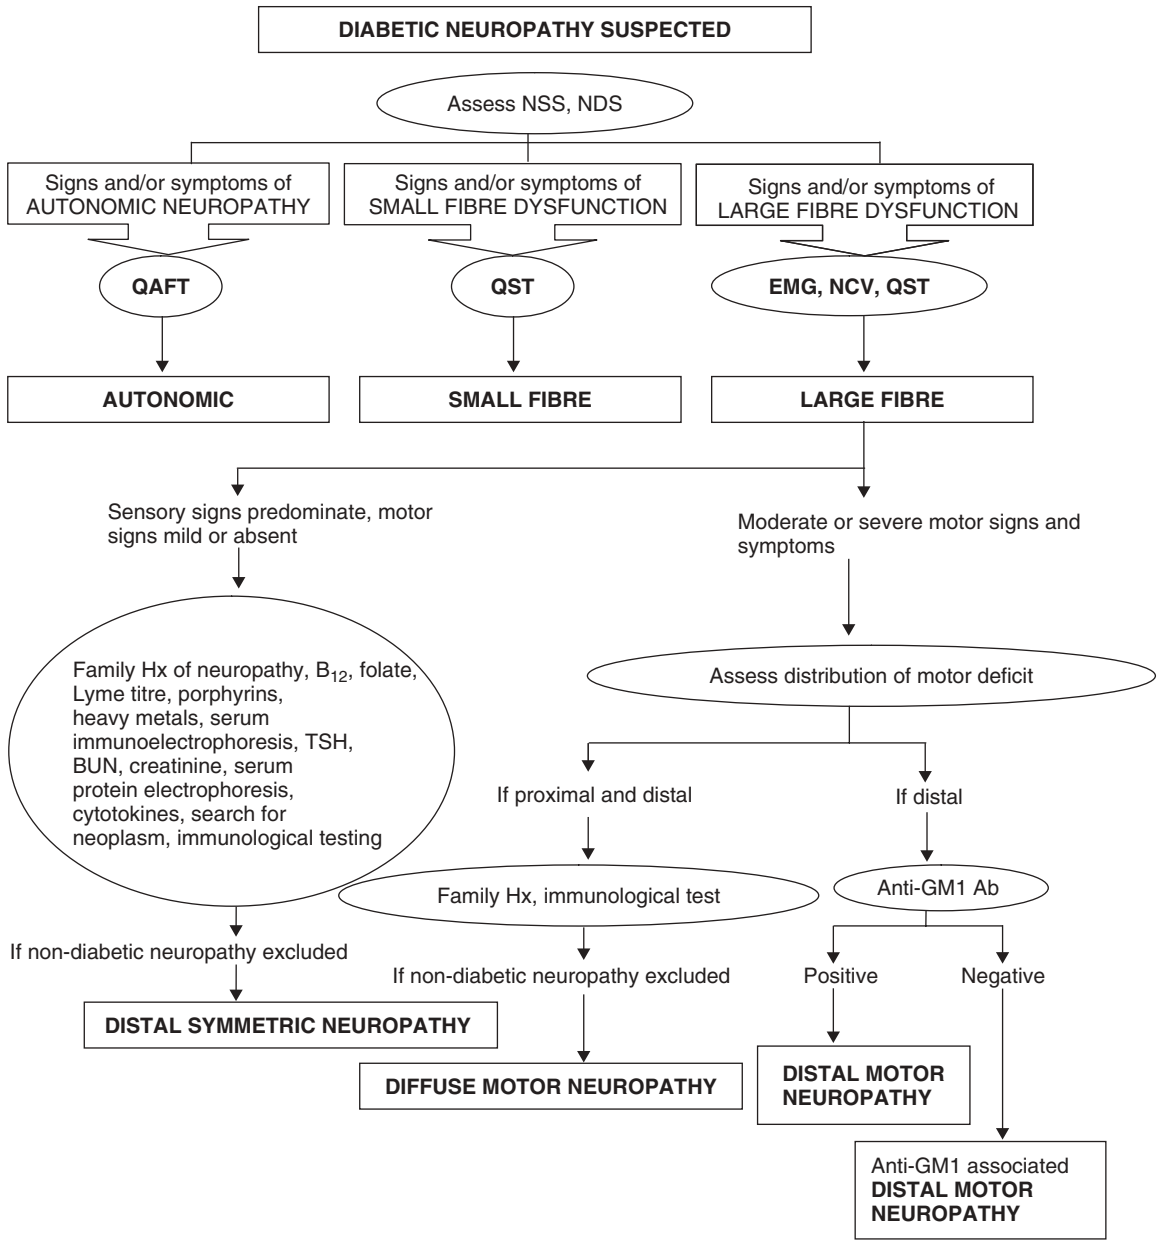

Figure 65.4 Diagnostic algorithm for assessment of neurological deficit and classification of neuropathic syndrome.[1] NSS, neurological symptom score; NDS, nerve disability score; QST, quantitative sensory test; QAFT, quantitative autonomic function test; EMG, electromyography; NCV, nerve conduction velocity.

Charcot neuroarthropathy

Charcot neuroarthropathy is a progressive condition associated with prolonged neuropathy and characterized by pathological fracture, joint dislocation and, if left untreated, disabling joint deformity. The most common location for Charcot neuroarthropathy is in the foot. The prevailing theory of Charcot progression suggests that autonomic neuropathy causes increased blood flow to the extremities, which increases bone resorption and causes osteopenia. Subsequent motor neuropathies cause muscular imbalance, which place abnormal stress on the affected extremity. Sensory neuropathies prevent the patient from sensing abnormal changes in the joints and bones, which may occur because of minor trauma, such as during walking.[61] It is further hypothesized that Achilles tendon shortening due to destruction of collagen fibres may be caused by accumulation of advanced glycation end products (AGEs).[62,63]

Patients with Charcot neuroarthropathy may present acutely with severe pain (or no pain if severe sensory neuropathy), a warm-to-hot swollen foot with increased skin blood flow (despite decreased warm[64] sensory perception and vibration detection) and possible radiographic evidence of osteopenia. The acute Charcot foot can mimic cellulitis or, less commonly, deep vein thrombosis, so these should be investigated first. It should also be noted that radiographic findings can be normal in the acute phase, with subsequent films showing severe subluxation or fracture. Strict immobilization and protection of the foot using a total contact cast are the recommended approach to treating acute Charcot neuroarthropathy. Pain and inflammation respond to bisphosphonates (e.g. slow i.v. pamidronate infusion over 12 h) within 3–4 weeks.[65] It should be noted that oral bisphosphonates may cause oesophageal dysfunction and increase the risk of obstruction and perforation. Achilles tendon shortening producing equinus is correctable by surgical lengthening and may prevent further progression. Patient education, protective footwear and routine foot care are required to prevent further complications such as foot ulceration. In cases of severe joint and bony destruction, reconstructive surgery is effective in salvaging the limb and improving mobility and QOL.[49]

Management of neuropathy

The high prevalence of certain subclinical diseases in the elderly may be associated with declines in peripheral nerve function. Importantly, these conditions are modifiable, so early intervention against these risk factors may prevent peripheral nerve function declines and the subsequent clinical consequences associated with PN. Vitamin B_{12} deficiency is a known cause of clinical neuropathy;[66] however, the impact of marginally poor vitamin B_{12} levels, found in 22–35% of community-dwelling older adults,[67–69] on peripheral nerve decline is unknown. Low vitamin B_{12} levels were associated with missing ankle tendon jerks among those aged 75 years and older.[70] There is emerging evidence that the dose and duration of metformin therapy reduces vitamin B_{12} and worsens neuropathy.[71] This has clear clinical implications for defining vitamin B_{12} replacement criteria.[72]

Nearly all peripheral arterial disease (PAD) in the elderly is subclinical, with 98% asymptomatic.[73] An Italian study in community-dwelling elderly found an association between subclinical PAD and poor nerve function.[74] This finding is of particular importance because 12% of older adults aged 70–79 years and 22% of those aged 80 years or more in the USA have subclinical PAD.[10] Subclinical PAD is underappreciated clinically, but highly preventable.[75,76]

The metabolic syndrome represents another prevalent risk factor for peripheral nerve impairments in the elderly. The prevalence of the metabolic syndrome in the USA is >40% in adults aged 60 years or older.[77] It is a risk factor for PN among diabetic adults.[78,79] In the Cardiovascular Health Study of older adults, participants who had normal glucose metabolism or a mildly elevated impaired fasting glucose (IFG) had lower heart rate variability (HRV), a marker of cardiovascular autonomic neuropathy, in the presence of two or more components of the metabolic syndrome.[80] In addition to the reduction of blood glucose levels, prevention and treatment of the other components of the metabolic syndrome (obesity, lipid abnormalities and high blood pressure) could be targeted to prevent peripheral nerve declines in older adults.

Once the diagnosis of neuropathy has been made, therapy to reduce symptoms and prevent further progression should be initiated. Diabetic patients who have large fibre neuropathies are incoordinate and ataxic and are 17 times more likely to fall than their non-neuropathic counterparts.[81] Older subjects have a higher incidence of neuropathy than younger subjects, especially involving large fibres. It is vitally important to improve strength and balance in the patient with large fibre neuropathy. Older adults who have or do not have neuropathy can benefit from high-intensity strength training by increasing muscle strength, improving coordination and balance and thus reducing fall and fracture risk.[82–84] Low-impact activities that emphasize muscular strength and coordination and challenge the vestibular system, such as pilates, yoga and Tai Chi, may also be particularly helpful. Strategies for management of large fibre neuropathies include the following:

- strength, gait and balance training;
- pain management as detailed below;
- orthotics fitted with proper shoes to treat and/or prevent foot deformities;

- tendon lengthening for equinus caused by Achilles tendon shortening;
- bisphosphonates to treat osteopenia;
- surgical reconstruction and full contact casting as necessary.

Strategies for the management of small fibre neuropathies include simple measures that can protect the foot deficient in functional C-fibres from developing ulceration and therefore, gangrene and amputation:

- Foot protection is of the utmost importance. Wearing padded socks can promote ulcer healing and/or reduce the likelihood of developing one.[85]
- Supportive shoes with orthotics if necessary.
- Regular foot and shoe inspection. Patients should inspect the plantar surface of their feet with a mirror on a daily basis (many are too obese to see their feet, let alone the undersurface).
- Extreme caution to prevent heat injury. Patients should test the bathwater with a part of the body that is not insensate before plunging a numb foot into the water. Patients should also be cautioned against falling asleep in front of the fireplace with their insensate feet close to the fire.
- Emollient creams should be used to moisturize dry skin and prevent cracking and infection.

Therapies aimed at pathogenic mechanisms

Retrospective and prospective studies have suggested a relationship between hyperglycaemia and the development and severity of diabetic neuropathy and significant effects of intensive insulin treatment on the prevention of neuropathy.[86] Intensive treatment of hyperglycaemia in the elderly is controversial. Additionally, no epidemiological or natural history study has defined the importance of late-onset diabetes in aged populations and IFG as risk factors for nerve function decline in very old adults. Recent data from the Cardiovascular Health Study suggest that IFG is a risk factor for autonomic neuropathy in the elderly.[80]

Studies in animal models and cultured cells provide a conceptual framework for the cause and treatment of diabetic neuropathy; however, the limited translational work in diabetic patients continues to generate debate over the cause of human diabetic neuropathy and to date we have no effective long-term treatment. Several clinical trials have found that treating oxidative stress may improve peripheral and autonomic neuropathy in type 2 diabetic adults.[19,87–89] Thiazolidinediones reduce hyperglycaemia through reductions in insulin resistance and may also reduce chronic inflammation, potentially impacting pathways leading to PN.[90–92] Exciting emerging evidence indicates that fibrates and statins are protective for peripheral nerve function decline in type II diabetic adults.[93,94] Older adults using statins show a greater benefit than younger adults because of their higher attributable risk of cardiovascular disease;[95] however, the impact of statins on PN in the elderly has not yet been evaluated. Unfortunately, no drugs that have been studied in clinical trials aimed at treating the pathogenic mechanisms of DPN have been approved by the US Food and Drug Administration (FDA).

The role of exercise and balance training for older adults with PN is promising. Several small studies in diabetic patients found that aerobic exercise improved quantitative test results for peripheral nerve function[96,97] and cardiac autonomic neuropathy.[98] Exercise may have an important role in the primary prevention of peripheral and cardiac autonomic nervous system decline. Among diabetic participants and/or those with PN, balance training is effective in improving balance outcomes and likely reducing risk of falls.[82,99,100]

Therapy aimed at treating symptoms in patients who have sensorimotor distal polyneuropathy

It is critical to discern the underlying condition in diabetic patients who have pain. Physicians must be able to differentiate painful diabetic neuropathy from other unrelated or coexisting conditions in patients who have diabetes. The most common of these are claudication, Morton neuroma, Charcot neuroarthropathy, fasciitis, osteoarthritis and radiculopathy (Table 65.4).

Treatment strategies should aim to decrease the afferent input, reduce local inflammation, suppress sympathetic fortification of the stimulus, reduce the impact of excitatory amino acids, alter the modulation of nociceptors and suppress Na^+ channel activity (Figure 65.5).

Amitriptyline is prescribed for diabetic neuropathy,[101] but anticholinergic side effects such as orthostatic hypotension and possible cardiac arrhythmias[101,102] warrant caution in its use. Contraindications to amitriptyline and other tricyclic antidepressants include cardiac conduction block, long QT syndrome, myocardial infarction within 6 months and ventricular arrhythmias or frequent premature ventricular contractions.[102] Older adults who have neuropathy are at risk for adverse events from tricyclic antidepressants, especially stability, balance and cognitive problems.[103] For this reason, patients over 40 years old should have a screening electrocardiogram before using these medications.[103]

Other commonly used drug classes include analgesics (local, simple and narcotic), antiarrhythmics and antiepileptic drugs (Table 65.5).[102] Based on positive results from randomized controlled trials and expert clinical opinion of members of the faculty of the Fourth International Conference on the Mechanisms and Treatment of Neuropathic Pain, recommendations for first-line medications for neuropathic pain include gabapentin, 5% lidocaine patch, opioid analgesics, tramadol hydrochloride and

Table 65.4 Common pain syndromes similar to painful diabetic neuropathy.

Condition	Key characteristics and differentiating features
Claudication	Doppler ultrasonography confirms clinical diagnosis of arterial occlusion Diabetic patients may present with normal extremities and absent foot pulses Peripheral arterial occlusion with underlying atherosclerosis Usually intermittent, worsened by walking; remits with rest; other signs/symptoms suggest arterial insufficiency
Morton's neuroma	Benign neuroma formation on third plantar interdigital nerve Generally unilateral More frequent in women Pain elicited when pressure is applied with the thumb between the first and fourth metatarsal heads
Osteoarthritis	Can be secondary to diabetes mellitus, but onset of pain is usually gradual and in one or two joints Differential diagnosis based on X-ray Morning stiffness, diminished joint motion and flexion contractures Pain worsens with exercise and improves with rest Radiculopathy can result
Radiculopathy	Can be caused by diabetes, but also from arthritis or metastatic disease Neurological examinations and imaging can localize lesion site Pain can occur in thorax, extremities, shoulder or arm, depending on site of lesion
Charcot neuroarthropathy	May result from osteopenia due to increased blood flow following repeated minor trauma in individuals with diabetic neuropathy Warm to hot foot with increased skin blood flow Decreased warm sensory perception, vibration detection
Plantar fasciitis	Pain in plantar region of the foot Tenderness along plantar fascia when ankle is dorsiflexed Shooting or burning in the heel with each step Worsening pain with prolonged activity Often associated with calcaneal spur on radiography
Tarsal tunnel syndrome	Caused by entrapment of the posterior tibial nerve Pain and numbness radiate from beneath the medial malleolus to the sole Clinical examination includes percussion, palpation for possible soft-tissue matter, nerve conduction studies, magnetic resonance imaging

tricyclic antidepressants.[103] Consideration of the safety and tolerability of different therapies is important in avoiding adverse effects, a common result of treatment of neuropathic pain. Dosages must be titrated based on positive response, treatment adherence and adverse events.[103]

Anti-epileptic drugs (AEDs) have a long history of effectiveness in the treatment of neuropathic pain. Since 1993, nine new AEDs (felbamate, gabapentin, pregabalin, lamotrigine, topiramate, tiagabine, levetiracetam, oxcarbazepine and zonisamide) have received FDA approval for the adjunctive treatment of partial seizures[104] (see Table 65.5) Three of these drugs have also been approved for generalized seizures (felbamate, lamotrigine and topiramate) and three (felbamate, lamotrigine and oxcarbazepine) for monotherapy.[104] Principal mechanisms of action include sodium channel blockade (felbamate, lamotrigine, oxcarbazepine, topiramate and zonisamide), potentiation of γ-aminobutyric acid (GABA) activity (tiagabine and topiramate), calcium channel blockade (felbamate, lamotrigine, topiramate and zonisamide), antagonism of glutamate at *N*-methyl-D-aspartate (NMDA) receptors (felbamate, memantine and dextromethorphan) or α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) (felbamate and topiramate) and mechanisms of action still undetermined (gabapentin and pregabalin, levetiracetam). Only two drugs have been approved by the FDA for the treatment of painful diabetic neuropathy, pregabalin and duloxetine. The serotonin/norepinephrine receptor inhibitor (SNRI) pregabalin produced significant improvements in pain scores within 1 week of treatment, which persisted for 6–12 weeks in four randomized controlled trials including 146–724 patients who had diabetic neuropathy.[105–108] Adverse events included dose-related somnolence, ataxia and confusion, peripheral oedema and constipation. A recent Canadian study evaluated cost-effectiveness of pregabalin versus gabapentin for the treatment of painful DN, concluding that pregabalin was more cost-effective than gabapentin.[109]

Lamotrigine (200–400 mg daily) is an anticonvulsant with dual-action inhibition of neuronal hyperexcitability. Two randomized placebo-controlled studies including 720 patients showed that the drug was inconsistently effective for the treatment of pain when compared with placebo, although it was generally safe and well tolerated.[110]

In addition to providing efficacy against epilepsy, these new AEDs may also be effective in treating neuropathic pain. For example, the AED lamotrigine may decrease hyperexcitability in dorsal horn spinal neurons by inhibiting glutamate release-2 mechanisms and decrease spontaneous activity in regenerating primary afferent nerve fibres.[111] In addition, the 'wind-up' phenomenon caused by nerve injury and the kindling that occurs in hippocampal neurons in patients with mesial temporal sclerosis both

Table 65.5 Drugs approved by the FDA for treatment of neuropathic pain syndrome.

Medication	Indication	Beginning dosages	Titration	Maximum dosage	Duration of adequate trial
Gabapentin	Post-herpetic neuralgia	100–300 mg every night or 100–300 mg 3× per day	Increase by 100–300 mg 3× per day every 1–7 days as tolerated	3600 mg per day (1200 mg 3× per day); reduce if low creatinine clearance	3–8 weeks for titration plus 1–2 weeks at maximum tolerated dosage
Pregabalin	DPN	50 mg 3× per day	Increase up to 100 mg 3× per day	600 mg per day	Start with 50 mg t.i.d. and increase up to 100 mg t.i.d. over 1 week
Lamotrigine	Post-herpetic neuralgia	200–400 mg every night	Start with 25–50 mg every other day and increase by 25 mg every week	500 mg per day	3–5 weeks for titration and 1–2 weeks at maximum tolerated dosage
Carbamazepine[a]	Trigeminal neuralgia	200 mg per day (100 mg b.i.d.)	Add up to 200 mg per day in increments of 100 mg every 12 h	1200 mg per day	
Duloxetine	DPN	30 mg	30 mg weekly	120 mg	2 weeks
5% lidocaine patch	Post-herpetic neuralgia	Maximum of three patches daily for a maximum of 12 h	None needed	Maximum of three patches daily for a maximum of 12 h	2 weeks
Opioid analgesics[b]	Moderate to severe pain	5–15 mg every 4 h as needed	After 1–2 weeks, convert total daily dosage to long-acting medication as needed	No maximum with careful titration; consider evaluation by pain specialist at dosages exceeding 120–180 mg per day	4–6 weeks
Tramadol hydrochloride	Moderate to moderately severe pain	50 mg 1 or 2× per day	Increase by 50–100 mg per day in divided doses every 3–7 days as tolerated	400 mg per day (100 mg 4× per day); in patients older than 75 years, 300 mg per day in divided doses	4 weeks
Tricyclic antidepressants (e.g. nortriptyline hydrochloride or desipramine hydrochloride)	Chronic pain	10–25 mg every night	Increase by 10–25 mg per day every 3–7 days as tolerated	75–150 mg per day; if blood level of active drug and its metabolite is $<100\ ng\ ml^{-1}$, continue titration with caution	6–8 weeks with at least 1–2 weeks at maximum tolerated dosage
Duloxetine	Diabetic neuropathic pain	30 mg b.i.d.	Increase to 60 b.i.d. No further titration		4 weeks
Serotonin/ norepinephrine Reuptake inhibitor					
Fluoxetine	Diabetic neuropathic pain	30 mg b.i.d.	Increase to 60 b.i.d. No further titration		4 weeks
Serotonin/ norepinephrine Reuptake inhibitor

[b]Dosages given are for morphine sulfate.

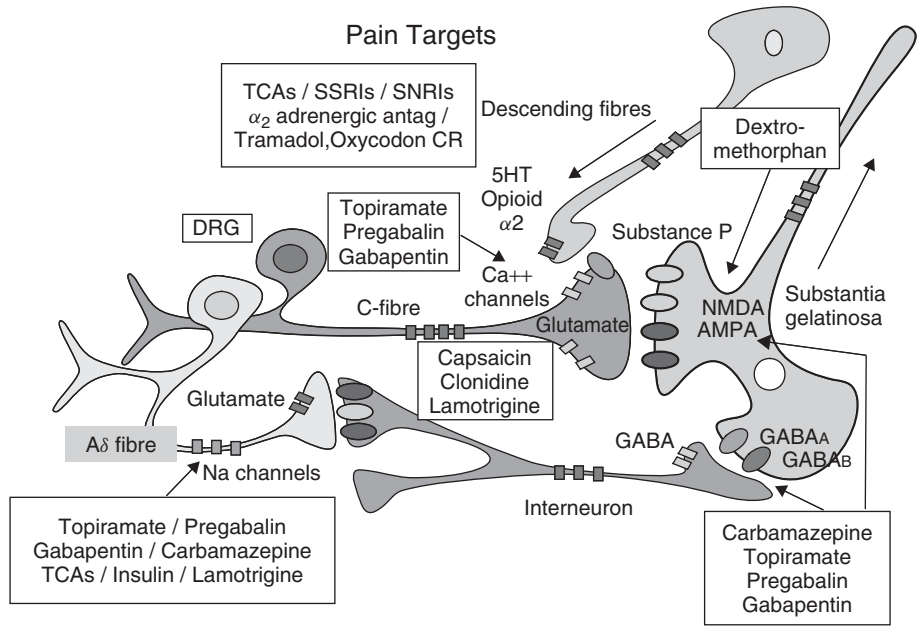

Figure 65.5 Different mechanisms of pain and possible treatments.[121] C fibres are modulated by sympathetic input with spontaneous firing of different neurotransmitters to the dorsal root ganglia, spinal cord and cerebral cortex. Sympathetic blockers (e.g. clonidine) and depletion of axonal substance P used by C fibres as their neurotransmitter (e.g. by capsaicin) may improve pain. In contrast, Ad fibres utilize Na^+ channels for their conduction and agents that inhibit Na^+ exchange such as antiepileptic drugs, tricyclic antidepressants and insulin may ameliorate this form of pain. Anticonvulsants (carbamazepine, gabapentin, pregabalin, topiramate) potentiate activity of γ-aminobutyric acid, inhibit Na^+ and Ca^{2+} channels and inhibit *N*-methyl-D-aspartate receptors and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors. Dextromethorphan blocks *N*-methyl-D-aspartate receptors in the spinal cord. Tricyclic antidepressants, selective serotonin reuptake inhibitors (e.g. fluoxetine) and serotonin and norepinephrine reuptake inhibitors inhibit serotonin and norepinephrine reuptake, enhancing their effect in endogenous pain-inhibitory systems in the brain. Tramadol is a central opioid analgesic. α_2 adrenergic antag, α_2 adrenergic antagonists; 5HT, 5-hydroxytryptamine; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; DRG, dorsal root ganglia; GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate; SNRIs, serotonin and norepinephrine reuptake inhibitors; SP, substance P; SSRIs, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.

enlist activation of NMDA receptors[112] that can be affected by felbamate.[104]

The evidence supporting the use of AEDs for the treatment of PN continues to evolve. Patients who have failed one anticonvulsant may respond to another, because drugs in this class often have different mechanisms of action.[103] When these mechanisms are understood, it may prove beneficial to combine drugs for a synergistic effect. For example, a sodium channel blocker such as lamotrigine may be used with a glutamate antagonist such as felbamate. In addition, certain drugs may possess multiple mechanisms of action which increases its likelihood of success (e.g. topiramate). If pain is divided according to its derivation from different nerve fibre types (e.g. Aδ versus C-fibre), spinal cord or cortical, then different types of pain should respond to different therapies (Figure 65.6).

Duloxetine has recently been approved for neuropathic pain in the USA. The efficacy and safety of duloxetine were evaluated in three controlled studies using doses of 60 and 120 mg per day over 12 weeks.[113] In all three studies, the average 24 h pain intensity was significantly reduced with both doses compared with placebo treatment. The response rates defined as $\geqslant$ 50% pain reduction were 48.2% (120 mg per day), 47.2% (60 mg per day) and 27.9% (placebo), giving a number-needed-to-treat (NNT) of 4.9 (95% CI, 3.6 – 7.6) for 120 mg per day and 5.2 (95% CI, 3.8–8.3) for 60 mg per day.[114] Patients with higher pain intensity tend to respond better than those with lower pain levels.[115] Most frequent adverse effects include nausea, somnolence, dizziness, constipation, dry mouth and reduced appetite. Physicians must be alert to suicidal ideation and exacerbation of autonomic symptoms and also aggravation of depression in patients with bipolar tendencies.

Although it would be preferable to rely on FDA-approved medications for the treatment of DN, no drugs have yet received an indication for this purpose. As shown in Table 65.5, only a few drugs, including two AEDs, have received FDA approval for the treatment of chronic neuropathic pain syndromes.[104] Carbamazepine has FDA approval for the treatment of trigeminal neuralgia and is

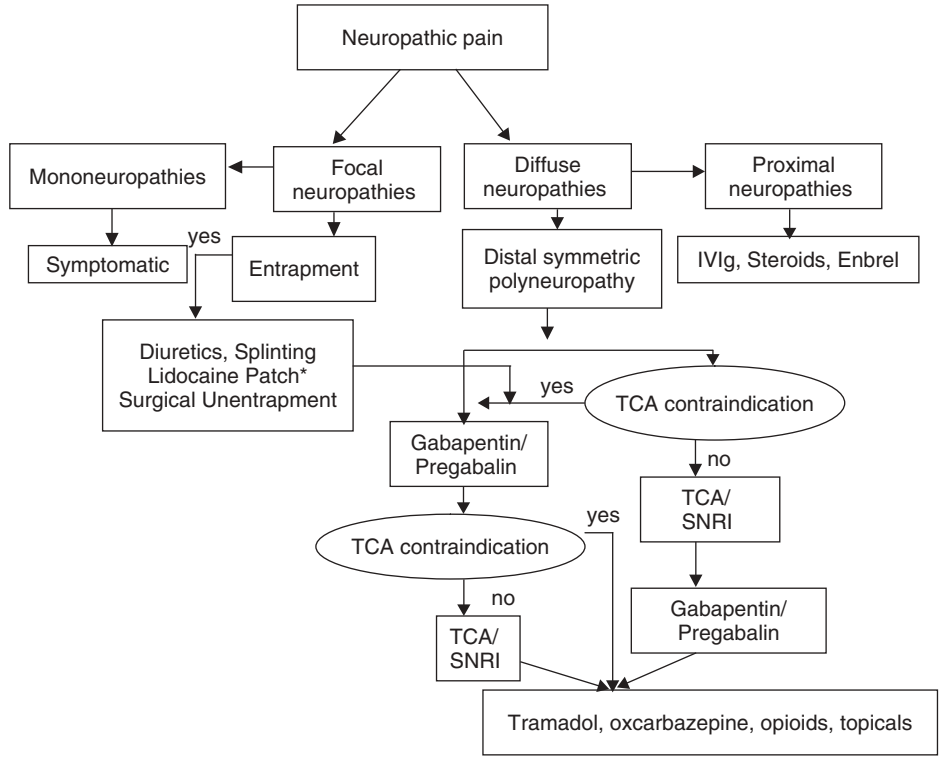

Figure 65.6 Algorithm for the management of symptomatic diabetic neuropathy. Non-pharmacological, topical or physical therapies can be useful at any time (capsaicin, acupuncture, etc.). The only two drugs approved by in the USA for the treatment of painful diabetic neuropathy are pregabalin and duloxetine. However, based on the NNT (number-needed-to-treat), tricyclic antidepressants are the most cost-effective. SNRIs, serotonin and norepinephrine reuptake inhibitors. Reproduced from A. Vinik, The approach to the management of the patient with neuropathic pain, *J Clin Endocrinol Metab* 2010;**1**:1–5. Copyright 2010, The Endocrine Society.

effective in controlling the lightning pain of DPN, and both gabapentin and 5% lidocaine patch[103] are approved for post-herpetic neuralgia.[103] The SNRI duloxetine is also approved for DPN, post-herpetic neuralgia and fibromyalgia.

Special considerations

Carbamazepine, an Na^+ channel blocker, is effective against trigeminal neuralgia, but is being replaced with the safer oxcarbazine, which is useful for 'lightning'-type pains. Lamotrigine may cause skin rashes if titrated up too rapidly and gabapentin, whose action still remains obscure and may cause serious central nervous system (CNS) side effects, failed in one of three studies and causes weight gain. Dextromethorphan, an NMDA receptor antagonist, was relatively weak and its successor memantine has not undergone successful trials. Topical capsaicin (three teaspoons of cayenne pepper + one jar of cold cream) depletes substance P, but is difficult to use and can be dangerous if it contacts mucous membranes. Results from topical lidocaine or it oral equivalent mexilitine are equivocal. The anticonvulsant drug topiramate has been used successfully to treat pain in diabetic patients and also promotes weight loss and restful sleep, suggesting that the drug may have other beneficial effects apart from relieving pain.[116] Tramadol and oxycodone are weak opioids which have also shown to be effective but require careful titration and observation.

Conclusion

Diabetic neuropathy is a heterogeneous disease with diverse pathology. Recognition of the clinical homologue of these pathological processes is the first step in achieving the appropriate form of intervention. Treatment should be individualized such that the particular manifestation and underlying pathogenesis of each patient's unique clinical presentation is considered. In older adults, special care should be taken to manage pain while optimizing daily function and mobility, with the fewest adverse side effects from medication. Older adults are at great risk for falling and fractures due to instability and weakness and require strength exercises and coordination training. Ultimately,

agents that address large fibre dysfunction will be essential if we are to reduce the gross impairment of QOL and ADLs that neuropathy visits upon the older person who has diabetes.

Key points

- Diabetic neuropathy is a common heterogeneous disorder.
- Neuropathy increases the risk of falls and fractures and requires that older persons have strength exercises and coordination training.
- Numerous drugs may ameliorate pain symptoms due to neuropathy.
- Diabetic neuropathies can effect the autonomic nervous system, small and large neurons.

CHAPTER 66

Disorders of the neuromuscular junction

Sivakumar Sathasivam and Andrew J. Larner
Walton Centre for Neurology and Neurosurgery, Liverpool, UK

Introduction

The most common adult-onset disorders of neuromuscular transmission are myasthenia gravis (MG)[1] and the Lambert–Eaton myasthenic syndrome (LEMS). Both conditions are antibody mediated and arguably the best understood of all neurological autoimmune diseases. The membrane ion channels and receptors at the neuromuscular junction (NMJ) seem particularly vulnerable to attack from circulating autoantibodies, perhaps because these structures lie outside the blood–nerve barrier. The most common, but not exclusive, target antigen in MG is the postsynaptic muscle nicotinic acetylcholine receptor (AChR) and in LEMS the targets are presynaptic neuronal voltage-gated calcium channels. In addition, antibodies to neuronal voltage-gated potassium channels are the most common cause of the neuromyotonia clinical variant of peripheral nerve hyperexcitability (PNH) and are also responsible for a non-paraneoplastic limbic encephalitis.

Myasthenia gravis

Clinical features

MG was possibly first described by Thomas Willis in the seventeenth century (*De Anima Brutorum*, 1672), but was only named as such by Jolly in 1895. The overall incidence of MG is between 2 and 10 per 100 000 people. It affects all races and can begin at any age after the first year of life. However, incidence is markedly age dependent, with about half of patients presenting after the age of 40 years. The condition is markedly underdiagnosed in people over the age of 75 years.[2] There are peaks of incidence at both 10–30 years and over the age of about 60 years in patients not harbouring an underlying thymoma, whereas onset of MG with thymoma is most common between the ages of 40 and 60 years. Men predominate in the over-60 age group, whereas women outnumber men 3:1 in the under-40 age group.

Symptoms and signs

The clinical hallmark of MG is painless fluctuating skeletal muscle weakness that worsens with exercise and improves with rest. There is a characteristic diurnal pattern of weakness, gradually worsening throughout the day and improving with rest or sleep. Some individuals find that symptoms improve in a cold ambient temperature.

Any skeletal muscle may be affected in MG, but certain muscles and muscle groups are especially susceptible, notably those supplied by the motor cranial nerves. More than 90% of patients have peri- and extraocular muscle involvement, with ptosis and diplopia being common symptoms. Typically there is asymmetric weakness of several muscles of both eyes accompanied by weakness of eye closure. Eye movements resembling internuclear ophthalmolegia (pseudo-INO) and one-and-a-half syndrome (pseudo-one-and-a-half syndrome) are described. Patients often attempt to correct partial ptosis by contracting the frontalis muscle, causing a characteristic wrinkled brow appearance. Repeated blinking causing diagnostic confusion with blepharospasm has been reported.[3] A twitching of the upper eyelid seen a moment after the eyes are moved from downgaze to the primary position, Cogan's lid twitch sign, is said to be a characteristic sign of ocular myasthenia, but sensitivity and specificity are relatively low, as it may be seen in other oculomotor brainstem disorders.[4] In 15–20% of patients, weakness is confined to the ocular muscles, ocular MG, whereas others present with or will develop the generalized form of MG.

The muscles of facial expression, mastication, swallowing and speech are the next most commonly affected group. Relatives may notice that a lack of facial movement makes the patient look depressed and that the smile has a transverse or snarling quality ('myasthenic snarl'). Jaw weakness may interfere with chewing; in extreme cases, the jaw hangs open and has to be supported by the patient's hand. Palatal weakness can result in dysarthria with a nasal quality and in reflux of liquids through the nose when drinking.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Dysphagia and choking reflect involvement of pharyngeal and tongue musculature and hoarseness and dysphonia caused by laryngeal weakness are frequently seen.

Neck muscle weakness is common and the head may droop forwards in severe cases; MG is one of the most common causes of the 'dropped head syndrome'.[5] In generalized MG, the proximal limb muscles are typically most affected, but predominantly distal[6] and sometimes very focal weakness are described.[7] Tendon reflexes are normal or brisk and sensation is intact.

Clinical examination should pay particular attention to shoulder abduction, elbow extension, wrist and finger extension, finger abduction and hip extension, as these are frequently weaker and fatigue more quickly than their antagonistic limb movements. In severe cases, all muscles can be involved, including the diaphragm and intercostal muscles, causing dyspnoea and hypoventilation. Muscle wasting may be seen on occasion in chronic, poorly controlled disease. Muscle strength should be quantified (MRC grading) as serial assessment may give an objective early warning of deterioration, and also help to monitor treatment efficacy. Measurements should include vital capacity (VC), timed elevation of the eyes and eyelids and forward abduction of the arms. A rapid decline in VC or a reading below 1 l are signs of imminent respiratory failure.

Muscle weakness can be worsened by a wide range of conditions, including intercurrent diseases, especially infections, fever, extremes of temperature and emotional upset. In addition, many drugs may adversely affect myasthenia[8] and should be used with caution in poorly controlled patients (Table 66.1). If possible, neuromuscular blocking agents should not be used during general anaesthesia. Sufficient muscle relaxation can usually be provided by inhalation anaesthetics alone. Many other drugs may increase weakness and it is a useful rule to monitor carefully all MG patients when starting a drug that is new to them.

Whether cardiac function is impaired in MG remains uncertain. Although there is no evidence for an increased risk of heart-related deaths, there may be subclinical alterations in cardiac function in some MG patients, possibly related to the autoimmune diathesis and reversible with acetylcholinesterase inhibitors. Focal myocarditis and non-specific myocardial changes have been reported in pathological series, especially in MG associated with thymoma.[9]

A central cholinergic deficit in MG, commensurate with that at the neuromuscular junction, has been suggested, with resulting impaired memory function (cholinergic deficits are thought to be important in both Alzheimer's disease and dementia with Lewy bodies). Some studies have suggested cognitive impairments in MG patients, some of which improve with immunotherapy, but others have found no evidence for such impairments in MG patients compared with normal controls and hence no support for the idea of impaired central cholinergic mechanisms.[10]

Table 66.1 Drugs that may worsen MG.

Neuromuscular blockers, including D-tubocurarine, pancuronium, curare and succinylcholine
Aminoglycosides, including gentamicin, streptomycin, kanamycin, neomycin and viomycin
Polymixins, including polymixin B and colistin
Beta-blockers
Calcium channel antagonists
Quinine, quinidine and procainamide
Chloroquine and hydroxychloroquine

Penicillamine-associated myasthenia gravis

Unlike the many drugs that may temporarily worsen MG, D-penicillamine may induce immune-mediated MG. Typically the disease is mild, often ocular, associated with the transient production of low-titre AChR antibodies in patients who are HLA Bw35 DR1 positive, responds to acetylcholinesterases and remits permanently within months of stopping D-penicillamine. However, clinical, genetic and immunological heterogeneity are reported, as in spontaneous MG, with occasional patients developing severe and persistent seropositive or seronegative MG requiring ongoing immunotherapy.[11]

Diagnostic investigations: bedside

The distinctive clinical picture may enable a confident diagnosis of MG to be made, but additional investigations are desirable since there is a differential diagnosis (see below). Diagnostic confusion arises most frequently when MG is mild or when one of the clinical features dominates the presentation. Patients may not volunteer a history of fluctuating weakness and it is useful to ask about this, particularly diurnal variability with sleep benefit, in anyone presenting with tiredness, ptosis, diplopia, dysphagia or hoarseness. Examination should include assessment of muscle power and fatigability with repetitive contraction. Even when symptoms are restricted to one area, it is sometimes possible to demonstrate weakness in the typical pattern described above.

Anticholinesterase (Tensilon) test

Although this is the least specific of the standard tests for MG, it is frequently used because it is relatively easy

to perform at the bedside and provides an immediate result, whereas other tests and their results (blood tests, neurophysiology) may be delayed.

Edrophonium chloride (Tensilon) is a short-acting acetylcholinesterase inhibitor. A test dose of 1–2 mg is given through an intravenous cannula, a further 5–8 mg being given if there is no adverse reaction. The test is positive if muscle strength improves within 1 min. Assessment should be as objective as possible and include VC measurement and forward elevation of the arms, in addition to monitoring of ptosis and diplopia. Increased muscle power lasts for about 5 min. Some patients may develop a severe bradycardia and occasionally ventricular fibrillation. Pretreatment with i.v. atropine (0.6 mg) is probably advisable and the test is best performed with ECG monitoring and definitely with resuscitation equipment discreetly to hand.

Positive responses to the Tensilon test may occur in a wide range of conditions, including LEMS, motor neurone disease, neuropathies, myopathies and even psychogenic weakness and intracranial tumours. This test is probably best reserved for the situation where there is a strong clinical suspicion of MG but the results of antibody tests are negative or not yet available and EMG is awaited.

Ice pack test

The 'ice pack test' or 'ice on eyes' test has been proposed as a useful method of distinguishing ptosis due to MG from other causes. An ice cube is applied to the ptotic eyelid for at least 2 min and the response noted: improvement in ptosis (>2 mm, positive response) is both sensitive and specific for the diagnosis of myasthenia and correlates with the result of the Tensilon test, although false negatives have been described.[12] Pooling of results from six studies ($n = 76$ MG patients, $n = 77$ patients with non-myasthenic ptosis) gave a test sensitivity of 89%, a specificity of 100% and positive and negative predictive values of 100 and 91%, respectively, for the ice pack test.[12] Utility of the ice pack test in the assessment of extraocular muscle weakness remains to be shown.[13]

Compared with AChR antibody assay and neurophysiological testing, the ice pack test has the advantages of being cheap, quick and not requiring specialist equipment. Moreover, compared with the Tensilon test, no specialist medications are required, it is free of adverse effects and its result, although not unequivocal, is usually easy to interpret.[12]

Sleep test

That rest improves myasthenic ptosis is widely observed. A standardized 'sleep test' or 'rest test' has been advocated for the diagnosis of MG, a positive result being resolution of ptosis or ophthalmoparesis after 30 min of sleep.[14]

Diagnostic investigations: laboratory

Laboratory tests are essential to confirm the diagnosis, as treatment may involve surgery and drug therapy with potentially serious adverse effects.

Acetylcholine receptor (AChR) antibodies

The autoimmune nature of MG was first suggested by Simpson in 1960,[15] the evidence for which is summarized in Table 66.2. The most specific blood test for MG is the presence of serum AChR IgG antibodies detected by radioimmunoprecipitation assay (RIA). This uses AChRs labelled with an iodinated toxin that binds specifically to these receptors. False positives are rare in the healthy British population, including the elderly, although 7% of a group of patients over the age of 65 years selected for their predisposition to autoimmune disease (assessed by raised antithyroid antibody titres) had raised levels. The assay does not detect AChR antibodies in patients with seronegative MG.

Anti-MuSK antibodies

About 10–50% of MG patients without AChR antibodies have antibodies directed to the muscle-specific receptor tyrosine kinase MuSK.[16] MuSK mediates the agrin-induced

Table 66.2 Evidence that MG is an antibody-mediated autoimmune disease.

Antibody can be demonstrated in the majority of patients with the disease: AChR antibodies are detected in 85% of patients with generalized MG
Passive transfer of the antibody to experimental animals reproduces the disease: IgG from myasthenics injected into mice induces the clinical and electrophysiological features of MG
Antibody interacts with the target antigen: electron microscope immunohistochemistry has shown that AChR antibodies, in addition to complement, localize to postsynaptic structures in a pattern appropriate to affect AChRs in a destructive autoimmune process
Immunization with antigen produces a model of the disease: animals immunized with purified AChR develop myasthenia
Lowering serum antibodies improves the disease: removal of circulating antibodies by plasma exchange results in marked, but transient, improvement in disease in most myasthenics. After treatment, the antibody titre rises and the weakness returns

clustering of AChRs during synapse formation and is also expressed at the mature neuromuscular junction. MG with MuSK antibodies is often associated clinically with persistent bulbar involvement, including marked facial weakness involving buccinators, orbicularis oris and orbicularis oculi and tongue muscle wasting and respiratory crises.[17]

Striated muscle and other antibodies

Antibodies that bind to components of striated muscle cell membrane are found in 30% of all MG patients and in 70–90% of those with a thymoma. Therefore, anti-striated muscle antibodies may be used as a serum marker for this tumour. In addition, subgroups of these antibodies reacting with titin or ryanodine receptors are particularly associated with severe MG and also with thymoma. Antibodies that react with myosin, α-actin, actinin, β-adrenergic receptors and muscarinic AChR have also been demonstrated in MG, but their pathophysiological significance, if any, remains unclear.

Neurophysiology: electromyography

The most commonly used neurophysiological tests are repetitive nerve stimulation (RNS) and single-fibre electromyography (SF-EMG). Results may be misleading in patients who have been on chronic high-dose anticholinesterase treatment because of drug-induced downregulation of AChRs. If there is any doubt about EMG findings, it is better, if possible, to stop these drugs for 1 week and then repeat the tests.

In RNS, a train of electric stimuli at 3–5 Hz is given to a nerve and compound action potentials are recorded from the relevant muscle. A decline in the amplitude of the fifth compared with the first potential of more than 10% (decrementing response) is judged positive. This is found in about 50% of mild MG patients and 80% of those with more severe weakness.

During SF-EMG, recordings are made from two or three different muscle fibres within a single motor unit. The finding of increased jitter, a breakdown in the timing relationship of activation between the muscle fibres, often accompanied by blocking of successive muscle discharges, is abnormal. When recordings are made from a range of muscles, abnormal responses are seen in up to 99% of generalized MG patients and 84% of those with pure ocular disease. This test is therefore highly sensitive. However, these findings are not specific, since jitter and blocking can occur in LEMS and in conditions where there is reduced muscle fibre density, such as motor neurone disease. Furthermore, SF-EMG can be difficult to interpret in elderly patients as jitter increases with age and normal values were established in individuals under the age of 60 years.

Table 66.3 Immune disorders reported in association with MG.

Thyroid disease: both hyper- and hypothyroidism
Rheumatoid arthritis
Systemic lupus erythematosus
Acquired peripheral nerve hyperexcitability (neuromyotonia)
Sjögren syndrome
Polymyositis
Selective or pan-hypogammaglobulinaemia
LEMS
Dermatological diseases: pemphigus, lichen planus, vitiligo, alopecia
Haematological disease: pernicious anaemia, red cell aplasia, neutropenia, aplastic anaemia, idiopathic thrombocytopenic purpura

Imaging

Contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) scan of the mediastinum should be obtained to look for thymoma. In those at high risk (raised AChR and striated muscle antibody titres), a negative scan should prompt re-imaging after 2–3 years.

Other tests

In all patients it is advisable to look for evidence of other autoimmune disorders, especially thyroid (Table 66.3). In difficult cases, specialist techniques are available, including muscle biopsy for quantification of endplate AChRs and immunohistological and electrophysiological studies.

Differential diagnosis

A number of conditions can mimic (seronegative) MG and cause diagnostic confusion, including LEMS, certain restricted myopathies, mitochondrial cytopathies especially with the chronic progressive external ophthalmoplegia (CPEO) phenotype, motor neurone disease, peripheral neuropathies, hyperthyroidism and psychogenic weakness. Intracranial mass lesions, including brainstem glioma and giant vertebrobasilar aneurysm, have been reported to present as 'MG' on occasion.

Clinical classification of MG and associated diseases

The progression of MG is variable and it is difficult to predict the outcome in an individual patient. However, the classification shown in Table 66.4, the Myasthenia Gravis Foundation of America grades,[18] serves as an aid both to prognosis and to planning of treatment, although some atypical cases sit uneasily within the classification.[7] Based on this, studies have established several useful clinical

Table 66.4 Clinical classification of MG.

Group 1	Ocular myasthenia
Group 2A	Mild generalized myasthenia with slow progression
Group 2B	Moderate generalized myasthenia with prominent bulbar involvement
Group 3	Acute fulminating myasthenia with rapid progression and respiratory crises
Group 4	Late severe myasthenia similar to group 3, but starting as group 1 and progressing in less than 2 years to become generalized

guidelines.[19] Only 10–15% of patients with MG limited to the ocular muscles for 2 years will progress to develop generalized disease. In generalized MG, the rate of progression is more variable. However, maximum severity is reached within the first year in two-thirds of patients and respiratory crises are more likely to develop with increasing age of onset. Typically, MG follows a chronic course. Spontaneous remissions occur in less than half of all patients and are usually temporary.

Autoimmune diseases tend to cluster both in individuals and in families. Hyperthyroidism, rheumatoid arthritis, PNH and systemic lupus erythematosus are the diseases most consistently reported in association with MG (Table 66.3).

Is MG different in the elderly?

Could the underdiagnosis of MG in the elderly[2] be ascribed, at least in part, to the disorder being in some ways different in this age group? Certainly the disorder is more common in men than women over the age of 60 years and thymoma is more common in the older age group. It has also been argued that the typical clinical features of MG may be more difficult to spot in older individuals, since age-related decrease in total eyelid area with sagging of the lower eyelids makes ptosis less easy to diagnose and diplopia may not be detected due to impaired vision from macular degeneration or cataract formation. The mean concentration of AChR antibodies is lower in elderly MG patients but seronegative MG is less common. Antibodies to titin are found in ~30% of patients with late-onset nonthymoma MG, but these antibodies are extremely rare in early-onset MG.[20] Use of steroids and immunosuppressive agents for the treatment of the elderly MG patient may pose greater risks of adverse effects, for example with steroid-induced osteoporosis, hence the need for prophylactic treatment.

Management

The management of MG varies with the type and severity of the disease, individual disease progression, concurrent illness, age of the patient and experience and familiarity of the treating physician with a particular treatment regime. Anticholinesterases, immunosuppressants, plasma exchange (PE), intravenous immunoglobulin (IVIG) and thymectomy are the most frequently used therapies (Figure 66.1).[19] Current treatment strategies result in at least 90% remission or substantial improvement leading to a good quality of life.

Anticholinesterase inhibitors

These are the first-line drugs for all MG patients and act by inhibiting acetylcholine breakdown at the NMJ.[19] They are used to provide long-term symptomatic improvement in mild disease, especially ocular, and as temporary adjunctive therapy in patients embarking on definitive treatment. They act within 10–30 min, have a maximum effect at 2 h and their effects last for about 4 h. The starting dose of pyridostigmine, the most widely used drug, should be 30 mg two to four times per day, gradually increasing according to response, usually up to a dose of 60 mg five times a day.

High doses will produce more adverse effects. The common muscarinic adverse effects include abdominal cramps, diarrhoea, increased sweating and excessive bronchial and oral secretions. Propantheline can alleviate these problems, but may mask the signs of overdose. The main nicotinic adverse effects are muscle fasciculations and cramps. Chronic high doses may increase weakness by downregulating AChRs. Pyridostigmine should be slowly withdrawn when immunosuppressive treatment has been established or after thymectomy.

Steroids

Steroids are useful as short-term immunosuppressants in MG.[21] They are used as an interim measure while titrating up the doses of other immunosuppressants and waiting for them to be effective. Some patients experience a temporary worsening of MG if steroids are started at high doses. This 'steroid dip' usually occurs 4–10 days after starting steroids. To overcome this problem, alternate day treatment has been shown to be effective. Oral prednisolone, the recommended first-choice drug, should be started at a low dose of 10 mg on alternate days, gradually increasing by 10 mg per dose to 60–80 mg on alternate days. Improvement usually occurs within 1–4 weeks. Owing to the adverse effects of prolonged steroid use, when remission occurs, the dose should be slowly reduced to the minimum effective dose, given on alternate days. In critically ill patients, high-dose daily steroids may be started and additional short-term treatments such as intravenous immunoglobulin and plasma exchange can be used to overcome any temporary worsening of MG.

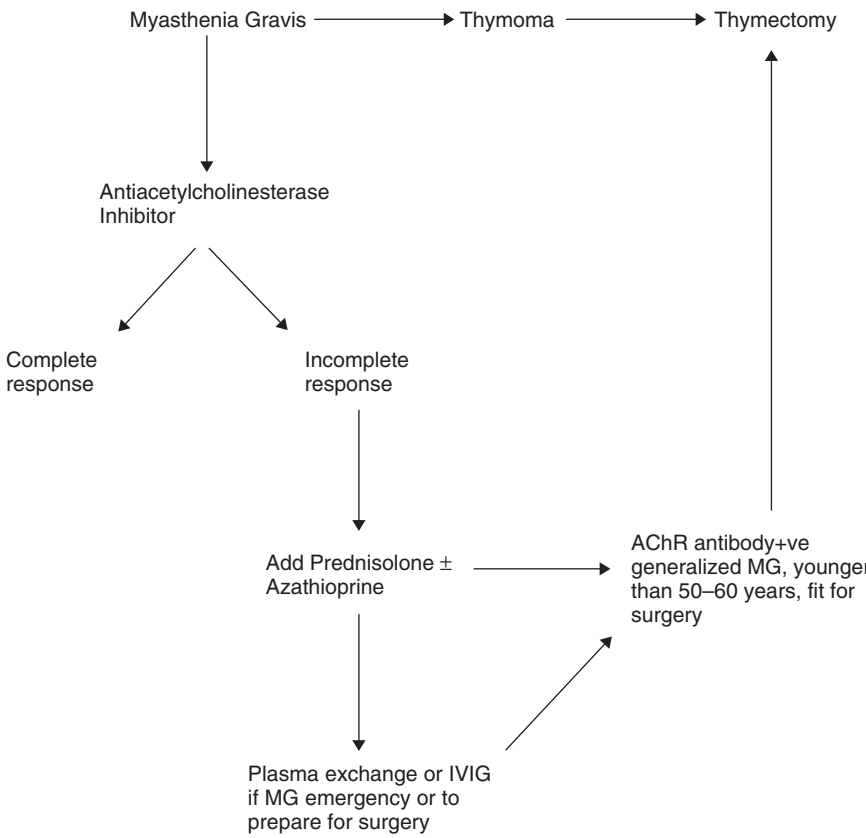

Figure 66.1 An algorithm for the management of MG.

Long-term steroid use is associated with many adverse effects, including cushingoid features, infections, hypertension, diabetes mellitus, osteoporosis, psychiatric disorders, insomnia and elevations in white cell count. It is worth highlighting that it is now routine to cover steroid treatment with a prophylactic bisphosphonate.

Long-term immunosuppressants

In many countries, azathioprine is the first-choice long-term immunosuppressant. It is usually used in combination with steroids to allow tapering of steroids to the lowest dose possible.[21] It has the disadvantage that treatment must often be continued for 6 months to 2 years before maximum clinical improvement is seen. Azathioprine is typically started at 50 mg per day and the dose is increased by 50 mg per week until a maintenance dose of 2.5 mg kg^{-1} is reached. After remission, the dose is slowly reduced by 25–50 mg per month provided that full control of symptoms is maintained. When used in combination with prednisolone, the steroid is withdrawn first.

Common adverse effects include hepatotoxicity, nausea, vomiting, rash, cytopenia and pancreatitis. In the long term, malignancy is a potential complication, but the absolute risk is difficult to evaluate because of the problem of separating the effects of the drug from age-related increases in the background incidence of cancer. Most patients tolerate the drug well and mild but stable haematological or liver-related blood test abnormalities without symptoms are not usually reasons for stopping treatment. Full blood count and liver-related blood tests must be monitored weekly for the first 8 weeks of therapy and 3 monthly thereafter. If there are progressive blood test abnormalities, the drug must be stopped, although it is often possible to restart treatment at a lower dose after the blood tests have returned to normal.

Several guidelines have suggested that methotrexate should be used as a second-line immunosuppressant in MG.[19,21] The adverse effects are usually mild (e.g. alopecia, gastrointestinal intolerance, mild abnormalities of liver-related blood tests, mucositis), although severe adverse events such as haematopoietic suppression, hepatotoxicity and pneumonitis can sometimes occur. Mycophenolate mofetil and tacrolimus should be considered in patients who are intolerant of or unresponsive to azathioprine or methotrexate.[21] Mycophenolate mofetil in particular appears to be well tolerated and has a relatively good adverse effect profile.[22] Ciclosporin and cyclophosphamide should only be considered if other immunosuppressants fail, as these drugs can cause serious adverse effects.[21]

Plasma exchange

In most MG patients, weakness improves after PE.[23] It is thought to act mainly by removing circulating antibodies. A standard protocol is five exchanges each of 50 ml kg^{-1} body weight over 5–7 days. Improvement typically begins within 1–2 days, is maximal at 1–2 weeks and lasts about 1–3 months. It is mainly used to treat myasthenic crises and for rapid stabilization of patients undergoing thymectomy. Prethymectomy PE improves outcome after thymectomy in MG. Most adverse effects are related to issues of vascular access such as infection, thrombosis, pneumothorax and, rarely, air embolism. Excessive fluid volume shifts can cause fluid overload and congestive heart failure or hypotension. Citrate infused for anticoagulation may lead to hypocalcaemia and disturbances in acid–base homeostasis.

Intravenous immunoglobulin

The indications for IVIG in MG are the same as those for PE.[23] Improvement is seen in most patients within 4–5 days and lasts from several weeks to several months. Typically, 0.4 g kg^{-1} body weight is given daily for 5 days. The mode of action of IVIG in MG is incompletely understood. Common adverse effects include fever, headache, nausea and allergic reactions. A severe anaphylactic reaction might occur in patients with IgA deficiency. Volume overload may occur in cardiomyopathy and solute-induced renal failure may occur in patients with pre-existing renal compromise. High infusion rates may cause thrombosis and stroke. However, the adverse effects from IVIG appear less severe than those from PE.

Thymectomy

This is the treatment of choice for a thymoma if there are no anaesthetic or medical contraindications.[24] If the patient is unfit, radiotherapy may be indicated. When MG is associated with a thymoma, the disease may be more aggressive, requiring the use of immunosuppressants in most patients following thymectomy. In non-thymoma patients, thymectomy is usually performed in patients with generalized MG, younger than 50–60 years of age and positive for AChR antibodies.[24] Although thymectomy has been used since the 1940s, pioneered in the UK by Sir Geoffrey Keynes, clinical trials have not been undertaken. An international trial comparing thymectomy plus steroid treatment versus steroid treatment alone is currently under way.[25] The most common surgical techniques performed are extended trans-sternal thymectomy and video-assisted endoscopic thymectomy, although the debate on which is better is ongoing.

The clinical benefit from a thymectomy may only become apparent 6–12 months after surgery. Factors associated with a good response to thymectomy include female gender, predominance of weakness affecting limb muscles and the presence of AChR antibodies.

Management in special circumstances

In pure ocular myasthenia, most patients do not respond adequately to pyridostigmine alone and prednisolone is needed.[24] Prednisolone is usually started at a low 10 mg alternate day dose, gradually increasing, as described above, to a maximum of 20–40 mg on alternate days. The diagnosis of ocular myasthenia needs to be re-evaluated if there is an absolute lack of response after 3 months. In patients with only partial response to steroids, a long-term immunosuppressant such as azathioprine needs to be considered.

Myasthenic and cholinergic crises are said to occur if weakness is severe enough for a patient to require ventilation. Myasthenic crisis is usually precipitated by infection or other intercurrent disease, surgery or too rapid a decrease in immunotherapy doses. Excessive treatment with anticholinesterase inhibitors causes the rarer cholinergic crisis. It can be difficult to distinguish between the two types of crisis. If in doubt, it is safe to stop the anticholinesterase inhibitors once the patient is on a ventilator. Infection, if present, must be aggressively treated. In myasthenic crises, IVIG or PE is usually indicated and the doses of immunosuppressants may be increased as appropriate.

When an MG patient requires anaesthesia, the local or spinal route is preferred if possible. If a general anaesthetic is required, a nasotracheal tube is inserted at operation to allow ventilation to be assisted postoperatively if needed. The tube is kept in for 1–2 days, by which time the VC usually recovers sufficiently to allow extubation. Anticholinesterase inhibitors increase bronchial secretions and are best avoided on the morning of the operation and for 24 h afterwards. Immunosuppressant drugs should be continued.

Lambert–Eaton myasthenic syndrome

The experimental approaches first used in MG, focusing on the criteria listed in Table 66.2, have established LEMS as the second antibody-mediated autoimmune disorder of neuromuscular transmission. Presynaptic motor nerve terminal voltage-gated calcium channels (VGCCs) are the main antigenic targets. LEMS may be divided into two types: paraneoplastic, occurring as a remote effect of a neoplasm, and spontaneous. Two-thirds of patients, mainly older male smokers, develop LEMS in association with a tumour, most commonly small cell lung carcinoma (SCLC) and more rarely lymphoma, certain adenocarcinomas and thymoma.[26] It is thought that VGCCs on tumour cells trigger the production of antibodies that cross-react with

antigenically similar nerve channels and that this leads to channel downregulation and a reduction in transmitter release. Spontaneous cases tend to be younger, have no smoking history and are usually women. About 3% of those with SCLC develop LEMS and the overall incidence is about 4 per million.

In the typical case,[27] LEMS most often presents with subacute ascending weakness of the proximal limb muscles, typically affecting the lower limbs first and causing a characteristic rolling gait. Ptosis and diplopia can occur. Bulbar and respiratory muscle weakness are much less common than in MG. Features of autonomic dysfunction are frequently found, including dry mouth (xerostomia), constipation, urinary hesitancy and impotence. Some patients complain of paraesthesias and muscle aches. On examination, the strength of the affected muscles can increase during the first few seconds of a maximal voluntary contraction, a phenomenon known as augmentation. Tendon reflexes are typically reduced or absent, although may be transiently restored to normal after 15–30 s of sustained muscle contraction, a phenomenon known as post-tetanic potentiation or facilitation. The course of LEMS is variably progressive.

The syndrome, most frequently the spontaneous form, is associated with other autoimmune diseases, including vitiligo, thyroid disorders, diabetes mellitus and pernicious anaemia.[26] Paraneoplastic LEMS may coexist with other paraneoplastic neurological syndromes, including subacute cerebellar degeneration and encephalomyelitis. Serum VGCC IgG antibodies to the P/Q subtype of channels are detected in up to 90% of patients with paraneoplastic LEMS and 76% of those with the spontaneous disease by an RIA using [^{125}I]-ω-conotoxin MVIIC, which binds specifically to these channels. On EMG, typically there is a marked reduction in the amplitude of the compound muscle action potential following supramaximal nerve stimulation, that increases following maximal voluntary contraction for 15 s. A 25% increase in amplitude is suggestive of LEMS and a 100% increase is diagnostic. On single fibre recordings, increased jitter with frequent blocking may be found, as in MG. Nerve conduction studies are normal. Patients may respond to edrophonium but not as dramatically as those with MG. Repeated screening tests for tumours should be carried out particularly in those patients with a high risk of malignancy such as smokers, as SCLC may not be obvious for up to 5 years after onset of LEMS. Whole-body positron emission tomographic (PET) imaging may have a role in detecting occult tumours in paraneoplastic syndromes.

The definitive management of paraneoplastic LEMS is treatment of the tumour. This often leads to neurological improvement.[19] In those cases of LEMS with tumour or at high risk of developing one, the first-line drug treatment is 3,4-diaminopyridine (10–20 mg up to five times per day), a potassium channel inhibitor that increases acetylcholine release from neurons. Side effects include perioral and other paraesthesias. Sometimes the addition of pyridostigmine produces a further small improvement in muscle strength.

Mild cases of spontaneous LEMS are also treated with these drugs. Severe weakness requires the addition of immunosuppressive agents. The combination of prednisolone (1–1.5 mg kg^{-1} body weight) and azathioprine (2.5 mg kg^{-1} body weight) seems to be the most effective and the treatment plan generally follows that for MG. However, the response is slower, improvement may be delayed for 6 months and after stabilization immunosuppressive drugs can rarely be withdrawn completely. Prednisolone may be useful in paraneoplastic LEMS when weakness fails to respond well to treatment of the tumour.

Patients may improve temporarily after plasma exchange and this can be used to supplement other treatments. Similarly, IVIG can increase muscle strength, mirrored by a decline in anti-VGCC antibody titres. Improvement lasts from 4 to 6 weeks.

Peripheral nerve hyperexcitability

The most common acquired clinical variant of generalized PNH is neuromyotonia (Isaacs syndrome) caused by antibodies to neuronal voltage-gated potassium channels (VGKC). This is a rare and heterogeneous syndrome characterized clinically by complaints of muscle stiffness, cramps, twitching, weakness and delayed muscle relaxation (pseudomyotonia). Symptoms are often triggered by muscle contraction and disability can be severe. About one-third of patients have some sensory features such as paraesthesias and central nervous system features can occur (Morvan syndrome). There is neurophysiological evidence of continuous motor unit activity of peripheral nerve origin. Spontaneous firing of single motor units as doublet, triplet or multiplet discharges with high intraburst frequency (40–300 per second) at irregular intervals is the hallmark finding. The persistence of these findings after proximal nerve blockade with local anaesthetic agents proves their peripheral nerve origin, suggesting that the discharges arise in the terminal arborizations of motor nerves.[28,29]

Neuromyotonia is paraneoplastic in up to 25% of patients and can predate tumour detection by up to 4 years, thymus and lung being the typical underlying tumours. There is no autoantibody that indicates whether PNH is paraneoplastic. VGKC antibodies are found in about 35% of all PNH patients, rising to 80% in those with thymoma. A paraneoplastic syndrome of limbic encephalitis complicated by epileptic seizures and hyponatraemia may also be

associated with VGKC antibodies, with or without clinical evidence of PNH.[30]

All forms of neuromyotonia usually improve with symptomatic treatment. Suitable agents include carbamazepine, phenytoin, lamotrigine and sodium valproate, in combination if necessary. Paraneoplastic neuromyotonia often improves and may remit after treatment of the underlying tumour. Immunomodulatory therapies may be considered in patients with likely autoimmune variants of PNH with debilitating symptoms which are refractory to symptomatic treatments. Plasma exchange often produces useful clinical improvement lasting about 6 weeks accompanied by a reduction in EMG activity and a fall in VGKC antibody titres.[29] Case studies suggest that IVIG may also be helpful. By analogy with LEMS, selected patients with severe neuromyotonia refractory to other treatments may benefit from serial immunomodulatory therapy every 6–8 weeks. There are no good trials of long-term oral immunosuppression. However, prednisolone with or without azathioprine or methotrexate has been useful in selected patients.[19]

Acknowledgement

This chapter is dedicated to our friend and colleague Dr Ian Kirkland Hart, who died suddenly on 10 November 2008, and is based upon his chapter in the previous (4th) edition of this textbook, published in 2006.

Key points

- MG, LEMS and PNH are all antibody-mediated NMJ disorders.
- MG incidence rises with age but is underdiagnosed in the elderly.
- MG is treatable, with more than 90% of patients returning to normal function, so the diagnosis should be considered in anyone presenting with ptosis, diplopia, dysphagia, limb or respiratory muscle weakness.

CHAPTER 67

Muscle disorders

David Hilton-Jones
John Radcliffe Hospital, Oxford; Milton Keynes Hospital Foundation Trust, Milton Keynes, Buckinghamshire; Muscular Dystrophy Campaign Muscle and Nerve Centre, Oxford, and Myasthenia Gravis Association Myasthenia Centre, Oxford, UK

Introduction

Myopathies may be inherited or acquired. Although the latter are more common in geriatric practice, several inherited myopathies may present for the first time in middle age or later and may raise genetic issues for other family members. The acquired myopathies, with a few notable exceptions, often recover with appropriate management. For all of the conditions that are discussed in this chapter, appropriate support, even in the absence of specific therapy, will help improve quality of life and reduce morbidity.

The clinical features of myopathies are relatively limited and include weakness and muscle wasting, fatigue, pain, tenderness, myotonia and muscle twitching. At the bedside it may be impossible to decide whether weakness and wasting are due to a myopathy or a neurogenic disorder. Thus, the differential diagnosis of myopathy includes anterior horn cell disorders (e.g. amyotrophic lateral sclerosis and spinal muscular atrophy), nerve root and plexus disorders, peripheral neuropathies and myasthenic disorders. The presence of upper motor neurone signs and sensory symptoms and signs clearly suggests a more proximal cause of problems than skeletal muscle, but in their absence it is important not to forget that weakness alone is often due to nerve rather than muscle disease. The role of laboratory investigations in helping to distinguish between neurogenic and myopathic diseases is discussed below.

There are several ways of approaching the classification of muscle disorders. For example, inherited disorders can be classified by phenotype or by gene/protein product. For everyday usage, a subdivision into acquired and inherited disorders is useful (Tables 67.1 and 67.2). In the elderly (Table 67.3), the most frequently encountered disorders are the idiopathic inflammatory myopathies, drug-induced myopathies and muscle disease in association with endocrine and metabolic disease.

Table 67.1 Acquired myopathies.

Idiopathic inflammatory myopathies
– Polymyositis
– Dermatomyositis
– Inclusion body myositis
– Myositis associated with connective tissue disorders
Toxic
– Alcohol
– Drugs
Endocrine and metabolic
– Acromegaly
– Hypothyroidism
– Hyperthyroidism
– Cushing syndrome
– Addison disease
– Disorders of vitamin D and calcium metabolism
Infection
– Viral
– Bacterial
– Parasitic
Paraneoplastic myopathies

Clinical assessment

The patient's history is likely to be more revealing than physical examination, although laboratory investigations may be required to establish the precise diagnosis.[1,2] In the history, particular attention must be paid to determining the site of onset and rate of progression of skeletal muscle involvement and the presence of associated symptoms such as muscle wasting and pain. There must be a detailed recording of the family history and drug history. For myopathies secondary to systemic disease (Table 67.1), the underlying cause may be identified from the history and physical examination. In practice, the most frequently encountered pattern of skeletal muscle involvement is that of painless proximal weakness affecting the pelvic girdle

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 67.2 Inherited myopathies.

Muscular dystrophies
– (See Table 67.8)
Myotonic dystrophies
Congenital myopathies
– Central core disease
– Nemaline myopathy
– Myotubular/centronuclear myopathy
– Multi-mini-core disease
Metabolic myopathies
– Glycogenosis (e.g. McArdle syndrome)
– Lipid disorders (e.g. disorders of fatty acid β-oxidation)
– Mitochondrial cytopathies
Channelopathies
– Sodium (hyperkalaemic periodic paralysis, paramyotonia congenita)
– Calcium (hypokalaemic periodic paralysis)
– Chloride (myotonia congenita)
– Ryanodine receptor (malignant hyperthermia, core diseases)

Table 67.3 Major myopathies in the elderly.

Idiopathic inflammatory myopathies
Toxic myopathies
Endocrine and metabolic myopathies
Oculopharyngeal muscular dystrophy

more than the shoulder girdle. In the acquired myopathies (Table 67.1), onset may be acute or chronic, whereas in the inherited myopathies (Table 67.2), progression is usually slow. Asymmetric involvement is uncommon but may be a striking feature in inclusion body myositis (IBM) and facioscapulohumeral (FSH) muscular dystrophy. Early involvement of distal muscles is seen in myotonic dystrophy and IBM.

There is early involvement of the extraocular muscles (causing ptosis and/or ophthalmoplegia) in myasthenia gravis, mitochondrial cytopathies, Graves' ophthalmopathy and oculopharyngeal muscular dystrophy. Ptosis and facial weakness are seen in myotonic dystrophy and facial weakness is a particular feature of FSH muscular dystrophy and some of the congenital myopathies. Myasthenia gravis most frequently presents with intermittent diplopia and ptosis. Subsequently there may be facial and bulbar muscle involvement.

Weak muscles eventually become wasted, but in many myopathies the bulk is maintained for a long time, whereas in neuropathies wasting is generally an earlier feature. The tendon reflexes also tend to be lost early in neuropathies. Muscle hypertrophy is rare in acquired myopathies but is a feature of some of the muscular dystrophies (e.g. Duchenne/Becker dystrophy).

Respiratory muscle weakness may be asymptomatic, but evidence of it can be found on examination in the form of paradoxical abdominal movement. The best method of evaluation is by measurement of the forced vital capacity (FVC). In the presence of diaphragmatic weakness, the FVC falls when the patient lies down.

Most myopathies are painless at rest. Acute dermatomyositis (DM) may be painful, but rarely markedly so, and there is a striking difference between the modest pain and severe weakness seen in this condition and the severe pain and stiffness and absence of weakness seen in polymyalgia rheumatica. Aching is a common feature in hypothyroid myopathy and bone pain a major feature of osteomalacia. Acute drug-induced and acute alcoholic myopathies are often painful. Exercise-induced muscle pain is seen in several metabolic myopathies[1] and in Becker muscular dystrophy.

Clinical features alone usually provide a strong pointer toward the diagnosis and help determine the path of laboratory assessment.[3]

Laboratory investigations

A fairly common pathway from the clinical evaluation to diagnosis is via biochemical studies, electrophysiological assessment and muscle biopsy. For the inherited myopathies, this pathway is gradually being supplanted in part or in whole by specific DNA tests.[3]

Biochemical studies

Despite its lack of specificity, estimation of the serum creatine kinase (CK) is a useful marker for muscle disease. High levels are seen in Duchenne and Becker muscular dystrophy, acute drug-induced and toxic myopathies, inflammatory myopathies, some forms of limb-girdle muscular dystrophy and some metabolic myopathies. Levels are normal in many congenital myopathies, myotonic disorders, chronic drug-induced myopathies and many metabolic myopathies. Moderate elevation (up to 1000 i.u. l^{-1}) may be seen in anterior horn cell disorders. The serum aspartate aminotransferase (AST) level generally parallels the CK level in muscle disorders and not infrequently its elevation in the presence of otherwise normal liver function tests is the first indication of a myopathic disorder – however, this may not be appreciated and some patients undergo unnecessary liver investigations, including biopsy, before the penny drops and the CK is measured.

Dynamic studies (such as estimation of lactate generation during exercise and magnetic resonance spectroscopy) are of value in the investigation of suspected metabolic myopathies involving carbohydrate and mitochondrial metabolism and tandem mass spectrometry is of value in evaluating disorders of fatty acid β-oxidation.[1]

Electrophysiology

In primary disorders of the muscle, electromyography (EMG) characteristically shows a reduction in the size and duration of the motor unit potentials and an increase in the number of polyphasic units. Fibrillation potentials and positive sharp waves indicate muscle fibre irritability and are seen in inflammatory myopathies and some metabolic myopathies. Myotonic discharges are seen in myotonic dystrophy and myotonia congenita.

EMG may help in distinguishing between neurogenic and myopathic disorders, which may sometimes be difficult on clinical grounds alone.

Muscle biopsy

With the exception of DNA tests, muscle biopsy remains the single most powerful tool for the specific diagnosis of myopathies.[4] The muscle to be biopsied must be chosen with considerable care.[3] Tissue handling is extremely important and correct processing requires specialist facilities.[1] Biopsy findings in individual disorders are discussed throughout this chapter. Biopsy samples are also used for biochemical studies and mitochondrial DNA analysis.

Molecular studies

There has been rapid progress recently in the identification of the genetic basis of many of the inherited myopathies (see Gene Tables at http://www.musclegenetable.org/). This offers the prospect of rapid and precise diagnosis and the option of prenatal diagnosis. However, a number of practical difficulties remain in moving tests from the research arena to accredited diagnostic laboratories.[5]

Acquired myopathies

The acquired myopathies (Table 67.1) are of particular importance because many of them are either treatable or reversible. The idiopathic inflammatory myopathies are the subject of considerable research activity, which has aided classification and our understanding of pathogenetic mechanisms and is starting to help in determining therapeutic approaches. Toxic and drug-induced myopathies are seen at all ages but are particularly important in the elderly because of polypharmacy. Myopathy, occasionally severe, is common in many endocrine disorders and usually responds rapidly to correction of the underlying condition. Disorders of calcium and vitamin D metabolism in the elderly are an important cause of muscle weakness. Several forms of paraneoplastic myopathy exist but, in general, the condition is overdiagnosed.

Idiopathic inflammatory myopathies

Dermatomyositis (DM) and polymyositis (PM) share many clinical features and there are common approaches to treatment, but recent studies have shown that they have very different immunopathogenic mechanisms.[6] Inclusion body myositis may not be a true primary inflammatory myopathy but it is often confused clinically with PM and is particularly important in the present context because it is seen most frequently in the elderly.

Myositis may be seen in association with connective tissue disorders (including systemic lupus, scleroderma, Sjögren syndrome, rheumatoid arthritis and mixed connective tissue disease) and these are sometimes referred to as *overlap syndromes*.[6] Care must be taken to distinguish a true inflammatory myopathy as the cause of weakness in these conditions from other associated causes, such as peripheral neuropathy, muscle ischaemia, cachexia and drug-induced myopathy. Overall, clinically relevant inflammatory myopathy in these overlap syndromes is uncommon.

Dermatomyositis (DM) (see Chapter 125, skin disorders)

Clinical features

DM can develop at any age, is twice as common in females than males and has an annual incidence of about two per million population. Onset of weakness is usually subacute (weeks) but, in rare cases, has a more explosive onset with profound weakness, respiratory muscle involvement and rhabdomyolysis with myoglobinuria developing within a few days. Exercise-induced muscle pain and discomfort on palpation may be present but severe discomfort of the type associated with polymyalgia rheumatica is not seen. Dysphagia is common.

Clinical evidence of skin involvement is present in most, but not all, cases. The commonest features are a non-specific erythematous rash over the face and upper anterior chest wall (areas exposed to sunlight), a red–purple discoloration over the knuckles and dilatation of capillaries at the base of the nail bed (Figure 67.1). Characteristic, but seen less often, is a violaceous (heliotrope) discoloration of the eyelids. Raynaud's phenomenon, which may long predate the myopathy and arthralgia, is frequent. Interstitial pulmonary fibrosis may be asymptomatic, cause breathlessness and cough or occasionally be relentlessly progressive despite treatment and lead to death. There is an association between lung involvement and the presence of serum anti-Jo-1 antibodies. Cardiomyopathy and rhythm disturbances are underestimated and may also lead to death. In about 20% of cases overall, but more frequently in older patients, there is an association with carcinoma, but not with a particular carcinoma. Thorough clinical assessment is therefore

Figure 67.1 Dermatomyositis. Note erythema over knuckles and dilatation of the nail-bed capillaries.

essential, including rectal, vaginal and breast examination, sigmoidoscopy or more extensive endoscopy if there is a suggestive history, abdominal and chest scanning, testing for faecal occult blood and basic haematological and biochemical studies.[7] Positron emission tomography (PET) is becoming increasingly available as a screening tool to detect occult malignancy.

Diagnosis and pathological features

The serum CK is usually elevated and in acute cases the level may be very high. It is a useful but not absolute indicator of disease activity. The erythrocyte sedimentation rate (ESR) is normal in the majority of patients. Autoantibodies are frequently found but their identification is of little value with respect to diagnosis or prognosis, except perhaps for the association noted above between anti-Jo-1 and interstitial lung disease.[8] EMG shows an alteration in the motor unit potentials (reduced duration and an increase in polyphasic units) and electrical irritability (fibrillation potentials and positive sharp waves).

The diagnosis is confirmed by the muscle biopsy findings. Characteristic features include perifascicular atrophy, focal myofibrillar loss and areas of infarction. Vascular changes include capillary necrosis, undulating tubules in endothelial cells, arteriolar thrombosis and lytic membrane-attack complex deposition in vessel walls. Inflammatory infiltrates are typically found in septa and around blood vessels (Figure 67.2) and consist of B-lymphocytes, helper T-lymphocytes and plasma cells.

Pathogenesis

On the basis of the characteristic immunopathological muscle biopsy findings noted above, it is believed that DM is caused by humoral immune mechanisms which lead to destruction of capillaries and occlusion of arterioles. Muscle fibre damage is thus secondary to ischaemia. This contrasts with PM in which cell-mediated immune mechanisms lead to muscle fibre destruction.

Treatment

Knowledge of the natural history of DM is limited and there have been no completely satisfactory controlled trials of drug therapy. Prednisolone is the mainstay of treatment and a reasonable starting dose is $1\,mg\,kg^{-1}$ body weight per day. In severe cases, this may be preceded by intravenous methylprednisolone 500 mg daily for 5 days, although the evidence for additional benefit is lacking. Azathioprine ($2.5\,mg\,kg^{-1}$ body weight per day) or methotrexate (10–20 mg weekly) are widely used in combination with prednisolone, as long-term steroid-sparing agents. The steroid dose is maintained for 1–3 months (at least until the CK has returned to normal) and then lowered slowly at a rate determined by the clinical response and to a lesser extent by changes in the serum CK. A rise in the CK may precede exacerbation of weakness. As the disorder settles, the prednisolone can be changed to an alternate day regime, which may reduce steroid side effects. If the patient

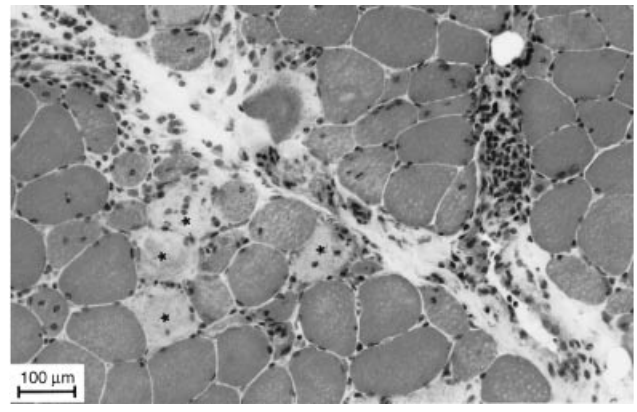

Figure 67.2 Dermatomyositis. Muscle biopsy (H&E, ×115). Note the perivascular inflammatory infiltrate and necrotic fibres (*).

does not respond to or cannot tolerate the above regime, then there are several other options. Alternative immunosuppressant drugs that are used (but without trial data) include mycophenolate mofetil and cyclophosphamide. Plasma exchange and leucapheresis appear to be ineffective. Intravenous immunoglobulin is almost certainly effective,[9] but there are insufficient data to recommend it over prednisolone as a mainstay of treatment, although it is fairly widely used in severe cases at first presentation together with high doses of steroids.

The cutaneous lesions respond to systemic steroid treatment. In the absence of significant muscle involvement, topical steroids may have a role. The skin is photosensitive and light-exposed areas should be treated with an ultraviolet blocking cream. Malnutrition (e.g. due to associated dysphagia) must be avoided to prevent muscle catabolism. Physical activity should be encouraged.

The prognosis with respect to muscle function and life expectancy is good if treatment is started early and there is no associated malignancy.

Polymyositis (PM)

Clinical features

Polymyositis is a disappearing disease as many cases previously diagnosed as PM have been reclassified as having IBM or myositis associated with connective tissue disease.[10] As in DM, the weakness is predominantly proximal but the onset is often insidious and the rate of progression slower. Muscle pain and tenderness are very uncommon. Elderly patients often give a history of deterioration of gait over 1–2 years, which is not infrequently attributed to arthritic hips.

Diagnosis and pathological features

The serum CK is usually elevated but may be normal in very slowly progressive or late stages of the disease. The ESR is unhelpful. Electromyographic changes are the same as those described for DM.

Muscle biopsy shows scattered necrotic and regenerating fibres. The vascular changes noted in DM are absent. Inflammatory infiltrates (Figure 67.3) tend to be within fascicles (endomysial) and are composed of cytotoxic T-lymphocytes and macrophages with fewer B-lymphocytes. A characteristic finding in PM, and also in IBM, is partial invasion of muscle fibres. Cytotoxic T-lymphocytes penetrate the basal lamina but not the muscle fibre membrane and appear to compress the fibres without causing necrosis. These fibres, and also non-invaded fibre, express class I major histocompatibility complex (MHC) protein products, which are not expressed in normal muscle.

Pathogenesis

In PM, it is presumed that cytotoxic T-lymphocytes recognize an antigen, bound to class I MHC products, on the muscle fibre surface. Muscle fibre function is compromised by the invading lymphocytes, which are also associated with lymphokine release. The nature and origin of the antigen are unknown.

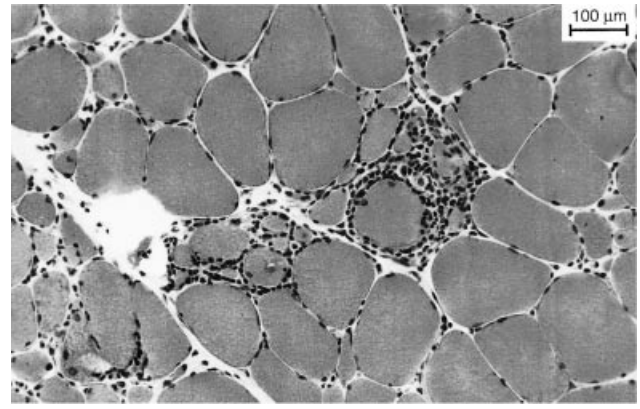

Figure 67.3 Polymyositis. Muscle biopsy (H&E, ×115). Note the endomysial inflammatory infiltrate.

Treatment

Despite the different pathogenetic mechanisms postulated, the immunosuppressive drug management of PM is the same as described above for DM. If there is extensive weakness and wasting at presentation, the prognosis for significant improvement is poor, although disease progress may be arrested.

Inclusion body myositis (IBM)

Clinical features

IBM is rare before the fifth or sixth decade of life and shows a strong male predominance.[11] Its incidence is uncertain and many cases have previously been labelled as (steroid-resistant) PM. Rare familial cases have been described.[12]

The characteristic pattern of muscle involvement, which is often asymmetric, involves wasting and weakness of quadriceps and distal weakness affecting finger flexion and ankle dorsiflexion. Symptomatic presentation is with falls due to the knees giving way and weakness of grip.

Dysphagia is relatively common and may be the presenting symptom.[13] Systemic features are not present. IBM has been reported in association with many other disorders, some autoimmune, but no consistent association has been recognized.[14]

Diagnosis and pathological features

The serum CK is normal or moderately elevated. EMG shows changes similar to those described for DM and PM but, in addition, 'neuropathic' features (long-duration, high-amplitude motor unit potentials) are often present. Whether this truly reflects neurogenic involvement or is a secondary consequence of primary muscle disease remains much debated.

The diagnosis has conventionally been established by light and electron microscopy.[15] Characteristic features (Figure 67.4) include the variable presence of inflammatory infiltrates (with a predominance of cytotoxic T-lymphocytes), partial invasion of muscle fibres, rimmed vacuoles, intracellular amyloid deposits and, diagnostically, 15–18 nm tubulofilaments (Figure 67.5).

There are arguments in favour of reviewing the conventional diagnostic criteria.[16]

Pathogenesis

Pathogenesis remains hotly debated. Although there is evidence of T-cell mediated cytotoxicity, it is not clear that this is of primary importance. The presence of myonuclear abnormalities suggests that IBM may be due to a disorder primarily affecting the cell nuclei. Protein aggregates in the characteristic inclusions contain amyloid and other proteins typical of the inclusions seen in the brain in Alzheimer's disease. Despite the pathological similarities, there is no clinical link between the two disorders, but it has been postulated that there may be similar protein degradation abnormalities in each disorder.[16,17]

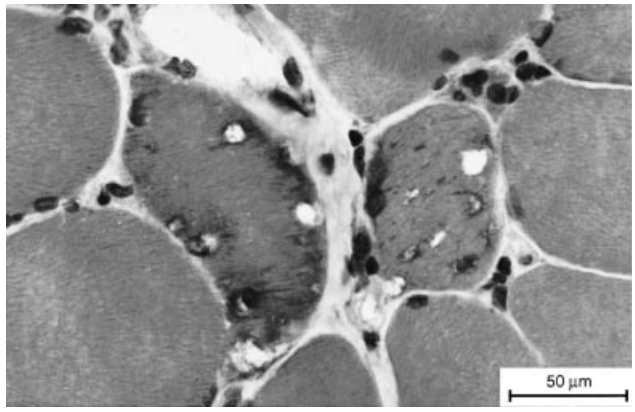

Figure 67.4 Inclusion body myositis. Muscle biopsy (H&E, ×460). Note the two fibres containing characteristic rimmed vacuoles.

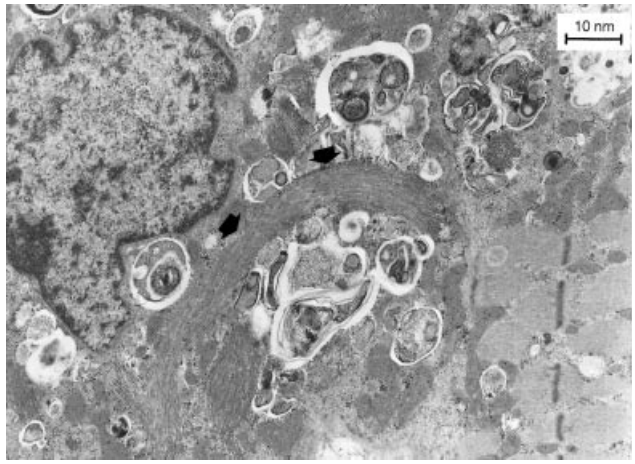

Figure 67.5 Inclusion body myositis. Muscle biopsy (electron micrograph, ×13 000). Bundle of characteristic 15 nm tubulofilaments (arrows).

Treatment

IBM appears to show little or no response to immunosuppressive therapies of the type that are successful in DM and PM and many specialists no longer recommend using such drug regimes. Early suggestions that intravenous immunoglobulin might be helpful have not been substantiated.[18]

The disease shows a relentlessly progressive course with loss of ambulation 10–20 years after onset.

Toxic and drug-induced myopathies

Toxic and drug-induced myopathies are an important, and almost certainly underdiagnosed, group of disorders, not least because prompt removal of the offending agent may lead to full recovery. Ethanol can cause a dramatic acute myopathy. It is much debated whether proximal weakness in chronic alcoholics is primarily myopathic or neurogenic in origin. Myopathy may be seen in association with drug abuse but of much greater significance are the myopathies associated with the therapeutic use of drugs.

Ethanol-related myopathies

Three forms of myopathy have been attributed to alcoholism. First, chronic alcoholics can develop painless proximal weakness, affecting the pelvic girdle more than the shoulder girdle. Serum CK may be modestly elevated. Muscle biopsy shows type II fibre atrophy.[19] Second, acute alcoholic myopathy follows a binge. There is muscle pain, swelling and weakness, which may be localized to one or two muscles or be generalized. The serum CK is markedly elevated. Myoglobinuria is present and may threaten renal function. Recovery of muscle function occurs over 1–2 weeks. Muscle biopsy shows muscle fibre necrosis and inflammatory infiltrates. Third, acute or subacute severe, painless, proximal weakness may be caused by hypokalaemia. Potassium loss may be secondary to diarrhoea or vomiting. Repletion of potassium leads to recovery.

Drug-induced

With the exception of drugs that cause hypokalaemia, the pathogenetic basis of most drug-induced myopathies remains unclear.[20] In practice, the most useful classification is based on the clinical features of the myopathy (Table 67.4). Statins have been associated with several forms of myopathy. Although the incidence is low, their widespread and ever-growing use means that most clinicians will encounter

Table 67.4 Patterns of drug-induced myopathy.

Painless
Painful
Acute rhabdomyolysis
Periodic weakness
Focal

statin-induced myopathy at some stage and therefore it merits separate discussion.

Painless myopathies

Painless myopathy is the most prevalent form of drug-induced myopathy, with corticosteroids being the commonest cause (Table 67.5). The clinical picture is of proximal weakness with either subacute onset or, more usually, chronic progression. Muscle atrophy develops in long-standing cases. Those drugs that produce hypokalaemia may also cause intermittent (periodic) weakness.

The clinical features of corticosteroid myopathy and Cushing syndrome are similar. Women are more susceptible to steroid myopathy than men and 9-α-fluorinated steroids (e.g. dexamethasone, betamethasone) have the greatest myopathic potential. The serum CK is usually normal. EMG may be normal or show 'myopathic' features. Muscle biopsy shows non-specific type II fibre atrophy (Figure 67.6). Full recovery usually follows drug withdrawal.

Painful

Many drugs may cause an acute or subacute painful myopathy and the list in Table 67.6 is certainly incomplete. Weakness is usually proximal but may be generalized and the muscles may be tender. The serum CK is often elevated and EMG shows changes of primary muscle disease. In some, there may be a direct toxic effect of the drug on muscle. In others, indicated in Table 67.6, there is an inflammatory myopathy.

[a]Drugs causing an inflammatory myopathy.

Acute rhabdomyolysis

Acute rhabdomyolysis represents an extreme form of necrotizing myopathy with myoglobinuria and the clinical presentation is acute with severe generalized weakness and muscle pain. Muscle swelling may require fasciotomy and renal failure is common. Serum CK is very high. Drugs that cause this syndrome (Table 67.7) include drugs of abuse and addiction and drugs already noted to cause either painless or painful myopathy.

Periodic weakness

Drug-induced hypokalaemia (Table 67.5) may cause persistent or intermittent (periodic) weakness. Areflexia may be present during bouts of weakness. Serum CK may be elevated.

Statins

Focal

Intramuscular injection of many drugs may cause local tissue damage. Repeated injections, particularly of certain antibiotics, pentazocine and opiates, may lead to muscle fibrosis and contractures.

Statin-induced myopathies

Statins (HMG-CoA reductase inhibitors) interfere with cholesterol synthesis and thus lower serum cholesterol levels. Already widely prescribed, some countries now allow these drugs to be sold over the counter without a prescription. There is no doubt that statins can cause myopathy, but despite numerous trials involving hundreds of thousands of patients, post-marketing surveillance and a publication rate of about one paper per week, for more than a decade, relating to statins and muscles, there remain many unanswered questions, including:

- What is the frequency of statin-induced myopathy?
- What is/are the underlying mechanism(s)?
- Are some statins more myopathic than others?
- Does the presence of a pre-existing muscle disease increase the risk of statin-induced myopathy?
- What other factors lead to increased risk of statin-induced myopathy?

Many reviews have appeared, mostly in the cardiology and lipid literature, and terms such as myositis and rhabdomyolysis have often been used inappropriately, causing some confusion.[21] Extraordinarily, many reports have relied solely on patient self-reporting without physician assessment and very few have included formal assessment of muscle function – not even the simplest bedside assessment of muscle strength. As to possible mechanisms, strong suspicion falls upon disturbance of intermediary metabolism although by and large this remains unproven. Statins block pathways associated with lipid synthesis and might therefore be expected to have some impact on muscle fibre membrane composition; membrane fragility underlies many other forms of myopathy, including many of the dystrophies. In addition, they block pathways involved with coenzyme Q (CoQ10) synthesis, an essential component of the mitochondrial respiratory enzyme pathway. This has led some enthusiasts to recommend prescribing CoQ10 with statins, but the theoretical mechanism has not been proven, nor the therapeutic approach shown to work.

Although the earlier literature referred to statin-induced myositis, there had in fact been only a handful of reports showing true myositis (i.e. inflammatory infiltrates in muscle) – rather, those inexperienced in the field of muscle disease used the term myositis to describe anyone with a substantially elevated serum CK level. More recently, there have been reports of myositis developing in patients on statins and persisting after the statin was withdrawn, to the extent of requiring immunosuppressant drug therapy.[22] But uncertainties remain. These patients had not had their CK measured before starting treatment and so possibly the myositis predated the introduction of the statin. The development of myositis might have been entirely coincidental – after all, with statins being so widely prescribed (approximately 1 in 20 of the UK population at present and growing), such coincidence is bound to occur. Also, in five of the eight reported cases, the pathological appearance was of a necrotizing myopathy, without inflammatory infiltrates, although MHC 1 expression, often regarded as a surrogate for an inflammatory process, was increased. Further assessment, by suitably experienced myologists, is required.

On the basis of currently available (but flawed) evidence, it would appear that the major statin-induced muscle syndromes include:

- asymptomatic elevation of serum CK;
- myalgia with elevated serum CK (probably the commonest);
- myalgia with normal serum CK;
- acute rhabdomyolysis with risk to renal function;
- a true myositis which may persist after discontinuation of the statin;

The most feared complication is acute rhabdomyolysis with the attendant complication of renal failure secondary to myoglobinuria. One of the earlier statins, cerivastatin, was withdrawn following a number of deaths attributed to this. Overall, the risk of rhabdomyolysis is extremely low but certain factors predispose to it, most notably the dose of the statin and the concomitant use of other drugs that interfere with statin metabolism.

A recent announcement from the US Food and Drug Administration (FDA) concluded that with respect to simvastatin, the risk of rhabdomyolysis was substantially increased at a dose of 80 mg daily compared with lower doses.[23] The risk is substantially increased when combined

with certain other drugs and they advised on the maximum dose of simvastatin to be used in combination with those drugs. Thus, if also taking diltiazem, simvastatin should be limited to 40 mg daily, if taking amiodarone or verapamil to 20 mg daily and if taking gemfibrozil or ciclosporin to 10 mg daily. A number of drugs should never be combined with simvastatin.

Although it has been suggested that a pre-existing myopathy increases the risk of statin-induced myopathy, the evidence is not convincing and it should certainly not be considered an absolute contraindication to their prescription. Patients should be counselled at the time of prescription about the potential myopathic effects and to report symptoms such as myalgia, weakness or myoglobinuria.

There have been many reports of patients who have been identified as having a myopathy (e.g. McArdle disease) following investigation of an elevated serum CK, which was measured only because the patient was on a statin! Another important catch is the patient with subclinical hypothyroidism causing myalgia, hypercholesterolaemia and an elevated serum CK. Interpretation of symptoms such as myalgia is difficult when patients have been forewarned of its possibility.

There remains debate as to whether CK should always be measured before starting statins, so as to have a baseline if there are future problems. An argument against this is cost, especially as the majority of patients will not develop muscle problems. Another difficulty is the lack of a clear-cut upper limit of normal for CK and that CK levels may be increased following normal patterns of physical activity – many normal individuals will be reported by the laboratory as having an elevated CK which may then cause anxiety and unnecessary investigation.

Finally, there have been reports of myasthenia gravis developing after starting a statin or pre-existing myasthenia worsening after starting such treatment. As discussed above with respect to other myopathies, it remains uncertain whether these are real problems or biased reporting of coincidence. However, it seems reasonable to caution patients accordingly.

Endocrine and metabolic myopathies

Myopathy, typically in the form of chronic painless proximal weakness, is common in endocrine disorders and of particular importance because treatment of the underlying disorder almost invariably leads to full recovery.[1] In the elderly, the most frequently encountered endocrine myopathies are those associated with thyroid disease, glucocorticoid excess (Cushing syndrome and iatrogenic steroid myopathy) and disorders of vitamin D metabolism.

Thyroid disorders

Hypothyroidism (see Chapter 98, thyroid disorders)

Symptomatic myopathy is present in about 80% of patients with hypothyroidism but is rarely the presenting feature. Symptoms include weakness (mild and proximal), fatigue, stiffness and myalgia. Examination may show delayed tendon reflexes and myoedema – a ridge or mound of contracted muscle seen transiently after pinching or percussing muscle.

The serum CK is elevated, often markedly, in most patients and thyroid function studies should be performed in any patient with unexplained elevation of the CK.

Thyroid function studies are invariably abnormal and the myopathy resolves on restoration of the euthyroid state.

Hyperthyroidism (see Chapter 98, thyroid disorders)

Up to half of thyrotoxic patients will have weakness as a symptom and over 80% of patients have signs of weakness at presentation. Onset of myopathy is usually subacute or chronic and the weakness, which is proximal, is generally greater than that seen in hypothyroid myopathy. However, in thyrotoxic myopathy the serum CK is often normal. The weakness resolves upon resolution of the thyrotoxicosis.

Graves' ophthalmopathy

Thyroid-associated eye disease, although most frequently associated with hyperthyroidism, can occur in euthyroid and hypothyroid patients.[24] Diplopia may be the only feature but the typical order of progression of eye symptoms and signs is eyelid lag and retraction, itchiness, redness of the conjunctivae, eyelid swelling, proptosis, diplopia, corneal ulceration, papilloedema and optic nerve compression. These changes may be unilateral.

Biochemical evidence of thyroid dysfunction is usually readily evident but if thyroid-associated eye disease is suspected and serum thyroid hormone and thyroid-stimulating hormone levels are normal, then immunological studies may be helpful.[25] Orbital ultrasonography, CT and MRI show characteristic extraocular muscle swelling which may aid diagnosis if laboratory support for the diagnosis is lacking.

The first stage of treatment is to return thyroid function to normal. If major eye signs persist, options include surgical decompression of the orbit, steroids and orbital irradiation.[26]

Pituitary–adrenal axis disorders (see Chapter 97, the pituitary gland)

The clinical features of Cushing syndrome (whether pituitary, adrenal or ectopic) and iatrogenic steroid myopathy (see the earlier sections) are similar.[1] Weakness starts around the pelvic girdle and later ascends to the trunk

and then the shoulder girdle musculature. Myalgia is common. It is rare for myopathy to develop without other features of glucocorticoid excess.

The serum CK is usually normal, EMG shows myopathic features and muscle biopsy shows type II fibre atrophy (Figure 67.6). The myopathy resolves once the glucocorticoid excess is removed.

Rarely, an acute myopathy [acute quadriplegic myopathy (AQM)] may develop following high-dose parenteral steroid therapy, with or without concomitant use of neuromuscular blocking agents, for example, for the treatment of myasthenia gravis or status asthmaticus.[27] Pathologically, it is characterized by loss of thick (myosin) filaments.[28]

Disorders of vitamin D metabolism

The myopathic disorders associated with osteomalacia and with primary hyperparathyroidism show clinical similarities.[1]

Osteomalacia

Pelvic girdle weakness, causing a waddling gait and difficulty climbing stairs and getting out of low chairs, is the presenting symptom in about one-third of patients with osteomalacia.[29] It is almost invariably associated with bone pain, most prominent in the ribs, pelvis and femora.

The serum CK is usually normal, as is muscle biopsy, although non-specific changes may be seen.

With appropriate treatment the weakness slowly improves, but the bone pain usually resolves more rapidly.

Primary hyperparathyroidism (see Chapter 95, endocrinology of ageing)

Weakness and fatigue may be late features of primary hyperparathyroidism but it is not clear whether this is neurogenic or myopathic in origin.[1] Successful treatment (usually involving removal of a solitary parathyroid adenoma) leads to resolution of the neuromuscular symptoms.

Paraneoplastic myopathies

Up to 20% of patients with DM, but probably significantly more in the elderly, have an associated malignancy (see earlier sections), but the pathogenetic mechanism is unclear. Serum electrolyte disturbances (hypokalaemia, hyperkalaemia, hyponatraemia and hypercalcaemia) caused by neoplastic disorders, including tumours of endocrine glands, are one cause of paraneoplastic muscle weakness. Benign or malignant tumours of endocrine glands may also cause weakness through hormone deficiency or excess.[30]

The term carcinomatous neuromyopathy is sometimes used to describe a syndrome of proximal weakness and wasting (usually pelvic more than shoulder girdle), of subacute or chronic course and with depressed tendon reflexes. Most evidence suggests that this is probably neurogenic rather than myogenic in origin.

Inherited myopathies

Muscular dystrophies

The term muscular dystrophy encompasses a group of progressive, inherited disorders in which the primary pathological process is degeneration of muscle fibres. Although clinically highly variable, common histological features include muscle fibre necrosis, abnormal variation in fibre size, central nucleation, fibre splitting and replacement of muscle by fibrous tissue.

The classification of the muscular dystrophies is in a state of change as the genetic and molecular basis of each disorder is identified. In everyday clinical practice, the most useful classification is based upon the mode of inheritance and phenotype (Table 67.8). Myotonic dystrophy is considered separately (see the following sections). Most muscular dystrophies present in childhood or early adult life, but there are important exceptions (including myotonic dystrophy). Some may first present in middle and late middle age, whereas others may be asymptomatic and be identified serendipitously when a relative is assessed following identification of another affected family member.

Dystrophinopathies

Duchenne and Becker muscular dystrophy are allelic disorders. A mutation causing complete absence of the protein dystrophin causes the severe Duchenne phenotype, but mutations resulting in the production of some functional dystrophin cause Becker muscular dystrophy, which itself has a variable clinical presentation.

In Duchenne muscular dystrophy, onset occurs between 2 and 4 years of age and death occurs in early adult life. In typical Becker muscular dystrophy, onset is during adolescence. Rarely, first presentation, with pelvic weakness, may occur in late middle age.[31] Cardiomyopathy is common and may be severe even in the absence

Table 67.8 Classification of the muscular dystrophies.

of significant skeletal muscle weakness.[32] About 10% of female Duchenne/Becker dystrophy carriers may manifest myopathic features, ranging from asymptomatic calf hypertrophy to severe limb-girdle weakness, the latter sometimes not presenting until middle age.

Limb-girdle dystrophies

About 90% are autosomal recessive and 10% autosomal dominant. The common phenotype is progressive limb-girdle weakness, usually affecting the pelvic girdle more than the shoulder girdle, but with a very wide range of age of onset and severity. In the majority, presentation is in childhood or early adult life. A few are associated with cardiomyopathy. None typically present beyond middle age. Diagnosis depends upon immunohistochemical techniques applied to muscle biopsy and DNA analysis.

Facioscapulohumeral (FSH) muscular dystrophy

FSH muscular dystrophy is relatively common (prevalence about 4 per 100 000 population). It is an autosomal dominant disorder associated with deletion of a repeat sequence, not within a gene, on chromosome 4.

The name describes the highly characteristic pattern of early muscle involvement. The patient may not be aware of facial weakness and it may be missed by an inexperienced clinician. The patient may report an inability to whistle, use a straw or blow up balloons. Weakness and wasting of the scapular fixator muscles (Figures 67.7 and 67.8) limits upper limb abduction and patients complain of difficulty combing their hair and reaching up to shelves. There is weakness and wasting of the humeral muscles (biceps more than triceps) but preservation of deltoid. Unlike other forms of muscular dystrophy, the weakness is often asymmetric (Figure 67.9). Tibialis anterior is involved early and weakness is nearly always found on examination. The patient may have symptomatic foot drop.

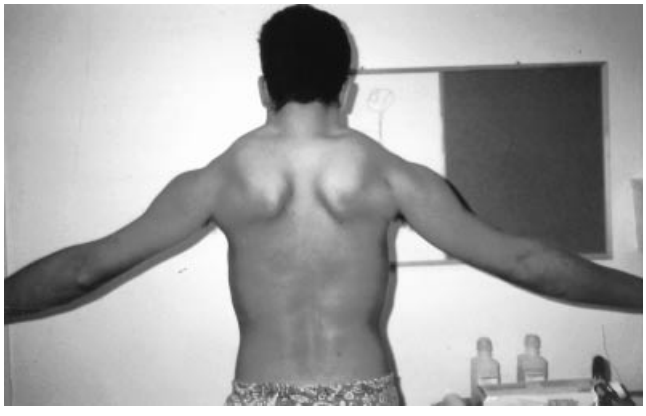

Figure 67.7 Facioscapulohumeral muscular dystrophy (see text).

Figure 67.8 Facioscapulohumeral muscular dystrophy (see text).

Figure 67.9 Facioscapulohumeral muscular dystrophy (see text).

The age of onset is highly variable but is typically in adolescence and early adult life. Mildly affected cases are common and family studies frequently identify asymptomatic individuals with mild weakness. There is slow progression of the weakness, with later involvement of the pelvic girdle. The serum CK may be normal or modestly elevated. Diagnosis is by DNA analysis.

Oculopharyngeal muscular dystrophy

This is an autosomal dominant, late-onset disorder which is probably underdiagnosed.[33] Onset is usually in the fifth decade or later and most frequently with ptosis (Figure 67.10), which can be asymmetric. There is overactivity of frontalis in an attempt to compensate for the ptosis (Figure 67.10). Dysphagia develops within a few years and is occasionally the presenting symptom.

In later stages, eye movements may be restricted (external ophthalmoplegia) but diplopia is rare. Limb involvement is usually confined to mild shoulder girdle weakness, but the pelvic girdle can be involved and rarely there is more debilitating limb weakness.

Figure 67.10 Oculopharyngeal muscular dystrophy (see text).

Figure 67.11 Myotonic dystrophy. Characteristic facial appearance. Note the ptosis and wasting of the facial muscles and temporalis.

Ptosis can be severe enough to impair vision – surgical correction can be highly successful. Dysphagia may respond to oesophageal dilatation or cricopharyngeal myotomy but requires detailed preoperative assessment.

Diagnosis is by DNA analysis, demonstrating an expansion in the PABPN1 gene. The differential diagnosis of late-onset ptosis and dysphagia includes myasthenia gravis and mitochondrial chronic progressive external ophthalmoplegia (CPEO) (see the following sections).

Myotonic dystrophy

Two forms of myotonic dystrophy (DM) are now recognized, sharing a common molecular mechanism. They are autosomal dominant multisystem disorders. In each, an unstable nucleotide repeat expansion probably has its effect through disruption of mRNA metabolism.[34,35] Diagnosis is by DNA analysis.

DM1 is the commonest form of muscular dystrophy in adult life.[36] The disease shows anticipation, by which subsequent generations tend to show a more severe expression of the disease, as a result of the instability of the underlying repeat expansion.

Clinical features of the 'classical' form include onset from late childhood to middle age, ptosis, weakness that involves initially facial muscles (Figure 67.11), sternomastoid and distal upper limb muscles but later spreads to proximal muscles, respiratory muscle involvement, frontal balding, cataracts, cardiac conduction defects, gonadal atrophy and impaired fertility, excessive daytime sleepiness and impaired smooth muscle function. Myotonia is most evident in the hands and patients complain of difficulty in relaxing their grip. Overall, IQ scores are lower than average. A severe congenital form is seen in a proportion of children born to mothers who themselves have the later-onset form.

In family studies, it is common to identify family members in late middle age who are unaware that they have the disorder. They may be asymptomatic, but frequently have had cataracts that were not recognized as being due to myotonic dystrophy. Even though oligosymptomatic, it is important to identify such patients because they are still at risk of developing cardiac conduction defects and respiratory insufficiency (with particular risk of both during and after anaesthesia).

Major management issues include the identification and appropriate treatment of cardiorespiratory problems and identification of asymptomatic family members who carry

the gene and are at risk of themselves developing cardiorespiratory problems or, for women, of having a congenitally affected child.[37]

DM2 shows many similarities, but tends to be a relatively milder disease presenting later in life, and the weakness is more proximal than distal.[38] Muscle pain is a common presentation.

Chronic progressive external ophthalmoplegia (CPEO)

Progressive ptosis and limitation of eye movements, with or without diplopia, may be seen in a number of disorders (Table 67.9). Myasthenia gravis must always be considered and diagnosis can be difficult if the disease is limited to the ocular muscles. In oculopharyngeal muscular dystrophy, ptosis is an early feature but limitation of eye movements occurs late and is rarely severe.

Most patients with mitochondrial CPEO have an abnormal muscle biopsy showing ragged red fibres (Figure 67.12). Mitochondrial DNA studies typically show a deletion. In the elderly, most cases are sporadic, but autosomal forms exist.[39]

Acknowledgements

I am grateful to Dr Waney Squier for providing the histological illustrations and to my patients for allowing their photographs to appear.

Key points

- Drug-induced myopathies are common and underdiagnosed.
- Statins are likely to become the commonest cause of drug-induced myopathy.
- A few inherited myopathies may not present until late middle age.
- The history and examination are generally more powerful tools than laboratory investigation.
- Inclusion body myositis is the commonest acquired myopathy in the elderly.

CHAPTER 68

Motor neurone disease

Hardev S. Pall
University of Birmingham and University Hospital Birmingham Foundation Trust, Birmingham, UK

Introduction

The first clear account of motor neurone disease (MND) emerged in the mid-nineteenth century,[1] although this consolidated earlier observations such as by Aran.[2] However, MND care remained fragmented well into the 1980s,[3] and it is only in the last 25 years that the disease has received much public and professional attention. In part, the increased profile of MND is due to a few public figures who were diagnosed with the disease, for instance, the actor David Niven and the sportsman Lou Gehrig. The role of patient support organizations in many different countries must also be acknowledged for fighting their corner to obtain more resources for treatment and research. Much of the current medical and legal interest in euthanasia and physician-assisted suicide has centred on MND and similar disorders. The preservation of mental capacity in the majority of patients with this condition and the relatively predictable pace of decline have made MND an ideal candidate disease for focusing debate on end-of-life issues. Developments in medications, both disease-modifying[4] and those involved in symptom control, assistive technology and innovative healthcare delivery systems have given hope and relief to patients with MND and to their caregivers. Multidisciplinary teams are now widely involved in MND care and there is a greater acceptance of involving palliative care services at an early stage.

Definition and terminology

The term motor neurone disease either can be used to describe the condition known as *amyotrophic lateral sclerosis* (ALS) or it can be a more general term for other motor neurone diseases including bulbar palsy and progressive muscular atrophy (PMA) which are closely allied to ALS and others such as Kennedy disease and Hirayama disease that have a less clear association. Conditions such as progressive bulbar palsy and PMA can develop into ALS although pure forms of these conditions also occur. The relationship of ALS to subtypes such as the 'man in a barrel' or flail arm MND (Vulpian–Bernhardt syndrome) and flail leg MND (pseudopolyneuritic MND) is not clear. PMA can either be a very slowly progressive disorder with an outlook better than for ALS or it can progress rapidly, sometimes over a few months, giving it a bimodal distribution of survival. Over half of all cases of PMA show the corticospinal tracts to be involved at autopsy and ubiquitin inclusions typical of MND are also found in the central nervous system (CNS).[5] Bulbar symptoms and signs are seen in a minority of patients with PMA. This chapter deals largely with the ALS form of MND. Bulbar palsy remains a useful term referring to dysarthria and/or dysphagia being the presenting symptoms, but in most cases the condition eventually progresses to MND. The usefulness of the term bulbar palsy is a prognostic one – the life expectancy in bulbar palsy is significantly worse than that in limb-onset MND. A subcommittee of the World Federation of Neurology made a significant contribution to the definition of MND and ALS when it met in El Escorial, Spain, to formulate a set of internationally agreed diagnostic criteria.[6] The El Escorial criteria for diagnosis of possible, probable and clinically definite MND have made it possible to compare directly the results of research investigations carried out in different countries. The criteria are summarized below:

- *Definite ALS:* Upper and lower motor neurone signs in bulbar and two spinal regions or in three spinal regions (cervical, thoracic and lumbosacral).
- *Probable ALS:* Upper and lower motor neurone signs in at least two regions with some of the upper motor neurone signs rostral to the lower motor neurone signs.
- *Probable ALS/laboratory supported:* Upper motor neurone signs in at least one region and lower motor neurone signs on electrodiagnostic testing in at least two regions.
- *Possible ALS:* Upper and lower motor neurone signs in one region (the same region) or upper motor neurone signs in two or three regions or upper and lower motor neurone signs in two regions with no upper motor neurone signs rostral to the lower motor neurone signs.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

The term 'suspected ALS' was dropped in the 1998 revised criteria. It previously referred to a condition in which lower motor neurone signs were found in two or three regions. Certain clinical features were listed as deflecting one from the diagnosis (although not absolute exclusions). These included sensory dysfunction, sphincter disturbance, autonomic signs, visual abnormalities, involuntary movement disorder and cognitive dysfunction. The criteria require the exclusion of other diagnoses by imaging and other investigations. The Airlie revision[6] also suggested that neurophysiological or pathological criteria could be used to identify lower motor neurone signs. The Awaji consensus[7] clarified the neurophysiological features of acute denervation in MND. These criteria are widely supported and adoption of these revisions may drop the 'probable ALS/laboratory supported' entity. There remains a group of patients who do not satisfy these criteria but who are thought to have MND on clinical grounds. These are mainly lower motor neurone syndromes. They emphasize the point that the El Escorial criteria with their several revisions remain important research tools but do not replace clinical judgment.

Clinical features

MND is a progressive neurodegenerative disorder of the upper and lower motor neurones, resulting in weakness, muscle wasting, fasciculation and spasticity as a part of the clinical picture. There is a profound difference between the motor pathways, which are severely affected, and the sensory pathways, which are relatively preserved. Sensory pathway involvement is sufficiently unusual as to spark off a search for an alternative diagnosis. About one-third of patients with MND present with bulbar symptoms, the others with limb problems. Older patients and women are more likely to present with bulbar symptoms. Only a few have other initial presentations such as dementia or respiratory failure. These groups follow significantly different clinical courses and the distinction between them remains important. Furthermore, the diagnostic pitfalls in the two main modes of presentation may be completely different (see below). MND is slightly more common in men, although recent information suggests a narrowing of the male:female ratio. The mean age at presentation is about 57 years. This is a few years younger than the mean age for other neurodegenerative disorders of adult life, such as Parkinson's disease (PD) and Alzheimer's disease. A few patients with MND develop parkinsonism as well and a further few develop dementia. The dementia of MND is a frontotemporal one and distinct from Alzheimer's disease. It is characterized by behaviour disturbance, impaired judgment, language and memory problems and a dysexecutive state.[8] Only small numbers of patients develop these features but they do underline the point that common mechanisms of disease aetiology may be involved in these seemingly disparate disorders. In an even smaller number of cases, patients can present with simultaneous development of both ALS- and PD-like features.

Limb-onset MND

This can arise in either arms or legs and common modes of presentation are with weakness, wasting, cramp, spasms secondary to spasticity and fasciculation. The symptoms are progressive usually over a period of months or occasionally over a few years. Loss of manual dexterity secondary to involvement of small hand muscles is a frequent presenting symptom, as is a disturbance in gait and, in older patients, falls. A cramp in muscles not normally thought of as being prone to cramp, for instance, forearm flexors or abductor pollicis brevis can be a useful clinical pointer. A history of progression is an essential requirement for the diagnosis. The disease commonly starts in just one limb. Clinical and prognostic separation of different limb-onset varieties of MND is still poorly developed, but distinct entities such as flail arms MND, hemiplegic MND and paraplegic MND are recognized. Pain, which is not uncommon in late disease, is usually not a problem at presentation and its early occurrence should encourage a search for alternative diagnoses. Although fasciculation is seen very commonly in MND, it is unusual for prominent fasciculation to be the sole presenting symptom in MND, but it is a common symptom in patients with benign fasciculation or those with a fear of developing MND. Patients with a family history of MND are exceptions, in that they frequently have fasciculation as a presenting symptom.

Bulbar-onset MND

This occurs in about one-third of patients with MND and is more frequent in women. The first presentation is usually with dysarthria or anarthria. Older patients are also more likely to have bulbar onset disease. Progression from dysarthria to anarthria can, in some cases, be so rapid as to lead to an erroneous diagnosis of stroke. Dysphagia is also common in the disease but is a surprisingly infrequent presenting symptom. Recurrent aspiration pneumonitis should alert the physician to the possibility of MND. Choking spells are also uncommon at presentation. Dyspnea secondary to respiratory muscle weakness with or without aspiration pneumonitis is another rare mode of presentation but can become a more troublesome problem later in the disease, as discussed below. Emotional lability is often encountered but only rarely at first presentation and then not as troublesome as other bulbar symptoms.

In establishing a diagnosis of MND, the absence of certain symptoms is just as helpful as the presence of others. Sensory symptoms are usually absent at first presentation

of MND and, when present, they are usually trivial in comparison with the motor problems. The presence of sensory symptoms in a patient at first presentation should activate a search for a condition other than MND. Clinically relevant sensory signs are even less common, and when they are found are often attributed to, but cannot always be explained by, the consequences of nutritional deprivation or pressure palsies secondary to profound wasting and weakness. Sophisticated electrophysiological measurements can demonstrate involvement of sensory pathways in up to 50% of patients. Urinary bladder function is generally preserved in MND. Urgency and frequency, encountered so commonly in other patients with limb spasticity, are uncommon in MND. Similarly, the anterior horn cells responsible for eye movements are relatively resistant to the diffuse process that damages other anterior horn cells in MND, with abnormalities being found occasionally in patients on long-term ventilatory support.

Familial MND

Up to 10% of MND is familial and largely inherited in an autosomal dominant pattern. The age of onset and the clinical course of this condition are similar to those of the sporadic disease, indicating that common mechanisms may be involved in disease causation. Missense and nonsense mutations in the gene encoding superoxide dismutase type 1 (SOD 1 or ALS 1) are found in about 10% of families with this disease.[9] Some mutations (e.g. A4V) encode for more rapidly progressive disease than others (e.g. G37R).[10] SOD 1 MND more commonly starts in the legs. Other genes have also been identified as causing MND but none are as well studied as SOD 1. SOD 1 toxicity is increased in experimental animals by the close proximity between mutation-carrying astrocytes and anterior horn cells. ALS 2 is a recessive disorder involving a gene encoding GEF signalling. Interest in other genetic causes of motor neurone disorders has focused on angiogenin, TAR DNA binding protein (TARDBP), vascular endothelial growth factor (VEGF), dynactin, senataxin, vesicle-associated membrane protein-associated protein B (VAPB), microtubule-associated protein tau (MAPT) and unknown loci on chromosome 9 linking MND with frontotemporal dementia.[11] The ubiquitinated inclusions found in MND contain TDP43, the protein encoded by TARDBP. TARDBP mutations are found in 2–5% of patients with familial MND and in about 2% of sporadic MND cases.[12] It is also controversially suggested that RNA processing defects play a role in MND. The X-linked disorder Kennedy disease or spinal bulbar muscular atrophy (SBMA) is an MND-like disorder with a better outlook than MND and should be considered in cases where maternal transmission of MND is likely or when specific clinical features (see the section on differential diagnosis below) alert one to the diagnosis. There are various genetic factors that may alter disease expression in sporadic MND. For instance, homozygous survival motor neurone 2 (SMN2) gene mutations are over-represented in the MND population. Mutations in the gene encoding vascular endothelial growth factor (VEGF)[13] may also have a disease-modifying effect. Other potential genetic risk factors for MND include mutations in the apurinic/apyrimidinic endonuclease (APEX nuclease) gene, the neuronal apoptosis inhibitory polypeptide (NAIP) gene, cytochrome *c* oxidase gene and the APO E4 genotype. Young patients with an MND-like syndrome may have mutations in the hexosaminidase A gene, causing an accumulation in tissues of GM2 ganglioside. The principles of investigation and management of familial disease are the same as those of sporadic MND with the exception of issues of genetic counselling and perhaps additional psychological support for those patients who have previously nursed other family members through a distressing and ultimately fatal condition. Genetic counselling is made more difficult by the incomplete penetrance of the mutant gene. Where ethical considerations permit this, FALS may provide the best opportunity to study the effects of potentially neuroprotective strategies in altering the course of disease expression in presymptomatic individuals who are known to carry pathogenic disease mutations. The human SOD 1 mutant gene has made it possible to develop a very good mouse model of MND.[14] This allows screening of potential therapeutic compounds before they are used in clinical settings.

Clinical course

Both bulbar-onset and limb-onset MND progress inexorably and are ultimately fatal. The rate of progression is variable but the clinical course is more predictable than for many other fatal conditions such as some of the malignant diseases. This point is important in enabling the healthcare needs of patients to be anticipated and planned for. Median survival in MND is approximately 3 years from the first symptom. Survival up to 5 years and beyond is certainly seen and 10% are said to survive over 10 years. However, survival to 10 years or beyond should activate a search for alternative diagnoses as some of the mimic syndromes have slower progression. Despite the anecdotal observation of more patients surviving to previously exceptional durations of disease, systematic studies do not show an overall increase in survival in MND. Although some patients appear to go through periods of relative stability, these are the exception rather than the rule in MND (except in young-onset MND where initial severe deterioration can be followed by prolonged stability). Each 6 month period usually sees an increase in disability. Women are over-represented in the bulbar-onset group and have a worse prognosis than men. Other prognostic factors include short

latency between symptom onset and diagnosis (perhaps coding for more rapidly advancing disease), older age at presentation and poor social support network. MND patients with a spouse-carer live longer.[15]

Differential diagnosis and diagnostic pitfalls

MND does not have a diagnostic test or reliable biomarker and is a rapidly progressive condition. This makes it imperative to look for alternative diagnoses that may be more treatable or carry a better outlook. Diagnostic errors are more likely to occur if there is pressure for early diagnosis. This is happening now owing to advances in treatment and to increased publicity for the disease. Patients who have fasciculation either as a constant finding, or more often as an intermittent symptom, confined to one muscle or segment such as one calf worry about having MND. In the absence of other signs of a progressive disorder, these patients are likely to have benign fasciculation requiring explanation and reassurance but no other intervention. In an Irish study of diagnostic pitfalls, errors included patients regarded as having clinically definite or clinically probable MND who later turned out to have postpolio syndrome or Kennedy disease. The searches for a biomarker for MND may change diagnostic certainty in years to come.

Cervical and/or lumbar spondylosis

Spinal root and cord compression by cervical and lumbar spondylosis is common. Root compression can lead to segmental muscle wasting and weakness and is a common cause of calf muscle fasciculation. In the elderly, multiple root compression can cause fairly widespread lower motor neurone signs. This, combined with the spasticity that can be caused by spinal cord compression, can mimic MND. However, sensory and bladder disturbances are common in spondylosis but are spared in MND. Neck pain and restriction of neck movements are also more common in spondylosis than in MND at its onset. Bulbar signs, when present, clearly point more strongly towards MND. Tongue wasting with fasciculation can be diagnostic in this setting and other bulbar signs can be suggestive – for instance, brisk jaw jerk or jaw clonus, spastic dysarthria or emotional lability.

Other spinal pathology

Occasionally the distinction between MND and spinal conditions such as syringomyelia can be difficult (a few patients with syringomyelia present with motor rather than sensory features), but spinal MRI can distinguish between these conditions. Other intrinsic spinal pathology may also mimic MND but such cases are rare in the West. Cysticercosis of the spinal cord has been linked with an MND-like presentation and needs to be considered in endemic areas, particularly when the presentation is with a disturbance in one limb, so-called monomelic myelopathy or amyotrophy. Hirayama disease is a disorder of younger men causing distal and usually unilateral arm amyotrophy.[16] It can be familial and may involve dynamic spinal cord compression during neck flexion, resulting in damage to genetically predisposed anterior horn cells. Inherited disorders of spinal neurones can be mistaken for MND including its familial form. Hereditary spastic paraparesis can be a predominantly motor disorder of the upper motor neurones and lower motor neurone disturbance is not a feature, but spontaneous clonus can mimic fasciculation and the unwary can be caught out. The prolonged history and relatively indolent clinical course are also powerful indicators away from MND. The term *primary lateral sclerosis* was coined to describe those patients who have a slowly progressive upper motor neurone disturbance without lower motor neurone features over at least a 3 year period of observation. The progression of this condition is slower than that of MND and the prognosis better. Spinal muscular atrophies, previously classified as forms of MND, are now recognized as distinct disorders with a more benign course. Kennedy disease or X-linked bulbospinal neuronopathy is a disorder characterized by lower motor neurone disturbance of spinal and bulbar neurones and was previously frequently mislabelled MND. This should happen less frequently now as features such as gynaecomastia, facial fasciculation and a family history of X-linked disorder should lead to the search for the trinucleotide repeat expansion in the androgen receptor gene.[17] Other clues include finding low sensory action potentials on nerve conduction studies. Sandhoff disease, a variety of gangliosidosis with hexosaminidase A deficiency, can present in an MND-like fashion and needs to be considered as a possible diagnosis in any very young patient with apparent MND.

Inflammatory lower motor neurone disorders

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a radiculoneuropathy with predominantly motor symptoms and signs and without upper motor neurone pathology. It can mimic the lower motor neurone disturbance of MND but the finding of slowed nerve conduction velocities and elevated CSF protein should lead to the correct diagnosis of a neuropathy rather than an anterior horn cell disorder. This is a treatable disorder often responding well to immunomodulation such as with intravenous immunoglobulins (IVIG). A more patchy related disorder, multifocal motor neuropathy (MMN) with proximal conduction block, also causes confusion.

In MMN, the response to steroids and plasmapheresis is poor and the response to IVIG is rather better to begin with (in 70%) than in CIDP. However, it may not be as sustained. It, too, is worth thinking about in the patient with few or no upper motor neurone signs and without bulbar involvement, with asymmetric onset often in upper limbs and with weakness out of proportion to wasting being important clinical clues. Those cases refractory to IVIG may respond to cyclophosphamide. Reflexes can be preserved and, although it is a neuropathy, fasciculation can be prominent. Limited autopsy studies suggest that anterior horn cells may also be affected. Antibody binding to the nodes of Ranvier indicates that this may be the site of damage. There is a syndrome of late deterioration in patients who have had polio in childhood or in early adult life. This postpolio syndrome can resemble MND but follows a different clinical course. Its recognition is easy if the history of pre-existing polio is known. Similarities between the viral condition and idiopathic MND have prompted searches for an aetiological association between the two disorders. Other enteroviruses have also been implicated in the aetiology of MND. Vasculitis affecting either the spinal cord or the spinal roots or both can resemble MND. Unusually marked sensory symptoms or other features of systemic vasculitis can act as clues. CSF examination can be helpful in this situation as the CSF protein concentration is often elevated in CNS vasculitis and there may be a pleocytosis even in the absence of clinical meningitis. The rise in CSF protein concentration is more marked than that usually seen in MND. The disturbance of anterior horn function associated with the vasculitides including polyarteritis nodosa may respond to immunosuppression.

Other neuropathies

Paraneoplastic neuropathy can mimic MND. Sometimes it is truly an MND-like disorder and on occasion even a Lambert–Eaton myasthenic syndrome (LEMS) has been mistaken for MND. Paraneoplastic disorders are associated with circulating antibodies, for example, voltage-gated calcium channel antibodies linked to LEMS. Sometimes it can be difficult even using electromyography (EMG) always to decide whether a lesion is just neurogenic or whether there is a combination of a neurogenic change and a myopathy. A rare myopathy that causes some difficulty is acid maltase deficiency, which can cause severe respiratory muscle compromise in mobile patients; a condition that is mimicked by a few sufferers of MND. A careful search for upper motor neurone signs may help to avoid diagnostic confusion. When it occurs in adults, lead toxicity can present a picture of a virtually pure motor neuropathy. No case of lead poisoning has been described in terms that could convincingly be recognized as MND. On current evidence, there is no case for treatment of MND with lead chelating agents. A similar controversy has surrounded the link between mercury and MND, but again there is no convincing evidence of an aetiological link. Porphyria and polyarteritis nodosa are causes of a motor neuropathy. Treatment of porphyria with avoidance of the precipitants of acute relapses and treatment of polyarteritis nodosa with immunosuppression can improve disease outcome remarkably. Some of the hereditary motor neuropathies (HMN2 and HMN5) can be mistaken for a predominantly lower motor neurone form of familial MND.

Differential diagnosis of bulbar MND

When bilateral tongue wasting and fasciculation are present, the diagnosis of MND is very likely to be correct. However, when the physical findings both in the limbs and in the mouth are equivocal, a diagnosis of myasthenia gravis must always be considered, as this is an eminently treatable condition. Usually, but not always, a history of fatigable ptosis or diplopia is helpful. These are not seen in ambulant patients with MND. A Tensilon test can aid diagnosis, but interpretation must be cautious as a weak positive Tensilon test can be found in MND. The major difficulty in making a diagnosis of myasthenia gravis is not thinking of the condition. Another rare cause of bulbar weakness and ptosis is the inherited disorder of older adults oculopharyngeal muscular dystrophy, for which there is now a reliable genetic test. A pseudobulbar presentation should activate a search for structural brain pathology such as cerebrovascular disease. It is common for the severe dysarthria or anarthria of MND to be thought of as dysphasia resulting from a stroke. The progressive history and the recognition that the patient's ability to express himself/herself using gesture or writing is totally intact at a time when they are unable to make any sound should clarify whether the problem is dysphasic or anarthric. A proportion of MND patients develop dementia and in rare cases this can be a prominent feature at diagnosis. Frontotemporal dementia may of course present with dysphasia, but this is rare in MND. A combination of dementia and amyotrophy (muscle wasting) with fasciculation can rarely signify a prion protein disorder of Creutzfeldt–Jakob type.

Investigations that aid diagnosis

The diagnosis of MND is a clinical one. The role of investigation is largely to look for other conditions that may mimic MND. These have been discussed above and, where appropriate, diagnostic tests have been suggested. All patients in whom a diagnosis of MND is considered should have nerve conduction studies and these may be combined with EMG. The EMG can confirm electrical evidence of denervation

in marginal cases or may demonstrate denervation in clinically normal limbs, but more importantly, nerve conduction studies which should be normal in MND may point to alternative diagnoses such as a motor neuropathy as seen in CIDP or multifocal motor neuropathy with conduction block (MMN). Elevated plasma creatine phosphokinase (CK) is a non-specific marker of lower motor neurone damage. In other clinical settings it can help with the diagnosis of muscle disorders. CK elevations in MND are more modest than in muscle disease. Generally, values are only increased to no more than 10-fold above the normal upper limit. CSF examination for elevated protein concentrations or pleocytosis may also be helpful in swaying one away from the diagnosis. Having said this, slight increases in CSF protein are seen in MND so that the elevation has to be marked for it to be of significant negative predictive value. Antiganglioside antibodies are found in low titre in many patients with MND and are found more consistently and at higher titres in patients with MMN and CIDP. Paraproteins are found more frequently in the serum of MND patients. Treatment of the paraprotein in these cases does not influence the outcome of MND. Other tests, ranging from looking for antiacetylcholine receptor antibodies to magnetic resonance scanning of the cervical spine, may be appropriate in certain clinical settings as discussed above. Currently there are no biomarkers of a diagnosis of MND.

Diagnosis of MND

Discussion of the diagnosis of MND is an important step in the management of the condition. Nerve conduction tests, an electromyogram, imaging studies and any other tests indicated should of course be completed prior to mention of the words, motor neurone disease. A busy outpatient clinic is hardly a suitable setting for the unhurried imparting of bad news. Following the tests and preferably on the same day, the diagnosis can be discussed with the patient and their family by the doctor and a counsellor with an interest in MND. Any healthcare professional with a knowledge of and interest in MND and the time to be able to discuss matters unhurriedly could develop counselling skills and become an MND counsellor. Patients and their families usually appreciate written information and most appreciate receiving a transcript of or letter about the consultation. The hospice movement in particular and the experience of oncology in general have taught us much about imparting bad news. The principles of breaking bad news range from the use of a private room to fractionating the news so that the patient is not completely overwhelmed by the information and to remembering to emphasize some positive features, for instance, our increasing ability to help all the symptoms of the disease. In our unit, the MND nurse counsellor plays an important role in maintaining contact with the patient and their family, even when they are at home. This outreach function has proved invaluable in reducing the morbidity of the disease, decreasing unplanned hospital admissions and, later on, in facilitating discussions about end-of-life issues As the diagnosis of MND is essentially based on the clinical picture and as there is no one diagnostic test for it, most patients will appreciate the offer of a second neurological opinion. This may be a counsel of perfection as many parts of the world have difficulty with access to one neurologist, let alone two. However, wherever feasible, this course is to be recommended as confident acceptance of the diagnosis by the medical team and by the patient and their family forms the basis of all subsequent management.

Epidemiology

MND is a ubiquitous disorder. The overall incidence and prevalence are greater in men than in women. However, the bulbar-onset type of MND is more frequently seen in women. The average age at first presentation is about 57 years (with only 5% developing disease before age 30 years) and the clinical course is relentlessly progressive over 3–5 years. False-positive and false-negative errors in diagnosis confound accurate study of its incidence, which is variously estimated at between 0.6 and 2.6 per 100 000 per year. The point prevalence ranges between 2.7 and 7.4 per 100 000. Although case ascertainment must play a part in this variability, geographic differences almost certainly account for some of the variation. Even within fairly small areas there can be considerable variation in the incidence of the disease, as shown, for example, by the differences on either side of the river in the Mississippi area of the USA. In the UK, fewer cases than expected seem to occur among the immigrant Asian and Afro-Caribbean population than in the native population. It is unlikely that this could be accounted for merely by differences in the age distribution of the populations. Age-specific incidence figures show an increase in the occurrence of MND into the 70s but with an apparent fall in the 80s and 90s,[18] partly explained by the small population groups in the age ranges. The incidence of MND is increasing especially in the elderly, in whom there is an over-representation of bulbar-onset disease. The occurrence of a type of MND on the island of Guam and on the Kii peninsula and the decreasing death rates from this disease in those areas indicate that the cause of sporadic MND may be exposure to a neurotoxic agent.[19] Several epidemiological lines of enquiry have looked into this but so far no convincing candidate toxin has emerged. Military personnel deployed in the first Gulf War are reported to have a higher risk of developing MND than the general population or than their non-deployed counterparts.[20] It is reported that patients with MND engage in more physical exercise than the general population (for instance, in Italian football players) and it is also likely that they have a stronger previous history of trauma including bony

fractures. These may, of course, be linked as fractures in young people occur more commonly in those engaging in physical activity. A case has been made for abnormalities of parathyroid hormone playing a role in the pathophysiology of this disorder, but the link seems tenuous. Exposure to solvents and, in particular, halogenated hydrocarbons has been associated with MND both as anecdotal cases and in the leather industry. Organophosphate exposure is also postulated as a risk factor. It has been suggested that MND is a late consequence of infection with the polio virus in a situation analogous to the development of an MND-like condition in later life in patients who suffered from polio in younger days. However, the postpolio type of MND is clearly different from ordinary MND.[21] If polio exposure played a part in MND, polio vaccination would have decreased the incidence of the disease – which is not the case. In about 10% of cases of MND, there is a family history of the disorder, suggesting an autosomal dominant mode of inheritance (see earlier). There is an over-representation of statin use in MND[22] and, although data are controversial, a case has been made for a neuroprotective role of dyslipidaemia in MND. Epidemiological information does not indicate an increase in the incidence of MND since the use of statins became more widespread. One study indicated increased MND risk in cigarette smokers. Ongoing MND epidemiology studies may help clarify this confused collection of associations.

Pathology of MND

Prominent degeneration of the pyramidal tracts is seen in the spinal cords of patients dying with MND characterized by loss of motor neurones with changes such as spheroid formation, chromatolysis and neuronophagia of motor neurones. Betz cell loss in the motor cortex is a feature of the upper motor neurone involvement in MND. Astrocytic gliosis can be prominent in a few cases and surviving cells can show accumulations of lipofuscin, which is associated with free radical attack on polyunsaturated fatty acids. Some pathological changes have been described in the posterior columns, the sympathetic pathways and even in Onuf's nucleus, underlining the clinical observation that sensory pathways and bladder innervation are only relatively and not absolutely resistant to the process of MND. A variety of inclusion bodies in anterior horn cells are associated with MND; some of these contain ubiquitin, a housekeeping protein involved in the designation of proteins due for removal. The inclusion bodies include TDP43 containing ubiquitinated inclusion bodies and hyaline conglomerate inclusions containing neurofilaments. Similar abnormalities are found in the brain stem nuclei of cranial nerves that are involved in MND. Those spared in MND, for instance, those of extraocular muscles, are less affected. The upper motor neurone cell bodies and dendritic processes show degeneration and inclusions and there is increased gliosis in layers II and III of the motor cortex and in subcortical white matter, with some changes also being found in the sensory cortex. More widespread changes are found in the brains of dementia patients who die with MND. These include finding intraneuronal inclusions that are ubiquitin positive but tau and alpha synuclein negative.[23] TDP43 is a constituent of the ubiquitinated inclusions in sporadic MND.[12] This protein is involved in RNA processing, suggesting that post-transcriptional genetic changes are involved in the disease process.[24] Tau 1 positive inclusions are found in astrocytes and other tau aggregates in the neuropil in MND patients with dementia. Dementia is an uncommon clinical feature of MND, afflicting up to 15% of patients, although significant cognitive decline can be identified in 35% of patients.[8] Spinal root atrophy is frequently seen at autopsy but involvement of peripheral nerves is rare. Some studies have shown loss of large myelinated fibres secondary to anterior horn cell loss. Biochemical abnormalities are also found in the parietal cortex and in the cerebellum, although these areas are largely clinically unaffected.

Small group atrophy of muscle fibres is seen on muscle biopsy affecting both type I and II fibres with some compensatory hypertrophy of surviving muscle cells. Mononuclear inflammatory infiltrate may also be seen, but whether as a cause or an effect of the disease process is unknown. On antemortem liver biopsy, a variety of abnormalities are linked with MND. These include intramitochondrial inclusions, giant mitochondria and abnormalities of endoplasmic reticulum. Neurofilament accumulations occur in the site of damage in MND. Neurofilament transport, degradation and phosphorylation all seem to be impaired in MND, but their role in disease pathophysiology is unclear.

Aetiology and pathophysiology

Much progress has been made in these areas of research. Some of these are discussed below. Although discussed under separate headings for ease of reading, there are many areas of overlap; for example, xenobiotic compounds may exert their toxic potential through free radical mechanisms and free radical action may be increased by the action of excitatory amino acids. Genetic factors have been considered above (under Familial MND).

Free radicals

Chemical species that are capable of independent existence and contain unpaired electrons are termed *free radicals*. In biological systems, oxygen and nitrogen free radicals, that is, the products of partial reduction of molecular oxygen or nitrogen, are particularly important. One of the enzymes that protects tissues against free radical attack is superoxide dismutase type 1 (SOD 1). This enzyme catalyses

the conversion of superoxide free radicals to hydrogen peroxide. Rosen *et al*.'s finding[9] of mutations in the gene encoding SOD 1 in 20% of families with FALS increased interest in free radicals in MND. Similar mutations are found in only 2% of sporadic MND. However, other abnormalities that represent impaired oxidant metabolism have been found in the spinal cords of patients dying with MND.[25] These include increases in a DNA oxidation product, 8-hydroxy-2-deoxyguanosine, and in some products of protein oxidation such as protein carbonyls. In sporadic MND, the concentration (in the spinal cord) of other antioxidants such as glutathione peroxidase is impaired. These observations suggest that free radical mechanisms may be one means of cell injury in MND. However, the means by which SOD 1 mutations cause damage in MND may not be merely through loss of dismutation activity of the SOD 1 protein but through some new and additional property of the mutant protein – the nature of this additional function remains unclear. It has been reported that mutations in the SOD 1 enzyme change its function from antiapoptotic to proapoptotic. Misfolding of the mutant protein leads to its ubiquitination and deposition in inclusion bodies and it is controversially suggested that all MND may result from misfolding of SOD 1.[26] In the extracellular space, mutant SOD 1 may function as a pro-oxidant by producing superoxide.[27] Mutant SOD 1 also binds early to mitochondria and to the endoplasmic reticulum, suggesting that these organelles are involved in the cytotoxic process.

On the basis of the hypothesis that impaired defences against free radical attack are important in the pathophysiology of MND, trials of therapy with antioxidants have been attempted. Metal chelating agents with antioxidant properties, such as *N*-acetylcysteine have also been used, with unconvincing benefit. Some practitioners have, on purely empirical grounds, recommended that patients take supplements of vitamin C, vitamin E and other commonly available antioxidants. In addition to causing direct damage to nucleic acids, structural support proteins and membrane lipids, free radicals and other reactive oxygen metabolites such as hydrogen peroxide can induce profound changes in intracellular signalling mechanisms. For instance, they can modulate the conversion of the inactive form of NFKB to the active form. They have an effect on gene transcription, for example, as shown by the redox-sensitive regulation of transferrin receptor and ferritin production. In cell culture, these gene dysregulatory effects can lead to neuronal loss by a process of apoptosis. There is therefore much interest in apoptosis in MND. Another cell-signalling compound whose activity is modified by oxygen free radicals is nitric oxide. This can combine with superoxide radicals to form peroxynitrite, a precursor of hydroxyl free radicals, which have a great capacity to cause intracellular damage and consequent cell death. Nitric oxide abnormalities are also linked with abnormalities of excitatory amino acid neurotransmission; this helps to establish a link between the two front-runners in the mechanism of tissue damage in MND, namely, free radicals and excitotoxicity.

Excitatory amino acids

Glutamate is a major neurotransmitter in the CNS. It is an excitatory amino acid which stimulates the anterior horn cell, that is, the main transmitter between the upper and lower motor neurones. Convincing evidence from cell culture studies and experimental animal models demonstrates the toxicity of excessive concentrations of glutamate. This damage is often referred to as excitotoxic damage. The finding of defects in the distribution of glutamate receptors in the spinal cords of patients with MND and the demonstration of a defect of the glutamate transporter in MND support the hypothesis of excitotoxic damage in this disease. The finding of elevated concentrations of glutamate in the CSF of patients with MND also lends support to this hypothesis. The toxicity of glutamate is believed to be mediated via an increase in calcium entry into cells.[28] This may occur through a lack of excitatory amino acid transporter type 2 (EAAT2) action, which results in failure to clear extracellular glutamate.[29] Calcium entry into cells is carefully regulated and can be disturbed by a variety of mechanisms, including free radicals and excitatory amino acids. This, along with the involvement of compounds such as nitric oxide (NO) in both excitatory amino acid neurotransmission and in free radicals, suggests that several mechanisms acting together may conspire to cause anterior horn cell damage in MND. The postulated role of excitatory amino acids in MND led to a search for antiglutamate drugs as treatment for MND. A number of agents have been examined for their antiglutamate properties – amongst these are the branched chain amino acids (leucine, isoleucine and valine), lamotrigine and riluzole. Riluzole shows positive results,[4] which are discussed below.

Growth factors

A whole family of peptide neurotrophic factors is known to affect the growth and survival of human neurones. Some of these have profound effects on human lower motor neurones but have not been shown to influence upper motor neurone survival. The survival of cells deprived of these trophic factors is reduced. Angiogenin is a growth factor involved in promoting primary and metastatic tumour growth. Mutations in the angiogenin gene are linked with being risk factors in sporadic MND and frontotemporal dementia MND. Others that are implicated include ciliary neurotrophic factor (CNTF), brain-derived growth factor (BDNF) and insulin-like growth factor (IGF). Glial-derived

neurotrophic factor (GDNF) has also been of interest in neurodegenerative disorders. *In vitro* GDNF is more potent than either CNTF or IGF at promoting neuronal survival. A decrease in the concentration of growth factors such as CNTF is associated with decreased motor neurone survival.[30] An initial clinical trial of CNTF was abandoned when no benefit was identified and significant adverse effects occurred. Some of the adverse effects could have been foreseen, for instance, through recognition of its interaction with leukaemia inhibitory factor. There was also some doubt as to whether the method of administration of the CNTF would have allowed the drug to reach the site of action, namely the spinal cord – beyond the blood – spinal cord barrier. IGF 1 can induce sprouting of spinal motor neurones and its binding sites are increased in the spinal cord in MND. Much of this spinal binding may be to glial sites rather than neuronal sites. IGF has also been tested in a clinical trial setting and has been found to be helpful in increasing muscle strength in MND without a significant effect on survival.[31] Parenteral BDNF proved ineffective in MND. A new, non-peptide neurotrophic factor with 5HT1a receptor activity (xaliproden) also failed to prolong survival when given along with riluzole in MND. Mutations in the gene encoding VEGF[13,32] and altered activity of the peptide in CSF have been reported in MND.

Viruses

A large number of viruses are linked with MND, but convincing evidence of a causal association is lacking. Agents as diverse as enteroviruses such as the polio virus, retroviruses such as HIV and human T lymphotropic virus 1 (HTLV 1) and even prions are implicated. There is conflicting evidence on the association between polio virus and MND. Enterovirus genome has been reported in the spinal neurones of patients dying of MND. It is suggested that a state of restricted replication may exist in these neurones, a situation akin to that seen in subacute sclerosing panencephalitis (caused by the measles virus) or in tropical spastic paraparesis (caused by HTLV 1). The similarities between the postpolio syndrome and MND have further suggested the possibility of an aetiological connection.

Autoimmunity

An increased incidence of known autoimmune diseases such as diabetes is described in MND. Paraproteinaemias may occur more frequently in MND, also pointing towards immune mechanisms in the disease process. However, in the majority of these patients the paraprotein does not recognize antigens on motor neurones. A guinea pig model of both the lower motor neurone disturbance and the upper motor neurone problems of MND can be induced by inoculation with spinal cord or brain homogenates and neurophysiological changes detected in other species following passive antibody transfer, but the disease is not replicated in these experimental animals after such antibody transfer. The spinal cords of patients dying from MND contain activated T lymphocytes, and immunoglobulin deposits in both the cerebral cortex and the spinal cords at autopsy further implicate dysimmune mechanisms in this disease. Treatments directed against a possible autoimmune disorder, for instance, with cyclophosphamide or with whole body irradiation, have failed to give positive results. A critical analysis of the data on autoimmunity in MND was carried out by Drachman *et al*.[33] In some cases, the paraprotein found in patients with MND has been identified as an *antiganglioside antibody*. Gangliosides are antigens found on neuronal tissues and antibodies against these have been identified in a number of peripheral nerve disorders such as Guillain–Barré syndrome and MMN with proximal conduction block. Low titres of antiganglioside antibodies are occasionally found in MND and, although this may be no more than coincidence or merely a reflection of tissue damage with secondary immunological response, it does implicate immunological mechanisms in MND.

Xenobiotic metabolism

In a number of disorders, it is becoming clear that a combination of genetic and environmental factors may be responsible for disease development. Some of these are well-established examples of the interaction of heredity and the environment. For instance, in the condition glucose-6-phosphate dehydrogenase deficiency, the genetic disorder in itself is not sufficient to lead to haemolytic episodes but cells that are deficient in this enzyme are unable to cope with the additional burden of environmental challenges such as the fava bean. The enzymes that deal with toxins arising from outside the body (xenobiotic toxins) frequently show polymorphisms, that is, there are fast and slow metabolizers of xenobiotic compounds. Most of the body's reserve in dealing with xenobiotic compounds resides in the liver in microsomal enzymes, including the cytochrome P450 system. The idea that a genetically predisposed individual, when exposed to a xenobiotic toxin that their enzyme makeup is unable to detoxify efficiently, ends up getting disease, whereas another individual may escape disease either because they haves the necessary enzyme activity to detoxify or they may not have been exposed to the toxin, can serve to explain the apparent sporadic nature of a number of diseases. This has been implicated in atherogenesis, in Alzheimer's disease, in diabetes and in Parkinson's disease, to name just a few. Heafield *et al*.[34] found abnormalities of the enzymes that metabolize sulfur-containing compounds in MND. These include the enzymes that catalyse sulfur

oxidation, which appears to be impaired, and those that methylate sulfur (thiol methyl transferase) which appear excessively active. Failure to oxidize a sulfur toxin would impair its excretion via the kidney. This, combined with increased methylation, would facilitate entry into central nervous tissue, where the brunt of damage occurs in MND. If the effect were an immediate one, as occurs in, for instance, migraine and chocolate ingestion, the connection would be obvious; but if each event of toxin exposure just resulted in the loss of a few anterior horn cells the overall effect might not be noticeable until late in life. Recent evidence of a role for paraoxonases in MND supports the idea of a complex interplay between genetics and environmental factors in the disease.[35]

Vascular insufficiency

In chronic hypoxic conditions, VEGF production is increased to attempt to overcome the hypoxic state. Finding mutations in the gene encoding VEGF[13,32] suggests that vascular phenomena may play a role in the development of MND. Pentoxifylline, a vasodilator molecule, was tested for clinical effect in a randomized placebo-controlled trial and initial indications are that the drug is not effective in slowing the progression of MND. Changes in spinal blood flow may be speculated to explain the association between physical exertion and MND.

Mitochondrial dysfunction

Structural mitochondrial abnormalities are found at an early stage of MND, in both neural and non-neural tissues.[36,37] The mouse model of MND (both wobbler and the SOD 1 mouse) show early mitochondrial dysfunction. Creatine and phosphocreatine are intricately involved with cellular energy metabolism and these considerations led to a search for a clinically useful therapeutic effect in MND to mirror the improvement seen with creatine use in the SOD 1 mouse. Unfortunately, these studies have been negative. Excitotoxic, apoptotic and oxidant mechanism have all been proposed as the pathway by which mitochondrial permeability is damaged. All are implicated in MND.

Inflammation

A prominent CNS inflammatory reaction is found in MND. Microglia are involved and their inflammatory mediators such as CD11b are overexpressed. COX 2 mRNA expression is increased in MND spinal cords. COX 2 inhibitors were until recently regarded as good candidates for use as treatment in MND. However, the newly identified problems of cerebrovascular disease in patients taking COX 2 inhibitors for rheumatic diseases have stopped these avenues being explored.

Symptomatic treatment

Cramp

This is prominent fairly early in the disease and may affect muscles not normally prone to cramp, for instance, forearm flexors. As the disease progresses, weakening muscles no longer cause painful cramp. Quinine sulfate is anecdotally helpful and, although evidence of its effectiveness is lacking, it is worth trying as a short-term measure. Antispastic medications such as baclofen and tizanidine may help in cramp control. The hepatotoxic effect of tizanidine needs to be monitored, particularly in those patients also taking riluzole. Other aggravating factors such as electrolyte imbalance may also need treatment. In a few cases, phenytoin has been used with good effect, particularly for painless hand cramp.

Fasciculation

Although this is a prominent physical sign in MND, it is uncommon for it to be symptomatic except in patients with benign fasciculation in whom it is more constantly a source of anxiety. Patients with MND are usually more bothered by more disabling symptoms and may not even be aware of the fasciculation, until pointed out by the physician. β-Adrenoceptor blocking agents such as propranolol are occasionally helpful in the few cases when pharmacological treatment is warranted. Low-dose benzodiazepines can also be useful in reducing the discomfort of fasciculation.

Spasticity

When spasticity is marked, it can interfere with the efficient function of limb and bulbar muscles and antispastic drugs, such as low doses of baclofen, can help reduce the spasticity. Dantrolene and benzodiazepines can also be applied but dantrolene is not widely used for this purpose and there are well-founded anxieties about the sedative and respiratory depressant actions of the benzodiazepines. Having said this, their use in some circumstances can alleviate much anxiety and reduce the pain associated with spasticity. The effect of baclofen on jaw clonus and masseter spasticity can be useful in helping chewing and sometimes even speech. In other neurological disorders, spasticity can be treated with intramuscular injection of botulinum toxin. In MND, there is a worry that weakening muscles with botox may help spasticity, but the cost in terms of increased weakness would be even more unacceptable than with baclofen and other antispastic drugs such as tizanidine. As a consequence, botulinum toxin injections are not currently recommended for the treatment of spasticity in MND. Tizanidine may prove helpful in some patients with MND and spasticity, but there are some anxieties about its possible adverse effects on the liver.

Salivary dribbling

Many patients with MND are troubled by this symptom, caused by immobility of bulbar muscles and dysphagia. The discomfort of excessive dribbling of saliva is often greater than that of spasticity or of cramp. It is also more difficult to treat. Patients with MND have decreased saliva production. The cause of dribbling is the impaired swallowing of saliva secondary to muscle weakness. Anticholinergic drugs can ease salivary dribbling by further reducing saliva formation. Drugs such as benzhexol and hyoscine/atropine are generally not well tolerated when given as a tablet. Hyoscine skin patches can be useful and better tolerated. In the author's experience, *oral* administration of 1% atropine eye drops is better tolerated and appears to give good symptomatic relief. The dose required varies but can be only two drops per day. Generally, systemic side effects are uncommon, but occasionally patients will complain of other anticholinergic adverse effects such as constipation, bladder disturbance and blurred vision. Sublingual hyoscine has also been used. Glycopyrronium injections or subcutaneous hyoscine infusions can be helpful in resistant cases. Radiotherapy of one parotid gland has been used when pharmacotherapy has failed, but in such cases the radiotherapy is also usually unsuccessful. Botulinum toxin is increasingly used to reduce saliva formation in those patients who are PEG (percutaneous endoscopic gastrostomy) fed. Botox can spread from the parotid to the pharyngeal muscles and can aggravate pharyngeal weakness, which of course is invariably present in patients with salivary dribbling. When saliva and laryngeal secretions are too thick and stringy to be expectorated, β-adrenoceptor blockers such as propranolol can help. When thick mucus is resistant to such measures, manually assisted coughing techniques and cough assist machines can help with its removal from the airway. Oropharyngeal suction can reduce the consequences of excessive salivary pooling and in some cases can help alleviate the fear of nocturnal choking spells caused by salivary pooling. As salivary dribbling at night can be even more troublesome than during the daytime, strategies that reduce nocturnal salivation can also help, for instance, avoidance of late-night meals or drinks.

Dysarthria

Most patients with MND develop dysarthria or anarthria at some time during disease progression. Sometimes this can happen in the absence of dysphagia but often the two symptoms coexist. In the early stages, speech therapy strategies can help and as disease advances increasing reliance must be placed on communication aids. These can range from a notebook and pen to sophisticated computerized aids, some of which can be linked to voice synthesizers to produce a semblance of the patient's voice. By the time writing aids are needed, dominant arm weakness can clearly add to the disability. The clinical art in dysarthria management is to determine what the most appropriate aid/appliance is for the degree of the patient's disability; for instance, mention of computer-aided speech can dishearten rather than help a patient with mild dysarthria. The assistance of a rehabilitation team including a speech therapist can be invaluable.

Dysphagia

A mild degree of impairment of swallowing occurs in early disease. As dysphagia advances and is coupled with impaired respiratory protective mechanisms (for instance, weakened cough), aspiration pneumonia becomes a serious concern and can cause death in MND. Judicious use of antibiotics can aid comfort. Dysphagia is more marked for liquids and very dry solids. Semisolid foods or foods with puréed consistency are more easily swallowed. Avoidance of very hot or very cold foods/drinks is also helpful. Occasionally, when the bulbar impairment is asymmetric, attempts to swallow can be more successful with the head rotated to one side. Help from dietitians and swallowing/speech therapists should be called upon. In recent years, PEG has dramatically helped feeding patients with severe bulbar MND. Gastrostomies are inserted endoscopically, sometimes using sedation but occasionally with just a pharyngeal local anaesthetic spray. Usually they are well tolerated and, although most patients have severe misgivings about having a gastrostomy, few regret having had one after insertion. PEG does not prevent aspiration and must not be seen as a means of stopping the patient from eating. Food or drink that the patient enjoys or can swallow can be taken by mouth. The patient and his/her family must appreciate that oral intake increases the risk of aspiration pneumonia and provided that they are cognizant of this increased risk, the patient may choose whether or not to eat and drink. PEG probably prolongs survival but is better regarded as a symptomatic treatment that frees up the patient from the chore of swallowing just to make up normal daily intakes of food and drink and avoids nutritional weight loss which would otherwise compound the weight loss caused by the disease process. In some centres, radiographically inserted gastrostomies (RIG) may be used instead of PEG. The 30 day mortality after PEG insertion is markedly increased in those patients whose forced vital capacity is less than 50% of predicted.[38] When recurrent respiratory infections complicate PEG placement, gastric motility-promoting agents such as metoclopramide may be worth trying.

Respiratory failure

This is the commonest cause of death in MND. Dyspnea is a common symptom and the fear of breathlessness

and choking is usually marked but frequently not voiced. Other symptoms include orthopnea, sleep disturbance that cannot be ascribed to pain or depression, early morning headaches and fatigue secondary to carbon dioxide retention. Some patients complain of excessive daytime sleepiness. Respiratory failure most often occurs secondary to respiratory muscle weakness including diaphragmatic weakness. Large-airway obstruction is uncommon. Aspiration pneumonia also accounts for some deaths in MND but the number of these is fortunately decreasing – aided by improvements in speech/swallowing therapists' involvement and by better multidisciplinary team efforts. Some of these patients may have coexisting pulmonary disease such as asthma and others may develop bronchospasm secondary to aspiration or infection. Whether for this reason or for some other pharmacological reasons, salbutamol and other β-adrenergic agonists via inhaler can be helpful in easing dyspnea in some patients with MND. In some patients, β-blockers given to ease other symptoms may be the cause of dyspnea and fatigue. The respiratory drive can be reduced in this group of patients with oxygen supplementation and its indiscriminate use cannot be supported. In selected patients, the judicious use of oxygen (domiciliary oxygen if necessary) supplements by mask or nasal cannulae can help relieve symptoms, as can anxiolytic medication including benzodiazepines. Both approaches carry a risk of respiratory depression but can serve a useful palliative role when patients have been fully informed. In some cases of advanced disease, it may not be appropriate to use antibiotics to treat the dyspnea associated with pulmonary infection. In this situation and in other cases of unremitting dyspnea, symptom control may require opiates, sometimes in combination with hyoscine. The respiratory depressant effect of opiates causes understandable concern in this situation, but this adverse effect should not impair the search for rapid and effective relief of symptoms in the terminal phases of MND. Non-invasive mechanical ventilation is effective as a treatment for palliating respiratory symptoms in MND. One randomized clinical trial involving 41 participants showed improved survival with non-invasive ventilation (NIV) (see review by Radunovic *et al*.[39]). The overall survival advantage was comparable to that with riluzole. Symptomatic patients who have impaired ventilatory capacity, as shown by reduced forced vital capacity or SNP, and who have carbon dioxide retention on blood gas analysis or have nocturnal desaturation on oximetry are suitable for considering NIV. NIV is effective in improving early morning headaches, fatigue, alertness and orthopnea. Any increase in depression caused by the need for assisted ventilation is offset by the sense of wellbeing caused by the mechanical ventilation. Overall depression rates are no different in the ventilated and non-ventilated patients. Nocturnal oximetry can help decide whether NIV is appropriate. Many patients face the problem of Advance Directives for the first time when considering using NIV. Patients with severe bulbar impairment do not tolerate the NIV well. Initially, most patients use the mechanical ventilation systems at night. They need to decide whether they would extend use into daytime hours, potentially even 24 h per day. What are to be the stop rules and how is withdrawal to be effected, for example, with removal of supplemental oxygen, removing end expiratory positive pressure then using a T tube and then using opiates or benzodiazepines to relieve distress and so on? Some patients decide to go on to a tracheostomy with full invasive ventilation. This decision can have a major emotional impact on patients and their carers. Leaving aside considerations of the resource implications of such a decision, patients and their families need to be counselled fully to prepare them to make these decisions. Most patients and their carers indicate a strong wish to make positive decisions regarding resuscitation status, antibiotic use for bronchopneumonia and treatment of multiorgan failure, and want the physician to introduce this topic.

Pain

Pain is common in MND (up to 40%), but this is not generally appreciated and less attention is given to this aspect than it deserves. A doctor's capacity to ease pain is far greater than their ability to ease many other symptoms. For this reason, questioning patients about pain can be a rewarding therapeutic experience for patient and physician alike. Sometimes the pain is caused by cramp but more often it is attributed to the effects of ligamentous strain secondary to weak muscles. Anxiety and fear are common exacerbating factors. In many cases, the cause of pain is obscure. In part, it may arise from subtle abnormalities of central pain pathways. The management of pain in a terminal care setting is the same whether the pain is due to secondary spread from cancer or due to MND. Weakened muscles and ligamentous stretching can lead to partial subluxation and support or orthoses to avoid further subluxation and use of intra-articular steroids and lignocaine can help ease the pain. Weak neck muscles can cause cervical pain and in some patients this can be helped by wearing a cervical collar. The right collar for each individual is one that can be worn comfortably and eases discomfort. Unfortunately, no one collar type fits this bill and the help of a rehabilitation team with experienced physiotherapist and occupational therapist can be helpful.

Depression

Emotional lability is common in MND, particularly in those with bulbar problems. As a result, patients may cry, sometimes inappropriately. However, the disabling nature of the disease can lead to appropriate crying due to either

frustration or depression. Frustration and other affective difficulties such as anger are more prevalent than clinical depression. They can be helped by supportive counselling. When the affective difficulties extend to causing impaired sleep, loss of appetite or loss of self-worth, pharmacotherapy may be needed for the depression. A low threshold to using antidepressant medication needs to be maintained either as the tricyclic antidepressants whose anticholinergic effects may help excessive salivation or as one of the selective serotonin reuptake inhibitors (SSRI), which are safer when, for instance, taken in overdose. Emotional lability which may show as pathological crying or laughter may be treated with the tricyclic drug amitriptyline or by fluvoxamine. Given the nature of the disease, it is surprising that suicide is not more common and perhaps this reflects the success of the support structure that carers and medical services have set up. A counsellor who may be a nurse or other professional with the appropriate knowledge, inclination and communication skills may be able to identify patients at risk of attempting suicide and be able to intervene to prevent it.

Leg weakness

Gait impairment is a frequent presenting symptom in limb-onset MND. Progressive weakness, wasting, fasciculation and cramp cause much morbidity. Weakness about the ankle causes most marked early morbidity. Foot drop can be managed in the early stages by physiotherapy, sometimes using foot drop splints. More sophisticated orthoses are sometimes needed. The decision on progressing from ambulant mobility to wheelchair needs to be made carefully and is never easy from a psychological viewpoint. A multidisciplinary team is more likely than an individual clinician to persuade a patient of the wisdom of this transition. Few MND patients have arm strength good enough to allow self-propulsion of a mechanical wheelchair. Some will benefit from an electric wheelchair but these too may require an attendant, as powered chairs can be heavy and difficult to lift, for instance, in and out of cars. Mobility inside the home also needs attention. Patients may be fine to walk on level ground but unable to go safely up and down stairs. This can require single-level existence, stair-lift or even a through-ceiling lift. Not many patients want the disruption of a through-ceiling lift but information from a disability team may persuade them to accept this.

Arm weakness

Hand weakness with wasting of muscles innervated by the T1 nerve root can be the first sign of MND. It is usually asymmetric and even with profound wasting in several myotomes, arm tendon reflexes are usually preserved and even exaggerated, indicating a combined upper and lower motor neurone lesion. Fine motor tasks are impaired and the patient may complain of cramp in the early stages. The combination of anarthria and dominant hand weakness is a particularly disabling one. Communication is severely hindered. In this setting, computer-aided communication with bespoke switching and pointing devices comes into its own. Physiotherapy and occupational therapy involvement becomes more important as the weakness increases. Passive exercises to prevent contractures and simple splints to aid comfort by maintaining neutral postures can help. Weak limbs with wasted muscles are prone to suffering secondary problems such as entrapment neuropathies of nerves previously cushioned by a mass of muscle. Avoidance of pressure over the elbow or the carpal tunnel is necessary. They are also prone to subluxation at several joints, for instance, at the shoulder when the arm is a flail dependent limb. Adequate arm support with appropriate local measures such as intra-articular steroid and local anaesthetic injection may be warranted. Splints and arm supports must be customized to maximize the efficient use of the weak arm.

Advances in drug treatment

Riluzole

Riluzole is a glutamate antagonist that acts on voltage-gated presynaptic sodium channels, inhibiting glutamate release and also increasing glutamate reuptake from the extracellular space. A large randomized dose-ranging multicentre study across Europe and the USA[4] demonstrated increased lifespan in patients taking riluzole compared with those on placebo at a dose of 100 mg per day. Side effects included potentially serious impairment of liver function, mild anaemia, leukopenia, malaise, gastrointestinal upset and dizziness. A Cochrane meta-analysis has shown the mean prolongation of survival to be 2–3 months after 18 months of treatment at a dose of 100 mg per day in patients with probable or definite ALS, with symptoms for less than 5 years, good ventilator reserve (FVC >60%) and age less than 75 years at the start of treatment. This represents a survival advantage of 9% at 1 year and the number-needed-to-treat to prolong one life is 11. From a scientific viewpoint, this development is exciting as for the first time a trial has shown significant benefit from a pharmacological intervention in MND. However, from a clinical viewpoint the trial results are less impressive but nevertheless encouraging. Few patients who start on medication have to give up owing to side effects. A few stop because of abnormal liver function and some give up when swallowing deteriorates to the point when tablets become a chore and they do not want to crush tablets and inject a suspension down a PEG tube. Riluzole is useful in offering hope to patients and their families and in providing a weapon with which to

combat the disease. This aspect of its effect and its impact on quality of life are not easily measurable.

Growth factors

Insulin-like growth factor or IGF 1 is a neurotrophic substance that has been shown to increase muscle strength in MND without any effect on survival.[31] This neurotrophic substance has been used widely outside the UK. Its effect may be mediated via a mechanism involving growth hormone. Other growth factors such as ciliary neurotrophic factor, brain-derived growth factor, glial-derived neurotrophic factor and xaliproden have been tried in MND and have failed to show clinically meaningful improvement.

Clinical trials of other agents

A trial of lithium carbonate as treatment for MND is under way in the UK and in the USA. Clinical trials that have failed to show positive response in MND include *N*-acetylcysteine as a chelator, branched-chain amino acids as inhibitors of glutamatergic transmission, the muscle growth promotor creatine and the vasodilator oxypentifylline. Drugs that block the presynaptic production of or release of glutamate may be neuroprotective. Gabapentin may be one such drug that has been used in MND. Its more conventional use is in pain management and epilepsy, where its mode of action is unknown. In a trial in MND, no significant benefit was found with gabapentin treatment, suggesting that the drug should not be used in this setting. A US trial of topiramate in MND failed to show benefit. Minocycline attracted interest among patients with MND[40] and findings of the *in vitro* effects of antibiotics on motor neurone function suggested this to be a fertile area for further study. However, there is no benefit from minocycline use in a larger study. Cox 2 inhibitors were similarly interesting until the recent worries about their vascular effects. Vitamin E, TCH346, tamoxifen and celecoxib have failed to show a positive response in clinical trials. Stem cell therapy holds more hope for many patients. Stem cell treatments seem promising as areas for future development and may not be far off translation into clinical practice.[41]

Multidisciplinary team approach

MND is an uncommon disease. The average general practitioner will see only one or two cases in a lifetime. As seen above, it is a disease that progresses rapidly and in which the patient's disability needs require addressing quickly before progression makes the measures ineffective and redundant. These requirements of prompt intervention, anticipation of future difficulties and awareness of the sources of help require a specialist team of healthcare professionals. Having said this, there is only weak evidence in favour of the MDT approach and that evidence favours its use to improve psychological wellbeing.[42] Several ways of delivering care are possible but a multidisciplinary approach has advantages by extrapolation from other disorders. The geographic area covered by an MND team or clinic will vary according to local needs and availability of resources, but the larger the area covered, the greater is the need for an outreach service that avoids making patients and carers travel long distances to hospital-based services. The core structure of an MND team should ideally include a consultant with an interest in MND and its rehabilitation needs (in the UK, usually a neurologist), a nurse counsellor, a point of quick contact that the patient and their family can access (e g. a nurse counsellor), a physiotherapist, an occupational therapist, a speech therapist, a dietician and a social worker (in the UK). Many others also have a contribution to make and can be involved by the core team as necessary. For example, a gastroenterologist's help is needed to insert a PEG for feeding, an orthotist may be needed for simple appliances and the assistance of a specialized rehabilitation centre may be required for patients with marked disability needs. Liaison with the community services is critical and requires one member of the MND team to maintain contact with community disability teams, general practices and social services departments. These comments apply to the health delivery system in the UK, but the general principles are equally applicable in other countries. The speed of response is emphasized – the time to provide a stair-lift is when the patient is still able to use it and not when they are bed-bound.

End-of-life issues

The hospice movement and the cancer services generally have made a contribution to the management of the terminal phase of MND. They can help with symptom management by liaison with the GP and the MND team and are increasingly involved in the early stages of the disease. In an audit of hospice care, 94% of patients dying with MND were judged as 'peaceful and settled' at death in the hospice. Some will have a fairly short period of deterioration, usually at home, and the patient and their carers may not wish for any outside help/intervention/interference. Many will welcome offers of help, whether the patient chooses to stay at home or comes to a hospice or a hospital ward. By this stage of the disease, treatment objectives and priorities must be clearly established, jointly with the patient and their carers. Usually this is a decision to relieve distress and discomfort. Judicious use of opiates and benzodiazepines helps to relieve distressing symptoms and, although there are well founded worries about the respiratory suppressant effects of these drugs, a prevalent medical view is that these worries must not stand in the way of symptom relief accompanied by a full explanation of the situation to the

carers and the patient. Ideally, these discussions should have been carried out before a crisis is reached so that the physician is aware of the patient's and their family's stance on this.

Much of the press and lay interest in end-of-life issues in MND has centred on voluntary euthanasia and physician-assisted suicide, and although these are important topics for society to give the medical profession clear guidance on, the concept of end-of-life issues is a wider one. It includes non-medical areas, for example, making a will, and may include, for instance, patients making their peace with estranged relatives. The patient may choose to discuss different aspects with different team members. They may wish a social worker or a counsellor to be involved in family reconciliations but a doctor in discussions on ventilatory support. MND care must take account of the cultural and psychosocial needs of the patient. Within the constraints that this places, early discussion of major management decisions is desirable, particularly for interventions such as PEG and ventilatory support. Advance directives on such interventions should be reviewed every at least every 6 months, as evidence shows that MND patients may change their minds over this period of time. A mentally competent patient is clearly able to make judgments about what is best for them. Mental capacity is usually satisfactory in MND except in those patients with frontotemporal dementia.

Physician-assisted suicide (PAS) remains illegal in the UK and in many other jurisdictions. Patient pressure is increasingly asking for the law to be relaxed, some patients even choosing to travel abroad to seek doctors' help in their suicide. Some of these patients are asking for clarification of what would constitute an offence for which their relatives may face prosecution. One survey of doctors' views showed that a significant minority support a change in the law to accommodate PAS. Others see the pressure for PAS as a failure of a medical system that cannot relieve a patient's distress sufficiently to deter them from such a course. Yet others are worried about the proper implementation of safeguards to protect vulnerable patients. The UK House of Lords has previously debated draft legislation and turned down the acceptance of PAS. Currently, society accepts and permits application of the principle of 'dual effect' in medical practice in palliative care. Doctors may give increasingly larger doses of medication including opiates and benzodiazepines to relieve patients' distress in a terminal disease such as MND, accepting that a second consequence of this action is respiratory depression and possibly, acceleration of death. However, the primary motive remains one of relieving distress and not accelerating death. Any crossing of the current boundaries must examine the concept of the 'slippery slope' to determine whether permitting PAS would necessarily lead, in steps, to other interventions that are currently undesirable or abhorrent.

Key points

- Early diagnosis and speedy multiagency interventions facilitate good palliative care in MND.
- Many MND-mimic disorders are eminently treatable.
- Riluzole and non-invasive ventilation prolong survival in MND.
- Early involvement of palliative care agencies helps with timely interventions such as PEG tube placement.
- Superoxide dismutase 1 mutations cause 20% of familial MND.
- End-of-life issues and symptom relief are inextricably linked.

CHAPTER 69

Control of chronic pain

Robert D. Helme[1] and Benny Katz[2]

Introduction

Pain is a percept defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.[1] Most health conditions associated with ageing carry a substantial burden of pain. Pain is always subjective as there is no way to validate objectively a patient's pain report. Every day acute pain occurs as an early response to a strong mechanical, thermal or chemical noxious stimulus such as experienced after an injury or surgery, where it may be immediate or delayed by hours or with infection that develops over hours and persists for a few days. Acute pain demands attention and an early response in order to obtain pain relief and protection from further tissue damage. Acute pain is easily recognized by clinicians, who are well trained to seek a cause so that treatment can be implemented without unnecessary delay. Acute pain affects about 5% of older people at any point in time.[2] Often self-limiting, acute pain usually resolves either spontaneously or with specific treatment often directed at the cause of the pain such as when immobilizing a fracture. The older patient presenting in acute pain should not be taken lightly.

In a proportion of cases, pain does not resolve spontaneously, with the patient progressing through a subacute phase to chronic pain. At this stage, pain no longer serves a protective role and is associated with social, functional and psychological consequences. Chronic pain is best defined as pain persisting beyond the period of normal recovery.[3] By consensus, this has been taken to be 3 months if pain has an ongoing cause. When chronic pain has accompanying physical, psychological and social consequences, multidisciplinary management strategies are required. Common sense dictates that in this situation the source of chronic pain should be understood and that investigations and treatments previously used but found to be ineffective be documented to ensure nothing remediable has been missed. There is, however, still a tendency to 'medicalize' the patient with chronic pain at the time of presentation to a new treatment team, with further investigations and repeated treatments, often with an over-emphasis on pharmacological and anaesthetic approaches. It becomes the managing physician's role in this context to recognize that curative approaches are no longer feasible or acceptable to the patient and that it is time for a symptom management approach to be adopted, aiming to reduce pain to tolerable levels, enhance the individual's coping strategies and minimize any pain-related handicap. This chapter summarizes pertinent data in this field and presents a model for the assessment and management of chronic pain in older people.

Pain and ageing

Overall, the prevalence of persistent pain increases with age and peaks between 45 and 65 years of age in males and between 65 and 75 years in females.[4] Prevalence estimates of persistent pain in older adults range between 25 and 50%. Among nursing home patients, the reported prevalence ranges are generally wider, being reported to be between 27 and 83% in one study.[5] This wide range, especially in residential care settings, indicates the difficulty in addressing a subjective experience in a population with a high prevalence of comorbidities, particularly those associated with cognitive and communication difficulties. This has been the focus of some published management guidelines.[6] There are also methodological differences that partially explain these variations.[5,7] Thus, high prevalence studies often use surrogate measures such as carer opinion and analgesic use to support the contention that the person is in pain. In community samples, the variation may be the result of using biased samples, different time windows for pain (e.g. pain in the last week or month versus all-of-life pain) or summing of pain experienced at different body sites. However, most of the variability is

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

more convincingly explained by using different criteria for determining the effect of pain in interfering with desired functional outcomes for the individual.

Most of this reported pain prevalence, however, is dictated by the high prevalence and persistence of musculoskeletal disease, especially degenerative joint disease in the spine, limbs, hands and feet. This is an example of somatic nociceptive pain. Other pain states are also important to older people although they may have less impact on prevalence studies because of their relatively limited duration, perhaps 1 year or less, compared with degenerative disease which lasts for decades. Visceral pain is characterized by poor localization and may be associated with strong emotional and autonomic responses. The principles for management of chronic visceral pain are the same as for somatic pain, with the rare exception of surgical lesioning of the posterior instead of the lateral columns of the spinal cord if pain is intractable to all treatments. Many of these conditions are described in detail in other chapters. A summary classification of clinical pain states into nociceptive, neuropathic, mixed and other, together with some examples that affect older people, is given in Table 69.1.

One of the most important pain-associated disease states of short duration in older people is cancer, as over half of cancer patients are aged 60 years or over and more than 90% experience pain with their disease. About 20% of cancer patients have pain associated with their treatment. Cancer pain can be nociceptive, neuropathic or mixed in type.

Other chronic neuropathic pain conditions that affect predominantly older people, albeit in smaller numbers, include peripheral nerve conditions such as post-herpetic neuralgia, with at least 50% of affected people aged over 70 years experiencing 1 year of pain and painful peripheral neuropathy, with diabetes as the commonest cause in 30% of cases. Neuropathy occurs in ~50% of diabetic patients and pain is a feature in about 20% of this group. Other causes of peripheral neuropathic pain include surgery, radiculopathies and nerve compressive syndromes, including vertebral canal stenosis. Central neuropathic pain after stroke, another age-related disease, occurs in 8% of stroke-affected persons. Trigeminal neuralgia, although relatively less common, is also observed more often in older people.

Table 69.1 Classification of chronic non-cancer pain.

Type of pain	Definition	Examples
Nociceptive pain	Pain derived from stimulation of pain receptors. It may arise from trauma and mechanical causes, inflammation, degenerative and other pathologies	Low back disorders (vertebral compression fractures, facet arthropathies, spondylosis) Rheumatoid and other inflammatory arthritides Visceral pain, e.g. chronic pancreatitis, cholecystitis, prostatitis, recurrent myocardial ischaemia
Neuropathic pain	Damage to the peripheral and/or central nervous system	Post-stroke pain syndromes, diabetic neuropathy, post-herpetic neuralgia, carpal tunnel syndrome, trigeminal neuralgia, radiculopathy, vertebral canal stenosis, surgery
Pain related to psychological or psychiatric disorders	Psychological/psychiatric factors are judged to play a major role in the onset, severity and maintenance of pain	Pain disorder (DSM4)
Pain of uncertain pathogenesis		Recurrent headaches, fibromyalgia, irritable bowel syndrome Complex regional pain syndrome type 1

The biopsychosocial concept of chronic pain

Pain is never a consequence of age alone and it is rare for it to have an entirely psychological genesis at any age. Many people cope with persistent pain and do not seek medical intervention as they perceive that the burden of treatment is greater than the burden of disease. In nearly all situations where chronic pain is a problem for the patient, there is evidence of nociceptive and/or neuropathic pathophysiology associated with maladaptive attitudes or beliefs and inappropriate behaviours operating in a potentially adverse social milieu. The current concept of chronic pain is that cognitions (appraisal of the situation and beliefs about pain and its treatment) are interposed between noxious stimulus input into the central nervous system and behavioural outcomes. Thus, an approach that targets only the pain stimulus and its nociceptive and neuropathic pathways, without taking into consideration the individual's appraisal of the situation and the role of their environment and support structures, may lead to suboptimal outcomes.

Chronic pain is frequently associated with mood disturbance. Epidemiological data based on community samples suggest that about 10% of older people aged over 70 years have depressive symptoms or have been treated for depression.[8] The prevalence of anxiety is less well defined as the instruments used to determine affective disturbance overlap on these domains. In pain clinic samples, older patients generally express less anxiety than their younger

counterparts. Other mood states, which are rarely pursued during clinical assessment, include frustration, anger and demoralization. There are validated psychometric instruments that may be used to explore these other facets of mood disturbance in older people, such as the Profile of Mood States,[9] but they have not been used in epidemiological studies.

There are multiple belief system constructs postulated in the psychological literature that might explain modulation of pain behaviours. The commonest approach is to consider coping strategies or their converse, catastrophic thinking, with feelings of despair, fear or helplessness. Other concepts, however, may also be relevant, such as locus of control, stoicism and fear avoidance. The relationship between pain and gender has not been clearly defined in older people, although certain conditions occur more commonly in elderly females, such as joint pain, chronic widespread pain and fibromyalgia. Chronic pain is more likely in widows living alone. The effects of ethnicity on pain expression in older people remains underexplored.

Age-related changes in the nociceptive system

Pain threshold is the level of stimulus intensity (mechanical, thermal, chemical or electrical) that a subject first perceives as being noxious. Pain tolerance is the maximum amount of a noxious stimulus that a subject can bear. The trend of psychophysical studies suggests that the sum of physiological changes in older persons results in higher pain thresholds, especially to very brief noxious stimuli, but lower pain tolerance.[10] This increase in threshold might suggest a compromise of the warning function of pain by shortening the time between perception of pain and the onset of tissue damage in the acute setting and under-reporting of mild pain so increasing the risk of undiagnosed disease or injury. On the other hand, decreased pain tolerance might lead to an increased vulnerability to persistent pain.

In addition, in the elderly, noxious stimuli delivered at low frequencies of around 0.2 Hz are capable of showing temporal summation, meaning that for the fifth repeated stimulus a noxious stimulus is rated to be more painful when compared with the first stimulus. This phenomenon only occurs in the young at higher frequencies, suggesting amplified or more severe pain in older people once stimulation is under way. In addition, it has also been demonstrated that after prolonged noxious stimulation endogenous pain modulation mechanisms in the older person are not activated to the same extent as in younger adults. The effect of these functional changes in experimental pain on the experience of clinical pain in older people is not yet completely understood, but will become clearer as further studies of these phenomena are undertaken.

The clinical literature is supportive of the notion that the older person feels less pain for a given level of nociceptor stimulation, but it is difficult to control for severity of disease, as attested in a largely anecdotal surgical literature in conditions as varied as analgesic requirements during surgery, fracture, peritonitis and ischaemic heart disease. There is also support for the view that severe clinical pain is less well tolerated in older people. Once an older person reports pain, they should be believed and managed accordingly. However, the converse may not be true. The absence of pain in an older person should not be interpreted as absence of pathology.

Assessment

When an older individual initially presents to a health practitioner with acute pain as a major symptom, it is appropriate for the clinician to be focused on the pathology causing the pain and then on the provision of symptomatic relief. However, when pain becomes chronic, the focus shifts to outcomes pertaining to quality of life, such as maintenance of independence and the balance between pain relief, increased function and side effects of treatments.

The ageing process is associated with multiple social, personal and health related losses. Persistent pain may be only one of the factors that modulates the wellbeing of the patient. Establishing how persistent pain affects overall quality of life is important in planning treatment. In some situations, when the patient is well known to the physician over many years, the relevance of the pain problem can be easily recognized and managed by the physician acting alone or in concert with an appropriate allied health professional, such as a physiotherapist. However, if the pain problem is complex and limited information is available to facilitate construction of a comprehensive management plan, even with or despite the input and best intentions of different therapists acting independently in the past, a multidisciplinary approach to management is to be preferred. In practice, the skills of a doctor, a psychologist and a physiotherapist, all experienced in the care of older people, are complementary and sufficient to allow for a broad multidimensional picture to be assembled on each patient. A nurse, occupational therapist and pharmacist may often contribute other perspectives to the assessment. The total time commitment in a complex patient may be several hours.

Domains of assessment

Assessment of chronic pain in the older person is similar to that in the younger person. It is best based on self-report, either through face-to-face interview or by questionnaire. Common problems in older people making the assessment more difficult are visual, hearing and cognitive impairments. There may be overlap of symptoms of comorbid

Table 69.2 Summary of assessment domains.

1	*The medical aspect:*
	What are the pathological processes that have resulted in the present pain syndrome?
	What are the patient's comorbidities and how are these likely to influence the assessment and treatment processes?
	Is the pain primarily nociceptor in origin, neuropathic, a combination of the two or unexplained?
	Is specific disease management or a symptom management approach required or both? Are there features to suggest more sinister pathology (red flags)?
	Is polypharmacy an issue complicating the management of the pain problem?
	What factors are likely to limit compliance?
2	*The functional aspect:*
	What functional implications are there for the patient from the pain as opposed to the pathology underlying the pain and other comorbid disease states?
3	*The affective aspect:*
	Is the pain associated with depression, anxiety, anger or other mood disturbance?
4	*The social aspect:*
	What impact does the pain have on social relationships and are relationships maintaining the chronic pain syndrome?
5	*The cognitive aspect:*
	What are the patient's beliefs about the cause, prognosis and treatment options for the pain?
	How are these factors interacting with their pain?
	What agreed simple measurable goals are there that will determine the success or otherwise of any intervention?
	Is general cognition failure interfering with assessment, coping or medical management?
	Is pain or its treatment interfering with memory and the ability to think?

medical conditions further compounding the difficulties in pain assessment in older people. A summary of assessment domains relevant to the pain problem is shown in Table 69.2. Details on assessment tools validated for use in older people that cover most of these issues are contained in an international consensus statement (2007),[11] the American Geriatrics Society Panel on Persistent Pain in Older Persons statement (2002)[12] and guidelines for the assessment of pain on older people by the British Pain Society and the British Geriatric Society (2007),[13] bring an additional clinical perspective to this task.

The medical/physical assessment

A thorough pain history should include information on the onset, duration, site, radiation, severity, character and temporal characteristics of the pain. The last includes such factors as whether the pain is intermittent, lasting for seconds to several days, paroxysmal (repetitive shocks) or continuous. Sometimes the frequency of intermittent pain is very revealing, especially if it is very brief and occurring only every few days, as this suggests that other factors contributing to the patient's distress are more relevant to their assessment. Precipitating, aggravating and relieving factors are very helpful in determining both the site of pain and its cause. There may be multiple sites of pain which are of differing pathogenesis such as seen in patients with nociceptive pain from degenerative disease of the spine combined with radicular pain in the limb of neuropathic type. Sometimes the interaction is from two distinct pathologies such as central neuropathic pain from stroke and degenerative disease of a major joint. A pain diagram may give a better representation of the type and distribution of the various pains. There are brief screening instruments which help differentiate nociceptive pain from neuropathic pain based on the pattern and quality of pain, but none are sensitive or specific enough, or have been validated independently in older people, to allow for confident use in the clinic. Some patients will deny the presence of pain but readily accede to experiencing soreness, hurt, an ache or some other descriptor that healthcare professionals would accept as being unpleasant or painful.

The severity of the pain rarely helps differentiate the type of pain which is present but is often useful in determining the success or otherwise of interventions. It may also give an insight in the patient with a long, complex, disjointed history to ask whether the pain is better, worse or the same now as it was at the time of its onset years before, bearing in mind that memory for pain is poor and correlates better with current mood state than previous pain records. It must be recognized that severity is only one approach to measurement of pain.

Severity is best determined using a simple instrument such as a 10-point scale of pain with zero representing no pain and 10 representing the worst possible pain imaginable. Some patients do better with a more limited word descriptor scaling instrument that essentially represents mild, moderate and severe pain. Older people do less well with visual analogue and pictorial scales. The important point is that the physician should be prepared to use a variety of scales and settle on the one that is best understood by the patient. Once this has been achieved, it is relatively easy to obtain a record of pain now, pain at worst, pain at best and average pain over a chosen time frame, which is conveniently represented in the Brief Pain Inventory (BPI).

These scales focus on the sensory dimension of pain. Unpleasantness scales have never been validated in older people. The McGill Pain Questionnaire (MPQ) evaluates the sensory, affective and cognitive aspects of pain. It has been validated for use in older people. It contains a five-point severity scale, the Present Pain Intensity and a

variety of descriptors in sensory, affective and evaluative domains, which are most useful in building a picture of the pain type. Examples of word descriptors include aching, burning, shooting, cruel and exhausting. The short-form MPQ, also validated in older people and which concentrates on sensory and affective domains, is simpler to use than the full instrument and is easily used in a clinical setting. The authors' preference is for the Gracely Box Scale (GBS),[14] as it combines a numerical rating scale, a verbal rating scale and anchor points directly based on psychophysical experiments matching words to the intensity of physical stimuli, although its efficacy in older people has not been formally documented and the verbal rating intervals have only been validated psychophysically in young adults. Other disease-specific instruments and non-verbal measures based on facial expression are available.

The history should also include exploration of current and previous treatments, including complementary and alternative therapies and why they may have been ineffective. For instance, too rapid introduction of a medication leading to cessation of treatment prematurely because of otherwise avoidable adverse events, inadequate amounts of medication at each dose point, inappropriate timing of medication or inadequate duration of treatment trials, poor tolerance and poor compliance often underlie the brief report that the treatment was not helpful. Past physical and invasive treatments should also be recorded with similar attention to detail to ensure they were appropriately administered. It is our experience that the medication list and schedule of use provided by a referring physician rarely matches the medications placed on the table by the patient.

The physical assessment should focus on the site and nature of the pathology, including deformity, degree of firmness or fluctuance of swellings, adherence to adjacent tissues and tenderness, in addition to posture, flexibility (active and passive range of movement) and crepitus of joints, dexterity of movements and gait and direct evidence of nervous system involvement with a focused neurological examination, especially with respect to detection of altered primary sensory perceptions. This includes the presence or absence of hypoalgesia, representing peripheral or central denervation and hyperalgesia, hyperpathia and allodynia representing a state of hypersensitivity mostly due to central sensitization at a spinal cord level. This may occur following injury to both somatic and nervous system elements. It should be remembered that this hypersensitivity is associated with enlarged receptor fields resulting in pain, both spontaneous and evoked, being experienced well beyond the limits imposed by the anatomical distribution of nerve roots, plexuses or peripheral nerves that innervate the affected body part. Autonomic activity and myofascial trigger point activity are generally attenuated in older people and therefore less prominent. Observation and recording of spontaneous movements and non-verbal pain behaviours during the physical examination are also often helpful.

Of fundamental importance in determining outcomes of management is the ability to perform preferred everyday activities, perhaps best assessed in the individual's usual environment. An effect of pain on personal activities of daily living such as showering, grooming, dressing, feeding and toileting is unusual, but instrumental activities of daily living such as shopping, cooking, home care and transportation are often impacted. Effects on discretionary and vocational activities that often provide social support to the isolated individual who lives alone and even the ability to attend to healthcare, are often very relevant to independent older people. Measuring distance walked and time taken is perhaps the most simple and revealing. The best outcomes are usually those that improve function. A wide variety of instruments, both self-report and performance based, have been validated for this purpose in older people and should be used to assess progress and reassess goals at appropriate intervals. A full physical, functional and environmental assessment may need to be undertaken over more than one appointment, particularly for more frail individuals.

Following this initial assessment, causes of pain that need urgent or specific interventions should be attended to first. If the exact pathology cannot be accurately ascertained, however, it should not be relentlessly pursued if there are no features to suggest a deleterious outcome. Often a long history without progression of symptoms or underlying pathology becoming apparent is reassuring. 'Red flags', indicative of severe underlying disease, include weight loss, chronic ill health and a history of other systemic illness such as malignancy, progressive neurological deficit, progressively worsening pain and increased intensity of pain at rest, and all need timely follow-up. The recurrence of severe pain in an individual whose pain was previously well controlled also warrants careful reassessment. Where there is good correlation between the clinical findings and radiological studies, specific management of the underlying pathology may be considered, for example, joint arthroplasty. Age *per se* should not be taken as an excuse to withhold beneficial surgical management. Another caveat operative in chronic pain is that functional and clinical severity may not correlate with the severity of pathology on imaging. This especially applies to radiographic assessment of osteoarthritis of the hips and knees and magnetic resonance imaging of the lumbar spine. Lumbar spondylosis and vertebral canal stenosis are common findings in the aged spine, even in asymptomatic individuals, and these findings should not become the focus of treatment unless the clinical assessment correlates with the radiological findings.

The psychological assessment

The psychological assessment should take into account affect, pain-related cognitions and pain-related behaviours. The assessment of depression and anxiety must take into consideration the changes associated with normal ageing, frailty and the effects of comorbidities. These symptoms often overlap with those observed in depressed patients, such as altered sleep and appetite. The Geriatric Depression Scale, which largely focuses on attitudes rather than somatic symptoms, remains the gold standard assessment tool. Others, such as the Beck Depression Inventory (BDI) and Centre for Epidemiologic Studies Depression Scale (CES-D), have also been widely used with older people. Two anxiety scales used with older people are the Hospital Anxiety and Depression Scale (HADS) and Spielberger's State–Trait Anxiety Inventory. Establishing the temporal relationship between the pain problem and the mood disorder is important. Treating a primary affective disorder requires a different approach.

Adaptive and maladaptive pain-related cognitions, in the form of beliefs, thoughts and appraisals, must be identified. These may relate to beliefs surrounding the meaning of the illness, the types of treatment that are available, the amount of control one has over pain and the strategies that one can use to cope with pain. Some cognitive factors that can lead to poor outcomes include beliefs that the severity of pain correlates with the severity of the underlying illness and perhaps therefore severe ongoing pain represents an undiagnosed cancer or severe ongoing damage. Other maladaptive beliefs are that only medications or an operation will resolve the pain or that all physical activity should be limited until the pain resolves. Pain-associated behaviours include expressions of pain such as grimacing or rubbing, lying down in company and avoidance of activities. This may include pain-related fear of movement (kinesiophobia) and avoidance of everyday activities (fear avoidance). An undue emphasis on passive strategies (e.g. massage, traction and heat) and over-reliance on others (e.g. doctors) to bring the pain under control is maladaptive. Some individuals have unrealistic beliefs regarding the efficacy of doctors or of prayer. Catastrophizing, for instance, feelings of fear and helplessness, is the most maladaptive behaviour. Conversely, cognitive factors that can lead to better outcomes include high self-efficacy (a person's positive appraisal of their ability to undertake coping behaviours), a belief that active strategies (e.g. relaxation exercise) are helpful and a belief that the patient is able to control or modulate their own pain. Another approach to these cognitive factors is that they represent either an (adaptive) internal locus or (maladaptive) external locus of control.

The social assessment

Living alone and widowhood are factors known to affect pain report and outcomes adversely.[15] Conversely, the concern and support of relatives are often helpful in the rehabilitation of chronic pain sufferers. There is often a fine line between appropriate family support and being oversolicitous for the patient's welfare. For example, if a spouse insists on undertaking activities for the patient this will lead to deconditioning and possibly exacerbation of musculoskeletal pain. An expectation of solicitous behaviour on the part of the patient can also result in social conflicts. The evaluation should also consider the possibility of carer stress, which may contribute to the severity of the patient's symptoms or their impact. The physician needs to make a judgement as to how much of the assessment should take place with and without family and carers being present, bearing in mind that successful outcomes are more likely if carers are actively involved in management strategies.

Assessment of pain in dementia

Given the high prevalence of chronic pain and dementia among older people, these two problems are likely to coincide. A brief cognitive screen is therefore advisable in the majority of older people presenting with chronic pain. Indeed, it is not uncommon for a patient who presents with an exacerbation of a previously known and controlled pain to have new onset cognitive impairment as the cause. Conversely, clinical studies suggest that under-treatment of pain in patients with dementia is common and observational studies have shown that patients with dementia tend to be given less analgesia than cognitively intact individuals with the same pathology, for instance, after femoral neck fractures.[16] There are many different types of dementia and even within a single diagnostic group individuals differ with regard to their cognitive and communication abilities. In recent years, as interest and concern in this area have increased, there have been numerous studies directed at improving our understanding of this combination of conditions.[17]

Dementia is usually associated with impairment of memory, affecting the ability to give a history of pain. Cognitive impairment is often associated with language impairment; for example, aphasia in vascular dementia and increasing paucity of vocabulary in advanced Alzheimer's disease. Multiple observations may be required for accurate and reliable diagnosis and an informant history should be sought. The inability of an individual to report pain does not exclude the possibility that they have pain of a severity to warrant treatment. The problem of severity assessment increases as the dementia worsens. For patients with

dementia who are communicative, the scales listed above are still relevant. There is no consensus as to which scale is the most appropriate, although there is some suggestion that word descriptor scales are able to be completed more frequently than numerical rating scales As with the cognitively intact patient, it is best to try a number of different scales and select the instrument that the person appears to manage best. In this way, most people with moderate to severe dementia are still able to have their pain assessed in the normal way.

In non-communicative patients, observer interpretation of pain behaviour becomes very important. Some features include change in facial expressions, such as brow lowering, orbit tightening, upper lid raise and eyelid closure, and others relate to vocalizations, guarding or protective posturing and general change in motor activity. Measures for these behaviours continue to be described in the literature. The first was the Assessment of Discomfort in Advanced Alzheimer patients.[18] Since then, a number of instruments have been described, but none were well validated when reviewed in 2006.[19,20] A better validated brief instrument for measuring pain in non-verbal older people was published after these reviews.[21]

In parallel experimental studies of pain in demented patients, reflex behaviours have been observed to increase in situations of acute pain, such as venepuncture and mobilization, using measures of facial expression and nociceptive motor reflexes. Other studies have documented increases in brain activity of pain-associated areas of cerebral cortex in mildly demented subjects over cognitively normal control subjects. On the other hand, these same demented subjects consistently rate weak pain at threshold the same as cognitively intact controls, but pain tolerance is measurably higher with more advanced dementia from Alzheimer's disease, supporting the clinical contention that pain is under reported in this cohort.

The validity and reliability of these observations do not necessarily apply in situations of chronic pain. Nevertheless, with a similar history obtained from both family and professional carers, an examination demonstrating consistent evoked responses to movement of the affected body part and examination findings showing hypoalgesia or hyperalgesia, hyperpathia and allodynia, a picture consistent with nociceptive or neuropathic pain can be assembled. Other factors, such as hunger, constipation, urinary retention and urinary tract infection, must also be considered as causes of new onset abnormal 'pain' behaviours.

Following this assessment, patient discussion of potential treatments with family and carers is required and consensus on outcome measures for trials of treatment undertaken for predetermined periods of time determined. These treatments will include medications, physical therapies, environmental modification and limited exercise programmes, as is the case for cognitively intact individuals. The outcome measures include functional outcomes important for activities of daily living and also a selection from the pain measures described above. What has been learnt from experimental studies, however, is that placebo treatments are ineffective in patients with advanced dementia affecting the prefrontal cortex, such as with Alzheimer's disease, and they should not be used as treatments.

Management strategies

This section on pain management is of a general nature. Where specific conditions are mentioned, the purpose is to highlight a point rather than to provide comprehensive advice on how to manage that condition. For convenience, we have divided management strategies into individual modalities. The initial treatment modality is often determined by the type of health practitioner the patient has selected; whether medical, physical, psychological or complementary therapist. If initial strategies are not effective, then a multidisciplinary approach is recommended rather than simply escalating single-modality therapies. For patients presenting with troublesome persistent pain, a multifaceted management programme is frequently employed from the outset.[22]

Pharmacological management

Pharmacological management is the most common approach to the management of pain in older people. Here we focus on options that are readily accessible to medical practitioners. The American Geriatrics Society (2009) has published guidelines for the pharmacological management of persistent pain.[23] Practice guidelines on interventional approaches to management of chronic pain have been published by the American Society of Anesthesiologists and the American Society of Regional Anesthesia and Pain Medicine (2010).[24]

Although pharmacological management has become the mainstay of pain management in older people, it also carries a great risk of adverse outcomes. Therapeutic guidelines for older patients are often extrapolated from data available for younger patients and those with malignant pain. These data should be interpreted with caution. Published studies tend to be based on highly selected populations atypical of the patients seen on a day-to-day basis. Positive trial outcomes are often achieved over short time frames at doses much higher than those able to be tolerated by frail

older individuals. Age-related changes in drug handling and sensitivity are discussed in Chapters 12–14. As medical science is constantly evolving, any recommendations made here must be reconsidered by the reader as new evidence emerges.

The timing of analgesic medication and efforts to ensure compliance may be as important as the selection of the medication itself. Analgesia may be administered as pain-contingent (as required), time-contingent (at fixed time intervals) or prophylactic, that is, usually about 30 min prior to an activity known to exacerbate pain, such as with routine exercises or wound dressing changes. For persistent pain, analgesic medications should be given to provide 'round the clock' cover.

Adverse drug side effects are common and often predictable. Tolerance to side effects may be achieved by commencement at a low dose followed by slow upward titration. Explanation of benefits and disadvantages of treatments need to be openly discussed with patients and carers, particularly as the goal is to optimize pain relief and/or function without causing intolerable side effects. Attempts to eradicate pain entirely often result in unacceptable drug side effects. These may be as troublesome as the pain itself. Side effects can usually be managed effectively by dose adjustment or added medication that does not compromise analgesic benefits as, for example, with opioid-related constipation treated with laxatives. Where there is doubt, a short trial off the medication, or at a lower dose, may help determine whether, on balance, the medication is of benefit to the patient. For chronic pain management, the oral or transdermal route is preferred. Parenteral analgesics should be avoided.

Non-opioid analgesia

Paracetamol (acetaminophen) remains the first-line treatment for mild to moderate chronic pain. Its efficacy is not significantly different to that of ibuprofen. No age-related dose adjustment is required. In chronic pain it is usually prescribed in a dose of 1000 mg four times per day. Given the short duration of action and dose required to obtain maximum analgesic effect, some patients do better on a dose of 500 mg every 4 h. Long-acting oral preparations are available. They may be of benefit in reducing the number of doses per day and provide better overnight analgesic cover. The major concern with paracetamol toxicity is liver failure. The risk is enhanced by the large range of paracetamol-containing analgesics that are widely available without prescription. Different brand names may leave the patient unaware that they also contain paracetamol, resulting in inadvertently exceeding the maximum recommended daily dose. Although there is no entirely safe dose, paracetamol hepatic toxicity is rare in doses below 4000 mg per day. The risk is increased in alcoholics and malnourished individuals. A lower maximum dose of 3000 mg per day is recommended in this population.

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective analgesics and represent one of the most widely used classes of prescribed medication. Their use is limited by frequent adverse reactions in older people, including peptic ulceration and haemorrhage, drug interactions, renal impairment and fluid retention. The introduction of the selective cyclooxygenase-2 enzyme (COX-2) inhibitors was met with enthusiasm as a safer alternative to conventional NSAIDs in terms of upper gastrointestinal toxicity. There is, however, increasing concern about the safety of COX-2 inhibitors, particularly in older individuals. Rofecoxib was withdrawn because of serious thrombotic cardiovascular events in some patients taking this medication. There is no evidence that the increased cardiovascular complications observed with rofecoxib represent a class effect of the COX-2 inhibitors. COX-2 inhibitors appear to affect renal function in a similar fashion to non-selective NSAIDs. Particular caution is required in patients with renal impairment or when administered with diuretics and angiotensin-converting enzyme inhibitors. NSAIDs are best reserved for use in transient or subacute musculoskeletal pain which is thought to have an inflammatory pathogenesis, that is, nociceptive pain. They are of no benefit in neuropathic pain. The coadministration of a proton pump inhibitor with a conventional NSAID should be considered in high-risk patients. Prolonged use of NSAIDs beyond 2 weeks is best avoided.

Analgesics with weak opioid effects

For patients with pain not adequately controlled with simple non-opioid analgesia there is an intermediate step before embarking on treatment with strong opioids. The medications in this group include codeine, tramadol and dextropropoxyphene. As a group their efficacy is not always predictable and side effects are common.

Codeine (methylmorphine) is an opioid analgesic with a short half-life often given in fixed combination tablets with paracetamol, aspirin or ibuprofen. Recommended for incident, predictable, short-lasting and infrequent pain, its role in chronic pain management is less clearly defined. The smallest codeine tablet contains 8 mg. There is little evidence to support its efficacy at this dose. The analgesic effects of codeine require its transformation to morphine. About 8% of Caucasians and 2% of Asians have a congenital absence of the cytochrome CYP2D6 responsible for this conversion and therefore obtain little pain relief. Several medications may also interfere with this conversion, including the selective serotonin reuptake inhibitors (SSRIs) fluoxetine and paroxetine and the antihistamine dipheniramine. The maximum dose for older people is 60 mg four times per day, although many frailer individuals will only tolerate 30 mg four times per day. Codeine has a strong

tendency to cause constipation. Other common side effects include nausea and confusion.

Tramadol (hydrochloride) is an atypical, centrally acting analgesic with weak action on the mu-opioid receptor. It is usually classified separately from the opioid analgesics as it has additional pharmacological actions, inhibiting noradrenaline and serotonin reuptake. Short-acting preparations are often used for acute pain as they cause less respiratory depression and constipation than other opioids. Slow-release tramadol may be used for chronic pain, including neuropathic pain. For older patients, the maximum recommended dose of tramadol is reduced to 300 mg per day. Drug interactions and frequent side effects limit its use. Up to one-third of patients are unable to tolerate tramadol, experiencing symptoms such as nausea, vomiting, sweating, dizziness, tremors and headaches. Serious side effects include delirium and hallucinations. A serotonin syndrome can be precipitated when other serotonergic medications are used concurrently, including SSRIs and tricyclic antidepressants. Features of the serotonin syndrome include delirium, confusion, agitation, hypomania, hyperactivity, restlessness, fever, sweating, tachycardia, hypertension, ataxia and tremor. It may occur dramatically or insidiously. Mild forms usually resolve within 24 h of ceasing the medications.

Dextropropoxyphene is now used less frequently than in the past. If used, great caution should be taken in the elderly. Its major metabolite has a long half-life and has the potential for causing central nervous system side effects, including hallucinations and seizures. The usual dose is 32.5–65 mg four times per day.

The analgesic properties of codeine, tramadol and dextropropoxyphene are limited by a ceiling effect. Further dose increases may cause toxicity without conferring additional analgesia. It is our preference to use a low dose of a strong opioid rather than these agents if additional analgesia is required.

Strong opioid analgesia

Opioids have an established role in the treatment of severe malignant pain. Opioids are increasingly gaining acceptance for the management of severe non-malignant pain. This trend is seen as positive, in the sense that individuals should not be left to suffer uncontrolled pain. There is no optimal or correct opioid dose; the optimal dose is determined by a balance between analgesia and side effects. In some cases an increased dose does not result in increased analgesia. There is no evidence to support escalating opioid doses beyond the equivalent of morphine 180 mg per day if no response has occurred at lower doses. Clinicians must observe strict regulatory requirements when prescribing opioids. Prior to their introduction, the physician should engage the patient and carers in a discussion concerning these restrictions and why they are important to observe. Most older people are concerned about possible addiction and the discussion needs to include the distinction between habituation and addiction. It is best to introduce opioids on a trial basis with agreed objectives on functional goals, and if these are not achieved the medication should be withdrawn. It may be necessary to have these issues documented in a written agreement in some cases.

There is a paucity of evidence to support the long-term use of opioid medication for chronic non-cancer pain, especially among older patients. Ongoing monitoring is required to ensure that pain control has not occurred at the expense of intolerable side effects such as impaired cognition, falls or severe constipation. The clinician must evaluate the benefits and adverse effects for each individual patient. An exacerbation of previously controlled pain should not simply lead to dose escalation without assessment as to why the pain has become worse. It is possible to mask the symptoms of pathology where specific treatment is more appropriate.

All opioids have the tendency to produce constipation, nausea, sedation, cognitive impairment and respiratory depression, necessitating commencement at a low dose with gentle titration. There is significant individual variation in side effects with different opioids. Selection of the most suitable agent may require trials of a number of different agents. Tolerance to these side effects occurs over time, apart from constipation, which tends to persist. The onset of nausea several days or weeks after commencement of an opioid analgesic is more likely to be due to constipation than intolerance of the opioid. Prophylactic treatment of constipation is generally required. Aperients act as a source of increased fibre, are faecal softeners, osmotically active or act as bowel stimulants. Many aperients contain multiple active ingredients. It is best to gain experience with a few over-the-counter preparations before prescribing more expensive options. Enemas should be a last resort. A severely constipated patient with overflow incontinence may need inpatient monitoring of treatment with a preparation usually reserved for use prior to bowel investigative studies.

The most commonly prescribed oral opioids are morphine and oxycodone. Morphine has traditionally been considered the opioid of choice. Increasingly oxycodone is being used as the first-line opioid analgesic agent for older individuals. This is based on a more predictable dose–response relationship as it does not undergo extensive first-pass metabolism in the liver. Cognitive side effects are said to be less frequent.

Initiation of opioid analgesia for chronic non-malignant pain is usually commenced with oxycodone 5 mg or morphine 10 mg. The dose is titrated according to response. Once the maintenance dose has been determined, a long-acting oral preparation can be used. A short-acting preparation should also be prescribed for breakthrough

or incident pain. Breakthrough pain occurs unpredictably on a background of controlled pain, whereas incident pain is predictable, occurring for example with physical activity or wound dressings. Breakthrough pain is treated after the pain occurs, whereas incident pain should be managed prophylactically prior to the pain-inducing activity. A short-acting opioid is used, usually in the order of one-sixth to one-third of the daily maintenance dose.

A sustained analgesic effect is desirable for people with chronic pain. Various long-acting opioid preparations are available, including oral and transdermal preparations. These have the advantage of avoiding fluctuating blood levels and are less likely to be associated with mood-elevating effects seen with shorter acting preparations. Two long-acting transdermal opioid preparations are currently available with others under development. Transdermal opioid delivery systems are characterized by a delayed onset of initial action, making them unsuitable for the treatment of acute pain. A prolonged duration of action allows for less frequent dosing. Stabilization with oral therapy is recommended before transferring to a transdermal patch. The oral agent should be continued for a few days following initiation of the transdermal opioid-containing patch.

After application of the patch, the opioid accumulates to form a depot in the skin from where it gradually enters the circulation. Drug effects continue after removing the patch as the opioid is released from this depot. Transdermal therapy does not offer the range of dose flexibility of oral preparations. There is no efficacy advantage over oral opioids and their side effect profile is similar, although considerable individual variation in side effects exists. It is worth trying another agent if the first is not well tolerated. However, transdermal therapy increases the range of options, especially when oral therapy is associated with persistent nausea, vomiting, severe constipation or for patients with swallowing difficulties or compliance issues. Their long duration of action does have the advantage of ensuring 'round the clock' dosing. Patients should be warned of the dangers of exposing the patches to direct heat, for instance with a hot pack or electric blanket. There is a potential for temperature-dependent increases in opioid released from the transdermal systems, resulting in possible overdose and death.

Buprenorphine is a partial opioid agonist at mu receptors and an antagonist at kappa receptors. Buprenorphine transdermal patches are produced in two dose ranges. Availability varies between countries. The lower dose range transdermal patches, releasing 5, 10 or 20 μg of buprenorphine per hour, is indicated for non-malignant pain not responding to non-opioid analgesia. They require changing every 7 days. The lowest dose buprenorphine transdermal patches may be used to initiate strong opioid therapy. The 20 μg per hour buprenorphine patch is approximately equivalent to a fentanyl 12 μg per hour patch. Higher dose transdermal patches releasing 35, 52.5 or 70 μg of buprenorphine per hour are indicated for moderate to severe cancer pain not responding to non-opioid analgesics. They require changing every 4 days.

Fentanyl is available in different forms, including a transdermal patch that is replaced every 3 days. Even the lowest dose fentanyl patch is too potent for patients who are not already on opioid therapy. The fentanyl 12 μg per hour patch equates to oral morphine ~45 mg per day. Older, cachectic or debilitated patients may be more sensitive to fentanyl because of reduced clearance and a prolonged half-life. As fentanyl is primarily metabolized in the liver, it has a role in patients with severe renal impairment. The used patches retain a significant quantity of residual fentanyl and must be disposed of appropriately. After patch removal, fentanyl concentrations fall slowly, decreasing by 50% after 17 h.

Methadone has a long and unpredictable half-life, making it difficult to prescribe. There is a potential for it to accumulate, resulting in agitation, tremor or seizures. In general, we recommend that methadone be reserved for use by clinicians experienced with its use, such as pain and palliative care specialists. Methadone may have a special role in settings with limited access to the more expensive long-acting opioid preparations. The use of pethidine (meperidine) for chronic pain is not recommended because of the potential for neurotoxicity associated with the accumulation of the metabolite norpethidine.

It has been shown that only approximately one-third of patients with chronic pain respond well to opioid analgesia, one-third respond partially and one-third do not respond.[25] Of the responders, only half continued to benefit in the long term. This compares poorly with their use in malignant pain, where 90% of patients will have opioid responsive pain. The risk–benefit ratio in older patients is currently unknown. In general, older patients respond to lower doses of opioids where fewer side effects are expected, but have a greater tendency for adverse effects. Opioids are not a panacea for chronic pain and are best employed as part of a multifaceted pain management programme.

Adjuvant analgesics

Neuropathic pain can be difficult to treat as conventional analgesics often fail to provide effective pain relief. Most therapeutic trials are based on a 50% reduction in the level of pain being considered an appropriate endpoint. Total eradication of pain is rarely achieved, the dose being limited by drug side effects. Although only partially effective, however, pharmacological therapy remains an important intervention. As less than 50% of patients will get adequate pain relief with a single drug, neuropathic pain is usually treated with a combination of conventional analgesics

and adjuvant agents. Adjuvant agents are not primarily analgesics, although they have been shown to be of benefit in the management of neuropathic pain. They comprise drugs from a number of different therapeutic classes including antidepressants, antiepileptic drugs, antiarrhythmics and *N*-methyl-D-aspartate receptor antagonists (NMDA antagonists).

Consensus guidelines are available to assist the clinician with the selection of therapeutic agents.[26] These must be interpreted with caution. The evidence is often based on short-term trials of 6–12 weeks' duration, often with very few older people being included and without evidence for long-term use spanning many years, as is often the case when they are used clinically. There have been few studies directly comparing the efficacy of the different agents or combination of agents. The trials tended to focus on common neuropathic conditions such as painful diabetic peripheral neuropathy and post-herpetic neuralgia, offering little guidance to other conditions such as pain arising from radiculopathy, surgery, spinal cord lesions or post-stroke central pain syndromes.

The most commonly used agents for neuropathic pain include antidepressants and antiepileptic drugs. Many of the earliest studies were undertaken with the tricyclic antidepressants amitriptyline and nortriptyline. Great caution should be used with these medications in older patients. The presence of depression is not required for the analgesic effects. They are inexpensive and usually administered once daily. Based on their efficacy in these relatively inadequate trials, they remain in the list of first-line agents for neuropathic pain, joined in recent times by newer agents with better side effect profiles, especially in older people. However, tricyclic antidepressants continue to have a role when access to the newer, more expensive alternatives is not available. Amitriptyline and nortriptyline are usually commenced at 10 mg 1 h before retiring and increased every few days by a similar dose until a benefit is achieved or side effects preclude further use. A dose of 50 mg is usually considered to be sufficient to achieve an analgesic effect if one is going to occur. Common side effects include dry mouth, postural hypotension, drowsiness and urinary retention.

Because of more favourable side effect profiles, SSRIs and selective serotonin and noradrenalin reuptake inhibitors (SNRIs) have largely replaced the tricyclic antidepressants for the treatment of depression. SSRIs have not been shown to be effective for neuropathic pain. The SNRIs duloxetine and venlafaxine have, however, been shown to be effective in neuropathic pain states such as diabetic peripheral neuropathy. In low doses venlafaxine only inhibits serotonin reuptake, but in higher doses it inhibits both serotonin and noradrenaline reuptake. Hence the analgesic effects of venlafaxine may not become apparent until higher doses are reached or a concurrent low dose of a noradrenaline reuptake inhibitor is added. Care should be taken with both dose escalation and dose reduction with these agents. They are contraindicated if monoamine oxidase inhibitors (MAOIs) are in use. Many precautions, adverse events and other drug interactions have been linked to these drugs. They should only be prescribed by practitioners familiar with their use.

Gabapentin and pregabalin bind to the alpha 2-delta subunit of voltage-gated calcium channels, decreasing the release of glutamate, adrenaline and substance P near primary afferent nerve terminals in the spinal cord. They have been proven to be of benefit in a number of painful neuropathic conditions, including post-herpetic neuralgia, painful diabetic peripheral neuropathy and spinal cord injury. The main dose-limiting side effects are somnolence, dizziness and unexplained peripheral oedema.

In some patients, particularly older people, gabapentin can cause or exacerbate cognitive or gait impairment. The usual starting dose of gabapentin in the frail elderly is 100 mg at night, increasing every few days, aiming for 300 mg three times per day. This is below the target therapeutic dose in most trials of 1800–3600 mg per day, but these doses are generally not tolerated by frail older patients.

Pregabalin has similar side effects to gabapentin but is easier to titrate and has no important drug interactions. The usual starting dose in the elderly is 75 mg at bedtime, titrating upwards to 150 or 300 mg daily, in divided doses. Dose reduction is required for both gabapentin and pregabalin in renal impairment and 25 mg capsules of pregabalin have recently become available.

Carbamazepine is the drug of choice for trigeminal neuralgia. A starting dose of 50 mg is suggested, as some older people are very sensitive to the adverse effects of this medication.

Lignocaine (lidocaine) 5% patches are effective for the management of post-herpetic neuralgia with allodynia and painful diabetic peripheral neuropathy. Blood levels are minimal with standard doses; the most common side effects are mild skin reactions. Cost may preclude its use. Lignocaine 5% gel may be considered as an alternative. Oral local anaesthetic preparations such as mexiletine have low therapeutic benefit to toxic ratios and are generally precluded from use in older people.

NMDA antagonists such as ketamine should be reserved for use by clinicians experienced with its use as side effects are common and often severe. The use of clonidine for prevention of withdrawal symptoms due to reductions in opioid doses is to be avoided in older people.

Complementary therapies

Complementary therapies comprise a group of healthcare practices and products that are not considered to be conventional medicine. These include herbs, acupuncture, mind–body techniques, massage and chiropractice.

The use of complementary therapies is increasing, perhaps because of personal beliefs or disillusionment with conventional medicine due to lack of efficacy or side-effects. Complementary therapies are generally safe when provided by a competent practitioner. Herbal therapies are biologically active, raising concern about potential interactions with conventional therapy. For example, St John's wort (*Hypericum perforatum*) when used in combination with other antidepressants may induce a serotonin syndrome as it is a weak MAOI. It may also interfere with anticoagulation when coadministered with warfarin. Many patients do not disclose their current use of complementary therapies and they are often not specifically asked by their physicians.

Glucosamine is widely used for osteoarthritis, often in combination with chondroitin sulfate. A Cochrane review of glucosamine for osteoarthritis reported significant advantage for pain and function over placebo, but no benefit when analysis was confined to the higher quality studies with adequate allocation concealment. There was also variation between product manufacturer and benefit. Most study populations were of people in their 50s and 60s. Although the efficacy of glucosamine is questionable, it is generally safe.[27]

Acupuncture has been demonstrated to be a safe therapy with a very low risk of serious side effects. A Cochrane review of acupuncture for knee and hip pain reported a small improvement with acupuncture compared with sham acupuncture. The effects of acupuncture relative to sham acupuncture are too small to be perceived by participants as beneficial. These benefits may be largely mediated through placebo effects.[28]

Other pharmacological measures

Depression and anxiety are common accompaniments of chronic pain. Many patients receive pharmacological therapies to relieve these symptoms. However, they are best used in the context of a multidisciplinary management programme rather than as a sole modality of treatment, unless the disorder is primarily affective in nature. Benzodiazepines do not have a direct analgesic effect. The high potential for adverse effects in older patients limits their usefulness for insomnia or anxiety associated with chronic pain. Corticosteroids play a valuable role in the management of a number of painful conditions, including polymyalgia rheumatica, temporal arteritis, rheumatoid arthritis and crystal arthropathies. Serious adverse effects limit their long-term use. Topical agents are also widely used by older people. The most common are those containing capsaicin, NSAIDs, local anaesthetics and the rubifacients methyl salicylate and nicotinate. Although of limited efficacy, they are relatively free of systemic side effects.

Psychological modalities of management

Most multidisciplinary chronic pain management programmes are based on the cognitive behavioural therapy (CBT) model. Such programmes consist of patient and family education, contingency management, relaxation training, training in goal setting and problem-solving skills, training in effective communication, behavioural reactivation and cognitive restructuring. The last requires attention to specific constructs identified in individual patients. These might include a fear of increased damage from activity or increased pain levels or excessive reliance on 'powerful others' such as doctors and medications. The efficacy of CBT in the general population has been shown to have unequivocal benefit. However, there have been limited studies in older people. It has been shown that 10 weekly sessions of CBT are effective in the institutionalized elderly[29] and that age is not a factor in determining the success of a CBT programme.[30] CBT is also useful in the treatment of depression in older people. CBT programmes should be undertaken under the supervision of a psychologist experienced in their use.

Physical modalities of management

Exercise therapy has been used as a part of CBT programmes. It is most effective if it has a specific goal orientation. Exercise therapy should include stretching, strengthening, aerobic exercise and postural correction where feasible. Weight loss can help in painful conditions involving the weight-bearing joints and can assist in slowing the progression of degenerative arthritis. Other techniques, such as bracing, trigger point deactivation, massage therapy, acupuncture, transcutaneous electrical stimulation (TENS), heat and cold, have also been used. Hydrotherapy and use of an exercise bike may promote increased range of movement and confidence. TENS is useful in subacute injury and post-herpetic neuralgia. Controlled trials of TENS using experimental pain models are usually only effective at high intensities of stimulation. TENS has the advantage of being able to be used for long periods at a time, but post-stimulus effects are short-lived.

The clinician should be aware of the dangers of an over-reliance on passive therapies, especially if the patient tends to have an external locus of control. Advice on simple manoeuvres for lifting and walking may be of great functional benefit; for instance, leaning on the supermarket trolley in patients with vertebral canal stenosis may increase their walking distance. The use of assistive devices, such as walking sticks and wheeled frames, can be useful in patients to improve function and reduce pain. However, such measures should be applied judiciously so as not to promote over-reliance on them or promote deconditioning. Physiotherapists can also counsel patients in approaches that avoid exacerbations of musculoskeletal pains.

Management of social circumstances

The patient's family must be educated about the nature of chronic pain. First, they must be assured that the problem is real and the patient is not in any way trying to 'fake the pain' to obtain some advantage. Second, they must be educated that although the aim is to decrease pain and maintain function, the patient may be better satisfied with the same pain but better function. The nature of how solicitous behaviour can modify the patient's function should be explained to carers. The family should also be educated about the need to maintain a paced level of physical activity and be taught the same methods of non-pharmacological pain management as the patient. Such measures may increase the sense of mastery of both patient and family. The family may play an important role in the management of patients with dementia, who may not be able to maintain a therapeutic approach without ongoing prompting and supervision. Frequently, loneliness and meaninglessness can present as somatic complaints, including pain. Pain management in these instances may be helping the patient source social or meaningful activities.

Procedural modalities of management

Ongoing pain may warrant consideration of anaesthetic or surgical interventions. Joint arthroplasty of the hip and knee is a good example of interventions that improve pain and function in appropriately selected older individuals. The place of vertebroplasty in vertebral collapse is not yet fully established. Other interventions such as CT controlled epidural injections of local anaesthetics and steroids may give short-term relief, especially into nerve root sleeves of patients with painful radiculopathies not settling with more conservative treatments. Most studies of anaesthetic interventions have not included older subjects, in particular those in residential care. Assessment needs to be undertaken on an individual basis. Referral to a multidisciplinary pain clinic or pain specialist should be considered when planning procedures in frail patients.

Key points

- Chronic pain is a common complaint among older people.
- Older people have higher pain thresholds and lower pain tolerance than young adults in studies of experimental pain. This is probably also true in chronic pain syndromes.
- Chronic pain requires meticulous multidimensional assessment and properly planned and monitored interventions using pharmacological, physical, social and psychological modalities.
- Chronic pain is best managed with a combination of pharmacological and non-pharmacological approaches.
- Empowerment is a key factor in ensuring satisfying and durable outcomes; the patient and their carers must be active participants in therapy at all times.
- Although there is limited high-quality information about the management of chronic pain affecting older people, this is likely to be rectified in coming years as chronic pain is increasingly recognized as an important geriatric syndrome.

CHAPTER 70

Multiple sclerosis

Florian P. Thomas

St Louis Veterans' Affairs Medical Center and Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

As individuals with multiple sclerosis (MS) grow older, not only does this condition typically lead to more disability,[1] but often they acquire additional unrelated medical problems such as diabetes, hypertension, hyperlipidaemia, cardiac and peripheral vascular diseases, osteoporosis and dementia. Consequences of MS accumulate, including paresis, neurogenic bowel and bladder, depression, cognitive decline, fatigue, gait imbalance and pain. Engagement in appropriate health behaviour is often limited. The death of a spouse may contribute to social withdrawal and loss of cognitive stimulation. Thus, advanced MS in an ageing individual may present formidable challenges, and treating one problem may make others worse. These numerous medical issues are often beyond the scope of a single healthcare provider, whatever the specialty. A person with MS, faced with advancing age and disability, may be obliged to engage multiple providers who schedule numerous appointments. Accessing these appointments may become near impossible owing to loss of the ability to drive, inadequate accessibility of public transportation and doctors' offices and lack of social networks necessary for assistance. Persons with MS may live without significant others or relatives who could provide logistical, emotional and social support. They may lack the resources to hire personal assistants or their significant others may also have medical problems that render them incapable of helping. Deterioration, depression and social isolation may be inexorable. Nursing homes rarely provide optimal care, but may prove the only viable, albeit unsatisfactory, alternative.

This picture is reality for many patients. Some have a more benign course, with minimal disability decades after the diagnosis and few comorbidities.[2] However, for the majority a comprehensive paradigm that engages persons with MS and their network in the healthcare process is required. This approach does not gloss over clinical features such as fatigue but addresses all manifestations of MS and comorbidities in an all-encompassing fashion. It seeks to integrate numerous providers in ongoing multilateral communication. Such a team will likely include internists, neurologists, nurses, psychiatrists, psychologists, rehabilitation therapists, social workers and urologists, among others. It optimizes access to insurance-covered home care and utilizes other community resources, for example, from the National MS Society, independent living centres or other organizations. Such an approach can significantly enhance quality of life.

The impact of disease-modifying drugs such as glatiramer acetate and beta-interferons on the gestalt of the ageing person with MS is only beginning to be felt. Such agents reached the market starting in 1993. People who turn 60 years of age in 2011 were in their early 40s when they would have received their first dose. Thus they could have lived with MS for up to 20 years before benefiting from these drugs.[3,4]

Although there is no cure for MS, the advent of these drugs fostered optimism among patients and healthcare providers that devoting time and energy in clinical practice, in clinical trials and the laboratory ameliorates outcomes. Although, as will be discussed here, access to optimal care remains limited for many affected individuals, multidisciplinary MS centres have been established in larger towns and cities, where the many needs of patients are being recognized and met.

This chapter discusses the major clinical entities and ancillary studies that must be considered in the care of persons with MS and focus on the health of individuals with MS as they age. It assumes that the disease onset is not recent and that the diagnosis is valid and confirmed. For a comprehensive discussion of the aetiology, pathogenesis, pathology, clinical presentation, ancillary studies and use of disease- and symptom-modifying drugs, the reader is referred to standard texts.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Pathophysiology, aetiology and epidemiology

With a putative overall prevalence of 1 in 1000, some 2.5 million persons worldwide are affected by MS, about 400 000 in the USA, with 10 000 new diagnoses each year.[5] The prevalence varies considerably with distance from the equator and between different countries and ethnic origins.

MS has been defined as an autoimmune disease in which inflammation is sustained by autoreactive T cells directed against components of myelin.[6] A broader concept accounts for the influence of B lymphocytes, for modulation by cytokines and their receptors, for an aetiological role of a primary oligodendropathy and the notion that not only clinically different, but even clinically identical, forms of MS may result from different pathomechanisms.[7] Cytokines not only function as immune modulators but also impact clinical features, including fatigue and cognition. Inflammatory cells including macrophages and lymphocytes cross the blood–brain barrier to enter the central nervous system (CNS). There, in cooperation with cytokines and antibodies, they recognize myelin and axonal antigenic targets and damage them functionally and structurally, thus causing slowing of nerve conduction, demyelination and axonal loss in the white and grey matter, which presents as clinical attacks with varying and multiple symptoms and signs. During remission, inflammatory oedema diminishes and demyelinated axons are repaired. However, irreversible destruction of axons starts soon after onset and contributes to incomplete recovery from attacks and disease progression.

Numerous microbial antigens have been implicated as inducers of autoimmunity, including viruses which may damage oligodendrocytes, such as Epstein–Barr virus (EBV).[8,9] Recently infection with the herpes zoster virus has been established as a risk factor.[9a] Sunlight exposure, vitamin D levels and tobacco use are independent risk factors, among others.[10,11] Evolving concepts include the notion of chronic cerebrospinal venous insufficiency.[12] Beyond the role of autoimmunity, MS likely reflects complex polygenetic–environmental interactions. The risk in families increases with relatedness.[13] The prevalence is related to increasing distance from the equator. The risk conveyed by ethnic origin is modified by geographic origin.

Clinical spectrum, diagnosis and treatment

As MS lesions can affect any anatomical region in the CNS, clinical features may reflect involvement of sensory and motor systems in the brain or spinal cord and of motor, sensory, visual, cerebellar, brainstem, bladder, bowel, sexual, cognitive and emotional functions. Fatigue, sleep disturbances and hormonal anomalies are common but underdiagnosed.

Taking a history may require repeated follow-up questions because the language that patients choose is often idiosyncratic. Open-ended questions yield more valid information. It is helpful to point out the distinction of positive (cramps, spasticity, tingling, vertigo) versus negative symptoms (weakness, numbness, imbalance), both in order to ensure that what the patient tries to convey and what the provider documents as a symptom are not at odds and in order to facilitate rational treatment and realistic expectations of the likelihood of success. For instance, some people use the word numbness to describe tingling or mild weakness rather than sensory loss; some experience tingling as painful, others as a nuisance. Although positive and negative symptoms often go hand in hand, patients should be aware that a medication can alleviate tingling but not numbness.

The diagnosis of relapsing MS requires that a person display dissemination in time and space, for example, optic neuritis and vertigo 3 months apart, for which no better alternative explanation is apparent, such as two separate cerebrovascular accidents affecting different CNS regions in an elderly smoker with hypertension, diabetes and hyperlipidaemia.[14] The accumulation of comorbidities with age (see below) may render a new diagnosis of MS and also the interpretation of new symptoms and signs in the case of an established diagnosis more difficult. Also, when primary progressive MS is entertained, it is important also to consider cervical myelopathy and primary lateral sclerosis, to give just two examples.[14]

Ancillary studies

Imaging studies such as magnetic resonance imaging (MRI) serve different purposes at different disease stages.[15] At onset, MRI can confirm the diagnosis and rule out other conditions. MS-like MRI lesions occur in many other conditions, including vascular disease, migraine and vitamin B_{12} deficiency. MRI can relate the clinical presentation to plaque location and quantitate disease activity, thus providing evidence of therapeutic efficacy. As a person with MS ages and clinical manifestations evolve, CNS imaging can evaluate for intercurrent illnesses such as subdural haematoma (e.g. after a fall), stroke, dementia or mass lesions. Plaques are often ovoid, concentrate in the corpus callosum and periventricular white matter and extend peripherally. New plaques show T2 hyperintensity and enhance with gadolinium. Later they no longer enhance, but maintain T2 hyperintensity and may become T1 hypointense, the so-called black holes which indicate axonal loss, gliosis and demyelination. White matter lesions are easier to detect than those in the grey matter. Brain atrophy starts shortly after onset, results from demyelination

and axonal loss and is accelerated in progressive MS, but slowed by disease-modifying drugs. Serial MRIs reveal a ratio of subclinical to clinical lesions of 5:1. The relationship between brain volume, clinical and MRI exacerbations and disability is beyond the scope of this chapter. Impaired renal function is a risk factor for gadolinium contrast-associated nephrogenic system fibrosis. When contrast is required, its dose should be minimized and alternative contrast agents considered.

Cerebrospinal fluid (CSF) analysis reveals CNS inflammation and may show lymphocytic pleocytosis, protein elevation and evidence of abnormal CNS immunoglobulins.[16]

Evoked potential studies (EP) are abnormal in 70% (somatosensory EP), 90% (visual EP) and 80% (brainstem auditory EP) and can serve to provide evidence for subclinical involvement of functional pathways, in particular when MRI is normal.[17]

Certain blood tests can confirm that no other more appropriate or concurrent diagnosis is warranted, including erythrocyte sedimentation rate, C-reactive protein, rheumatological assays, vitamins B_{12} and D, folate, thyroid function, infections such as syphilis, Lyme disease and hepatitis, HgA1c and urine analysis and culture.

Clinical subtypes

Multiple forms of demyelinating inflammatory CNS disease can be distinguished which differ in pathogenesis, clinical manifestations and treatment options.[18]

At onset, 85% of individuals have relapsing–remitting MS (RRMS), with attacks about every 2 years, characterized by a fairly well-defined deterioration in neurological status followed by variable recovery. Two to three times as many women as men are affected. The typical age at diagnosis is 20–50 years. MS attacks typically evolve from first symptom to maximum deficit over 1 day to 1 week, although onset may be faster or slower. Remission from maximum deficit to maximum improvement usually occurs over 1–3 months, but again may be slower or faster. Some symptoms and signs are more likely to improve than others: Sensory symptoms remit completely in >75% of cases. Monoparesis or hemiparesis remits completely in 50%, but fewer than 20% of patients with tetraparesis or paraparesis recover to normality. With sphincter symptoms, only 15% regain complete control. Resolved symptoms can manifest again with intercurrent illnesses or heat exposure (Uthoff phenomenon). About 50% of patients after 10 years and about 90% after 25 years no longer experience relapses and remissions but progressively accumulate disability: they have developed secondary progressive MS (SPMS), because cumulative and ongoing CNS damage has surpassed a critical threshold, for example, the oligodendrocyte progenitor pool and intact tissue can no longer compensate. In progressive relapsing MS (PRMS), relapses are superimposed on a chronic progressive course already at onset.

FDA-approved subcutaneous or intramuscular beta-interferons[3] and subcutaneous glatiramer acetate[4] reduce the frequency of MS attacks and of disease activity and slow disease progression and brain atrophy. In cases of disabling MS attacks, intravenous or oral methylprednisolone is indicated to hasten recovery. FDA-approved mitoxantrone and natalizumab may be used to 'rescue' patients non-responsive to more benign drugs. Potentially life-threatening side effects, including acute myelogenous leukaemia and cardiotoxicity, and opportunistic infections, respectively, must be balanced against their efficacy. Other chemotherapeutic agents such as cyclophosphamide, methotrexate, mycophenolate mofetil and azathioprine, although not FDA approved, can also be considered for selected patients.

Primary progressive MS (PPMS) accounts for 10–15% of patients: relapses and remissions do not occur. Spinal cord features predominate clinically and by MRI. Onset is later and men and women are equally affected. The distinction of PPMS and SPMS is important because no drugs have been found effective in PPMS, but challenging because 28% of individuals with a progressive course eventually experience relapses.[19] Other subtypes refer to disease stage such as clinically isolated syndrome (CIS) and specific presentation and pathomechanisms such as neuromyelitis optica (Devic syndrome, NMO) and transverse myelitis (TM). The severity and completeness of spinal cord involvement in TM and NMO typically are more dramatic than in classical MS.

Patients with so-called 'benign' MS and little disability decades after the diagnosis typically have a monosymptomatic course without spinal cord features, rare exacerbations, onset at a young age and few lesions by MRI. However, these characteristics do not allow a prediction of such a course in a given individual and a decision against disease-modifying drugs must be individualized.[20]

Visual, brainstem and cerebellar dysfunction

The optic nerves are affected in over 60% of patients. Optic neuritis is a common presenting feature. As new onset optic neuritis is not common in older adults, readers are referred to standard texts for a detailed discussion. Symptoms include blurring of variable severity, scotomata, impaired colour perception and eye pain worse with eye movement.

Common cerebellar manifestations include nystagmus, scanning dysarthria, intention tremor of the limbs, ataxia, dysarthria and titubation. Dysarthria can also result from cerebral and brainstem lesions. Severe tremor can be extremely disabling and is very difficult to treat pharmacologically. Counterweights attached to the arm can reduce its amplitude and facilitate activities of daily

living such as eating. Ataxia is amenable to physical (PT) and occupational therapy (OT).

Brainstem lesions can cause neurological manifestations by disrupting motor, sensory and autonomic fibre tracts, the nuclei and intra-axial fibres of cranial nerves and connecting fibres between nuclei. Eye movement abnormalities including nystagmus, internuclear ophthalmoplegia and diplopia result from lesions that affect the third, fourth and sixth cranial nerves, their nuclei and connecting fibres. Even subtle manifestations such as impaired pursuit and nystagmus can interfere with reading and driving and must be differentiated from decreased visual acuity. The seventh cranial nerve and nucleus involvement resembles Bell palsy, but may be bilateral. Owing to its proximity, the sixth cranial nerve is often affected simultaneously. Vertigo is common in MS and with ageing in general and can be very disabling. Modestly effective drugs such as meclizine can compromise alertness and cognition. When there is a positional component, the Epley particle repositioning manoeuvre should be considered.

Sensory manifestations

Sensory loss can involve any of the senses and be spotty, radicular, reflect a spinal cord level or involve parts of a limb or an entire limb. Symptoms may resolve as patients recover from an attack or they can persist. Propriceptive and vibratory loss and other modalities are often dissociated. In addition to dysesthesias such as tingling, pins and needles, burning (and countless other descriptors), some patients describe a sensation of tightness around the chest or abdomen due to a spinal cord plaque.

Pain

Pain affects about 50% of people with MS and is severe in about 25%. Its causes and features are numerous: pain can originate in the optic nerve, brain or spinal cord, including root entry zones, and may be tingling, boring, aching, excruciating, episodic or chronic, radiculopathic and debilitating (e.g. tic douloureux). Spasms can affect limb muscles and the bladder. Constipation can cause visceral pain. Often several types of pain coexist. Disability can lead to a sedentary lifestyle and weight gain, which together with poor posture and degenerative joint disease can contribute to musculoskeletal back and joint pain. Headaches are more common in MS than the general population. Interferons occasionally cause vascular headaches, hence a pre-existing history of migraine must be considered when choosing a disease-modifying drug.

Treatment is challenging, in part because medications can exacerbate clinical features such as fatigue, memory and sphincter problems, in part because their benefit is often limited and they may be habit forming. Discussions with patients should address the difference between 'healing' and 'curing'. 'Healing' is a multidimensional path toward wellness, which allows individuals to explore opportunities for mental, emotional and spiritual balancing despite chronic illnesses. 'Curing', by contrast, with its focus on symptom eradication, is often unrealistic in the case of chronic illnesses.

Treatment success is more likely if a multidisciplinary team that includes a psychologist, a pain physician and a rehabilitation therapist works with a patient. A patient-oriented exploration of the gate control theory of pain[21] can serve as a springboard for pain management. In the context of mind–body strategies, patients learn that the pain experience is influenced by emotional (e.g. depression), mental (e.g. catastrophizing) and physical (e.g. type of injury) factors and that it can increase one's perception of stress, which in turn can make pain worse through increased muscle tension and anxiety. Issues that must be addressed include catastrophic thinking which manifests as a sense of helplessness and inability to shift one's focus away from pain and fear and avoidance of activity. Two strategies that can reduce pain and stress focus on relaxation and mindfulness.[22]

Although a full discussion is beyond the scope of this chapter, medication management begins with an analysis of the causes of the pain syndromes and associated conditions. The armamentarium includes muscle relaxants and drugs otherwise used to treat seizure or mood disorders,[23] but also acetaminophen and non-steroidal anti-inflammatory drugs (NSAIDs) for musculoskeletal pain. CNS polypharmacy and drug dosing must be kept at a minimal effective level, because many pain medications exacerbate fatigue and cognitive, sexual and neurogenic bowel and bladder dysfunction. It is the sum total of CNS active medications that determine side effects, not just the most recent addition. Although, for instance, agents such as nortriptyline and topiramate are useful, they can also lead to or worsen cognitive impairment and fatigue, especially if a patient already takes anticholinergics for bladder problems or muscle relaxants. Some medications can be associated with weight gain (e.g. tricyclics), others with weight loss (e.g. topiramate). Opioids should be considered in severe chronic pain and be used in conjunction with an opioid treatment agreement and random urine drug screening. Long-acting opioids may be preferable. For refractory pain, intrathecal drug administration is an option.

Muscle weakness and other motor manifestations

Any muscle group can be affected, but the legs are typically more involved than the arms, likely because of the longer course of the corresponding corticospinal fibres. Patients may have weakness limited to part of limb, e.g. foot drop,

or an entire limb, or have hemiplegia, paraplegia or tetraplegia. While spasticity, spasms, extensor plantar responses, hyperreflexia and reflex spread are common, hyporeflexia can result from intra-axial spinal root involvement and complete spinal cord lesions. Baseline spasticity and spasms can transiently worsen after interferon injection and with many intercurrent infections, bladder or bowel distension, pressure ulcers, deep vein thrombosis and fractures which may go unrecognized in the face of severe sensory loss, osteoporosis and minimal trauma. Spasms and spasticity can result in intense and frequent pain and also fatigue.

PT, OT and exercise have multiple benefits. They can reverse deconditioning, reduce fatigue, spasms and spasticity, improve strength, enhance social interactions and emotional wellbeing, benefit constipation and facilitate weight control. Weight-bearing exercise may reduce osteoporosis. Overexertion must be avoided. Weight loss itself can reduce pain and increase endurance. Crutches and bracing may improve function. Weakness can respond to cooling such as with cooling vests and AC adjustments. Swimming may allow for exercise that avoids body temperature increases.

Drugs such as baclofen, tizanadine and diazepam improve spasticity and spasms, but can cause lethargy and weakness, in particular at higher doses. Withdrawal from such drugs can cause confusion and seizures. It may ensue when a provider is not aware of a patient's prescription or does not know that such medications should not be stopped abruptly. Botulinum toxin may be helpful when spasms and spasticity are restricted. In refractory spasticity/spasms, intrathecal baclofen is often helpful, as high spinal levels are achievable without compromising cognition.

Periodic leg movement and restless leg syndrome, while common in MS, warrant consideration of intercurrent conditions such as peripheral neuropathy and metabolic disturbances. Dopamine agonists, benzodiazepines and opioids can be beneficial.

Gait and coordination disorders

Some of the most challenging manifestations of MS are tremor and ataxia. Gait disorders are often complex and reflect the sum total of abnormalities in several functional systems, such as apraxia, ataxia, weakness, proprioceptive dysfunction, vertigo and visual impairment. Ageing compounds these issues. Abnormal posture and gait may damage joints. The risk of falls and near falls is high. A fall frequency of one per week is common and with a high prevalence of osteoporosis due to female preponderance, steroid use, sedentary lifestyle and likely hypothalamic dysfunction, fractures are a common result. Thus imbalance must further intensify the focus on primary and secondary prevention of osteoporosis and vitamin D deficiency. Community ambulation is compromised before household ambulation. Gait disorders can be amenable to rehabilitation, particularly in the context of a specialized balance clinic. Many patients avoid assistive aids or use inappropriate simple canes, for fear of the stigma associated with them. Often the benefits of quad canes, walkers and wheeled walkers must be repeatedly pointed out. Dalfampridine is an FDA-approved aminopyridine derivative that improves walking speed in persons with MS. At some point, a referral to a wheelchair and seat cushion specialist may be indicated. Assistive devices must be continuously adjusted for ongoing changes, including disability, skin breakdown, weight, hand function, development of entrapment neuropathies resulting from compression and repetitive movement (due to wheelchair use) at the wrist and elbow, cognitive function and many others.

Arm weights and bracing can reduce the amplitude of tremors. Many drugs have anecdotal efficacy, including baclofen, clonazepam, gabapentin, levatiracetam, primidone, propranolol, topiramate and odansetron. Deep brain stimulation or radiosurgery may be considered.

Fatigue and sleep disorders

Generalized physical and mental fatigue affects about two-thirds of people with MS.[9] Fatigue is one of the most common and often undertreated features of MS. It jeopardizes a person's quality of life and ability to work and participate in family life. It can be unprovoked or result from exertion. MS attacks presenting as monosymptomatic fatigue present diagnostic challenges. Fatigue is worse in the afternoon, during the luteal phase of the menstrual cycle and with high ambient temperatures (Uthoff phenomenon), all of which slightly raise body temperature and thus impair impulse conduction in demyelinated axons. Magnetic resonance spectroscopy and positron emission tomography may show frontal lobe abnormalities. Fatigue is distinct from tiredness, sleep deprivation, depression, deconditioning and weakness, any of which, however, may be comorbidities. Medications, hypothyroidism, anaemia and many other medical conditions must be considered as causes, but may also be cofactors of fatigue.

Once intercurrent illnesses and precipitating factors have been addressed and patients have been educated about energy-conserving and fatigue-avoiding techniques such as moving strenuous activities to the cooler times of the day, using cooling vests or hats and drinking cold liquids, medications such as amantadine, modafinil and methylphenidate should be tried. Fatigue may also improve with the institution of disease-modifying drugs and antidepressants.

Sleep disorders in multiple sclerosis are heterogeneous and often profound. Insomnia and fatigue/tiredness often coexist. Sleep studies may reveal restless leg syndrome, periodic limb movements, circadian rhythm disruption and hypersomnolence. As disordered sleep in general and sleep

apnea are associated with daytime tiredness, poor daytime function, cognitive impairment, depression and many other medical complications, their diagnosis and treatment are crucial. However, continuous and bi-level positive airway pressure (CPAP and BiPAP) treatment has one of the lowest adherence rates of any medical intervention and therefore requires close follow-up to optimize individualized settings and maximize comfort. This is particularly true given that sleep in people with advanced MS is often compromised in all stages by pain, impaired bed mobility and the need for trips to the bathroom due to neurogenic bladder symptoms.

Neurogenic bowel

About half of MS patients suffer gastrointestinal symptoms, typically constipation. Rare incontinence results from unawareness of rectal filling. Symptoms are associated with impaired voluntary squeeze pressure and rectal sensation by rectal manometry. Cord involvement is common and may indicate affection of sympathetic and parasympathetic pathways. Colonic transit time may be slowed because of autonomic involvement or physical inactivity. Cofactors, partially amenable to intervention, include a sedentary lifestyle due to physical disability, fatigue, depression, poor nutrition and CNS polypharmacy with anticholinergics, antidepressants and muscle relaxants. Lack of thirst and voluntary reduction of fluid intake for fear of urinary incontinence can contribute. The judicious use of stool softeners, stimulants and bulk forming agents including bisacodyl and docusate enemas, may provide relief. With complete spinal cord dysfunction a bowel programme is often indicated that is executed at the same time every day or every other day and takes advantage of the gastrocolic reflex by following a meal. Digital rectal stimulation performed by the patient or caregiver is often helpful. Features of a neurogenic bowel must be addressed, because constipation leads to haemorrhoids and prolonged bowel movements expose the skin to significant pressure and possibly shear injuries, thus contributing to pressure ulcers. Moreover, the experience of incontinence can lead to social avoidance and isolation.

Neurogenic bladder

Bladder function becomes abnormal in 80–95% of patients, often during the secondary progressive stage, but is a problem at the onset in 10%. Its early presence is an unfavourable prognostic sign. Clinical features include urgency, hesitancy, dribbling, need for double voiding, recurrent urinary tract infections (UTI) and incontinence. The last can lead to embarrassment and withdrawal from the workforce and social interactions. Neurogenic bladder results from detrusor hyperreflexia (small, spastic bladder) with urgency and frequency in two-thirds of patients, detrusor atonia and hyporeflexia (underactive bladder) in one-third and impaired coordination between the detrusor and the sphincter muscles (detrusor–sphincter dysynergia, DSD) in 50%, with the detrusor contracting against a contracted sphincter. Neurogenic bladder may coexist with prostate disease or pelvic floor weakness. Inability to void completely leads to high residual bladder content (post-void residual, PVR), which increases the risk of UTI, bladder stones and hydronephrosis. Whereas clinical features often do not permit a pathophysiological analysis, urodynamic studies can accomplish this and facilitate evidence-based treatment.

Pelvic floor exercise, Crédé manoeuvres, biofeedback and both cholinergic (e.g. betanechol) and anticholinergic drugs (e.g. tolterodine, oxybutinin) and botulinum toxin, depending on urodynamic findings, combined with alpha-blockers and testosterone inhibitors in men with prostate disease, are often beneficial, but side effects may limit optimal dosing. Urine acidification may be a useful adjunct to reduce the likelihood of infections. When these interventions are inadequate, external catheters, chronic indwelling and intermittent catheterization are options.

Diapers are almost never the right answer, but often reflect reality, owing to lack of awareness and resources, in particular in nursing homes and when the person with MS or the caregiver lacks the means or insight to choose other more labour-intensive options. Diapers result in near-constant exposure of the skin to moisture and the toxic properties of urine (and faeces), which can contribute to skin breakdown and recurrent UTIs.

While external catheters address male incontinence, high PVRs persist. Furthermore, many patients have difficulties keeping them on, which can result in unanticipatable (and thus particularly embarrassing) incontinence. Penile retraction, often in the setting of severe spinal cord disease, may make the placement of an external catheter impossible. If not used appropriately or undersized, external catheters can cause skin ulceration and damage to the glans (hypospadia).

Chronic indwelling catheters increase the risk of UTI and bladder stones. Intermittent catheterization (IC) is an appropriate long-term solution if hand dexterity and cognitive function are not an issue or if done by a caregiver, but carries a risk of urethral damage and infections. The development of prostate disease and urethral strictures may make IC difficult and traumatic. Suprapubic catheters are associated with a lower risk of UTI than chronic indwelling catheters but, like these, are linked to continuous bladder wall irritation and an increased risk of bladder stones and bladder cancer. Urine may continue to drain through the urethra, necessitating the use of an external catheter. Additional long-term options include various surgical diversion techniques such as an ileal bladder.

The threshold for testing for UTI in a person with MS and changing symptoms should be low. Blind antibiotic treatment on the mere suspicion should be instituted only after obtaining a urine culture. False-positive symptoms of a UTI are not rare. Frequent use of antibiotics carries the risk of selection of multi-drug-resistant organisms that require intravenous antibiotics.

Glomerular filtration rate is often reduced, possibly due to recurrent UTIs, antibiotics, ionic contrast agents, voluntarily reduced fluid intake in order to avoid incontinence and NSAIDs used for pain. This may be subclinical in many patients with MS but may become significant in the setting of comorbid diabetes, hypertension and vascular disease.

Sexual dysfunction

About 80–90% of men and 45–75% of women with MS have sexual dysfunction. The prevalence rises with age and disease duration. Sexual satisfaction is important regardless of age and contributes to a general sense of wellbeing. For issues of fertility readers are referred to other standard texts. Features reflect all components of the sexual response cycle including mood/affect, libido, arousal, lubrication/erection, ejaculation and orgasm. Sexual function may remain intact in the presence of neurogenic bowel and bladder. Causes of sexual dysfunction include involvement of crucial cerebral (frontal, temporal, parietal) and spinal cord (long tracts, sacral parasympathetic and thoracic sympathetic segments) structures. Much rarer manifestations include hyperlibidinism.[24] Sexual satisfaction is compromised by depression, poor sleep, pain and spasm, sensory loss in erogenous areas, poor partner relations and miscommunication. Patients' many concerns need to be addressed, such as urinary and bowel accidents during intercourse, inadequate personal satisfaction and pain during intercourse, for example from muscle spasms, and the dual role of a significant other as sex partner and caregiver. While involving the partner in the discussion, care must be taken to not violate the principles of privileged health information. When evaluating a person with MS and sexual dysfunction, contributory roles of disordered sleep, mood and affect, venous and arterial disease, smoking, sex and other hormones, neuropathy and medications[25] must be considered. Patient and partner education is crucial. The sexual response cycle and the importance of experimentation and communication with the partner must be discussed.[26] Sexual dysfunction due to sensory loss can be alleviated by masturbation, use of vibrators in addition to sensate focus and pleasure mapping. Oral sex may be a helpful alternative to penetration. Concerns about neurogenic bowel and bladder are addressed by timed voiding and defecation and by limiting fluid and caffeine intake before sex. Pharmacological options include lubricating jellies, sex hormones (in case of deficiency) and agents such as phosphodiesterase-5 inhibitors (PDEI5) and aprostadil. When one PDEI5 does not work at maximum dose, others should be tried. Adverse interactions with alpha-blocking agents and nitrates must be considered. The EROS clitoral therapy device, vacuum pumps and occasionally penile implants are other options. Important roles rest with counsellors in optimizing partner communication and with rehabilitation therapists in facilitating positioning and avoidance of muscle cramps during sexual activity in addition to pelvic floor strengthening exercises.

Other autonomic changes

In addition to bowel, bladder and sexual dysfunction, MS can entail cold, purple feet due to sympathetic vasomotor dysregulation, which must be differentiated from atherosclerosis and orthostatic hypotension, which can be compounded by medications and dehydration.

Cognitive involvement

Cognitive decline affects over 50% of individuals with MS. Particularly in an ageing person with MS, an extensive differential diagnosis must be considered, including Alzheimer and multi-infarct dementia, medication effects, sleep disorders, heart and vascular disease, thyroid dysfunction and cobalamin and folate deficiencies. MS-related cognitive impairment is mild in 50%, moderate in 40% and severe in 10%. When mild, it may not be apparent to the casual observer or during a routine mental status examination. Mild impairment can be present very early in the course of MS, including with clinically isolated syndrome. Deteriorating work performance and a history of motor vehicle accidents may be tell-tale signs. When prompted, patients or significant others may mention word-finding difficulties or cognitive deterioration in the later part of the day. In mild to moderate impairment, the underlying personality usually remains intact. Typical issues are impaired multitasking and creativity, losing things around the house, leaving appliances running, etc. Common problem areas include the speed and accuracy with which information is processed, attention, executive functions, learning and memory, visual–spatial processing, verbal fluency and word-finding difficulties. Comprehension usually stays intact, but may be slowed. Memory problems focus on recall and retrieval, whereas the ability to learn new information often remains intact. Characteristically, patients can compensate for deficits until cognitive dysfunction becomes severe.

Early neuropsychological testing can establish a baseline when dysfunction is subtle and provide useful comparison as the condition progresses. Testing identifies strengths and weaknesses and contributes to vocational rehabilitation, optimizes social function and provides a basis for

cognitive rehabilitation, which may make use of cueing, memory aides and exercises such as crossword puzzles. Adjustment at work may be beneficial, including providing an opportunity for a nap in case of cognitive fatigue and avoiding shift work.

It is the treating provider's responsibility to discuss whether a person with MS is capable of operating a vehicle safely. This discussion requires sensitivity, since loss of a driving permit can be a watershed event which compromises independence and self-perception and since the insight into the risk to oneself and others may be lacking. Patients must be made aware of alternative means of transportation, their rights under the ADA (Americans with Disabilities Act), local opportunities to access 'call-a-ride' or other not-for-profit organizations that may provide assistance. Social workers can assist patients in optimizing access to community resources. A formal driving evaluation is often indicated to assess both cognitive and non-cognitive impairment. Non-cognitive obstacles to driving such as inadequate limb function can be addressed by vehicle modifications. When a person's disability precludes accessing a regular vehicle safely, a wheelchair-accessible van may be required. Unfortunately, the cost of vehicle modification is often prohibitive.

There is evidence that cognition benefits from disease-modifying drugs, cholinesterase inhibitors and drugs otherwise effective for fatigue (amantadine and modafinil) and walking speed (aminopyridine).

Mood and affective involvement

With a 50% prevalence, depression is 2–3 times more common than in the general population and the risk of suicide is elevated sevenfold.[27] MS attacks may manifest with depression, confusion and psychosis. While demyelination, inflammation, atrophy and plaques in several brain regions are linked to depression, emotional disturbances also reflect the response to a potentially devastating illness that has an unpredictable course, can result in disability and chronic pain, isolation, loss of social status and independence, nursing home admission and can contribute to divorce. Depression may be a side effect of beta-interferons and corticosteroids.

Pseudobulbar affective disorder, also known as forced or pathological laughing and crying or involuntary emotional expression disorder, can be disabling. A quinidine/dextromethorphan combination can alleviate this symptom. Euphoria, despite significant neurological problems, is recognized as 'la belle indifference'. Irritability is frequently brought up by both patients and significant others and contributes to relational stress. Other manifestations of disinhibition may lead to embarrassing social situations.

Psychopharmacological treatment and counselling by professionals with experience and expertise with chronic neurological diseases is warranted. The choice of medications must not only consider that many such drugs are beneficial for coexisting pain, but also that they can worsen fatigue, alertness, cognition, constipation, urinary retention and sexual function.[25] Individual psychotherapy is a highly effective but greatly underutilized intervention in patients with MS and comorbid mental health problems.

Seizures and other paroxysmal manifestations

Although rare, seizures are twice as common as in people without MS and become more prevalent in the later stages. Although difficult to visualize with standard magnetic resonance technology, cortical plaques may function as epileptic foci. Other paroxysmal symptoms include restless legs, tic douloureux (trigeminal neuralgia), spasms, dystonias, periodic leg movements, drop attacks, and Lhermitte sign. For a review of therapeutic options, the reader is referred to standard texts.

Prognosis

Persons with RRMS and PPMS reach an Expanded Disability Status Scale (EDSS) score of 6 [unilateral assistance (cane or crutch) required to walk at least 100 m with or without resting] on average in 15 and 8 years, respectively.[1] Predictors of poor prognosis include male gender, frequent attacks early on, early motor or cerebellar dysfunction, a large number of T2 and enhancing lesions and early atrophy. Long-term use of disease-modifying drugs influences prognosis,[3,4] as do various polygenetic polymorphisms and immunological parameters. The life expectancy of a person with MS is correlated with disability and is about 7 years less than in the general population.[28] Pneumonia is a common cause of death.

Comorbidities

When a person with MS who is older or has had MS for a long time and permanent disabilities presents with a new or worse symptom or sign, providers must answer several challenging questions: Does the new clinical presentation represent a manifestation of MS? Or if unrelated to MS, does it emanate from the nervous system? Or does it reflect dysfunction of another organ or a side effect of one or several drugs? The differential diagnostic considerations of acquired conditions that must be entertained when a person initially presents with symptoms and signs suggestive of MS must continue throughout the patient's lifetime whenever there is a change or evolution in clinical presentation.[14] A common belief on the part of patients is that each and every symptom must be due to MS. For

instance, a person may contact the neurologist about a supposed MS attack manifesting as weakness and fatigue, after a week of diarrhoea, vomiting and limited oral intake for which no medical attention has been sought. Patients must be educated that they should not prejudge the cause of a medical issue but rather let their healthcare professionals sort things out. A patient's assumption as to the aetiology may result in possibly life-threatening delay of care such as when fatigue is thought to be MS related but in fact results from atrial fibrillation.

Worsening fatigue may also result from diverse conditions such as UTI, congestive heart failure, thyroid disease, insomnia, cobalamin deficiency, poor glucose control, renal failure or depression, or from non-adherence to drugs such as modafinil or amantadine or inappropriate use of prescription or street drugs.

Similarly, worse spasms or spasticity may reflect MS or intercurrent illnesses, in particular UTI. And in individuals with severe spinal cord involvement and paraplegia or tetraplegia, spasms, spasticity and fatigue may be the only manifestations recognized by the patient of a deep vein thrombosis or fractures that result from minimal trauma in the presence of severe osteoporosis.

There is mounting evidence that vitamin D impacts not only bone health but also immune regulation. Low levels have been linked to a higher risk of MS, relapse rate and MS progression.[10] The prevalence of insufficiency $<75\,ng\,ml^{-1}$ and deficiency $<25\,ng\,ml^{-1}$ in the general population and among people with MS is striking. Therefore, levels should be checked regularly, particularly in recognition of the decrease in serum vitamin D during fall and winter. Since vitamin D toxicity is minimal with adequate renal function and normal calcium levels, many healthcare professionals advocate supplementation to a target approximately $50\,ng\,ml^{-1}$, often together with calcium. This practitioner treats deficiency with ergocalciferol 50 000 U weekly, followed by a repeat level which then governs continued care, including of insufficiency, with vitamin D 2000–4000 U daily.

Bone density is commonly decreased because of steroid and other medication use, low sun exposure (due to heat sensitivity and mobility problems) resulting in vitamin D deficiency, sedentary lifestyle and possibly autonomic and hormonal imbalances. Bone densitometry should be performed at regular intervals in men and women with MS and abnormal findings must be treated aggressively.

Several studies have characterized the link between tobacco use, risk of MS and of MS progression and EBV exposure.[8,11,29] Although proof of causality is difficult, there is sufficient evidence to warrant a very strong ongoing emphasis on cessation with any user who has MS.

Individuals with a sedentary lifestyle, elevated body mass index and history of steroid use are at increased risk of impaired glucose tolerance, which has been shown to affect peripheral and central nervous system function. Certain drugs, such as tricyclic antidepressants, elevate blood sugars. Individuals who use crutches or wheelchairs are at increased risk for upper limb nerve entrapment, which can also compound functional deficits due to MS. The presence of focal and systemic neuropathies may not be easily ascertainable by symptoms alone, given pre-existing sensory abnormalities due to MS. When history and examination suggest neuropathy, a work-up entailing laboratory tests, including glucose tolerance and glycosylated haemoglobin assays and electrodiagnostic studies, should be done.

Individuals with advanced MS or with spinal cord lesions and paraplegia or tetraplegia are at high risk for pressure ulcers. Cognitive impairment, non-adherence to pressure relief regimens, obesity, smoking, incontinence, dependent leg oedema and inadequate care at home, in nursing homes and in hospitals are contributing factors. Not infrequently, patients, caregivers and healthcare professionals underestimate the extent of pressure ulcers. If not treated early, their care can require many months of hospital care. Optimal care is often only available from providers with expertise not just in wound care but also in the specialized medical issues of individuals with paralysis.

Complementary and alternative medicine (CAM)

Surveys indicate that over 50% of people with MS have used therapeutic modalities such as antioxidants, low-fat diet, omega-3, high-dose vitamins, acupuncture, yoga, tai chi and countless others.[30] Their benefit in a given patient is difficult to assess given the placebo effect and the fluctuating nature of MS symptoms. Many studies are under way that seek to prove efficacy. It is important to convey to the patient that the provider is open to discussion and guidance regarding this approach. If the subject of CAMs is not out in the open, providers may not realize that a patient is non-adherent to prescription drugs and relies solely on CAMs. The provider may be unaware of ill-advised choices. Some patients resort to bee-sting therapy, which, likely via the introduction of foreign protein, may activate the immune system; others use high-dose vitamin B_6 (pyridoxine), which can (like the deficiency state) compromise neurological function. Many patients use cannabinoids, which can contribute to sedation when combined with prescription drugs that affect the CNS. It may be a violation of the law to prescribe controlled substances to patients using illegal substances. Also, patients may spend extraordinary amounts of money on ineffective or counter-productive medications and dietary supplements.

Access to healthcare

In regards to accessing health care, the combination of multimorbidity, mounting disability, cognitive decline, depression, loss of independence in activities of daily living, and shrinking social networks can be extremely challenging. While difficult in an urban setting, difficulties may be impossible to overcome in rural communities. This situation compromises the delivery of general health care, and even more so that of preventive medicine and mental health care.[31] Problems are compounded by the often limited ability to remember and appreciate the need for multiple appointments, lack of sufficient insurance coverage for specialists and drugs, great distances to providers, dearth of accessible transportation and doctors' offices, and limited expertise of many providers regarding the specific needs of patients with MS.[32] Referral to a multi-disciplinary team that offers 'one-stop-shopping' to patients may be helpful.

Fostering healthy living and resilience

The ability to adapt to acute illness and disease progression is referred to as resilience. Being self-confident and feeling good about oneself is a quality that fosters recovery from relapses in addition to adaptation to disease progression. It is important for people with MS to assume responsibility for their lives and take charge of their health. This means being educated about MS and other medical problems and their treatment and coming to medical appointments prepared with a list of issues, questions and goals to discuss.

Resilience comes naturally to some, but can also be learned. Many patients require assistance with emotional coping in order to avoid the negative feelings that can contribute to the physical features of MS. Recurrent themes that patients will voice include the uncertain prognosis, grief over the disability and other limitations linked with MS, the changing self-image and the social and physical accommodations needed from the patient, family and friends. Appropriate self-appraisal (e.g. effective and able versus powerless) is vital for successful adjustment to the uncertainty.[33] Counselling often allows patients and significant others to acquire such coping skills and improve their quality of life.

Educating patients about the benefits of healthy living may give them a sense of control and empowerment and motivate them to engage in tobacco cessation and regular (adapted if necessary) exercise with its benefit to mood, neuronal integrity and function, cognitive training, weight control and ultimately higher quality of life.[34]

Key points

- Persons with multiple sclerosis have increasing disability with ageing.
- Glatiramer acetate and beta-interferons are disease-modifying drugs.
- Generalized fatigue is present in two-thirds of persons with multiple sclerosis.
- Neurogenic bowel and bladder occur commonly in multiple sclerosis.
- Depression and cognitive impairment are common concomitants of multiple sclerosis.

Dementia and Cognitive Disorders

CHAPTER 71

Delirium

Joseph H. Flaherty
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Overview

Delirium is a dangerous diagnosis. It is common; it is commonly missed; and it is associated with several adverse outcomes. Although most clinicians label patients with delirium as having an 'acute change in mental status', the formal diagnostic criteria according to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-Text Revision) paints a more complete and descriptive picture of these patients if put into sentence form: 'A sudden onset of impaired attention, disorganized thinking or incoherent speech. The patient usually has a clouded consciousness, perceptual disturbances, sleep–wake cycle problems, psychomotor agitation or lethargy and is disoriented'.[1]

History and pathophysiology

Although the term 'delirium' was not used, references to patients with delirium date as far back as the time of Hippocrates. Delirium has only attracted attention as a syndrome or a diagnosis in the past three decades, with the first textbook dedicated solely to delirium being published in 1980.[2] The reasons for this long misunderstanding of what to call this constellation of symptoms are related to the various ways in which delirium can present (hypoactive, hyperactive or a combination of the two) and the complex pathophysiology that causes such a variety of presentations. Although research into the pathophysiology of delirium is in its infancy in clearly defining the contribution each neurotransmitter system and biochemical mechanism has on the clinical picture of delirium, one proposed pathoaetiological model of delirium (Figure 71.1) is important in helping clinicians understand the complexity of a patient with delirium.[3] By keeping the complex systems and mechanisms in mind when trying to diagnose or manage a patient with delirium, clinicians will better be able to understand the challenges in making an accurate diagnosis (especially in the face of dementia) and the significant limitations that medications have in the 'treatment' of delirium.

Prevalence and incidence for various sites and situations

Delirium is one of the most serious illnesses that patients can have or develop and one that clinicians should not miss at the reported rate of 32–66%.[4] Typical rates of delirium on admission to a medical unit are between 20 and 30%. In a thorough systematic review of 42 studies meeting selection criteria with a focus on medical inpatient settings, only eight performed delirium assessment within 24 h of admission. The prevalence of delirium on admission among these well-performed studies ranged from 10 to 31%, but the low 10% was thought to be an underestimate as this study had strict selection criteria. In the same systematic review, the incidence during hospitalization among 13 studies was 3–29%.[5]

In general, surgical patients have been found to have higher rates of delirium than medical patients. In a review of primary data-collection studies, Dyer *et al*. found that rates are highest postoperatively among coronary artery bypass graft patients, ranging from 17 to 74% (>50% in five of the 14 studies reviewed).[6] They also found that rates among orthopaedic surgical patients ranged from 28 to 53% (>40% in five of the six studies). Of the two urological studies reviewed, rates ranged from 4.5 to 6.8%. Past biases have blamed anaesthesia agents for most cases, which wrongly have kept alive the belief, like that in the case of the intensive care unit (ICU), that delirium is unpreventable. Several studies which have evaluated the association between routes of anaesthesia (general, epidural, spinal, regional) and the risk of postoperative delirium have found that the route of anaesthesia was not associated with the development of delirium.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

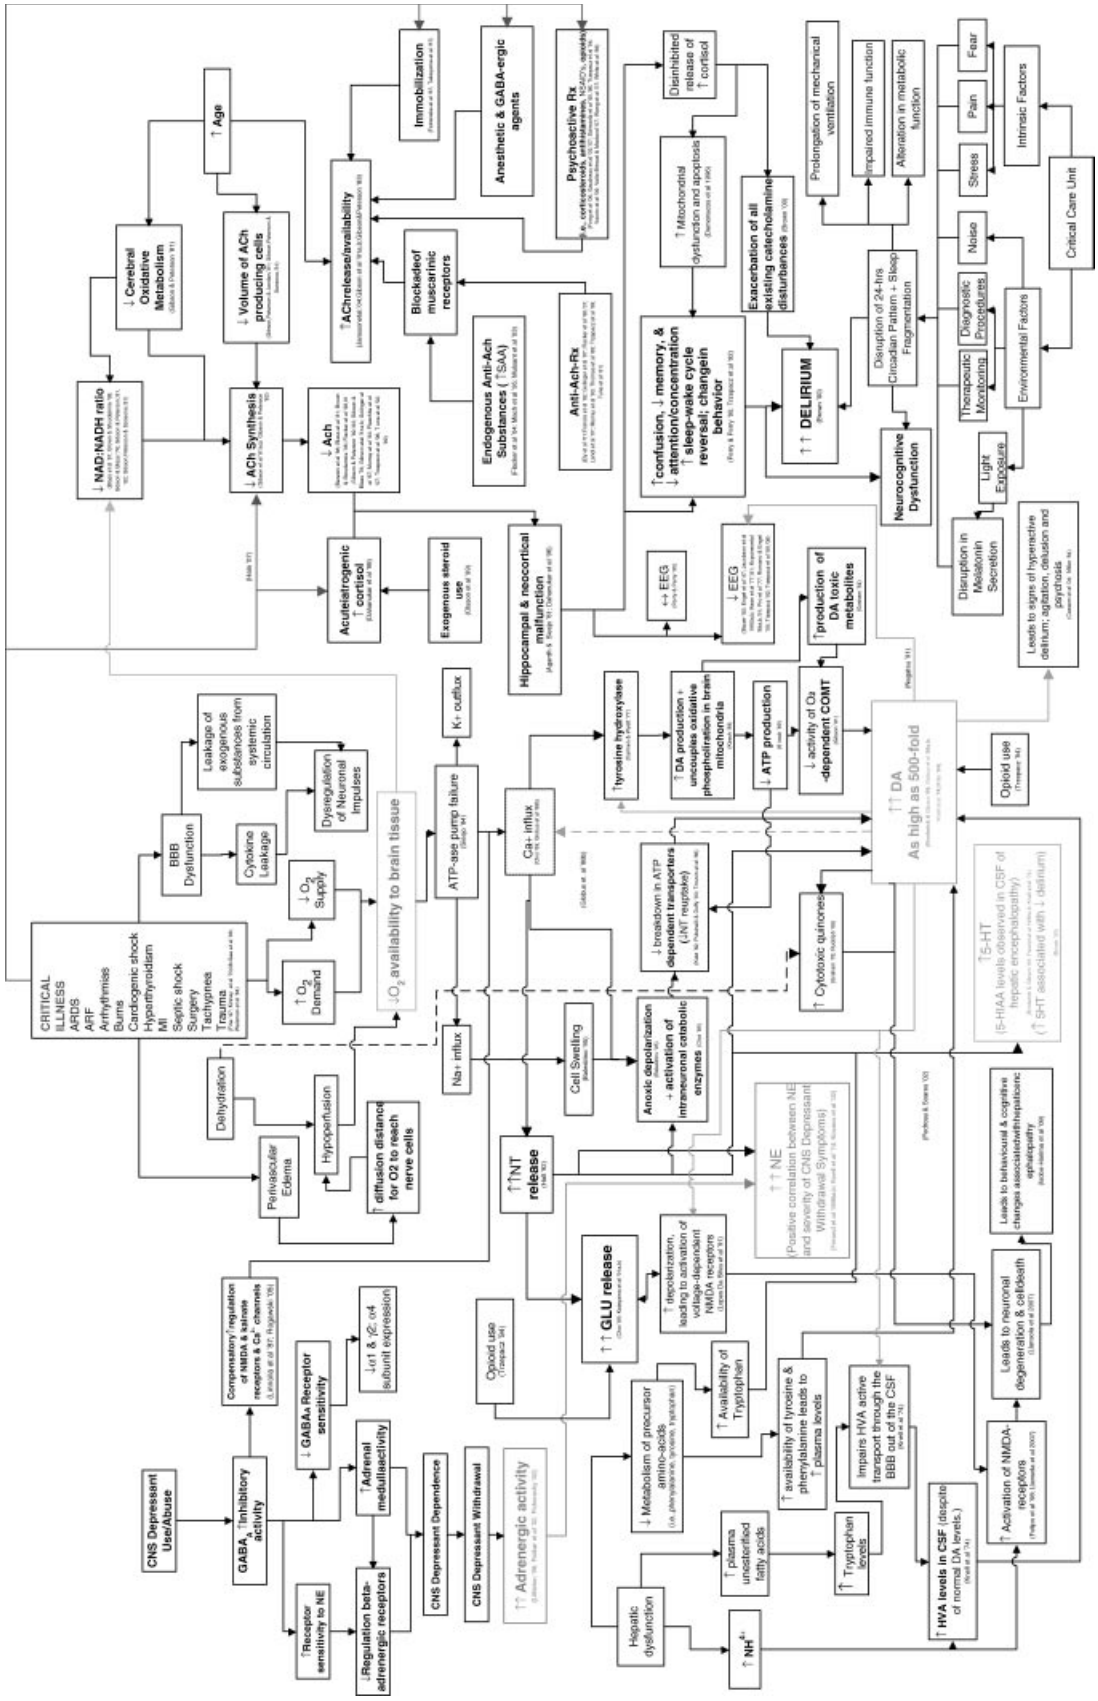

Figure 71.1 The pathoetiological model of delirium. Reprinted from Maldonado JR (2008).[3] Copyright (2008), with permission from Elsevier.

One of the sites with the highest rates of delirium, but perhaps the most controversial because of so many complicating factors, is the ICU. Rates as low as 19% and as high as 80% have been found.[7,8] For years, however, people have ignored these facts, have called it inevitable and unpreventable and have even labelled it 'ICU psychosis' so as to blame it on the ICU.

Discharge or 'transition' of patients out of the acute hospital setting has seen many changes over the past three decades. Data from post-acute care facilities (under such names as subacute-care facilities, skilled nursing facilities, rehabilitation centres and long-term care facilities) reveal two major issues: patients are discharged from acute hospitals with persistent delirium and delirium at these sites persists for an extended period of time. Kelly *et al*. found that 72% of 214 nursing home patients who were hospitalized for delirium still had delirium at the time of discharge back to the nursing home. The delirium persisted for 55% of the patients at 1 month and 25% at 3 months after discharge.[9] Marcantonio *et al*. found that 39% of 52 patients with hip fractures were discharged with delirium, which persisted for 32% of the patients at 1 month and 6% at 6 months after discharge.[10] In a large study of over 80 post-acute care facilities using the Minimum Data Set (MDS) to identify patients with any symptoms of delirium, Marcantonio *et al*. found a prevalence rate of 23% on admission. Among these patients, 52% still had the symptoms at 1 week follow-up.[11]

Two studies that looked at point of prevalence within nursing facilities discovered a similarly high rate of delirium. Mentes *et al*. evaluated 324 long-term nursing home residents using the MDS and found that 14% of patients had delirium.[12] Cacchione *et al*. prospectively evaluated 74 long-term nursing home patients and identified 24 (33%) with delirium.[13] While neither study could determine whether the delirium was a persistent one after a hospital stay or was an incident (new episode of) delirium, it is evident that delirium is common among nursing home residents.

Home care is an understudied site concerning delirium. However, two studies (detailed in the section 'Prevention and management interventions') showed lower rates of delirium among ill, older persons cared for at home compared with similarly ill, older persons cared for in the hospital. It is unclear whether something positive is being done in the home that prevents delirium or whether something negative is occurring in the hospital that contributes to the development of delirium.[14,15]

Associated adverse outcomes

Data about the adverse outcomes associated with delirium mainly come from studies of older patients in the hospital setting. Here, delirium has been found to be associated with hospital complications, loss of physical function, increased length of stay in the hospital, increased instances of discharge to a long-term care facilities and high mortality rates. Mortality rates for hospitalized delirious patients have been reported to be 25–33%, as high as the mortality rates for acute myocardial infarction and sepsis. There has been some question in the past about whether delirium was independently associated with these adverse outcomes or whether it was merely a marker of severe illness and physical frailty, since most studies identified older age, underlying cognitive impairment, severe, acute and chronic illness and functional impairment as the predisposing factors. However, when adjusting for these factors, delirium has been found to be independently associated with poor outcomes in most studies.

Associated adverse outcomes among delirious ICU patients have shown prolonged ICU stay, prolonged hospital stay and increased mortality compared with patients without delirium.[7,8] Data from post-acute facilities have also shown associated adverse outcomes, related to loss of physical function and mortality.[9,11,13]

The comprehensive approach to delirium

In order to improve the adverse outcomes associated with delirium, it is not enough just to improve our skills in diagnosing delirium and treating the underlying medical causes. The following are the necessary components of a comprehensive approach for those involved in the care of older persons and healthcare systems that interface with older persons:

1 *Awareness*: Be aware of how commonly delirium occurs and where it occurs and get others involved in the care of older persons to do the same.

2 *Diagnosis*: Know why it is important to differentiate and how to differentiate between delirium and dementia.

3 *Evaluation*: Identify and treat the underlying causes of delirium.

4 *Prevention*: Implement strategies or care systems that can prevent delirium.

5 *Management*: Manage patients who develop delirium.

Although there are no available studies to date that implement all five interventions, a multifaceted approach is warranted because of the nature of this multifactorial problem.

Awareness

Delirium should become part of the medical jargon for all who care for older persons. Furthermore, given the frequency with which delirium is seen and the seriousness of this diagnosis, a vital sign for mental status has been recommended,[16] and rates of incidence and outcomes

associated with delirium could be considered as quality-of-care measures.

Diagnosis

Delirium is not dementia. There is no difference in the core features of delirium in the DSM-IV-TR version compared with the previous version, DSM-IV, except that the DSM-IV-TR version recognizes that delirium can arise during the course of dementia.[1] Although this appears to be a minor detail, the message that this gives to healthcare professionals is a critically important one: '*delirium is not dementia*'. Most types of dementia have a progressive downhill course. Delirium should be considered reversible. A mislabelling or lack of differentiation between these two diagnoses is thought to be the reason why delirium is missed by physicians and by nurses. Misdiagnosis or late diagnosis may also partly explain why delirium is associated with adverse outcomes. Table 71.1 details some of the differentiating characteristics between delirium and dementia, based on DSM criteria, keeping in mind that one of the criteria not in Table 71.1 is that delirium must occur in the context of a medical illness, metabolic derangement, drug toxicity or withdrawal.

Altered level of consciousness (LOC) is an excellent clue in differentiating delirium and dementia because it is not always possible to know the patient's baseline mental status. Without ever having seen the patient before, one can determine whether the patient's LOC lies towards the agitated or vigilant side of the spectrum of LOC or towards the lethargic, drowsy or stuporous side of the spectrum.

One can ask orientation questions, but since disorientation and problems with memory are present in both delirium and dementia, the key in determining delirium from dementia is *how* the patient answers. The delirious patient will often give disorganized answers, which can be described as rambling or even incoherent.

The classic identifiers of delirium are acute onset and fluctuating course, both of which are usually obtained by close caregivers (family or nurses). Although acute implies 24 h, the term subacute is used to emphasize that subtle mental status changes can be overlooked by caregivers. Over a period of many days, the patient may appear to be slowly declining mentally due to the underlying dementia. If left unchecked, the initial delirium may impair other necessary functions, leading to further medical problems, such as dehydration and malnutrition, further complicating the delirium. This snowball effect explains in part why the aetiology of delirium is typically multifactorial. Therefore, if it is unclear how long the change has been occurring, patients should be put in the category of delirium and an evaluation should be made.

Attention is also one of the classic identifiers of delirium, which may often be helpful if the patient's baseline mental status is not known. It can be tested by having a conversation. Patients may have difficulty maintaining or following the conversation, perseverate on the previous question or become easily distracted. Attention can also be tested with cognitive tasks such as days of the week backwards, spelling backwards or digit span.

Psychomotor agitation or lethargy, hallucinations, sleep–wake cycle abnormalities and slow or incoherent speech can all be seen in patients with delirium, but these features are not necessary for the diagnosis.

Table 71.1 Differentiating delirium from dementia.

	Delirium	Dementia
Consciousness	Decreased or hyper-alert 'Clouded'	Alert
Orientation	Disorganized	Disoriented
Course	Fluctuating	Steady, slow decline
Onset	Acute or subacute	Chronic
Attention	Impaired	Usually normal
Psychomotor	Agitated or lethargic	Usually normal
Hallucinations	Perceptual disturbances May have hallucinations	Usually not present
Sleep–wake cycle	Abnormal	Usually normal
Speech	Slow, incoherent	Aphasic, anomic, difficulty finding words

Evaluation

General guidelines for the medical evaluation of patients are to consider all possible causes, proceed cautiously with appropriate testing and keep in mind that delirium is usually caused by a combination of underlying causes.

After a physical check and ascertaining the history, which includes obtaining details from anyone considered a caregiver (e.g. family, nurse's aide) and a thorough medication list, the mnemonic D-E-L-I-R-I-U-M-S can be used as a checklist to cover most causes of delirium (Table 71.2). Drugs are notorious for causing delirium. According to most authors in this area, 'virtually any' and 'practically every' drug can be considered deliriogenic. Several drugs have been found *in vitro* to have varying amounts of anticholinergic properties. However, since the pathophysiological and neurotransmitter mechanisms of delirium go beyond anticholinergic mechanisms, a more practical approach is to remember certain categories of medications that have been reported to cause delirium, some more common than others. The mnemonic A-C-U-T-E C-H-A-N-G-E I-N M-S is long, as would be expected, but highlights why

Table 71.2 Causes of delirium.

D	Drugs
E	Eyes, ears
L	Low O_2 state (MI, stroke, PE)
I	Infection
R	Retention (of urine or stool)
I	Ictal
U	Underhydration/undernutrition
M	Metabolic
(S)	Subdural

Table 71.3 Medications that can cause (have been reported to cause) an A-C-U-T-E C-H-A-N-G-E I-N M-S (mental status).

A	Antiparkinson drugs
C	Corticosteroids
U	Urinary incontinence drugs
T	Theophylline
E	Emptying drugs (e.g. metoclopramide, compazine)
C	Cardiovascular drugs
H	H2 blockers
A	Antibiotics
N	NSAIDs
G	Geropsychiatry drugs
E	ENT drugs
I	Insomnia drugs
N	Narcotics
M	Muscle relaxants
S	Seizure drugs

drugs are such a common cause of delirium (Table 71.3). In order to be as inclusive as possible and because many older reports did not discuss strict delirium criteria or such criteria were not commonly used, the following paragraphs describe not just delirium as a side effect, but also psychiatric side effects that might indicate presence of delirium, such as hallucinosis, paranoia, delusions, psychosis, general confusion, aggressiveness, restlessness and drowsiness.[17]

Levodopa (an antiparkinson drug) has been reported to cause mental status changes at a rate of 10–60% and include hallucinosis on a background of a clear sensorium, delusional disorders and paranoia. Abnormal dreams and sleep disruption may precede the more frank delirium symptoms and may be an early clue to their onset. Selegiline has been reported to cause mental status changes described as psychosis, aggressiveness and even mania.

Corticosteroids have been reported to cause 'psychiatric complications' in up to 18% of patients with doses above 80 mg per day. The mental status changes seen have been described as depressive/manic, an organic affective disorder with associated paranoid-hallucinating features and general 'confusion'.

Although short-acting urinary incontinence drugs have a greater potential to cause delirium, newer sustained release agents have also been reported.

Theophylline 'madness' probably meets delirium criteria. One of the first case reports described a patient with a toxic blood level that correlated with hyperactive periods marked by flailing of limbs, intense emotional lability, incessant crying and ripping out of intravenous lines and nasogastric tubes.

'Emptying' drugs is a reminder that drugs such as metoclopramide and droperidol that are often used for nausea and vomiting have potential for mental status changes. Reported mental status side effects include restlessness, drowsiness, depression and confusion. The mechanism is likely because of their antidopaminergic properties.

Cardiovascular drugs rarely cause mental status problems, but because they are so commonly prescribed for older persons, it is worthwhile to remember that some are more likely to cause problems, and also a few that have been reported in case reports. One of the first reports of confusion due to digoxin toxicity was over 100 years ago. Since then, reports of confusion even at therapeutic levels have been published. Antihypertensive agents that may cause mental status changes have primarily been reported in the literature through case reports. However, since they are so commonly used, it is worthwhile being suspicious about a few of them. These include beta-blockers (including in the form of eye drops), angiotensin-converting enzyme inhibitors and calcium channel antagonists.

H2 blockers, because they are primarily renally excreted and may have some H1 activity (antihistamine receptor subtype-1), may cause delirium, especially if patients have underlying risk factors such as renal insufficiency and dementia.

Antimicrobials, like cardiovascular drugs, rarely cause mental status changes, but are very commonly used; some examples worth being aware of are penicillin, erythromycin, clarithromycin, gentamycin, tobramycin, streptomycin, trimethoprim-sulfamethoxazole, ciprofloxacin, some cephalosporins and the antiviral acyclovir, particularly at high doses. Most reports propose that the mechanisms by which antimicrobials cause mental status changes are related to impaired renal function, drug–drug interaction and occasionally idiosyncratic behaviour. Several types of non-steroidal anti-inflammatory drugs (NSAIDs) have been reported to cause delirium, even the selective cyclooxygenase-2 inhibitors.

'Geropsychiatric' medications are too large a category for an in-depth discussion, but a few comments are warranted to create some balance between reflexively blaming these drugs for the delirium just because 'any drug that works in the brain, can cause a problem in the brain' and understanding that although no centrally acting psychiatric medication is completely safe, certain ones may

be safer than others and psychiatric illnesses, especially depression, need to be treated. Tricyclic antidepressants (TCAs) can cause delirium with an overall incidence ranging from 1.5 to 20%. The highest rates, of course, seem to be among older, previously cognitively impaired and medically ill patients. Serotonin selective reuptake inhibitor (SSRI) antidepressants have a much safer side effect profile than the TCAs as far as delirium is concerned. However, one of the main side effects of SSRIs, hyponatraemia, can present as delirium in older persons. This has been reported with fluoxetine, fluvoxamine, paroxetine and sertraline. Although frank delirium due to SSRIs is rare, most reported cases seem to point towards drug interactions as a plausible cause. However, to emphasize that no centrally acting drug is completely safe, in a study of 10 healthy volunteers, paroxetine increased ratings of confusion and fatigue. There are also case reports of confusion due to antidepressants such as mirtazapine and venlafaxine. SSRIs alone and combinations such as sertraline and tramadol (a mu-receptor pain medication), trazodone and buspirone, and trazodone and methylphenidate have been reported to cause symptoms similar to those described in the serotonin syndrome.

The use of benzodiazepines (BDZs) was associated with an increased relative risk of developing cognitive impairment in one study among hospitalized patients, even those with normal mini-mental status examination scores on admission. Postoperative use of BDZs has also been found to increase the risk of delirium. Short-acting BDZs, even in small doses, have been reported to cause problems and the clinician should be aware that withdrawal from BDZs in the elderly may also present as delirium, perhaps more so when discontinuing short-acting compared with long-acting BDZs. However, there are models of successfully withdrawing patients from BDZs and this should be attempted whenever possible.

Antipsychotics can cause delirium, even the low-potency antipsychotic agents. Whether the antipsychotic prescribed is considered a typical or an atypical antipsychotic, the clinician needs to keep in mind that none of these drugs have pure mono-neurotransmitter activity. Rather, they have varying degrees of activity, either agonist or antagonist to many of the neurotransmitters implicated in the pathophysiology of delirium, such as dopamine, acetylcholine, serotonin and histamine. Therefore, like other geriatric psychiatric medications, antipsychotic drugs can and should be considered as a potential cause of delirium. Patients with Lewy body dementia have an increased sensitivity to neuroleptics. The clinical challenge here is that sometimes it is difficult to differentiate between Alzheimer's dementia and Lewy body-type dementia.

The ENT drugs in the mnemonic are a reminder of the multiple drugs, in particular over-the-counter (OTC) medications, that are taken for respiratory or sinus illnesses. The most worrisome of these ENT medications are the combination formulas, which contain two and sometimes three or even four active ingredients. Antihistamines, particularly the drug diphenhydramine, can cause problems at high doses, at moderately high doses, after a first-time oral dose in compromised elderly patients and even with topical use. Mental status changes have been reported to occur at high doses, at low doses and even from overuse of nasal inhalation of common OTC decongestants such as pseudoephedrine, phenylpropanolamine and phenylephrine. Expectorants and antitussins are probably safe provided that they are only used by themselves. One of the most commonly used, if not overused, ENT medications is meclizine. It has the potential to cause mental status changes because of its central anticholinergic action at the chemoreceptor trigger zone. The anticholinergic properties were thought to be the cause of confusion and steady cognitive and functional decline in an older patient who had been on meclizine for 3 years. Within 1 month off the drug, the patient's function and mentation improved. When rechallenged, the patient had cognitive and functional decline within 1 week.

'I' is a reminder that medications used for insomnia because of their effect on sedation have the potential to cause varying degrees of delirium. Most OTC sleeping aids come under a multitude of brand names without specifying the potentially dangerous deliriogenic medications dyphenhydramine or scopolamine.

Narcotics can be used safely in older persons with little risk of developing delirium, but a few important details need to be remembered. Meperidine is particularly risky in older persons, likely due to the anticholinergic activity of its active metabolite normeperidine. The main problems associated with the use of narcotics are probably related to toxicity, overuse or overdosage in patients with impaired hepatic or renal function.

Muscle relaxant is a misnomer because these medications act centrally in the brain, not locally at the muscles. Some of the commonly used muscle relaxants include cyclobenzaprine, methocarbamol and carisoprodol and have been reported to cause delirium.

Seizure medications have been reported to cause various types of cognitive impairment, including drowsiness, agitation, depression, psychosis and delirium. The cognitive impairment is thought to be related to serum levels, but clinicians should keep in mind that most anticonvulsants are protein bound and if the patient's nutritional status is poor then there is potential that the amount of free drug will actually be higher than what is measured by the serum level.

In conclusion, although the list of medications that can cause delirium is long, the mnemonic A-C-U-T-E C-H-A-N-G-E I-N M-S can help clinicians recognize some of the more common and some of the rare offenders. For patients

who present with delirium or for patients who are at risk for delirium, the following general guidelines concerning medication management can be used:

1 Use non-pharmacological interventions whenever possible instead of a medication.

2 Do not treat vague symptoms with a medication (for example, do not routinely give H2 antagonists for vague gastrointestinal complaints).

3 Include an assessment of OTC medications as potential offenders.

4 Evaluate all drugs for drug–drug and drug–disease interactions.

5 If a drug is started, decide on how long that drug will be used. The old rule of 'start low and go slow' needs to be expanded to 'start low, go slow and know when to stop'.

6 The justification for prescribing medications should be based on therapeutic reasons and not on preventive reasons and until the patient is no longer at risk for delirium or the delirium has resolved.

7 Do not treat adverse effects of drugs with another drug unless completely necessary (as may be the case with long-acting narcotics and laxatives).

The 'E' in the D-E-L-I-R-I-U-M mnemonic stands for emotions and reminds the clinician that depression can have psychotic features and as such may present similarly to patients with delirium. Although depression has classically been considered the masquerader of dementia, given some of the DSM-IV criteria for delirium such as disorganized thinking or psychomotor lethargy, depression should be considered a reversible cause of delirium.

Low O_2 (oxygen) states, 'L' in the mnemonic, should highlight to the clinician that older patients with acute cardiovascular or pulmonary illnesses can present with delirium. It could be said that 'delirium is as serious as a heart attack' because not only can the mortality rate of delirium be as high as that of myocardial infarction (MI) but also older delirious patients can have MIs that are commonly missed or present atypically. It is unclear whether patients, because of the delirium, cannot either describe or tell clinicians about chest pain or whether there exists a cardiocerebral syndrome in which the stress of the MI affects the adrenergic system causing a stress on the balance in the central nervous system, that is, in cognition. Not only are patients with stroke at risk of developing delirium as a complication of the stroke or the underlying comorbidities associated with the stroke but also delirium may be the presenting feature of some stroke patients.

Infections are one of the most common underlying causes of delirium among older people. The most common types of infections that cause delirium are urinary tract infections and respiratory infections. However, with the recent rise in antibiotic-associated diarrhoea due to *Clostridium difficile* bacteria, some clinicians have urged caution not to overdiagnose urinary tract infections that may be asymptomatic bacteriuria. Subtle infections such as cholecystitis and diverticulitis should be in the differential diagnosis. Although meningitis should also be considered, it is not clear whether or not cerebrospinal fluid analysis is warranted in the initial work-up of delirious patients without other symptoms that point towards a central nervous system infection.

Retention of urine and faeces can both cause delirium, although typically the presentations differ. Urinary retention causing delirium has been well reported in the literature under the term cystocerebral syndrome. The original report was of three cases, all involving older men who became acutely agitated and nearly mute. All three patients had large volumes of urine in their bladder and, in all three patients, the agitated delirium resolved within a short time after emptying the bladder. A proposed explanation is that the adrenergic tension related to the urinary retention might increase in the central nervous system and the consequent increase in catecholamines might produce delirium. Although this pathophysiological explanation has not been proven, clinicians should be very aware of this syndrome. One of the best ways to evaluate quickly for urinary retention is with a hand-held bladder ultrasound. Although the equipment has a fairly high initial cost, cost savings from the reduction in the use of straight catheterizations may help balance this issue.

Faecal retention as a cause of delirium has not been reported in the literature. However, since older patients, for multiple reasons, are at risk for faecal impactions, clinicians should be suspicious of this problem when the delirium is of the hypoactive type.

Ictal states are a rare cause of delirium and are not difficult to diagnose clinically for patients with tonic clonic seizures. However, patients who experience absence seizures may go unnoticed by caregivers and may only seem to have fluctuating mental status changes. Although an electroencephalogram (EEG) is not indicated in the initial medical evaluation of delirium, it should be considered when pertinent history is obtained.

Underhydration is used in the mnemonic, not only to emphasize the fact that dehydration can be one of the underlying causes of delirium but also to highlight the fact that those at risk for dehydration are at risk for delirium. Although there is much debate and consternation about which, if any, physical signs are pathomnemonic for dehydration among older persons, one quick method is to calculate the blood urea nitrogen (BUN) to creatinine ratio. Although there are several circumstances when the BUN/creatinine ratio may not be accurate, there are data to suggest that a ratio of greater than 17:1 puts the patient at risk for delirium.[18] Given this easy and commonly accessible parameter and given the data supporting the use of dehydration or difficulty with hydration as a target for

interventions, as will be seen below, dehydration should be considered to be at the top of the list as a contributing cause and not only as a risk factor for delirium and should be treated as aggressively as possible keeping in mind the limitations of each patient related to their cardiovascular status.

Undernutrition or malnutrition is rather complex and difficult to understand as a cause of delirium, most likely because, unlike other causes of delirium, it is less likely to be reversed quickly. It is evident, however, that malnutrition among hospitalized patients is not only common but also is associated with longer hospital stays, postoperative complications and even higher mortality. Clinicians and all healthcare providers in the hospital should be aware that restricted diets are likely to exacerbate malnutrition. Malnutrition is most directly related to delirium probably through the issue of medications that are protein bound. Patients who are malnourished may have lower protein stores and therefore protein-bound drugs will have a higher free concentration that puts the patient at risk for delirium. Other proposed relationships between malnutrition and delirium, which have yet to be fully elucidated, include those mechanisms looking at cytokines. Metabolic abnormalities that cause delirium are not difficult to identify because of the availability of commonly used laboratory tests. A complete metabolic panel will usually identify hyponatraemia or hypernatraemia, hypocalcaemia or hypercalcaemia and abnormalities of liver function or renal function. Thyroid function tests and vitamin B_{12} are typically put in this category.

Although delirium is not spelled with an 's' at the end, using the mnemonic D-E-L-I-R-I-U-M-S emphasizes to the clinician that delirium usually has more than one cause. The 's' also reminds the clinician that a subdural haematoma can cause a mental status change. Although the mortality rate of subdural haematomas among younger people is fairly high, the prognosis for older people is quite good provided that the diagnosis is not missed. The other difference between older and younger patients with subdural haematomas is that older patients may develop the subdural haematoma over a period of a few hours or days. Although there could be some debate as to whether or not all older patients presenting to a hospital with delirium should have some sort of brain imaging, most would agree that because this is a very reversible problem and which would cease to be reversible if the diagnosis is delayed, imaging should be considered if there has been a history of head trauma or falls or any suspicion that there was an unwitnessed fall.

One of the other causes of delirium not represented in the mnemonic is pain. Recognition of pain is improving, now identified as the *fifth vital sign*, and should be considered as a readily treatable cause of delirium, especially associated with elective surgery.

Prevention and management interventions

Before identifying which interventions are effective and which are not, it is important to understand the goals of interventions concerning delirium. They are (1) to prevent the development of delirium, (2) to reduce the adverse outcomes associated with delirium in those patients for whom delirium is not prevented and (3) to provide healthcare professionals with alternatives to physical restraints and pharmacological methods in the management of delirium. It is also important to emphasize that delirium is a complex issue related to the challenge of identifying who is at risk of developing it, diagnosing it if it does develop and getting other healthcare professionals to do the same. Interventions that are successful will involve several components, many of which are not easily measured. These include education about the risk factors and diagnosis of delirium, a 'culture' change about how *not* to use what seems logical and protective (for example, physical restraints or pharmacological sedation) and a realization that multicomponent interventions are not simple but can be done.

The most consistent message about successful interventions is to use an interdisciplinary team approach and follow geriatric principles. One of the most rigorous studies to date because of the assessment methods used and the close follow-up of patients was a prospective study of a multicomponent intervention to prevent the development of delirium in hospitalized older patients.[19] The study identified patients at risk for delirium on the basis of a previously developed predictive model. The study used the following six out of seven risk factors for the development of delirium: baseline cognitive impairment, eye or visual problems, altered sleep–wake cycle, dehydration, restricted or decreased mobility or hearing impairment (Table 71.4). The seventh risk factor, addition of more than three medications, was not used in the study, but is included in Table 71.4 for completeness (B-E-W-A-R-E). The standardized intervention protocols that were used in the study included the first six targeted interventions as described in Table 71.4 (P-R-E-V-E-N-T). Delirium developed in 15% of 426 usual care patients compared with only 9.9% of 426 intervention group patients [odds ratio (OR), 0.60; 95% confidence interval (CI), 0.39–0.92). The total number of days of delirium and the total number of episodes of delirium were also significantly lower in the intervention group, but the severity of delirium and recurrence rates were not significantly different. The interdisciplinary team included a specialist geriatric nurse, two specially trained persons familiar with the standardized intervention protocols, a certified therapeutic recreation specialist, a physical therapy consultant, a geriatrician and trained volunteers. The importance of this study is twofold. This study probably underestimates the success of a multicomponent intervention such as this because of the likely contamination that occurred

Table 71.4 Risk factors for delirium (B-E A-W-A-R-E) and targeted interventions (P-R-E-V-E-N-T) based on an intervention trial to prevent delirium.

B	Baseline dementia?
E	Eye problems?
A	Altered sleep–wake cycle?
W	Water or dehydration problems?
A	Adding >3 medications, especially sedating and psychoactive ones?
R	Restricted mobility?
E	Ear problems?
P	Protocol for sleep (back massage, relaxation music, decreased noise, warm milk or caffeine-free herbal tea)
R	Replenish fluids and recognize volume depletion
E	Ear aids (amplifier or patient's own hearing aid)
V	Visual aids (patient's own glasses, magnifying lens)
E	Exercise or ambulation as soon as possible
N	Name person, place and time frequently for reorientation
T	Taper or discontinue unnecessary medications. Use alternative and less harmful medications

throughout the hospital through implementing some of the standardized protocols. Since the study was done within one hospital, it was unable to randomize patients to separate floors and, thus, some intervention patients were on floors that also included patients from the usual care group. This was evident based on the 15% rate of delirium in the usual care group, which is lower than in previous studies.

A pre–post-intervention trial that focused on education of emergency department staff and admission to an acute geriatric unit ($n = 374$) showed positive results. The incidence of delirium decreased from 41% in the pre-intervention group to 22.7% in the post-intervention group at 4 months and 19.1% at 9 months.[20]

A few studies have targeted a very high risk group for delirium: older patients with surgical repair of hip fractures. Two randomized trials have focused on the prevention and management of delirium. In one study, 126 patients who were 65 years or older and admitted for surgical repair of hip fracture were randomized to geriatric physician consultation or usual care. The geriatric consultation was 'proactive', which meant that the consultation began preoperatively (for 61% of the patients) or within 24 h of surgery and a geriatrician made daily visits for the duration of the hospitalization. Targeted recommendations were made on the basis of a structured protocol emphasizing geriatric principles as well as postoperative medical care. Recommendations covered areas such as treatment of severe pain, elimination of unnecessary medications, regulation of bowel/bladder function (including discontinuing bladder catheters by postoperative day 2), adequate nutritional intake and early mobilization. The overall adherence rate by the orthopaedics team to the recommendations was 77%. Delirium developed in 32% of the 62 consultation group patients compared with 50% of the 64 usual care group patients (OR, 0.64; 95% CI, 0.37–0.98). There was a greater reduction in severe delirium, occurring in 12% of the consultation group and 29% of the usual care group (OR, 0.40; 95% CI, 0.18–0.89). Median length of stay did not differ in the two groups (5 days).[10] In the other study ($n = 120$), the multicomponent interventions were education of nurses, systematic screening, consultation by a nurse specialist and scheduled pain protocol. Mortality rates were inconclusive and there was no change in hospital length of stay (LOS) or physical function. However, there was a decrease in delirium duration and severity, but not incidence.[21] One randomized trial with a focus on just the management of hip fractures patients with delirium used multiple strategies for recognition of delirium, staff education, cooperation between orthopaedics and geriatrics and management of delirium and complications ($n = 49$). The study showed improved function and decreased duration and incidence of delirium in the intervention group.[22]

Randomized trials for the management of medical inpatients who already have delirium have not been as successful. Two trials utilized the same multicomponent intervention of systematic detection of delirium, a geriatric physician consultation with a geriatric nurse specialist doing follow-up. The first trial ($n = 227$) showed no change in mortality, LOS, function, discharge location or delirium duration.[23] The second trial ($n = 88$) showed no change in mortality, LOS or function, but there was a minor change in delirium severity.[24] A third randomized trial ($n = 174$) performed comprehensive geriatric assessments in the intervention group compared with a control group. It also utilized individually tailored treatment directed at the management of delirium, which turned out to mean that a significantly higher percentage of patients in the intervention group compared with the control group received physiotherapy, nutritional supplements, hip protectors, acetylcholinesterase inhibitors for underlying dementia and atypical neuroleptics for the delirium (and lower percentage of typical neuroleptics). The study showed no change in mortality, LOS or rate of institutionalization. Delirium was 'alleviated' significantly faster in the intervention group.[25] Finally, a fourth trial ($n = 400$) that focused on both the management and prevention of delirium was successful. A multicomponent intervention targeted staff education, assessment, prevention and treatment of delirium with an additional intervention towards the caregiver. The study showed a decrease in mortality (two versus nine deaths, $p = 0.03$), decrease in LOS (10.8 versus 20.5 days) and a decrease in the percentage of patients with delirium at day 7 (30 versus 60%).[26]

Another approach in the management of delirium is the delirium room (DR). The DR is a specialized four-bed

room to provide 24 h nursing care and observation by at least one nurse in the room and is completely free of physical restraints.[27] The hallmarks of the DR are the following. The four-bed DR is an integral part of an acute care for the elderly (ACE) unit. As such, the patients in the DR receive not only 24 h close observation but also the benefits of the geriatric principles for which the ACE unit has been shown to be effective in preventing loss of functional decline. Nursing inservices and protocols developed by nurses on how to identify and manage delirious patients are necessary. The DR is not isolated from the rest of the floor, rather it is the closest room to the main nurses' station. Having a location on the floor called the *Delirium Room* (see Figure 71.1) raises the awareness among healthcare professionals that delirium is a serious diagnosis, with serious consequences. Putting delirious or potentially delirious patients together in a room does not increase agitation as previous literature might suggest. Although the report of the DR was descriptive, it showed that over a 12 month consecutive time frame, out of the 69 patients with a diagnosis (according to the *International Classification of Disease*, 9th edition) of delirium in the DR, negative associations found in other studies of delirious patients were minimized. No physical restraints were used and only 29% of the patients received new orders for medications considered to be pharmacological restraints (haloperidol, risperidone or lorazepam), all at total daily doses of less than 2.0 mg. Only 13% of the patients lost physical function and none of the 69 patients died during their stay in the hospital. Mean length of stay for these patients was not significantly different compared with the length of stay for all other patients over the age of 70 years during the same time frame.[27]

Two studies of 'home–hospital care' have shown lower rates of delirium among medical patients cared for in the home compared with similar patients cared for in the hospital.[14,15] In the study by Caplan *et al*.,[14]100 patients with a mean age of 76 years (71% from home, 25% from nursing homes and 4% from hostels) with medical illnesses such as acute infections requiring intravenous antibiotics, deep venous thrombosis, minor cerebrovascular accidents or cardiac failure, were randomized within 24 h of diagnosis to either home or hospital. Although the researchers used the term 'confusion' instead of the formal diagnosis of delirium, they found a lower incidence of confusion (0 versus 20.4%; $p = 0.0005$) in the home group compared with the hospital group. Other geriatric complications were also found to be at a lower rate in the home group compared with the hospital group: urinary complications (incontinence or retention) (2.0 versus 16.3%; $p = 0.01$) and bowel complications (incontinence or constipation) (0 versus 22.5%; $p = 0.0003$).[14] The study by Leff *et al*.[15] identified older patients who required hospital-level care for pneumonia, congestive heart failure, chronic obstructive pulmonary disease and cellulitis. Of those who went home for treatments associated with hospital care, compared with patients who completed their treatments in the hospital (average length of stay 2.9 versus 4.9 days), the adjusted OR for incident delirium was 0.25 (adjusted 95% CI, 0.11 to 0.58).[15]

The take-home message for delirium is that although it is a difficult problem to prevent or manage when unpreventable, it can be done usually through a multicomponent intervention. No single simple intervention is likely to succeed and it is not possible to tease out which of the multiple components are having an effect and which are the detractors. Nonetheless, multicomponent interventions still need to be considered as the standard of care because delirium is such a complicated multifactorial problem.

Physical restraints

Physical restraints should not be used for patients who are at risk of developing delirium or who have already developed delirium (see Chapter 133, Restraints and immobility). The use of physical restraints is associated with developing delirium and is significantly related to severity of delirium. Furthermore, the proposed reason for the use of physical restraints among delirious patients, to prevent injury primarily related to falls, is misconceived. Of three studies of restraint reduction programmes in long-term care institutions, two showed no change in fall rate and one showed an increase in fall rate. However, all three studies showed a decrease in fall injury rates.[28–30] Of two studies in the hospital setting, restraint reduction was not associated with an increase in falls.[31,32] The rate of restraint use in the study by Powell *et al*.[31] went from 52 per 1000 patient-days to just 0.3 per 1000 patient-days. Although neither study reported injury rates before and after restraint reduction, Mion *et al*.[32] reported that injury rates after the restraint reduction programme were low. Importantly, they were modestly successful (≥20% reduction) in two of six ICUs in restraint reduction and reported that no deaths occurred as a result of a fall or disruption in therapy, including in the case of ICU patients on mechanical ventilators.[31,32] Furthermore, the fact that restraint-free environments can be achieved, as in some geriatric departments in European hospitals,[33] ACE units in United States hospitals[27] and some nursing facilities[34,35] adds to the evidence that restraint-free care should be the standard of care.

Pharmacological restraints

Currently, no antipsychotic or other pharmacological agent is approved by the US Food and Drug Administration (FDA) for the treatment of delirium. On the basis of the

available data concerning medications used in the management of delirium and the commonly accepted reason to use them (for patients whose behaviour interrupts the necessary medical care or puts themselves or others at risk of physical harm), antipsychotics should be considered a form of restraint until further evidence shows otherwise. Delirium is not analogous to psychosis. In patients with schizophrenia, antipsychotics can improve behaviour and function, with sedation being a common side effect. In patients with delirium, antipsychotics have not been shown to do this. It is argued that they control behaviour, but it is unclear whether this is through the sedation effects of the drugs or their effect on the neurotransmitters thought to play a role in delirium. To complicate matters further for older persons, one of the main problems with antipsychotic drugs, whether atypical or typical, is that they are not pure in their mechanism of action. For example, although risperidone primarily affects serotonergic (5-HT2A) receptors, it also affects to some extent dopaminergic and alpha-1 receptors. Although olanzapine affects the 5-HT2A receptors, similarly to risperidone, its sedation properties are probably due to its effect on the histaminic receptors. Clozapine also affects histaminic and muscarinic receptors and quetiapine has varying effects on histaminic and alpha-1 receptors and also has a small affect on dopaminergic and 5-HT receptors.

The available data for the use of antipsychotics in the management of delirium are poor because of the populations studied, types of studies done or the presence of the common mistake of not including a placebo group in order to measure the natural course (duration) of delirium without pharmacological intervention. As can be seen in Table 71.5, although several studies have examined the effects of antipsychotics in delirium, none of them were placebo controlled. It is important to note in the table the number of days when improvement is seen. Without a placebo-controlled group, it is unclear from the current evidence whether improvement in these studies follows the natural course of delirium or if it is from the use of the antipsychotic. It is evident from the lack of evidence that randomized placebo-controlled trials are needed. It should be noted that in a randomized controlled trial of a non-pharmacological intervention to prevent delirium, Inouye *et al*. found that even in the control group patients who developed delirium, the average total number of days of delirium was ~2.5.[19] Although this study did not go into detail about the percentage of delirious patients who received antipsychotics or the dose, another study[27] found that only 29% of 69 delirious patients received any form of pharmacological restraint (antipsychotics, benzodiazepines, sedatives/hypnotics) and this group had an average length of stay in hospital <5 days.

The proper dosages of antipsychotics have also never been established. One recent text recommends that if severe agitation is present, haloperidol doses of 0.25–1.0 mg can be used as often as every 20–30 min with a maximum 24 h dose of 3–5 mg. This dose is recommended because D2-dopaminergic receptors are saturated at low doses and therefore, theoretically, doses above 5 mg over a 24 h period are likely only to increase adverse events without providing additional clinical benefit. The goal should be an awake patient who is manageable, not a sedated patient, and the drug should be tapered and discontinued as soon as possible.

On the basis of the currently available data, the following conclusions can be drawn:

1 There is not enough evidence for the routine use of antipsychotic or other pharmacological approaches in the management of delirium.

2 On the basis of general geriatric principles, non-pharmacological interventions that have no or less risk should be tried before any pharmacological approach.

3 If pharmacological agents are used, the lowest possible dose should be tried first, keeping in mind the goal that is intended (patient manageable and awake, not oversedated).

4 On the basis of the very limited data, the category of drug of choice *seems* to be antipsychotics, not benzodiazepines or sedative-hypnotics.

Key points

- Delirium is common among older persons in the hospital, especially in surgical patients and patients in the intensive care unit (ICU) and in post-acute care settings, but not so common among patients with acute illnesses cared for at home.
- Delirium is a dangerous diagnosis and has been found to be associated with hospital complications, loss of physical function, increased length of stay in the hospital and ICU, increased incidence of discharge from the hospital to a long-term care facility and even higher mortality.
- The comprehensive approach to delirium involves awareness, diagnosis, evaluation, prevention and management. The causes of delirium can be remembered using the two mnemonics D-E-L-I-R-I-U-M-S and A-C-U-T-E C-H-A-N-G-E I-N M-S.
- Successful prevention and management interventions include a multicomponent intervention with protocols targeting risk factors to prevent the development of delirium, a geriatric consultation service for patients with hip fracture and a specialized four-bed room to provide 24 h nursing care, called the *Delirium Room*.
- Physical restraints should not be used in patients with delirium and rarely should pharmacological restraints be used.

Table 71.5 Available clinical studies examining the use of antipsychotics in delirium[a].

Study (methods)	*N* Mean age ± SD (years) (Age range, years) Type of patients	Drugs	Placebo?	Outcome and time frame (if reported)
Breitbart, 1996[36] (prospective, blinded, randomized)	30 39 ± 9 (23–56) All patients had AIDS	Haloperidol Chlorpromazine Lorazepam	No	DRS: average scores decreased from 20 to 12 by day 2 for haloperidol and chlorpromazine. Lorazepam: 'all patients had treatment limiting adverse side effects'
Nakamura, 1997[37] (prospective, open-label, randomized)	66 68 ± 15 vs 64 ± 13 (40–92 vs 23–86) Post-surgical and medical patients	Haloperidol Mianserin	No	DRS: 70% in each group improved by day 3 (DRS scores decreased from 22 to 10 in both groups)
Sipahimalani, 1998[38] (retrospective)	22 64 ± 20 (19–89) Psychiatric consults	Haloperidol Olanzapine	No	DRS: >50% reduction in scores 5/11 haloperidol group 6/11 olanzapine group Peak response[b]: 6.8 days haloperidol; 7.2 days olanzapine
Schwartz, 2000[39] (retrospective)	22 54 vs 58 (21–74 vs 19–91) Psychiatric consults; various medical illnesses	Haloperidol Quetiapine	No	DRS: >50% reduction in scores 10/11 in both groups Peak response: 6.5 days haloperidol; 7.6 days quetiapine
Kim, 2001[40] (prospective, open-label)	20 46 ± 18 (19–74) 11/20 patients had leukaemia	Olanzapine	No	DRS: >50% decrease in scores = 14/20 Peak response: 3.8 ± 1.7 days
Breitbart, 2002[41] (prospective, open-label)	79 61 ± 17 (range 19–89) Cancer patients	Olanzapine	No	MDAS: 76% had 'resolution' by day 7 according to MDAS <10
Sasaki, 2003[42] (prospective, open-label)	12 67 ± 15 Post-surgical and medical patients	Quetiapine	No	DRS: Japanese version: 100% had resolution (DRS-J <12) Average 4.8 ± 3.5 days
Kim, 2003[43] (prospective, open-label)	12 74 ± 4 (64–88) Medical patients	Quetiapine	No	DRS: 'stable' (not clearly defined) by 5.9 ± 2 days
Parellada, 2004[44] (prospective, open-label)	64 67 ± 11 Medical patients	Risperidone	No	DRS: 90% had DRS <13 by day 3
Han, 2004[45] (prospective, blinded, randomized)	24 66 ± 8 vs 67 ± 16 Mostly medical; some fractures	Risperidone vs haloperidol	No	MDAS <13: 42% risperidone vs 75% haloperidol (no significant difference) Average time to MDAS <13 was 4 days
Liu, 2004[46] (retrospective)	77 68 ± 10 vs 50 ± 15 (40–85 vs 15–77) Psychiatric consults	Risperidone vs haloperidol	No	'Recovered' based on 10-point visual analogue scale and two psychiatrists: 7 ± 4 days risperidone 8 ± 5 days haloperidol

Table 71.5 (*continued*).

Study (methods)	***N*** **Mean age ± SD (years) (Age range, years) Type of patients**	Drugs	Placebo?	Outcome and time frame (if reported)
Pae, 2004[47] (retrospective)	22 Mean 69 ± 10 (range 48–85) Neurosurgery, orthopaedic, oncology	Quetiapine	No	DRS: >50% decrease in scores: 19/22 Average scores from 22 to <15 in 7 ± 4 days
Lee, 2005[48] (prospective, open-label, randomized)	31 61 ± 18 vs 63 ± 15 Psychiatric consults	Amisulpride vs quetiapine	No	DRS-R-98: >50% decrease in scores 81% vs 80% 'Stabilization' based on DRS-R-98 in 6.3 vs 7.4 days

CHAPTER 72

Memory clinics

Antony Bayer
Cardiff University, Cardiff and University Hospital Llandough, Penarth, UK

Introduction

Clinics specifically for the diagnosis and management of early dementia were first developed in the USA in the late 1970s. These were primarily research based, linked to developing Alzheimer's disease (AD) and ageing research centres and acted as a focus for expert assessment, investigation, treatment and advice.[1] Initially described as 'dementia clinics', the terminology soon changed to the more acceptable name of 'memory clinics' or 'memory assessment clinics'. Although the new titles are less stigmatizing, they run the risk of serving as a euphemism, avoiding an open and honest approach to the reality of dementia.

Predominantly service-oriented memory clinics were set up in the UK in the early 1980s,[2,3] offering multidisciplinary, outpatient-based assessment and diagnosis for mainly older people with memory and other cognitive problems, in an acceptable and accessible environment. At first, many of these clinics were funded from outside the National Health Service and were based mainly in university departments of geriatric medicine or old age psychiatry. Existing services tended to consider memory clinics to be a luxury, allowing academics to indulge their narrow clinical interests away from the reality of budgetary considerations and the priorities of practical dementia care. However, this reflected the concentration of service provision on dealing with the behavioural and psychological symptoms of advanced dementia and on crisis intervention and institutional-based management. The first memory clinics played an important role in raising awareness of the value of elective intervention and interdisciplinary care for people with early dementia and acted as a focus for the development of specialist knowledge and expertise in early diagnosis and management of people presenting with cognitive impairment.

Most of the early UK clinics were also very actively involved in research, especially recruitment into clinical trials of the emerging anti-dementia drugs. Largely thanks to the work of these centres, specific drug treatment for AD became available in the late 1990s and the focus of activity shifted towards the provision of an effective clinical service for patients presenting with memory disturbances and best use of medication, together with psychosocial interventions and patient and carer support and education.[4] The evolution of hospital-based memory clinics into more community-based memory teams was the natural consequence, working alongside or as an independent part of traditional mental health teams for older people.

Initially criticized for being too academic and isolated from mainstream practice, and ill-equipped to provide care after diagnosis, memory clinics have now become an integral part of quality dementia assessment and care services. The clinical guideline on the management of dementia published by the UK National Institute for Health and Clinical Excellence (NICE) and the Social Care Institute for Excellence (SCIE) in 2006 recommended the development of memory assessment services as the single point of referral for all people with a possible diagnosis of dementia.[5] They were seen as providing a responsive service to aid early identification, including a full range of assessment, diagnostic, therapeutic and rehabilitation services and an integrated approach to the care of people with dementia and the support of their carers, in partnership with local health, social care and voluntary organizations. The National Dementia Strategy in England, published in 2009,[6] suggested that memory clinics might form the core of new services for early diagnosis and identification of dementia in 'every town and city' in the country.

Although most memory clinics focus on the diagnosis of early dementia and mild cognitive impairment (MCI), some have a broader remit, whereas others target people with purely subjective memory loss or younger people with early-onset dementia or people with learning disabilities. Many concentrate on diagnosis and assessment with a view to best use of available medication and those in academic centres continue to conduct a lot of research, including clinical trials of newer drug treatments. The emphasis on assessment for drug treatment should not detract from

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

the importance of providing the holistic, multiprofessional and multiagency approach to dementia care that should be central to the activity of all clinics.

Referral may be open access (those willing to see all-comers) or restricted to secondary or tertiary referrals or to selected individuals who meet predetermined criteria. In general, patients referred by their general practitioners (GPs) seem more likely to have dementia than self-referrals, although the reassurance given to those without organic disease (the 'worried well') should not be underestimated.[7] Memory clinics should never be merely rebranded old age psychiatry outpatient clinics or community-based services solely monitoring anti-dementia drugs.

Developments around the world

Memory clinics are now a feature of health services for older people in centres around the world, but they vary in terms of case mix, types of activity undertaken, whether they are primarily based in neurology, psychiatry or geriatric settings and their interface with other relevant agencies. Nearly all involve multiprofessional assessment, often with everyone coming together to share results in a diagnostic consensus meeting. The subsequent input into long-term support and follow-up can be very different, with some clinics seeing diagnosis and immediate care as the limit of their responsibility and others taking on the role of planning optimal long-term management. Memory clinics are sometimes the centre of a broad model of care, with preliminary home visits by a nurse and/or psychologist before clinic attendance and further home visits afterwards to discuss assessment results and plan future management.

In some countries, sometimes with government support, networks of clinics have developed to coordinate clinical, research and educational activity related to dementia. For example, in The Netherlands, memory clinics are well established and have led to the development of quality markers to facilitate description and comparison of activities and quality standards.[8] Most Dutch clinics actively involve the general practitioner, routinely provide a home assessment visit and have a strong research emphasis. In France, the national Alzheimer Plan has supported a major effort to ensure that each health district has its own memory unit (Consultation Mémoire) for dementia diagnosis and follow-up, building upon the expert memory clinics developed in the 1990s. At a regional level there are specialist Centres Mémoire de Ressources et de Recherche (CMRR), providing diagnosis in the most complex cases and delivering research and training. Other initiatives have included use of standard assessment and follow-up documentation, common educational projects and multicentre clinical research projects.

In Switzerland there is a collaborative group of memory clinics, enabling an active programme of education and training for health professionals and clinical research. The primary care doctor plays an important role in initial assessment before comprehensive diagnosis and treatment recommendations are made in the memory clinic, including memory training and caregiver support activities. There is also close involvement with the national Alzheimer's Association. The limited number of memory clinics in Germany and Austria are mainly university based and research oriented and are not covered by statutory health insurance, so have yet to become a standard component of local dementia care. In rural and isolated areas in Europe, the structures necessary to provide services are often lacking and novel approaches are therefore needed. For example, in Lapland there is a memory clinic bus which tours around offering memory testing and counselling services.

In the southern hemisphere, memory clinics providing multidisciplinary assessment and management for community-living people with dementia are developing in every continent, although still mainly based within the private sector or university centres in the larger cities. In Australia, a government-funded regional network of Cognitive, Dementia and Memory Services (CDAMS) were established in the 1990s across the state of Victoria, although elsewhere in the country the development of memory clinics has been more sporadic. The multicultural nature of Australian society presents particular challenges to ensure equity of assessment, service provision and utilization and highlights the need for clinics to be sensitive to the needs of people from a range of cultural and linguistic backgrounds,[9] a challenge also being addressed in many clinics in North America and Southeast Asia.

Why the need?

The worldwide growth in memory clinics has largely developed because of increasing demand and expectations of patients and families, frustrated by the difficulties of obtaining informed diagnosis and advice from existing services. They are not a replacement or alternative to these, but rather a more focused service providing a consistent approach to assessment, more specific diagnosis and a single resource for expert information and support (Table 72.1). Demographic changes are rapidly leading to greater numbers of patients with age-related cognitive disorders and there is appropriate reluctance to attribute forgetfulness merely to age. The growing awareness that memory failure is not inevitable and that effective intervention is available has led to a desire for comprehensive assessment, diagnosis, advice and treatment to be provided by professionals with specific expertise.

In many areas, existing services for diagnosis and management of memory disorders have been inadequate, with no clear professional responsibility and a widespread lack of specialist expertise and experience. There is a growing

Table 72.1 Potential benefits of memory clinics.

Benefits for patients and families
Non-stigmatizing, specialist resource breaking down potential barriers to recognition/diagnosis
Increases choice and improves patient experience and engagement
Expert multidisciplinary assessment and diagnosis of cognitive disorders
Ensures treatable conditions are not overlooked
Early identification of dementia and intervention
Anti-dementia drugs are effectively targeted, monitored and stopped as appropriate
Education and practical support for patients and carers
Empowers people with dementia while they are still able to maintain control over their lives
Provides advice on memory aids and memory training
Opportunities for counselling and psychosocial management
Improves quality of life by promoting and maintaining independence for as long as possible
Continuing care in the community may reduce need for institutionalization
Access to research studies
Benefits for service provision
Addresses growing demand for specialist diagnosis and treatment
Encourages earlier referral and multidisciplinary management
Develops awareness of dementia in primary care
Cost-effective way of significantly increasing the number of people able to be seen
Provides standardized assessment and diagnosis
Gateway to services
Efficient targeting and monitoring of scarce resources (including medication and psychosocial interventions)
Expertise in legal and ethical issues
Facilitates audit, planning and evaluation of services
Elective decisions may help to avoid crises in care
May reduce hospitalizations and lengths of stay
Postponement of institutionalization may reduce costs
Focus for professional education and research activity

appreciation of the complexity of the needs of these patients and that optimal assessment and management requires a multidisciplinary rather than a monodisciplinary approach.

Even in expert hands, assessment and management of mild cognitive disturbance are not always straightforward, with a difficult differential diagnosis ranging from the trivial to the very serious and from the easily reversible to the irreversible. Not all forgetful old people have dementia and not all demented old people have AD (Table 72.2). Comprehensive assessment reduces the chances of inappropriate labelling. There is a multiplicity of available assessment tools and investigations and, without access to the definitive diagnostic test of histopathology, some informed selection needs to be made. Once a working diagnosis has been reached, there is also a wide spectrum of available medical,

psychological and social interventions that require tailoring to the individual.

The availability of specific drug treatment for AD and some other dementias and the need to identify suitable patients and to monitor drug efficacy are the most obvious justifications for early diagnosis. However, the emphasis on a medical model of care and the perceived influence of the pharmaceutical industry in driving forward the expansion of memory clinics should not detract from the broader psychosocial benefits of early recognition and intervention.

Although reversible dementia is uncommon, nearly all patients will have problems that can be helped and appropriate intervention can be instigated at a stage when it is likely to be most effective. A positive diagnosis reduces the risk of inappropriate management and avoids wrong assumptions being made. It empowers people with dementia to become involved in decision-making while they are still able to do so. The opportunities for forward planning may improve the psychosocial health of carers and also help to lessen the risk of crises in care at a later stage. Certainly a proactive approach is likely to be more efficient and also more humane than one that is crisis driven.

Are they effective?

In common with most health service developments, the rapid growth in memory clinics has occurred despite lack of evidence of effectiveness from randomized controlled comparisons with usual care. However, lack of evidence does not mean that they are ineffective and, given growing societal pressures and the considerable evidence on the effectiveness of the individual elements of memory clinics, the odds are in favour of their benefit.[10] A recent model suggested that memory services need only achieve a modest increase in average quality of life of people with dementia, plus a 10% diversion of people with dementia from residential care, to be cost-effective.[11] There is certainly evidence that community-living older people with cognitive impairment have fewer hospitalizations and nights hospitalized if their problem is diagnosed, compared with those who have never received such a diagnosis.[12]

Two completed randomized controlled trials have looked at the benefits of diagnosis of dementia in a memory clinic. A cluster randomized trial in The Netherlands showed that in comparison with usual care, an integrated multidisciplinary approach to dementia diagnosis in a hospital-based memory clinic setting increased health-related quality of life of the dementia patients for at least 12 months.[13] An Australian trial looked at the quality of life for carers of community-dwelling patients with mild to moderate dementia, who were randomized to attend a memory clinic or act as a control group. Those carers attending the memory clinic were found to have significant improvement in psychosocial health-related quality of life, particularly in the domains of alertness behaviour and social interaction, which was maintained at 12 months. However, there was no significant improvement in carer burden or knowledge of dementia.[14] The ongoing AD-Euro trial is comparing the clinical and cost effectiveness of post-diagnostic dementia guidance and treatment by memory clinics to usual care.[15]

Luce *et al*.[16] compared consecutive referrals to the memory clinic in Newcastle upon Tyne with referrals to the traditional and well-established old age psychiatry service in the same city. Memory clinic patients were younger, had lower levels of cognitive impairment and a wider range of diagnoses, with those diagnosed as having dementia being at least 2 years earlier in the course of the disease than those seen in the standard service. The authors concluded that memory clinics target a distinct patient group compared with traditional old age psychiatry services, identifying cases of dementia much earlier and having the potential to make valuable contributions to patient care in terms of access to treatments, services and support networks and in terms of obtaining information and preparing for the future.

Another British study in the more rural area of Dorset[17] compared consecutive new referrals to a memory clinic with consecutive new domiciliary requests within the same old age psychiatry service over the same period of time. The clinic patients had fewer behavioural and psychological symptoms of dementia, but were otherwise similar in demographic and clinical characteristics. Subsequently they were less likely to have a psychotropic drug prescribed, but were more likely to have documented risk management, care planning and follow-up, with a trend towards fewer moves into residential care and psychiatric ward admissions.

Surveys of memory clinic users' opinions of their experiences are generally very positive. van Hout *et al*.[18] used questionnaires with patients, relatives and GPs to measure their perception of the quality of care of an outpatient memory clinic. Positive opinions were recorded on the way in which the results were communicated, the usefulness of the assessment and the attitude of the clinicians. In contrast to GPs and relatives, patients were less positive about the clarity of the diagnostic information received and both relatives and GPs were negative on information and advice given to relatives. A subsequent study by the same researchers highlighted the importance of providing information not only on issues considered relevant by clinicians, but also tailored to the individual needs of patients and carers.[19] An Australian study of GPs' satisfaction with services provided by memory clinics also found them to be positive about the completeness and utility of the assessment and diagnostic information provided, but relatively less satisfied with advice regarding the family's coping and community support services for the patient.[20] It was considered that the service enhanced the capacity of GPs to provide ongoing care to people with dementia, but that the establishment of firmer communication and collaborative protocols between the clinics and GPs would improve their usefulness.

The memory clinic team

In order to provide a comprehensive service, memory clinics are characteristically multidisciplinary in nature, with a number of different professionals, each offering a particular expertise. Involvement is often based less on possession of any specific sub-specialist qualification than on interest and knowledge. In some centres the medical input may be from a geriatrician, in others from a neurologist and in others from a psychiatrist. Ideally there should be all three specialties involved. The other constant member of the memory clinic team tends to be a psychologist, not just to carry out neuropsychological assessment to aid diagnosis and management, but also to advise on and to undertake psychosocial interventions with both patient and family. Another invaluable team member is a specialist nurse, who can help with both the medical and psychological assessment and management. This can be carried out beyond the physical confines of the clinic, facilitating and reinforcing the process in the patient's own environment. Finally, dedicated administrative help is essential, not only to ensure the efficient running of the clinic, but also to cope with the forgetful patients who phone repeatedly to check the time of their appointments.

Beyond these core team members, there needs to be easy access to other professionals, such as speech and language therapists, occupational therapists and social workers. Increasingly there is also a need for someone competent to provide genetic counselling and advice to worried relatives. Developments in drug therapy suggest an important potential role for the pharmacist and newer diagnostic techniques may require greater involvement of radiologists and neurophysiologists. Volunteers and support workers from the local Alzheimer's Society are becoming closely associated with some clinics, providing additional practical support and counselling to newly diagnosed patients and their families.

The optimum size of the team is likely to be between four and seven, united by a common feeling of direction and purpose. Although each member should be able to identify the specific and general contribution they can make, a flexible working style which crosses conventional professional boundaries will provide greatest job satisfaction and most effective care for patients.

As in other aspects of geriatric practice, getting the multidisciplinary team to work effectively is essential for the smooth running of the clinic. Good teamwork takes time to develop and whoever is the team leader (usually the senior physician or psychiatrist) needs to strike a balance between over-structuring clinic activities and allowing individuals to function totally independently. The team will not work effectively when one particular professional (or profession) considers the guarding of their perceived area of expertise as a priority, setting up artificial borders which others fear to cross. A belief in the importance of professional hierarchies, concerns over territory and differences in terminology will act as barriers to effective care delivery and can lead to wasteful duplication of effort and apparently contradictory management advice. Individual members should be encouraged to view the value of their contribution as depending on the functioning of the whole team.

What happens in a memory clinic?

There would seem to be general agreement that a memory clinic can provide in one setting all the essential components of comprehensive assessment leading to diagnosis for older people presenting with memory problems, followed by appropriate interventions (Table 72.3). The assessment will include full history and medical examination, detailed neuropsychological and neurobehavioural assessment and appropriate laboratory tests and neuroimaging. Some clinics have a totally standardized approach, where everyone gets everything, whereas others will tailor the assessments to what is specifically indicated and what has not been done before. Whereas some clinics will restrict themselves to a one-off evaluation, confirming a diagnosis and perhaps recommending an appropriate intervention, others will aim to provide ongoing support and more comprehensive management. Certainly diagnosis divorced from effective intervention is likely to be unsatisfactory for all.

Relevant physical examination
Investigations (including neuroimaging)
Formulate diagnosis and discuss appropriately (with patient and family with consent)
Provide relevant written information and contact details of local contacts
Consider management options:
• Treat comorbid medical conditions appropriately
• Review existing medication and consider anti-dementia drugs
• Ensure good nutrition and hydration
• Psychotherapeutic interventions
• Memory aids and problem-solving skills
• Safety issues (including driving) and promotion of independence
• Legal and financial/estate planning and eligibility for benefits
• Social interventions (home care, social clubs, respite)
• Carer education and practical and emotional support
Arrange appropriate follow-up

Clinics should be held close to the community they serve. Holding them away from the stigmatising settings of geriatric or psychiatric hospitals will help to encourage referral and attendance. Remembering to keep appointments is an obvious problem for this client group and sending reminders a few days before and asking people to confirm that they will be coming will help to reduce non-attendance. Forewarning people about how long the assessment will take is advisable. In some clinics assessments take all day, moving from one professional to another, and many patients find this tiring and cannot cooperate fully. Some psychometric tests need to be repeated at a set interval, so initial assessment will require more than one visit. Certainly, given the gravity of the potential diagnoses, a case can be made for all patients to be tested on at least two occasions a few weeks apart. We have found that a maximum of 60–90 min per visit (of which 30 min may be taken up with cognitive testing) is optimum.

Patients should be asked to come with someone who knows them well and can provide corroborative background. The presence of a close relative or carer will also help to ensure that advice and information provided in the clinic are acted upon. Ideally there need to be two clinic rooms, allowing an opportunity for patient and informant to talk separately to different team members.

History and medical examination

The essential first step in clinic assessment must be to obtain a detailed and accurate history. Cognitive impairment in elderly patients is often unrecognized. A patient who superficially appears alert, pleasant and cooperative and denies any significant symptoms is too often assumed to have no problems and mild dementia is easily overlooked. Establishing the reason for referral is a good place to start.

The onset and duration of symptoms are crucial and claims that difficulties date from some seemingly relevant event such as an accident, bereavement or hospital admission must not be accepted unquestioningly. Often a sudden change in circumstances merely draws attention for the first time to pre-existing problems. Changes in role are often of significance and questions should be asked about loss of competence in everyday skills and activities (e.g. driving, travelling away from home, handling correspondence and finances, taking medication regularly). The nature and progress of any changes should be established.

It is essential to take a history from both the patient and from a carer or friend (a neighbour may be of more value than an uninvolved relative) and specific examples of practical difficulties should be elicited. Associated mood disturbances, personality change and behavioural difficulties must be sought. Specific questions should be asked about delusions and hallucinations. Present and past consumption of alcohol, use of prescribed and non-prescribed drugs and the patient's general medical condition need to be established. A family history may give pointers to the diagnosis and sometimes explains a patient's excessive concern or apprehension. Much useful information is often available in previous medical records.

The Cambridge Mental Disorder of the Elderly Examination (CAMDEX) attempts to standardise the clinical information gathered in the course of a diagnostic interview with history being obtained from both the patient and a relative. Some details are therefore duplicated, but it serves as a useful starting place for those less confident in eliciting all the relevant issues. Informant questionnaires, such as the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) can be completed by relatives before clinic attendance as an aid to establishing their report of changes in everyday cognitive function compared with 10 years before. Numerous other assessment scales, for example of neuropsychiatric symptoms, depression, activities of daily living, quality of life and carer burden, are available[21] and can be incorporated into clinic practice. They are valuable as an objective basis for documenting change and as a source of data for audit and research.

A medical examination, with particular attention to the cardiovascular system, central nervous system and special senses (eyes and ears) is also required. This may help to elucidate the cause of the memory problems, may identify physical consequences of the condition (poor nutrition, neglected personal hygiene, signs of physical abuse) or may identify coexisting morbidities. Focal neurological signs will suggest vascular disease or a space-occupying

lesion and extrapyramidal signs will raise the possibility of Parkinson's disease or dementia with Lewy bodies (DLB). Primitive reflexes (e.g. palmo-mental, grasp, pout, rooting) are common in most forms of dementia, although not always easy to elicit. Myoclonus may be seen in prion disease, Huntington's disease and early-onset AD and muscle fasciculation may suggest motor neurone disease associated with fronto-temporal dementia (FTD).

Cognitive assessment

Following the history, an objective assessment of cognitive functioning is required. This will aim to establish strengths and weaknesses of a variety of functions relative to a standardized, norm-referenced scoring system. In this way, the nature and extent of cognitive deficits can be determined, informing diagnosis and management and acting as a comparator for past and future assessments. Ideally an experienced psychologist should undertake testing, although much useful information can still be obtained by any suitably trained professional. The Addenbrooke's Cognitive Examination Revised (ACE-R)[22] is an easy to use and acceptable screening measure with good sensitivity and specificity in clinic settings and incorporates the Mini Mental State Examination (MMSE) and clock face drawing. A simple screen of executive function, such as verbal fluency, will help to identify subcortical deficits. When possible, assessment should be made of premorbid intellectual status, to assist in the satisfactory interpretation of other test scores. Tests must also be appropriately selected to take account of limitations imposed by deficits such as language impairment and dyspraxia. For example, recognition memory tests may reduce the demand on expressive language, normally required in recall memory tests. A standardized measure of mood is also desirable.

There is a very wide choice of psychometric tests suitable for use with memory clinic patients and choice will be governed by the main purpose of the examination and the time available, and also personal preference and experience. Computer-based assessment of cognitive function is becoming more available and has the advantage of being sensitive to small changes in performance and allowing detailed assessment of attention and motor responses. At present its use is still confined mainly to research settings. An outline of the assessments used routinely in the Cardiff memory clinics is shown in Table 72.4.

Whatever tests are chosen, they must be acceptable to the person being tested and with no content that belittles their adult status. Consent to the assessment procedure needs to be obtained and the tester should spend some time in explanation of the purpose of specific tests and be competent to answer queries regarding their usefulness and acceptability. Sensory and physical limitations should be accommodated as much as possible, by the provision of adequate lighting, additional specialist earphone amplifiers, suitable seating and minimum distractions. During testing, realistic reassurance should be provided, with feedback phrased positively to highlight strengths as much as weaknesses. At the end of testing, patients should be given an opportunity to make their own observations on their performance.

Table 72.4 Cognitive tests commonly used in the memory clinics in Cardiff.

Premorbid ability
National Adult Reading Test (NART)
Cognitive screen/test battery
Mini-Mental State Examination (MMSE)
Addenbrooke's Cognitive Examination Revised (ACE-R)
Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)
Frontal Assessment Battery (FAB)
Specific cognitive abilities
Story recall (immediate and delayed)
Irving Names Learning Test (NLT)
Kendrick Cognitive Tests (object learning and digit copying)
Rey–Osterrieth Complex Figure Test (ROCF)
Clock drawing
Verbal fluency (controlled oral word association test and category)
Trail-making Test A and B
Graded Naming Test (GNT)
Mood
Geriatric Depression Scale (GDS-15)

Observations of the person's concentration, cooperation, anxiety and motivation during assessment should be carefully weighed against performance. The approach of the patient to each test and his or her satisfaction with the outcome is often as revealing as the particular score obtained. Results should be considered in the context of the patient's previous education and experience, their age and presence of sensory impairments and comorbidity and diagnostic cut-offs for each score treated as guides rather than absolutes. In particular, a 'normal' score does not exclude the possibility of significant problems, including dementia. In such cases, more detailed testing will often reveal minor detriments in a range of tests, which are inconsistent with the patient's expected level of functioning. It is nearly always desirable, and sometimes essential, for assessment to be repeated at a future date in order to detect any progressive deterioration. Longitudinal follow-up increases the accuracy of diagnosis, particularly in mild dementia.

Laboratory tests

A routine screening battery of laboratory tests will be indicated in most patients when first seen.[5] These should

include a full blood count, urea and electrolytes, liver function tests, calcium and phosphate, random blood glucose, thyroid function and vitamin B_{12} and folate. A more extensive range of tests may be indicated in younger people with dementia and in those with atypical presentations or signs and evidence of systemic illness. These might include plasma viscosity or C-reactive protein and autoantibodies for inflammatory disease and tumour markers for malignancy and paraneoplastic syndromes. Syphilis serology is now not carried out as a routine, but still needs to be considered. Genetic testing, for example for apolipoprotein genotype, is not yet diagnostically useful, but may be rarely indicated to look for known APP and PS-1 and PS-2 mutations when familial dementia is suspected. It should only be undertaken after appropriate counselling, preferably in collaboration with a specialist genetics service.

An electrocardiogram is desirable in any patient with possible vascular disease and in patients with a bradycardia or history of dysrhythmia who are being considered for acetylcholinesterase inhibitor (AChEI) drug treatment. An electroencephalogram is rarely indicated, but may be useful in suspected encephalitis, metabolic encephalopathy, seizures or prion disease and in confirming the presence or absence of delirium, in which it is almost always abnormal. Examination of cerebrospinal fluid is indicated in patients with suspected infectious, inflammatory, autoimmune or demyelinating disease and is used in some centres to measure amyloid and tau levels to improve diagnosis of early AD and identify patients with MCI who are more likely to convert. In normal pressure hydrocephalus (NPH), lumbar puncture may help to predict suitability for surgery. Rarely, nerve conduction studies may help to diagnose FTD associated with motor neurone disease, muscle biopsy may be useful in mitochondrial disorders and even cerebral biopsy may be justified in suspected primary cerebral vasculitis.

Neuroimaging

The role of neuroimaging in the routine management of memory clinic patients is largely determined by its availability. Certainly neuroimaging no longer merely fulfils the negative role of excluding 'treatable' conditions that mimic or cause dementia, but contributes positively to differential diagnosis and provides useful prognostic information. Depending on availability, computed tomography (CT), magnetic resonance imaging (MRI) and single photon emission computed tomography (SPECT) might all contribute to clinical care. Various other techniques are available in research centres. Recent diagnostic guidelines suggest that at least one structural CT or MRI examination should be made over the course of a dementing illness to rule out space-occupying or vascular lesions and that SPECT (or PET) may be used in cases of significant diagnostic uncertainty.[5]

Imaging with CT is probably the radiological investigation most often used in memory clinic patients, owing to its wide availability. It can show good detail of the brain structure and is especially useful in identifying dementia due to space-occupying lesions, hydrocephalus or large cerebral infarcts. Smaller lacunar infarcts are less easily seen and absence of infarcts does not exclude the possibility of vascular disease. Cortical atrophy is a common finding in older patients, not necessarily associated with clinically abnormal brain function. Some patients with AD will have a normal scan, but the presence of medial temporal lobe atrophy is usual. The presence of localized atrophy will also lend support to diagnoses of FTDs and focal syndromes such as posterior cortical atrophy. Overall, CT may be expected to impact on diagnosis and treatment in about one in eight of dementia cases.

MRI is less widely available, less tolerated by patients and more expensive than CT. However, contrast sensitivity and spatial resolution are better, even without the use of contrast agents, and it does not suffer from bone artefacts. Evidence of generalized atrophy is no more diagnostically useful than with CT, but measurement of the size of the hippocampus and entorhinal cortex plays an important role not only in diagnosis of AD, but also in identifying patients with mild cognitive impairment who are at risk of progressing to dementia. Smaller infarcts can be seen more clearly than with CT and MRI has the potential to detect focal signal abnormalities that may assist the clinical differentiation between AD and vascular dementia (VaD). Severe temporal lobe atrophy and hyperintensities involving the hippocampal or insular cortex are more frequently noted in AD. Basal ganglionic/thalamic hyperintense foci, thromboembolic infarctions, confluent white matter and irregular periventricular hyperintensities (leukoencephalopathy) are more common in VaD. Leukoencephalopathy involving at least 25% of the total white matter must be present to diagnose small-vessel cerebrovascular disease.

Functional imaging using HMPAO-SPECT allows regional cerebral blood flow to be visualized and quantified. In established AD there is a reduction of flow in mainly temporo-parietal regions, although this finding is inconsistent in the early stage of the disease when diagnosis is most problematic. In FTD, SPECT shows diminished perfusion anteriorly. In VaD, multiple focal deficits may be seen. FP-CIT SPECT distinguishes DLB and Parkinson's syndromes from AD. PET scans are largely limited to research centres. FDG-PET shows characteristic alterations in cerebral glucose metabolism early in AD and FTD. PET imaging of amyloid binding (PIB-PET) appears to be highly sensitive and specific for AD, even at preclinical stages. This seems likely to play an important role in diagnosis and treatment decisions in future years.[23]

What interventions can be offered?

At the very least, patients assessed in memory clinics should receive an informed discussion of their diagnosis and prognosis, with arrangements made for ongoing review, support and management. In a few patients, there will be a reversible cause for their symptoms (e.g. medication side effects, hypothyroidism, vitamin B_{12} deficiency, cerebral vasculitis, Wernicke–Korsakoff syndrome) that will respond to specific treatment. The proportion of patients with reversible dementia is probably less than 4%, but concurrent medical conditions causing mild cognitive disturbances are much more common and are potentially treatable.[24] Although treatment of these conditions may not always lead to complete resolution of cognitive symptoms, it is important to identify any concomitant conditions to avoid unnecessary disability and misdiagnosis.

Depression, whether primary or secondary, is especially deserving of energetic treatment, generally using a selective serotonin reuptake inhibitor (SSRI), such as citalopram or sertraline, or the noradrenergic and specific serotonergic antidepressant (NaSSA) mirtazapine, that are free of significant cognitive side effects. Even in patients with established dementia, appropriate medical intervention may help cognition and slow progression of the disease. Control of vascular risk factors, especially hypertension, may favourably influence the clinical course of both degenerative and vascular cognitive impairment. Timely use of specific drug treatments for AD and probably VaD and DLB will give significant benefit to a majority of patients taking them.

Certainly all patients with cognitive difficulties and their carers will benefit from informed discussion about their problems and appropriate psychosocial interventions.[25] Advice can be given on the appropriate use of memory aids, memory training and specific psychological interventions for patients and families. Financial and legal advice will usually be appropriate and practical suggestions to help with problems of daily living and safety concerns, particularly the advisability of continued driving. Issues surrounding advanced directives are attracting growing attention. Meeting the needs of carers is also important, by providing information, individual counselling, access to support groups and respite care through contact with local Alzheimer's organizations and relevant community services.

Diagnostic disclosure and meeting information needs

Most advocates for people with dementia and their carers now believe that, in most cases, patients should be told what is wrong with them, what the implications are, what can be done for them and what treatment is likely to involve. Breaking the news in a timely and tactful manner is an important role for memory clinic staff. Reactions of AD patients to being told their diagnosis include relief (as the diagnosis provides an explanation for their difficulties), disbelief (as they may lack insight and do not feel ill), loss (grieving for failing intellectual abilities and limitations in the future) and fear of becoming a burden. All can be satisfactorily addressed.

Practice of diagnosis disclosure amongst specialists is changing. In the 1990s, less than one-third of old age psychiatrists and geriatricians 'usually told' people with mild dementia their diagnosis, whereas recent studies report that a majority of specialists now regularly disclose diagnosis.

Memory clinic patients should be given the opportunity to learn as much or as little as they want to know about their condition, with information provided in a sensitive and measured way[26] (Table 72.5). Patients and carers both have individual needs and each should be addressed separately. In addition to clearly describing diagnosis, specific attention should be given to comprehensible and practical information about coping strategies, care services, likely course of the disease and treatment, specific drug treatment and follow-up. Wald *et al*.[27] proposed the 'rule of threes' for information provision to carers of people with dementia. At diagnosis, they want information about what dementia is, what medications are available and explanation about behavioural and psychiatric symptoms of dementia. At an early follow-up appointment, they want information about services, the course of the illness and what to do in a crisis. At a later follow-up appointment, they want information about support groups, benefits and financial and legal issues. At a later stage, they want information about psychological therapies, the effects of the illness on carers and complementary therapies.

Information giving is not only a medical responsibility. All members of the multidisciplinary team should consider every therapeutic encounter to be an opportunity for education and information provision. Dedicated time should be put aside during every memory clinic consultation for information provision – it should never be merely an after-thought at the end of the assessment. Verbal information should be backed up by written information, with recommendations for further reading. Increasingly people are turning to the Internet for more detailed information and trustworthy websites should be recommended to those interested. Mention should be made of local support groups and meetings and contact details of local Alzheimer support organizations. A telephone contact number for information and advice is always appreciated and unlikely to be abused.

Memory aids

The most simple and effective methods of helping patients with cognitive difficulties are the establishment of regular

Table 72.5 Recommendations for telling a diagnosis of dementia to patients and family.

Communication of the diagnosis should ordinarily occur in a *joint meeting with patient and family*
Use *simple language*. Avoid technical jargon that may conceal the truth
Use a graded approach that is patient led and allows the information given to be matched to what the patient wants to know
Allow sufficient time to explain and to answer questions from the patient and family
Assess the patient's and the family 's *understanding* and arrange *follow-up* (to reinforce information provided, clarify misunderstandings and answer questions that are outstanding)
Use the term 'Alzheimer's disease' (or other appropriate medical diagnosis) rather than just dementia and ensure that they understand the sense of both terms
Mellow the bad news with the possibility of therapeutic approaches (not just drugs). Avoid conveying the feeling that 'nothing more can be done'
Make it clear that a reorganized family network can *alleviate burden and maintain quality of life*
Inform the patient about the possibility of taking decisions about his/her future.

Adapted from OPDAL Study Group.[26]

routines, the careful organization of daily activities and the use of environmental cues and external memory aids. None of these require the patient to learn new strategies of thinking or remembering and may therefore be potentially useful in those with even moderately severe dementia. Written aids such as diaries, checklists and carefully positioned notes as reminders are often of benefit and reusable sticky note pads are ideal for sticking in conspicuous places. Labelling or colour coding of switches and doors may sometimes be helpful. A timer or digital alarm watch may act as a reminder to take medication, to attend to cooking or other household tasks or to refer to an appointments diary for guidance as to planned activities. In the kitchen, use of a microwave cooker may avoid food being incinerated in a conventional oven, red warning lights on electrical appliances may help to remind when they are on and use of kettles that whistle may ensure that a planned cup of tea is made and prevent open pans boiling dry. More sophisticated electronic devices and programmable organizers are generally too unfamiliar to the present generation of older people to prove useful, but assistive technology that does not require the person to operate it is attracting much interest. Such telecare can be used to monitor people's activities and trigger an alarm if there is a potential risk, such as flooding from taps left running, gas left on or leaving the house unexpectedly. Sensors and tracking devices can follow people's movements, but raise ethical issues if informed consent cannot be obtained.

Memory training

The idea of cognitive training as a method of improving, retaining or regaining skills is attractive to those worried about memory loss and to relatives who hope that developing problems might be minimized. Recent evidence suggesting that education and continued intellectual activity may reduce the risk of developing AD has further increased interest in this area. Computer-aided brain-training programmes are widely promoted, but so far they seem to meet best the needs of healthy elderly (and not so elderly) people and the worried well.

Experience of formal training programmes designed to improve the cognitive skills of healthy elderly subjects and those with cognitive deficits is limited.[28] Those most likely to gain appear to be well motivated, healthy individuals wishing to conserve their mental faculties as a prophylactic measure. There is little evidence of sustained benefit or generalizability in those with established dementia and regular tests and 'exercises' for the memory can easily become counterproductive. Positive benefits to patients may even be at the cost of increased distress to carers.

Specific approaches have included relaxation techniques, organization of material (e.g. with the use of categorization, associative cues and mnemonics), regular and repeated practice sessions, using spaced retrieval to rehearse information, techniques for improving visual imagery (e.g. peg-word methods, face–name association) and verbal strategies (rhymes, first letter cueing, alphabet searching, etc.). Reactivating therapy, including manual and creative activities, self-management skills and orientation tasks, has been claimed to improve cognitive performance and psychosocial functioning of people with mild dementia. Training in groups with other people with memory impairment or with family members and carers may provide opportunities to harness a wider range of training resources and facilitate expression of mutual support. Another approach is to involve family members in providing the cognitive training at home.

Drug treatments

Memory clinics are now central to the effective prescribing of specific anti-dementia drug treatments. Careful initial assessment and diagnosis are essential before any

pharmacological intervention is considered and the impact of treatment and the indication for its continuing use must be kept under regular review. The size of any drug effect that can be considered worthwhile is open to debate. Statistically significant improvement on psychometric tests does not necessarily equate with meaningful change in quality of life and a noticeable improvement or stabilization is more important than change in test score. Patients and carers tend to be more positive than professionals when assessing apparently small benefits of treatment, with three-quarters believing that halting progression of symptoms of early dementia for about 6 months justifies intervention. Such modest effect would seem comparable to that achieved by the drugs now available

The AChEI drugs have become the mainstay of treatment for AD and may also have benefits in mixed dementia, Parkinson's disease dementia and DLB. They act by inhibiting the breakdown of acetylcholine within the synapse, increasing its availability to muscarinic and nicotinic receptors. In mild to moderate AD, the available AChEI (donepezil, rivastigmine and galantamine) have all been shown to be clinically effective and safe compared with placebo, with improvements in cognition, ADL and overall clinical global impression. There had been some disagreement about their cost-effectiveness but NICE guidance in the UK now supports their use in mild and moderate AD.[29] All AChEIs have qualitatively similar cholinergic adverse effects, including nausea, vomiting, diarrhoea, fatigue and dizziness. These are generally mild and short-lived, resolving despite continued therapy. Caution with the use of AChEIs should be observed in the presence of bradycardia and atrial or ventricular conduction disorders. Muscle cramps, insomnia and nightmares are more common with donepezil and can sometimes be reduced by administering the drug in the morning rather than at night. About 40–60% of AD patients respond to AChEIs. Although similarities appear to be greater than the differences between the available AChEIs, it may be reasonable to consider switching drugs if patients do not tolerate or respond to the first drug used.

Memantine is a non-competitive NMDA (glutamate) receptor antagonist that blocks pathologically elevated glutamate. Glutaminergic overstimulation and consequent calcium overload have been implicated in neurodegeneration and memantine offers neuroprotection, while still allowing physiological receptor activation. The drug is licensed for treatment of moderately severe to severe AD, with patients on memantine in clinical trials showing significantly less deterioration in functional, cognitive and global measures. The emergence of troublesome behavioural symptoms, especially agitation, may also be less, with reduced need for institutionalization and less demands on caregiver time. The addition of memantine to donepezil treatment may show benefit over donepezil alone.

There are many drugs for dementia undergoing research, not only for symptomatic relief but also for disease modification, for example, through interference with amyloid or tau processing in AD and amnestic MCI. Memory clinics continue to provide an ideal setting for patient recruitment and involvement in phase 2 and 3 clinical trials and opportunities for involvement in research should be encouraged.

Over-the-counter medications that have been used to treat mild cognitive impairment and dementia include *Gingko biloba*, vitamin E, folic acid and omega-3 fish oils, but there is no good evidence of efficacy. Often patients and carers will be interested in the effectiveness of complementary and alternative medicine. These non-conventional therapies include herbal medicine, aromatherapy and massage, acupuncture, dietary supplements and melatonin and bright light therapy. The evidence base supporting their use is poor, but there have been few rigorous studies of good scientific design, with adequate patient numbers and using robust outcome measures. Patients and families are attracted by the 'natural' image of these therapies and may feel they have nothing to lose given the inadequacy of conventional treatments. Some will find considerable benefit from them and staff in memory clinics should be able to provide informed information about their safety and local availability, while not necessarily promoting their use.

The memory clinic as part of local dementia services

The World Health Organization and World Psychiatric Association consensus statement[30] on care for elderly people with mental health problems highlighted specific principles that should underpin service development. Good-quality dementia care should be comprehensive, taking into account not just the medical aspects of the problem but also the psychological and social consequences. It should be accessible and user friendly, minimizing obstacles to effective assessment and intervention. It should be responsive, listening to and understanding the problems brought to its attention, and able to act promptly and appropriately. Finally, assessment and care should be individualized, tailored to the needs of the patient and their family.

The consensus document emphasizes that a team approach is essential, not just multidisciplinary but trans-disciplinary, going beyond traditional professional boundaries and providing responsive, coordinated and community-orientated intervention. An effective memory clinic team can be the foundation of a comprehensive dementia service, encouraging early recognition and

specialist referral, providing thorough initial assessment and careful diagnosis and ensuring appropriate high-quality support and care which can be flexibly integrated with other local service providers.

Key points

- Memory clinics offer responsive assessment, diagnosis, treatment and advice for people with memory disorders and for their families. They also act as a focus for professional education and clinical research.
- Most clinics centre on diagnosis and management of mild cognitive impairment and dementia, emphasizing the benefits of early presentation, psychometric assessment, differential diagnosis, appropriate use of drug treatments and psychosocial interventions.
- They have a multidisciplinary approach, with medical, psychology and nursing input and close working relationships with other professionals and dementia services.
- Potential benefits include improved quality of life of patients, reduced carer burden, less hospitalization and possible postponement of need for institutional care.

CHAPTER 73

Alzheimer's disease

James E. Galvin
New York University Langone Medical Center, New York, NY, USA

Introduction

Alzheimer's disease (AD) is the most common form of dementia in older adults.[1] AD symptoms include a loss of memory, impaired judgment and decision-making capacity, a decline in the ability to perform activities of daily living (ADLs), changes in behaviour, mood and personality and increasing dependence on caregivers with expanding degrees of burden and stress.

Alois Alzheimer described the first case in 1906, characterizing a 51-year-old woman who presented with delusions of spousal infidelity, memory and language problems. After her death, using recently developed silver staining techniques, Alzheimer described numerous senile plaques and neurofibrillary tangles characteristic of the disease.[2] For the next 60 years, AD was thought to be an infrequent pre-senile cause of dementia until it was recognized that the clinical symptoms and course and neuropathological findings of disease in individuals younger than 65 years was identical with those found in older adults.

The Alzheimer Association estimates that there are over 5 million people in the USA with AD and that within a generation the number of AD patients will exceed 15 million people.[3] In the USA, AD is the fifth leading cause of death, after cardiovascular disease, cancer, cerebrovascular disease and bronchopulmonary diseases. AD is the third most expensive disease after cardiovascular disease and cancer in terms of total dollars with an annual total (direct and indirect) cost of approximately $172 billion. While the costs of AD increase across the stages of severity, AD patients currently fill nearly half of all nursing home beds. This economic impact will continue to grow as the US population continues to age and the number of AD patients increases. At the time of writing, the cumulative costs of care for people with AD from 2010 to 2050 in the USA will exceed $20 trillion.[3] At present, only symptomatic therapies are available that provide cognitive, functional and behavioural benefits but do not alter the disease course.

Neuropathology

Macroscopically, AD is characterized by cortical atrophy and ventricular dilatation (Figure 73.1a). Volume is most noticeable on coronal sections with shrinkage of medial temporal lobe structures including hippocampus. The characteristic pathological changes in the AD brain are the accumulation of amyloid β-protein in the form of senile plaques and of tau protein in the form of neurofibrillary tangles. Amyloid β-protein (Aβ) is a 39–43 amino acid peptide cleaved from a larger precursor protein [amyloid precursor protein (APP)] found on chromosome 21.[2] Aβ deposits extracellularly as senile plaques that can be visualized by haematoxylin and eosin staining (Figure 73.1b), with the fluorescent dye thioflavin S (Figure 73.1c), by immunohistochemistry using antibodies raised against Aβ epitopes (Figure 73.1d) or with silver impregnation (Figure 73.1e). Amyloid can appear either as loose, non-fibrillar diffuse plaques (Figure 73.1d) or a more compacted, fibrillar form (Figure 73.1b), often with dystrophic neurites coursing through the plaque (neuritic plaque, Figure 73.1e). Cerebral amyloid angiopathy (CAA) is due to the deposition of amyloid in the walls of arteries and arterioles and, less often, capillaries and veins of the central nervous system (Figure 73.1d). The walls of these vessels become very fragile and have a propensity to rupture, leading to superficial cortical haemorrhages. In addition to focal motor and sensory symptoms, repeated haemorrhages can lead to cognitive decline.

Tau protein is a microtubule-associated protein encoded on chromosome 17.[2] Its normal function is to stabilize microtubules and it has numerous sites available for phosphorylation. When hyperphosphorylated, tau forms insoluble filaments that deposit in the cell body of the neuron as a neurofibrillary tangle (NFT) and in the axons and dendrites as neurophil threads (NTs). NFTs in AD are composed primarily of paired helical filaments (two strands of 10 nm diameter filaments that twist around each other

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

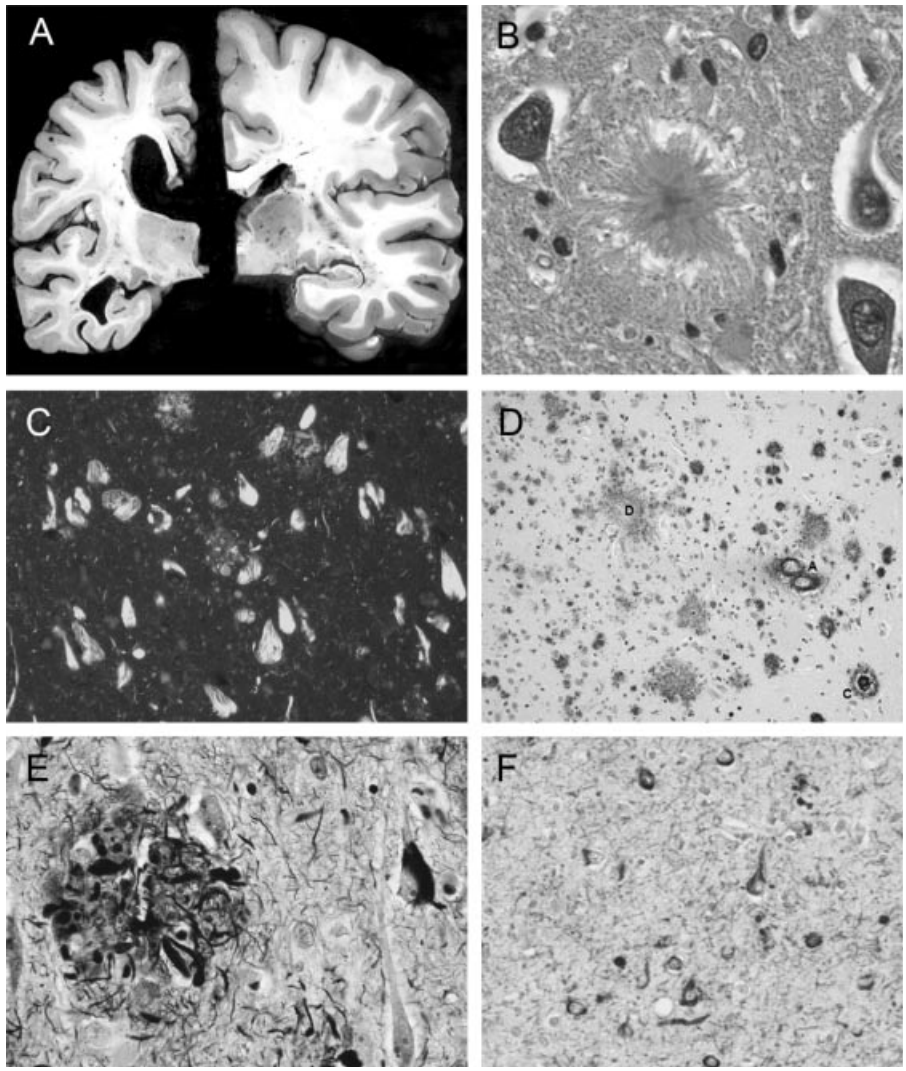

Figure 73.1 The neuropathology of AD. (a) Coronal sections of brain at the level of the hippocampus. On the left is a patient with AD, and on the right is an age-matched individual without cognitive impairment. Note the cortical atrophy and dilatation of the ventricles in the AD patient. (b) Extracellular Aβ senile plaques visualized with haematoxylin and eosin stain. (c) Thioflavin S fluorescent staining of amyloid plaques and neurofibrillary tangles. (d) Immunohistochemistry using Aβ antibodies demonstrating extracellular diffuse and fibrillar amyloid plaques and amyloid deposition in cerebral vessels. (e) Silver impregnation demonstrating fibrillar amyloid with dystrophic neurites and neurofibrillary tangles. (f) Immunohistochemistry using tau antibodies demonstrating neurofibrillary tangles and dystrophic neurites. See plate section for a colour version of these images.

like a helix). NFTs first appear in the hippocampus and entorhinal cortex in the AD brain (Figure 73.1f) and later involve the limbic and neocortex as the severity of dementia worsens. Hyperphosphorylated tau can be visualized by the same methods as amyloid since both proteins undergo transformations to a β-pleated sheet.

Epidemiology and genetics

A number of risk factors have been associated with AD (Table 73.1).[4] Age is clearly the most predictive risk factor. Although cases have been described as early as the third decade, the majority of cases occur after age 65 years. The prevalence of AD doubles each decade from 5% before age 65 years to nearly 50% at age 85 years. After age 85 years, studies are inconclusive as to whether the risk continues to increase; however, pathology characteristic of AD is frequently found in the brains of individuals over 90 years of age. In the oldest old, the course and progression of AD appear to be slower than for those individuals who develop the disease at younger ages. Family history of dementia in first-degree relatives appears to increase the risk of

Table 73.1 Alzheimer risk factors.

Age
Female gender
Family history
Low education
Head injury
Apolipoprotein E ε4 allele
Cardiovascular risk factors: hypertension, diabetes, hyperlipidaemia, homocysteine
Late-life depression
Trisomy 21 (Down syndrome)
Mutations in amyloid precursor protein (APP), presenilin 1 (PS1) or presenilin 2 (PS2)

developing AD. Up to 25% of patients are able to identify a family member with the disease. There is an association between female gender and AD that persists after correction for differences in life expectancy between men and women. The reason for this remains unknown. Earlier epidemiological studies supported a role of postmenopausal estrogen levels; however, the Women's Health Initiative found that estrogen replacement in later life increased rather than decreased the risk for AD.

Low educational attainment may also increase the risk of AD. There is increasing evidence supporting the hypothesis of cognitive reserve, that is, individuals with greater education are better able to stave off the effects of AD pathology in the early stages. Head injury associated with a loss of consciousness has been associated with increased risk of AD. Depression, particularly developing in late life, appears to be a prodromal symptom of AD. There is recent evidence to suggest that the same risk factors for cardiovascular disease may be important contributors to the risk of developing AD, including hypertension, high cholesterol, diabetes and homocysteine.[1,4] Epidemiological studies and chart-reviews have suggested that long-term use of non-steroidal anti-inflammatory drugs (NSAIDs) may reduce the risk of AD; however controlled clinical trials have failed to replicate these results and instead suggest that the use of NSAIDs may increase risks of gastrointestinal, cardiovascular and cerebrovascular disease.

There are also several genetic risk factors. The best characterized risk for late-onset disease is associated with epsilon 4 (ε4) allele of apolipoprotein E (ApoE).[5] ApoE is a cholesterol-carrying protein that may also play a role in handling of Aβ. Three isoforms of ApoE are present, ε2, ε3 and ε4. The ε3 allele is the most common, the ε2 is the least common and the ε4 allele is found in ~20% of the population. The ε4 allele is over-represented in AD, with ~60% of patients carrying at least one ε4 allele. Conversely, the presence of at least one ε2 allele appears to confer some protection. In Caucasians, compared with the ε3/ε3 genotype, individuals with one ε4 allele have a threefold increased risk whereas individuals with two ε4 alleles have a 15-fold increased risk of AD. This relationship holds true across most racial and ethnic groups.[5] The linkage between ApoE and senile plaques suggests that cholesterol homeostasis may play either a direct or indirect role in the pathogenesis. However, because the ApoE genotype is not causative, genetic testing is not recommended as it neither improve diagnostic certainty nor changes the management of the disease. Additional risk genes are being investigated and validated with genome-wide association studies.[6]

Autosomal dominant, early-onset cases of AD are associated with mutations in the amyloid precursor protein (chromosome 21), presenilin 1 (chromosome 14) and presenilin 2 (chromosome 1).[7] These three mutations appear to increase the production of the 42 amino acid long Aβ protein which has an increased propensity to aggregate. These mutations are rare, but can be suspected in a strong family history of AD with age of onset before 65 years. Even so, the mutations account for a small proportion of AD cases. The real value of the mutations has been in the creation of cell culture lines and transgenic animals that has greatly advanced research efforts. Associated with these genetic risk factors is the virtually certainty of AD developing in individuals with trisomy 21 (Down syndrome) with an additional copy of the region encoding the amyloid precursor protein. By the late 20s, Down syndrome patients begin to accumulate amyloid in their brains and nearly all patients are symptomatic by their mid-50s.[1]

Diagnostic criteria

Although AD can only be definitively diagnosed by autopsy, current clinical criteria permit experienced clinicians to make accurate diagnoses most of the time: 92% or more of the time, an expert clinician's diagnosis is confirmed by autopsy findings. The diagnosis of AD is one of inclusion using standardized clinical criteria: the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR)[8] and the National Institute on Ageing – Alzheimer's Association (NIA-AA).[9] The DSM criteria are broader in nature and capture more impaired individuals whereas the NIA-AA criteria apply more rigorous definitions that incorporate new findings regarding the use of biological markers of disease. In general, the current diagnostic criteria are characterized by a two-step procedure with (1) the identification of a dementia syndrome and (2) the exclusion of other aetiologies of a dementia syndrome, using biological and neuroimaging examinations.

The diagnosis can also be based on the criteria of the DSM-IV-TR[8] (Table 73.2). According to the DSM, the essential feature of dementia is impairment in short- and long-term memory, associated with impairment in abstract thinking, impaired judgment, other disturbances of

Table 73.2 DSM-IV criteria for dementia of the Alzheimer type.

The development of multiple cognitive deficits manifested by both
1 Memory impairment (impaired ability to learn new information or to recall previously learned information)
2 One or more of the following cognitive disturbances:
a Aphasia (language disturbance)
b Apraxia (impaired ability to carry our motor activities despite intact motor function)
c Agnosia (failure to recognize or identify objects despite intact sensory function)
d Disturbances in executive functioning (i.e. planning, organizing, sequencing, abstracting)
The cognitive decline causes significant impairment in social or occupational functioning and presents a decline from a previous level of functioning
The course is characterized by gradual onset and continuing cognitive decline
The cognitive deficits above are not caused by any of the following:
1 Other central nervous system conditions that cause progressive deficits in memory and cognition
2 Systemic conditions that are known to cause dementia
3 Substance abuse conditions
The deficits do not occur exclusively during the course of a delirium
The deficits are not better accounted for by another Axis I disorder (depression, schizophrenia)

Adapted from American Psychiatric Association, Task Force on DSM-IV. *Diagnostic and Statistical Manual of Mental Disorders: DSM-IV*, 4th edn, American Psychiatric Association, Washington, DC, 1994.

higher cortical function or personality change. Disturbances in these cognitive domains should be severe enough to interfere with social or occupational functioning or disrupt interpersonal relationships with others. An important caveat in the DSM criteria is that the diagnosis cannot be made in the presence of a delirium.[8] There are plans to update the DSM criteria but these are not available at the time of writing.

According to NIA-AA guidelines, the diagnosis is first established by determining the presence of dementia. Dementia is defined as cognitive or behavioural symptoms that (1) interfere with social or occupational functioning, (2) represent a decline from previous level of functioning and (3) are not explained by another disorder. Dementia is established by a combination of a detailed history from the patient and a knowledgeable informant and an objective assessment of cognitive ability. Changes in cognitive ability should involve at least two of the following domains: memory, reasoning and problem solving, visuospatial abilities, language and/or changes in personality, behaviour or social comportment. Once the dementia syndrome is established, the diagnosis of probable AD can be made when the patient has (1) dementia, (2) an insidious onset with gradual progression and (3) worsening of symptoms over time either by observation or report of patient and/or informant. The presentation of deficits can either by amnestic (memory impairment) or non-amnestic (language, visuospatial, executive dysfunction).[9] The diagnosis of AD should not be applied when there is clear evidence of cerebrovascular disease, Lewy body dementia, frontotemporal degeneration or another concurrent neurological, psychiatric or medical condition that can affect condition.[9] If the patient meets criteria for probable AD but has evidence of other disorders that can affect cognition, a mixed dementia syndrome is most likely present.

More importantly, the NIA-AA criteria take into consideration the role of biological markers of disease (biomarkers).[10] Recent advances in biomarker research such as magnetic resonance imaging (MRI), positron emission tomography (PET) scans and cerebrospinal fluid (CSF) biomarkers characterize the underlying pathophysiological processes associated with AD such as evidence of Aβ deposition measured by CSF Aβ levels or PET scans or markers of neuronal injury by CSF tau levels, glucose hypometabolism by PET or cortical atrophy by MRI.[9] Although the use of biomarkers is not advocated for routine clinical use, these tests may increase the diagnostic certainty of AD in difficult cases (Table 73.3).[9]

Evaluation of the AD patient

Clinical evaluation

Knowing that the risk of AD increases with age, older adults are a natural choice for screening for AD. At present, however, there are no formal recommendations for or against dementia screening. The US Preventive Services Task Force (http://www.ahrq.gov/clinic/3rduspstf/dementia/dementrr.pdf) concluded that the evidence is insufficient to recommend for or against routine screening for dementia in older adults. Many of the current brief screening measures such as the Mini-Mental State Examination (MMSE)[11] have good sensitivity but only fair specificity in detecting cognitive impairment and dementia.[12,13] The accuracy of the MMSE depends on a person's age and educational level: using an arbitrary cut-point (typically $\leq$23) may potentially lead to more false-positives among older people with lower educational levels and more false negatives among younger people with higher educational levels.[12]

On the other hand, the early recognition of dementia, in addition to helping make diagnostic and treatment decisions, allows clinicians to anticipate problems the patients may have in understanding and adhering to recommended therapy. Early diagnosis is also beneficial to the patient's caregiver(s) and family member(s) in helping to anticipate

Table 73.3 Probability of AD with biomarkers (NIA-AA criteria).[a]

and plan for future problems that may develop as a result of progression of cognitive impairment and for long-term care. Long-term care planning and advanced care decisions are important in all forms of chronic diseases, many of which are treated by neurologists and psychiatrists. Discussions covering these topics early in the course of chronic disease should probably be considered part of the norm, rather than the exception. Organizations such as the American Medical Association, American Geriatrics Society, American Academy of Neurology and American Academy of Family Physicians all recommend that clinicians remain diligent in the early identification of symptoms of AD in their patients.

So who should be evaluated for AD? The Alzheimer Association has published 10 warning signs of symptoms that are most commonly seen in AD (Table 73.4).[3] Although not every individual needs to be extensively worked up, developing a working list of reasons to consider AD as a possible diagnosis is reasonable (Table 73.5). Individuals with identified risk factors warrant further evaluation, as do individuals with memory complaints, with or without functional impairment. Additionally, even if an individual does not complain of memory or cognitive problems, informant complaints (spouses, adult children) should trigger further investigation. Evaluation should include a detailed history from the patient in addition to another source (spouse, caregiver, adult child) to gain insight into how the patient has changed from prior level of function. Historical points should highlight memory impairment (repetition; trouble remembering recent conversations, events, appointments; frequently misplacing items), executive function (deterioration of complex task performance; decreased ability to solve problems; difficulty with calculations; impaired driving), use of alcohol, prescription drugs and over-the-counter medications and the presence of focal neurological symptoms. A complete neurological examination will help to identify other causes of dementia (Table 73.6). Characteristic features of the four most common causes of dementia are given in Table 73.7 to help with differentiation.

Cognitive evaluation

Performance-based tools

In terms of assessing cognitive function, the 30-item MMSE test, which takes around 10 min to complete, has frequently been used for initial assessment of AD, and its sensitivity increases if a decline of the score over time is taken into account.[11] The MMSE covers six areas: (1) orientation, (2) registration, (3) attention and calculation, (4) recall, (5) language and (6) ability to copy a figure. However, although the MMSE is quick and easy to administer and can track the

overall progression of cognitive decline, it is not considered to be a good test for definitive AD diagnosis,[14] particularly because of its greater emphasis on orientation (10 of 30 points), which is typically not impaired in the earliest stages of dementia. In addition, there are several issues associated with the MMSE, including bias according to age, race, education and socioeconomic status.[15]

Several diagnostic tests are now available for use in primary care as alternatives to the MMSE; these are continually being updated and simplified in order to provide brief, easy to administer and effective diagnostic tools.

The Mini Cognitive Assessment Instrument (Mini-Cog) combines an uncued three-item recall test with a clock-drawing test that serves as a recall distractor; it can be administered in about 3 min and requires no special equipment.[15] The Mini-Cog and the MMSE have similar sensitivity (76 versus 79%) and specificity (89 versus 88%) for dementia, comparable to those achieved using a conventional neuropsychological battery (75% sensitivity, 90% specificity). The Mini-Cog's brevity is a distinct advantage when the goal is to improve recognition of cognitive impairment in primary care, particularly in milder stages of impairment.[15] It has also been suggested that cognitive impairment assessed by the Mini-Cog is a more powerful predictor of impaired ADLs than disease burden in older adults. In addition, the Mini-Cog also has proven good performance in ethnically diverse populations of the USA in which widely used cognitive screens often fail, and is easier to administer to non-English speakers.[15] Furthermore, low educational status, which has been shown to impair

Table 73.7 Characteristic features of the four leading causes of dementia.

Cause of dementia	Symptoms
Alzheimer's disease	Early failure of information storage and new memory creation. Disturbances in attention. May include early language or behavioural disturbances
Frontotemporal dementia	Early behavioural disturbances, particularly social misconduct and eating changes. Early language problems that may be fluent or non-fluent
Lewy body dementia	Early extrapyramidal signs (slowness, stiffness, tremor), visual hallucinations, visuospatial impairment, REM sleep behavioural disorders and fluctuations in attention and concentration
Vascular dementia	Early executive dysfunction usually associated with a focal neurological sign. Presence of vascular lesions in neuroimaging and temporal relationship between focal neurological signs and onset of cognitive symptoms

detection using the MMSE, does not affect the Mini-Cog, which is thus less biased by low educational status and literacy level.

Newer instruments, such as the Montreal Cognitive Assessment (MoCA), are gaining credibility owing to improvements in sensitivity, addressing frontal/executive functioning and decreasing susceptibility to cultural and educational biases.[16] The MoCA is a 10 min cognitive screening tool developed to assist first-line physicians in the detection of MCI. It has high sensitivity and specificity for detecting MCI in those patients who perform within the normal range of the MMSE. Compared with the MMSE, which had a sensitivity of 18% to detect MCI, the MoCA detected 90% of MCI subjects and, in patients with mild AD, the MMSE had a sensitivity of 78%, whereas the MoCA detected 100%.[16]

Informant-based tools

Another key test used in primary care is the AD8 screening interview, which is a brief, sensitive measure that reliably differentiates between individuals with and without dementia by querying memory, orientation, judgment and function.[12,13] The AD8 (Table 73.8) comprises eight Yes/No questions asked of an informant to rate change and takes ~2–3 min for the informant to complete. In the absence of an informant, the AD8 can be directly administered to the patient as a self-rating tool. The AD8 has a sensitivity of 74–80% and a specificity of 80–86%, with excellent ability to discriminate between non-demented older adults and those with mild dementia (92%), and is highly correlated with AD imaging and CSF biomarkers.[13] Use of the AD8 in conjunction with a brief assessment of the participant, such as a word list, could improve the detection of dementia in the primary setting to 97% for dementia and 91% for MCI.[12]

Laboratory Evaluation

In terms of laboratory evaluation for dementia, testing for comorbid medical illnesses that may cause or contribute to onset or progression of dementia is generally recommended.[17] Depression is a common, treatable comorbidity in patients with dementia and should be screened for in older adults. Vitamin B_{12} insufficiency is common in the elderly and vitamin B_{12} levels should be included in routine assessments of the elderly, but screening for other vitamin and nutritional deficiencies is not recommended unless historical information suggests these deficiencies as a clinical possibility. Because of its frequency, hypothyroidism should be screened for in elderly patients. Lastly, unless the patient has some specific risk factor or evidence of prior syphilitic infection or resides in one of the few areas in the USA with high numbers of syphilis cases, screening for the disorder in patients with dementia is generally not justified.[17] This includes collecting spousal history of exposure when applicable.

Genetic testing for patients with suspected dementia is not recommended unless there is clear, generational evidence of an autosomal dominant form of dementia. Even then, genetic counselling is recommended, prior to testing. The routine use of ApoE genotyping in patients with suspected AD is not recommended at present because of cost and because it adds little to the diagnostic accuracy.[17] In patients with clinical diagnoses of AD, the addition of ApoE testing increased the positive predictive value (using the prevalence of AD in this dementia autopsy series) of a diagnosis of AD by ~4% (from 90 to 94%) if an ApoE ε4 allele was present. In patients with a clinical diagnosis of non-AD, the absence of an ApoE ε4 allele increased the negative predictive value by 8% (from 64 to 72%).[18] No other serum or CSF biomarkers have established clinical validity at present and are therefore not recommended, although this is likely to change in the future.

Making the diagnosis

As shown in the algorithm in Figure 73.2, each of the above steps can help to identify the patient-at-risk, establish a likely diagnosis and further treatment recommendations. After establishment of a diagnosis of possible or probable

Table 73.8 The AD8 dementia screening test.

Remember, 'Yes, a change' indicates that there has been a change in the last several years caused by cognitive (thinking and memory) problems	**YES, a change**	**NO, no change**	**N/A, don't know**
1. Problems with judgment (e.g. problems making decisions, bad financial decisions, problems with thinking)			
2. Less interest in hobbies/activities			
3. Repeats the same things over and over (questions, stories or statements)			
4. Trouble learning how to use a tool, appliance or gadget (e.g. VCR, computer, microwave, remote control)			
5. Forgets correct month or year			
6. Trouble handling complicated financial affairs (e.g. balancing chequebook, income taxes, paying bills)			
7. Trouble remembering appointments			
8. Daily problems with thinking and/or memory			
TOTAL AD8 SCORE			

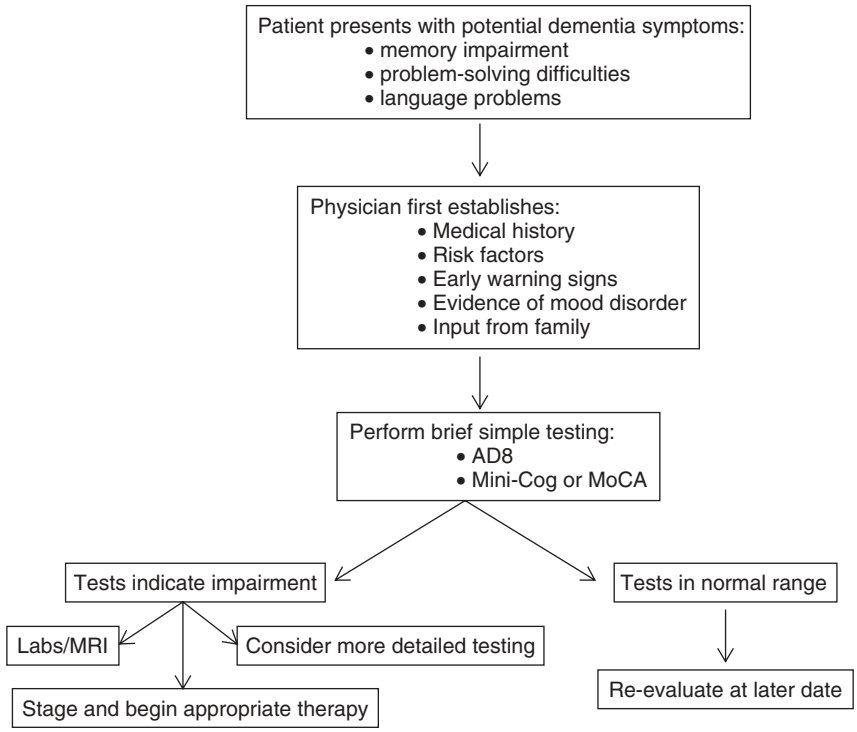

Figure 73.2 Algorithm for the diagnosis of AD in the office setting. This algorithm outlines steps for evaluating older adults for AD or other causes of cognitive impairment. Upon presentation of a patient with dementia-related symptoms elicited by from the patient or caregiver, the physician should first review the medical history to discover the onset, presentation and progression of symptoms, review potential risk factors and evaluate for confounding conditions such as depression. Simple office testing with a performance measure (Mini-Cog or MoCA) and an informant questionnaire (AD8) will enhance the clinician's ability to detect early impairment. If the patient performs in the normal range, periodic reassessment is warranted. If tests indicate cognitive impairment, the clinician should complete the work-up with routine laboratory tests to rule out reversible causes of dementia and neuroimaging. Additionally, the physician can refer to a specialist for more detailed neuropsychological testing. If AD is suspected, the patient should be staged and started on appropriate therapies and referral to community resources.

AD, the patient should be staged to assist in selection of appropriate pharmacotherapies, make referrals to community resources and assist in prognosis (Table 73.9).

There are barriers to the early detection of dementia for the clinician to consider. The first is misidentification of the early stages of dementia by patients and family members as the normal ageing process.[1] Forgetfulness is not a normal part of ageing but is often accepted as an inevitable consequence of growing old. If a patient or family member does not perceive the presence of a memory disorder, they are much less likely to come to medical attention until more advanced stages. A second issue is that social skills are often maintained in the early stages of AD. If a person lives alone, friends and acquaintances may not be able to detect cognitive decline due to lack of exposure. This and the fact of denial and lack of insight by the patient as to the extent of the cognitive problems may also lead physicians to miss early stages of dementia since the patient may not complain and cognitive screening is not part of a routine medical visit in most instances. Even if symptoms are identified by the patient and/or the family, there may be a reluctance to report them due to the social stigma of being diagnosed

Table 73.9 Simple staging scheme for AD.

Stage[a]	Characteristics	Example signs
Mild MMSE 19–27 CDR 0.5 or 1 GDS 3 or 4	• Symptoms are subtle • Self-care capacity, social skills and neurological function remain generally intact • Difficulty with complex tasks; if still working, a decline in job performance • Depression and apathy	• Repeating questions, statements or stories • Misplacing items • Forgetting recent events or conversations • Trouble operating household appliances • Less interest in hobbies
Moderate MMSE 10–18 CDR 2 GDS 5 or 6	• Ability to think, reason, communicate and function deteriorates dramatically • Beginning of behavioural symptoms	• Difficulty in using household appliances • Unable to travel alone • Difficulty in telling time • Restlessness, wandering, insomnia
Severe MMSE 0–9 CDR 3 GDS 7	• Individuals lose capacity for self-care and become completely dependent • Long-term care placement common	• Difficulty in eating, dressing • Incontinence • Cannot answer the telephone • Gait disturbances • Aggression, agitation, irritability

[a]MMSE, Mini-Mental State Examination; CDR, Clinical Dementia Rating; GDS, Global Deterioration Scale.

with AD. The diagnosis can also have consequences for obtaining insurance, employment and driving privileges. These factors can all contribute to delay in diagnosis and should be discussed with the patient and caregiver.

Biomarkers of AD

Cerebrospinal fluid biomarkers

According to the NINCDS–ADRDA guidelines, CSF examination is recommended as an exclusion procedure, largely undertaken to rule out other potentially correctable causes of cognitive decline, such as infection.[9] Since then, research has focused on the validity of AD-specific biomarkers that are reflective of the central pathogenic processes of β-amyloid aggregation and hyperphosphorylation of tau protein. These markers have included β-1–42-amyloid, total tau and phospho-tau: a decrease in the β-1–42-amyloid peptide and an increase in the tau and phospho-tau proteins may be the earliest signs of AD.[13,19] Indeed, both tests produce results with very good sensitivity and specificity. However, at present, these tests are probably not an option owing to patients' reluctance to undergo lumbar puncture and the costs associated with the assays.

Structural brain imaging

Structural brain imaging tests, which include non-contrast computed tomography (CT) or MRI, can evaluate changes consistent with AD and eliminate alternative causes of cognitive impairment.[17] Whenever possible, an MRI scan will provide a greater assessment of regional atrophy and periventricular vascular changes than can be gained from a CT scan. Quantitative MRI and PET amyloid imaging are recent techniques currently being developed to diagnose AD earlier in clinical practice. Within an AD diagnostic framework, the ideal role of structural brain imaging tests is to increase the specificity of clinical criteria.[17]

Functional brain imaging

PET scanning appears to have promise for use as an adjunct to clinical diagnosis, but further prospective studies with PET are needed to establish the value that it brings to diagnosis over and above a competent clinical diagnosis. One of the largest series of dementia cases that underwent PET scans and also had autopsy confirmation yielded a sensitivity of 93% and a specificity of 63%.[20] PET diagnostic accuracy increases with more advanced stages of dementia (87.2% for MMSE score >20 and 100% for MMSE score <20).[21] There are somewhat specific patterns of brain hypometabolism for each dementia subtype. In AD, hypometabolism is noted in the posterior temporoparietal cortices.[21] Fluorodeoxyglucose (FDG) PET may also be superior to MRI measures of hippocampal atrophy because changes in cerebral glucose metabolism antedate the onset of memory decline, whereas the MRI hippocampal changes may not reflect early disease.

Management

Disclosing the diagnosis

Disclosure of the diagnosis of AD to the patient and family may be difficult and consideration of the emotional

responses should be taken into account. A family conference may be the most appropriate setting and the physician should be prepared to answer questions from the patient and family regarding the certainty of the diagnosis, the prognosis and implications for care. Recent research suggests that there is little long-term psychological effect of disclosing an AD diagnosis and both caregiver and patient self-ratings of depression and anxiety may be alleviated by having a frank, honest discussion about the disease.[22]

Setting treatment goals

Setting realistic treatment goals is critical to increasing patient and caregiver adherence. Because the currently available medications are symptomatic, it is important that the patient and family do not leave the physician's office under the impression that they will 'get better' by taking the medications. Although some patients do show improvement in different cognitive areas, the goal of current therapy for AD is to stabilize the patient for a period of time or to progress at a slower rate. As each patient has unique living and social situations, the clinician can work with the family to set expectations and discuss the limitations of current therapy.

Therefore, treatment goals should be discussed at the time of diagnosis. The first is to establish realistic expectations of treatment and review the course and complications of the disease. Goals should be set to (1) maintain quality of life, (2) maximize function and ADLs, (3) stabilize cognition, (4) treat mood and behavioural problems and (5) reduce caregiver burden.[1] Other discussion topics should include advanced directives, financial planning, referral to community resources, driving, durable power of attorney and discussion of long-term care planning. Addressing issues early in the diagnosis will empower the patient and caregiver to participate in the decision-making process.

Currently available management options for dementia

Although current pharmacological and behavioural interventions do not prevent eventual disease progression, they arguably lead to improvements in understanding, self-efficacy and quality of life for the patient and family. Recognizing dementia in its early phase may provide substantial benefits, including financial, medical and legal planning. It will also enable patients, their families and their caregivers to understand and deal better with the nature of the condition and subsequent changes in behaviour, allow caregivers to become familiar with appropriate support and social services and help maintain patients' functioning at the highest level possible.[23]

Managing mood disorders and behaviour problems

Traditionally, cognitive function has been the main focus of interest in treatment and research for people with dementia. It is becoming increasingly recognized, however, that non-cognitive symptoms are those that are most disturbing to families and caregivers and may seriously impact not only the patient's wellbeing, but also the family's, caregivers' and providers' approaches to managing the patient.[24] The most common symptoms are agitation, aggression, mood disorders/behavioural disturbance, apathy, depression, psychosis and hallucinations, with sexual disinhibition, elation/euphoria, appetite and eating disturbances and abnormal vocalizations occurring less frequently.[1,24] These have been grouped together under the umbrella term 'behavioural and psychological symptoms of dementia' by the International Psychogeriatric Association.[25] As the disease progresses, these symptoms become predominant problems and impose an enormous toll both emotionally and financially. They are also a common reason for institutionalization of people with dementia and they increase the burden and stress of caregivers.

Non-pharmacological interventions

Non-pharmacological interventions are recommended as the most appropriate initial strategy for managing inappropriate behaviours in dementia for the following reasons: (1) they address the psychosocial/environmental underlying reason for the behaviour and (2) they avoid the limitations of pharmacological interventions, namely adverse side effects, drug–drug interactions and limited efficacy.[24,26] Increased involvement of caregivers often has a secondary benefit of providing overburdened caregivers with an opportunity to receive support, information and skills. Further, environmental factors (e.g. confusing or noisy surroundings) or interpersonal factors (e.g. arguing with the patient) are often the primary triggers of behavioural problems. Attention to these factors through non-pharmacological approaches can be effective in alleviating or preventing behavioural problems in individuals with dementia. Unfortunately, in practice, pharmacological approaches involving psychotropic or sedative medications are often used as the first-line treatment, despite the modest evidence of efficacy from clinical trials where high placebo response rates are frequently seen, rather than first attempting a non-pharmacological approach.

An increasing number of non-pharmacological therapies are now available for people with dementia (Table 73.10). It should be noted that there are several areas of overlap between these therapies, hence each approach is rarely

Table 73.10 Non-pharmacological approaches and principles to behavioural therapies.

Standard therapies
Behavioural therapy
Reality orientation
Validation therapy
Reminiscence therapy
Alternative therapies
Art therapy
Music therapy
Activity therapy
Dance therapy
Aromatherapy
Bright-light therapy
Multisensory approaches
Brief psychotherapies
Cognitive behavioural therapies
Interpersonal therapy
Reducing behavioural symptoms
Provide the patient with a predictable routine (e.g. exercise, meals and bedtime should be routine and punctual)
Allow the patient to dress in his or her own clothing and keep possessions
Ask permission before touching patient or their belongings
Explain instructions to the patient in simple language
Simplify tasks; break up a complex task into steps and provide instruction for each step
Use distraction and redirection of activities to divert the patient's attention
Ensure that comorbid conditions are optimally treated
Provide a safe environment (e.g. no sharp-edged furniture, no throw rugs)
Equip doors and gates with safety locks
Install grab bars by the toilet and in the shower
Use calendars, clocks, labels and newspapers for orientation to time
Use colour-coded or graphic labels as cues for orientation in the home environment
Use lighting to reduce confusion and restlessness at night
Avoid glare from windows and mirrors, noise from a television and household clutter
Reduce excess stimulation and outings to crowded places
Consider using a day-care programme

used in isolation. It is therefore important for a clinician to have some knowledge of a number of these approaches, enabling a combination of treatments tailored to the individual requirements of the patient to be offered.[24] Therapy is now directed towards person-centred forms of care and, using this approach, greater attempts are made to understand the individual's experience of dementia and to employ strategies to improve quality of life.[26]

Pharmacological interventions

There are currently no means of reversing the pathological processes of AD. Therefore, the specific goals of therapy are to preserve cognitive and functional ability and to minimize behavioural disturbances and slow disease progression with maintenance of patients' and caregivers' quality of life. Early initiation of cholinesterase inhibitors (ChEIs) may temporarily stabilize or delay disease progression, which provides obvious desirable benefits for patients and caregivers. Studies have shown that both caregiver burden and overall cost are reduced by anticholinesterase therapy.[27] Beneficial response to a ChEI (i.e. stabilization or delayed deterioration of cognitive or behavioural problems) may be assessed from the physician's global assessment of the patient, the primary caregiver's report, a neuropsychological assessment or mental status questionnaire or evidence of behavioural or functional changes.

Five drugs have been approved for treating AD: four ChEIs approved for mild to moderate disease, one of which is also approved for severe AD, and a glutamate *N*-methyl-D-aspartate (NMDA) antagonist approved for moderate to severe disease (Table 73.11).

Mild to moderate disease

ChEIs have been the cornerstone of treatment for patients with mild to moderate AD for over a decade. Four ChEIs are currently available: tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon) and galantamine (Reminyl). These agents raise acetylcholine levels in the brain by inhibiting acetylcholinesterase, they tend to stabilize memory during the first year of treatment and they may slow the subsequent decline.

The systematic reviews and randomized controlled trials carried out to date, all of which involved at least 6 months of follow-up, found a significant difference that favoured the ChEI compared with placebo, ranging from 2.12 to 3.4 points on the ADAS-Cog scale. Donepezil 5 and 10 mg per day doses have been associated with significant improvements of–2.01 and–2.80 points, respectively, on the ADAS-Cog scale at 24 weeks, compared with placebo; donepezil 10 mg per day was also associated with a significant 1.84-point improvement over placebo on the MMSE at 52 weeks.[28] In addition to their effects on cognition, these agents have also demonstrated beneficial effects on measures of behaviour, ADLs and global patient function.

A meta-analysis which analyzed clinical results from 29 randomized, placebo-controlled trials of patients with mild to moderate AD found that ChEI therapy was associated with significant modest benefits in terms of neuropsychiatric and functional outcomes.[29] Current guidelines acknowledge that preventing or delaying further loss

Table 73.11 Pharmacological therapies for AD.

Drug	Approved indication	Suggested dosage	Side effects	Additional notes/caution
Cholinesterase inhibitors				
Tacrine (Cognex)	Mild to moderate AD	Four times daily dosing regimen	Poor tolerability and significant hepatotoxicity	Second-line agent owing to pharmacological characteristics and side effects Causes elevation of liver enzyme levels in 40% of patients; therefore, biweekly liver tests are necessary during dosage escalations and every 3 months thereafter
Donepezil (Aricept)	Mild to severe AD	Once daily, beginning with 5 mg per day, which can be increased to 10 mg per day (maximum dosage) after 4 weeks. Also available as an oral disintegrating tablet	Adverse effects are mild and include nausea, vomiting and diarrhoea	Gastrointestinal-related adverse effects can be reduced if the medication is taken with food Some patients exhibit an initial increase in agitation, which subsides after the first few weeks of therapy
Rivastigmine (Exelon)	Mild to moderate AD	*Oral* Twice daily, beginning with 1.5 mg twice daily. Also available as a 2 mg ml^{-1} oral solution *Transdermal patch* Once daily, 4.6 or 9.5 mg The target dose is 9.5 mg per 24 h patch (a 10 cm^2 patch) and requires a simple one-step dose titration to the therapeutic dose	Adverse effects include nausea, vomiting, diarrhoea, weight loss, headaches, abdominal pain, fatigue, anxiety and agitation. Gastrointestinal-related adverse effects less prominent with patch	Higher dosages are more efficacious than lower dosages No laboratory monitoring is required
Galantamine (Razadyne)	Mild to moderate AD	Twice daily, beginning with 4 mg twice daily After 4 weeks, the dosage is increased to 8 mg twice daily to a maximum of 12 mg twice daily Available in an extended-release formulation (8, 16 and 24 mg) that can be taken once daily. Also available as a 4 mg ml^{-1} oral solution	Most common side effects are nausea, vomiting and diarrhoea	Gastrointestinal-related adverse effects can be minimized by titrating the dosage gradually and taking the medication with meals
NMDA antagonists				
Memantine (Namenda)	Moderate to severe AD	Twice daily, beginning with 5 mg twice daily, increasing the dose to 10 mg twice daily over 3 weeks	Adverse effects include fatigue, pain, hypertension, headache, constipation, vomiting, back pain, somnolence	Moderate to severe AD may respond better with memantine–donepezil combination than with donepezil alone

of ADL function is an important goal of AD therapy and significant preservation of ADL function has been observed with donepezil, galantamine and rivastigmine compared with placebo. Patients treated with ChEIs and/or memantine may also experience behavioural benefits in terms of reduced severity of existing behavioural disturbances and fewer new behavioural symptoms, usually agitation/aggression and irritability, whereas depression, apathy and anxiety do not respond.[27] In an open-label study using the neuropsychiatric inventory (NPI), donepezil was shown to reduce significantly the severity of neuropsychiatric symptoms in patients with mild to moderate AD (mean total score: 25.4 versus 15.2 at baseline versus 12 weeks; $p<0.001$). With the exception of elation, all domains of the NPI were significantly improved from baseline. During the subsequent 12 week period, in which patients either continued with donepezil therapy or switched to placebo, these improvements were sustained with donepezil therapy, whereas patients receiving placebo experienced significant worsening in NPI scores.[30]

ChEIs have also been shown to reduce AD caregiver burden: in patients with moderate to severe AD, donepezil treatment for 24 weeks significantly reduced caregiver time spent assisting patients with basic and instrumental ADLs (–52 min per day; $p<0.005$). A small study has demonstrated that rivastigmine treatment reduces caregiver time spent assisting with ADLs (up to 690 h over 2 years).

Long-term treatment with ChEIs may also decrease the risk for nursing home placement.[31] A retrospective analysis of a large US medical claims database showed that over a 27 month follow-up period, more patients who were not treated with ChEIs were placed in nursing homes (11.0%) than those who received either rivastigmine (3.7%) or donepezil (4.4%).[32] These studies suggest that ChEIs enable patients to live longer in community settings, with associated personal, social and economic benefits.

Moderate-to-severe disease

Memantine is approved for the treatment of moderate to severe AD, based on a study in which patients with moderate to severe AD who received 20 mg memantine monotherapy showed less decline in cognition and function, while maintaining good tolerability, after 6 months than those who received placebo.[32] The ChEI donepezil has also recently been approved for use in severe AD. Donepezil has also been associated with reduced burden for caregivers of patients with moderate to severe AD. In one trial, the caregivers of patients receiving donepezil therapy reported spending almost 1 h less per day on assisting with ADLs than the caregivers of placebo-treated patients.[33]

There is also evidence that combination therapy with ChEIs plus memantine improves clinical and functional outcomes compared with placebo or ChEIs alone.[34]

Medical foods

Medical foods represent a new alternative to be considered for integration into a comprehensive therapeutic regimen for patients with AD. They comprise a US Food and Drug Administration (FDA)-regulated product defined by Congress as part of the Orphan Drug Act. Such products currently being marketed in the USA for the management of dementia include Axona (caprylic triglyceride) and CerefolinNAC. Other medical foods are also being developed, such as Souvenaid.

Axona has been developed for the clinical dietary management of the metabolic processes associated with mild to moderate AD. It is a formulation of caprylic triglyceride, a medium-chain triglyceride that is metabolized to ketone bodies, predominantly β-hydroxybutyrate (BHB). BHB is a common metabolic substrate that is normally produced by the body for neurons in starvation states where glucose is less available.[35] A double-blind crossover study conducted in patients with AD or MCI demonstrated that Axona therapy was associated with significant improvements in ADAS-Cog; however, the effect was only seen in patients who were ApoE ε4 non-carriers. Similar results were reported in a 90 day randomized, placebo-controlled study in patients with mild to moderate AD.[35] Gastrointestinal disturbances were the most commonly occurring adverse events in the clinical trials. In the 90 day study, one-quarter of patients taking Axona experienced diarrhoea compared with 14% in the placebo group. Gastrointestinal side effects are reportedly reduced by administration of Axona with a meal or mixing it with a drink.

CerefolinNAC, which contains L-methylfolate, methylcobalamin and *N*-acetylcysteine, is indicated for the distinct nutritional requirements of individuals under a physician's treatment for neurovascular oxidative stress and/or hyperhomocysteinaemia, including patients diagnosed with AD. The efficacy of its ingredients regarding cognitive performance has been assessed in various trials.[36]

Souvenaid combines omega-3 fatty acids, choline, uridine monophosphate and a mixture of antioxidants and B vitamins. In a randomized controlled trial involving more than 200 patients with very mild AD, Souvenaid was well tolerated and improved memory, compared with placebo.[37]

Behavioural management

Behavioural management with psychotropic agents

Pharmacological interventions are necessary when non-pharmacological strategies fail to reduce behavioural symptoms sufficiently. Although ChEIs and memantine may improve these symptoms, if behavioural disturbances persist despite their use then a psychotropic agent may be necessary.

If a psychotropic agent is needed, the rule 'start low and go slow, but go' (i.e. the agent should be initiated

in a low dosage that should be increased slowly) should be followed and the patient should be closely monitored for side effects and adverse events. The dosage should be increased until an adequate response occurs or side effects emerge; potential drug interactions should also be considered. After behavioural disturbances have been controlled for 4–6 months, the dosage of psychotropic agent should be reduced periodically to determine whether continued pharmacotherapy is required. The choice of psychopharmacological agent is determined by specific target symptoms; some behaviours, such as wandering and pacing, are not amenable to drug therapy.

Atypical antipsychotics

Atypical antipsychotic drugs have been commonly used off-label in clinical practice for the treatment of serious dementia-associated agitation and aggression, although they have not been approved by the FDA for such use. The FDA analysis of the 17 registration trials across six antipsychotic drugs indicated a statistically significantly elevated risk of death in drug-treated patients (either heart-related or from infections) that was 1.6 times greater than in placebo-treated patients. These findings should be taken seriously by clinicians in assessing the potential risks and benefits of treatment in a generally frail population and in advising family members about treatment options. In general, psychotropic agents should be used only when non-pharmacological approaches have failed to control serious behavioural disruption adequately within 5–7 days.[38] A useful rule of thumb is that a behaviour needs to addressed pharmacologically when that behaviour interferes with patient care, patient safety or the safety of another individual. At all times, the prescriber in conjunction with the patient and caregiver should address the benefit–risk balance in this patient population. Other concerns regarding the use of antipsychotics involve a higher incidence of side effects in elderly patients, including sedation, falls and extrapyramidal signs, with recommendations that their use in this patient population should be carefully monitored.

Additional options for pharmacotherapy include trazodone, carbamazepine and valproate, although the data are inconclusive. Tricyclic antidepressants, antihistamines and benzodiazepines should be generally avoided in this population. Selective serotonin reuptake inhibitors appear to have efficacy for the treatment of agitation in patients with AD. Studies have demonstrated benefits for agitation with citalopram, compared with placebo, and similar efficacy, compared with risperidone.[39]

Future therapies

ChEIs and memantine are symptomatic therapies that help maintain neuronal function but do not have a significant impact on the underlying disease process. Their benefits are mild and treatments that modify the disease course are urgently needed. AD is currently thought to be a complex, multifactorial syndrome, unlikely to arise from a single causal factor; instead, a number of related biological alterations are thought to contribute to its pathogenesis. This may explain why the currently available drugs, developed according to the classic drug discovery paradigm of 'one molecule one target', have turned out to be palliative. In the light of this, drug combinations that can act at different levels of the neurotoxic cascade offer new avenues towards ameliorating the symptoms of AD.

Conclusion

The rising prevalence of AD suggests that all health providers will have an increasingly important role in the diagnosis and subsequent management of disease. A key factor in the optimal treatment and outcome of AD is the timely and accurate diagnosis of dementia, with diagnostic tools that can identify dementia early and precisely. There has been an unprecedented growth of scientific knowledge about AD. The distinctive and reliable biomarkers that are now available through structural brain imaging with MRI, PET and CSF analyses, along with a clearer definition of the clinical profile of amnestic disorders that occur early in the course of disease, have made it possible to identify AD with high accuracy, even in its early stages. New criteria for AD diagnosis are being proposed that may allow the detection of not only symptomatic disease but also prodromal states. Of the newly available diagnostic tools for use by primary care physicians, the Mini-Cog, MoCA and AD8 may be particularly useful as brief, easy to administer and effective diagnostic assessments that can be used in everyday clinical practice.

The treatment of AD consists of both pharmacological and non-pharmacological interventions. Non-pharmacological interventions are recommended as the most appropriate initial strategy for managing inappropriate behaviours in dementia. An increasing number of non-pharmacological therapies are now available. Given that there are currently no means of reversing the pathological processes of AD, the primary objectives of pharmacological interventions are to preserve cognitive and functional ability, minimize behavioural disturbances and slow disease progression. To date, five drugs have been approved for treating AD: four ChEIs, which have been the cornerstone of treatment for patients with mild to moderate AD for over a decade, and an NMDA antagonist. On occasions, it may be necessary to prescribe a psychotropic agent, with atypical antipsychotic agents commonly used off-label for serious dementia-associated agitation and aggression, and antidepressants, having been prescribed for patients with AD who also suffer from depression. Future therapies may include amyloid-modifying drugs,

acetylcholine receptor agonists, mitochondrial inhibitors and tau-based and neuroprotective approaches.

Key points

- AD is the most common form of dementia.
- Both pharmacological and behaviour therapies may improve the outcomes in AD.
- Plaques are formed by amyloid β-protein.
- Phosphorylated tau produces neurofibrillary tangles.

CHAPTER 74

Mild cognitive impairment

Eric G. Tangalos and Ronald C. Petersen
Mayo Clinic, Rochester, MN, USA

Introduction

The concept of mild cognitive impairment (MCI) as an intermediate state between normal cognition and dementia entered into the vernacular of geriatric medicine in the past 15–30 years. What this chapter may add to our understanding is that it is a relatively precise clinical diagnosis and a useful research tool. More often than not, the clinical diagnosis of MCI may have be applied to patients who are either normal or who have dementia. Although this misclassification may be a disservice to the diagnosis of MCI, the bigger disservice is to the patient. Geriatricians need to use the diagnosis appropriately for patient care, understand the treatment limitations, apply appropriate management strategies and embrace the research opportunities presented by this construct.

History

Mild cognitive impairment as a term was introduced into the literature in 1988 by Reisberg *et al*.,[1] but referred to a severity index of stage 3 as identified on the Global Deterioration Scale. Another instrument, the Clinical Dementia Rating Scale, sought to identify very early dementia given the possibility of identifying disease early and intervening as soon as possible.[2] By 1999, MCI had been proposed as a prodromal condition for Alzheimer's disease (AD) with the focus on memory as a chief clinical complaint for incipient disease.[3]

It was evident by the turn of the decade that not all forms of MCI evolved into AD. However, the general construct served most clinicians well enough. The difficulty was then, and still is today, that all too often MCI is used to soften a diagnosis of what should really be dementia. In 2004, Winblad *et al*.[4] sought to expand and revise the criteria.[5] From the symposium concerned, the criteria now used by the National Institute on Aging-Sponsored Alzheimer Disease Centers Program Uniform Data Set and the Alzheimer Disease Neuroimaging Initiative (ADNI)[6] have helped us design protocols to improve our understanding of the dementing process. The clinical phenotypes now include amnestic MCI (aMCI) and non-amnestic MCI (naMCI) with the subtypes of single- and multiple-domain classifications (Figure 74.1).

While specific changes in cognition are frequently observed in normal ageing, there is increasing evidence that some forms of cognitive impairment are recognizable as an early manifestation of dementia.[3] MCI is a heterogeneous state and there remains controversy over aspects of the construct. However, the utility of this paradigm is the recognition that dementia is not a dichotomous state and therefore refining our understanding of the layers of transition will improve the understanding of cognitive decline and ultimately benefit patients. Appropriate diagnosis lets us address our patients' needs with the best available therapies, be they drug or non-drug interventions.

In general, our shortcomings in approaching patients with cognitive decline have been to avoid a diagnosis and delay our interventions. The reasons are multiple, although taking the time to make a diagnosis means that much more time will be needed to explain the diagnosis and take action. Any assault on our independence with special concern regarding the loss of driving privileges plays poorly to the American mindset. We live in a land where our first right of passage is our driver's license and where all roads lead to the shopping mall. We do not live in walking communities and the last thing we give up is our driver's license. There have also been financial disincentives in the past when clinicians used a psychiatric code to define cognitive disease although MCI and the dementing syndromes can b now e classified with ICD-9 medical codes.

Although no symptomatic or disease-modifying drug therapies are available for MCI, there is much that can be done. The domains of cognition, function and behaviour define this population and where they reside in the spectrum of disease. Their preserved abilities can also

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

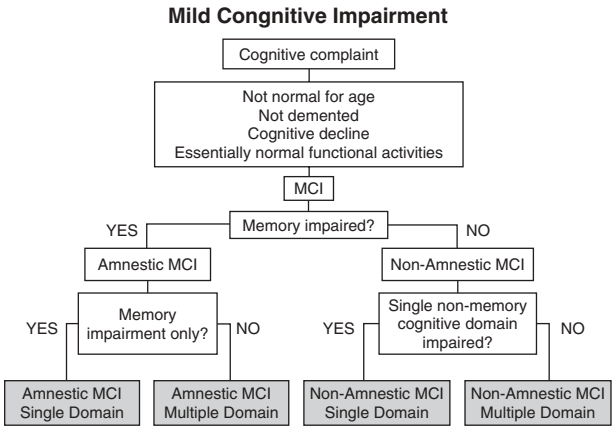

Figure 74.1 MCI flowchart. Reprinted from Petersen[5] with permission.

serve as markers for how the disease is progressing and how well they are living within a defined environment. Even without a drug treatment of MCI, understanding the environment that surrounds every one of these patients and how they function within their universe is most important. Overlearned behaviours and an environment that limit or prohibit excess disabilities should be stressed even for patients with MCI. Much can be done and running towards a diagnosis is better than running away from it.

Cognitive impairment, be it MCI or dementia, can still be defined by the capacities that are preserved and the capacities that are lost. This is where the issue of driving comes into play, but the concept applies to all kinds of tasks and opportunities. We counsel that a diagnosis is not an all-or-nothing phenomenon and many individuals with MCI or even early dementia sit on advisory boards to provide a patient voice in understanding better the needs of the patient. Unfortunately, explaining these concepts and what is both retained and what is lost takes time, especially for the primary care provider.

As our understanding of disease advances, the triad of cognition, function and behaviour not only defines the type of care that may be appropriate but also contributes to our understanding of where the best site of care might be. Our ability to address the environment early in the care of patients with MCI or other age-dependent deficiencies may improve the quality of life for our parents, avoid common pitfalls and provide for more cost-effective and successful management of the being, not just the disease they may have. A goal set by the Alzheimer's Association back in 1987 was to create an environment where a person can function with *minimal* failure and *maximal* use of retained abilities. There is even more opportunity today to create this success with earlier diagnosis and earlier intervention.

Our earliest work in the Mayo Alzheimer's Disease Research Center taught us that even normal individuals change as they get older. Not only does reaction time slow but on measures of Verbal IQ and measures of Performance IQ, the things we do day in and day out are better preserved.[7–9] In all of our attempts at providing care to the elderly, these are the principles that shaped us early and continue to play out in the advice we give out every day. Overlearned behaviours, repetitive tasks and rehearsed activities make it easy and comfortable for us to go about the routines of the day. The things we are confronted with that take an element of problem solving become all the more difficult as we age.

In addition, the concept of MCI plays extremely well as we design hypothesis-driven research; be it with regard to clinical markers, psychological assessment, neuroimaging, biomarkers or drug and non-drug interventions.[10] This is perhaps equally important as the clinical diagnosis and has generated research opportunities worldwide. The construct of MCI has been incorporated into research on ageing from multiple perspectives, including clinical research, epidemiology, neuroimaging, mechanisms of disease, clinical trials and caregiving.[10]

Definitions and terminology

Mild cognitive impairment (MCI) refers to cognitive impairment that does not meet the criteria for dementia. Various researchers have proposed several criteria for and subtypes of MCI.[3,11,12] These criteria and subtypes differ somewhat, although there is considerable overlap. The Mayo criteria are the ones most commonly applied in the literature:[13]

- memory complaint, preferably corroborated by an informant
- memory impairment documented according to appropriate reference values
- essentially normal performance in non-memory cognitive domains
- generally preserved activities of daily living
- not demented.

It is important to emphasize that these remain clinical criteria. Considerable judgment is involved in making the distinction between impairments that are normal for the elderly population and, at the other extreme, that do not represent dementia. However, it should be noted that this is the manner in which we apply criteria for dementia and AD also. Each follows a construct, has a literature base and serves the patient best when appropriately applied.

MCI is heterogeneous in terms of clinical presentation, aetiology, prognosis and prevalence.[12,14,15] In recognition of the narrower scope of the original Mayo criteria and others that relied heavily on memory problems, the concept was expanded. The intention of this was to broaden the scope and extend the emphasis of detection of other dementias in their prodromal stages.[5,13,16] A useful classification criteria separates MCI into amnestic and non-amnestic groups and

further into single and multiple domains. The amnestic type of MCI is generally thought to represent prodromal AD.[17] Other subclasses may have different underlying mechanisms of cognitive impairment and may be associated with other non-AD disease processes [e.g. vascular dementia, frontotemporal dementia (FTD) or dementia with Lewy bodies (DLB)], but there is limited pathological evidence for this paradigm.[18]

The term MCI, without qualification, was traditionally and is still often used to refer to the amnestic type; however, using MCI without qualification is not the current state of affairs. This chapter includes the current breakdown into the various subtypes.

Single-domain amnestic MCI

Single-domain amnestic MCI (aMCI) refers to those individuals with significantly impaired memory who do not meet criteria for dementia. The criteria outlined above were initially developed to define MCI in general, but subsequently have been understood to identify only this type.[3,13]

Memory impairments that qualify for MCI are generally represented by defects that are 1.0–1.5 standard deviations (SDs) or more below age-corrected norms. Although this seems straightforward, different tests of memory likely have different sensitivity and specificity and norms are not available for all populations.[14]

Multiple-domain amnestic MCI

Many individuals with aMCI complain only of memory loss; however, they may have additional subtle impairments in other cognitive domains, for example, executive function, that are revealed with careful neuropsychological testing.[16,19–21] Some would interpret the latter finding as excluding patients from this subtype of MCI according to the criteria listed above.[14] This highlights the operational difficulties with the application of the criteria and was a primary reason for expanding the diagnostic categories to include single- and multiple-domain impairment.[5] Such persons may manifest subtle problems with activities of daily living, but they do not meet criteria for a formal diagnosis of dementia.[15] The multiple domains are, by definition, only slightly impaired (i.e. less than 0.5–1 SD below age- and education-matched normal subjects).

aMCI is often thought of as a precursor to AD.[17] Although memory performances are often similar in patients with aMCI and AD, the addition of impairments in multiple cognitive domains are also prominent in patients with AD.[3] Suffice it to say, the greater the extent of additional non-memory domains the smaller the distinction between MCI and AD becomes and the greater is the risk of conversion to dementia.
