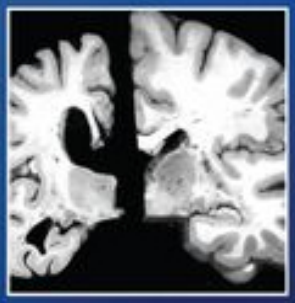
FIFTH EDITION

PATHY'S PRINCIPLES AND PRACTICE OF GERIATRIC MEDICINE



WILEY-BLACKWELL

To my mother, Ivy, and father, Radovan, for giving me the opportunity.

–Alan J. Sinclair

To all my older friends and patients who have taught me geriatrics, to my wife Pat and my children Robert, Susan and Jacqueline who have supported me throughout my career, and to my grandchildren Amanda, Conor, Katelyn, Nicole, Paige and John who are my eternal joy and hope for my future of elder care.

–John E. Morley

To all the teams working at the Gérontopôle, to my father Professor Pierre Vellas who created the Universities of the Third Age, and to Professor J.L. Albarede, our mentor.

–Bruno Vellas

Pathy's Principles and Practice of Geriatric Medicine

Edited by

Alan J. Sinclair
Dean and Professor of Medicine
Bedfordshire & Hertfordshire Postgraduate Medical School
University of Bedfordshire, Luton, UK

John E. Morley
Dammert Professor of Gerontology
Director, Division of Geriatric Medicine and Director, Endocrinology
Saint Louis University Medical Center
St Louis, MO, USA

Bruno Vellas
Professor of Medicine
Clinic of Internal Medicine and Gerontology
Gérontopôle, Toulouse University Hospital
Toulouse, France

FIFTH EDITION

Volume 1

WILEY-BLACKWELL

Preface to the Fourth Edition, xxiii

Preface to the Fifth Edition, xxv

Foreword, xxvii

Introduction: Historical perspectives, 1
Michael J. Denham and John E. Morley

Part 1 | Ageing: Biological, Social and Community Perspectives

1 A biological perspective of ageing, 13
H. James Armbrecht

2 The demography of ageing, 23
Kenneth G. Manton and John E. Morley

3 The physiology of ageing, 33
Rafi T. Kevorkian and John E. Morley

4 Psychological aspects of ageing, 43
Peggy A. Szwabo

5 Ageing of the brain, 49
Jean-François Démonet and Pierre Celsis

6 Epidemiology of ageing and disability, 55
Lenise A. Cummings-Vaughn

7 Social and community aspects of ageing, 67
John E. Morley and Nina Tumosa

8 The developmental origins of ageing, 81
Avan Aihie Sayer and Cyrus Cooper

9 Sexuality and ageing, 93
John E. Morley and Debbie T. Tolson

10 Physical fitness and exercise, 103
Maria A. Fiatarone Singh and John E. Morley

11 Health literacy and cultural sensitivity, 121
Nina Tumosa

Part 2 | Medicine and Prescribing in Old Age

12 Preventive geriatrics, 135
Gerald M. Mahon, Joseph H. Flaherty and Suzanne M. Mahon

13 Polypharmacy, 145
Oscar A. Cepeda and John E. Morley

14 Patient safety, 153
Susannah Long and Charles Vincent

Section 1 Eating Disorders and Nutritional Health

15 Epidemiology of nutrition and ageing, 173
Wija A. van Staveren and Lisette C.P.G.M. de Groot

16 The anorexia of ageing, 185
Ian M. Chapman

17 Weight loss, 197
David R. Thomas

18 Dehydration, 209
David R. Thomas

19 Vitamins and minerals, 217
Seema Joshi and John E. Morley

20 Obesity, 237
Joan Khoo, Richard Y.T. Chen and Gary A. Wittert

Section 2 Gastro Disorders

21 Changes in gastrointestinal motor and sensory function associated with ageing, 249
Christopher K. Rayner and Michael Horowitz

22 Gastrointestinal bleeding, 265
Syed H. Tariq

23 Liver and gall bladder, 275
Margaret-Mary G. Wilson

24 Sphincter function, 289
Syed H. Tariq

25 Constipation, 303
Charlene M. Prather

26 Management of diarrhoea, 313
Lenise A. Cummings-Vaughn

27 Diseases of the pancreas, 321
John S. Morris and John E. Morley

Section 3 Haematological Disorders

28 Anaemia, 331
Anjali S. Kamat and David R. Thomas

29 Disorders of haemostasis, 343
Kingsley K. Hampton

30 Disseminated intravascular coagulation, 353
Kingsley K. Hampton

31 Anticoagulants, 357
Hamsaraj G.M. Shetty and Philip A. Routledge

32 Myelodysplasia, 363
Martha Wadleigh, David S. Rosenthal and Richard M. Stone

33 Management of myelodysplastic syndromes and acute leukaemia, 375
Heidi D. Klepin and Bayard L. Powell

Section 4 Cardiovascular Diseases and Health

34 Epidemiology of heart disease, 389
Ahmed H. Abdelhafiz

35 Cardiac ageing and systemic disorders, 405
David J. Stott and Terence J. Quinn

36 Arrhythmias, 413
Abhay Bajpai and A. John Camm

37 Ischaemic heart disease, 437
Wilbert S. Aronow

38 Lipid management, 449
Adie Viljoen and Anthony S. Wierzbicki

39 Hypotension, 461
Suraj Alakkassery

40 Hypertension, 471
Anthony S. Wierzbicki and Adie Viljoen

41 Heart failure, 483
Michael W. Rich

42 Cardiac surgery, 499
Ulrich O. von Oppell and Adam Szafranek

43 Peripheral arterial disease, 517
Leocadio Rodríguez Mañas, Marta Castro Rodríguez and Cristina Alonso Bouzón

44 Venous thromboembolism, 529
Gordon D.O. Lowe

45 Cardiac rehabilitation, 535
Niccolò Marchionni, Francesco Fattirolli, Francesco Orso, Marco Baccini, Lucio A. Rinaldi and Giulio Masotti

Section 5 Respiratory Diseases

46 Epidemiology of respiratory infection, 551
Joseph M. Mylotte

47 Pneumonia, 555
Joël Belmin

48 Aspiration pneumonia, 565
Takashi Ohrui and Hiroyuki Arai

49 Interstitial lung disease and lung cancer, 573
Christopher Dyer

50 Chronic obstructive pulmonary disease and asthma, 579
Christopher Dyer

51 Pulmonary hypertension, 589
Dennis J. Shale

52 Pulmonary rehabilitation, 601
Peter Spiegler and Jonathan Ilowite

Section 6 CNS Disorders

53 Neurological signs of ageing, 609
Andrew J. Larner

54 Sleep apnoea and sleep disorders, 617
Paul Montgomery and Lindsay Dianne Shepard

55 Headache, 629
Stephen D. Silberstein and William B. Young

56 Normal pressure hydrocephalus, 643
Dennis S. Oh and Peter McL. Black

57 Acute stroke care and management of carotid artery stenosis, 655
David Doig and Martin M. Brown

58 Stroke and stroke rehabilitation, 675
Lalit Kalra

59 Communication disorders and dysphagia, 691
Pamela M. Enderby

60 Acute and chronic subdural haematoma, 701
Eric Schmidt and Emmanuel Moyse

61 Epilepsy, 711
Pamela M. Crawford

62 Syncope and non-epileptic attacks, 721
Richard C. Roberts

63 Parkinson's disease, 731
Joël Belmin

64 Non-parkinsonian movement disorders, 739
Katie Kompoliti and Cynthia L. Comella

65 Diabetic neuropathy, 751
Aaron I. Vinik and Elsa S. Strotmeyer

66 Disorders of the neuromuscular junction, 769
Sivakumar Sathasivam and Andrew J. Larner

67 Muscle disorders, 779
David Hilton-Jones

68 Motor neurone disease, 793
Hardev S. Pall

69 Control of chronic pain, 809
Robert D. Helme and Benny Katz

70 Multiple sclerosis, 823
Florian P. Thomas

Appendix Function assessment scales, i
John E. Morley

Index, xi

A colour plate section is to be found in Volume 2, between pages 1414 and 1415

Preface to the Fourth Edition, xxiii

Preface to the Fifth Edition, xxv

Foreword, xxvii

Section 7 Dementia and Cognitive Disorders

71 Delirium, 837
Joseph H. Flaherty

72 Memory clinics, 851
Antony Bayer

73 Alzheimer's disease, 865
James E. Galvin

74 Mild cognitive impairment, 881
Eric G. Tangalos and Ronald C. Petersen

75 Vascular dementia, 895
Marie-Laure Seux

76 Mental stimulation and dementia, 903
Joe Verghese

77 Exercise and dementia, 911
Yves Rolland

78 Drug development and Alzheimer's disease, 923
Julien Delrieu, Antoine Piau and Bruno Vellas

79 Other dementias, 943
Wee Shiong Lim

80 Treatment of behavioural disorders, 961
Ladislav Volicer

81 Geriatric psychiatry, 977
Abhilash K. Desai and George T. Grossberg

82 Organization of services in geriatric psychiatry, 991
Susan Mary Benbow and David Jolley

83 Depression in later life: aetiology, epidemiology, assessment, diagnosis and treatment, 1001
Natalie Sachs-Ericsson and Dan G. Blazer

84 The older patient with Down syndrome, 1017
John E. Morley

Section 8 Special Senses

85 Disorders of the eye, 1025
Nina Tumosa

86 The ageing auditory system – pathology and epidemiology of age-related hearing loss, 1033
Mathieu Marx and Olivier Deguine

87 Disorders of the vestibular system, 1047
Charlotte Ågrup and Linda M. Luxon

88 Smell and taste, 1061
Richard L. Doty

Section 9 Bone and Joint Health

89 Paget's disease of bone, 1075
Horace M. Perry III

90 Management of osteoporosis; its consequences: a major threat to quality of life, 1083
Roger M. Francis

91 Gait, balance and falls, 1091
Dulce M. Cruz-Oliver

92 Foot problems, 1111
Arthur E. Helfand and Donald F. Jessett

93 Hip fracture and orthogeriatrics, 1131
Christine Lafont

94 Diseases of the joints, 1145
Terry L. Moore

Section 10 Endocrine and Metabolic Disorders

95 Endocrinology of ageing, 1155
John E. Morley and Kim J. Moon

96 Water and electrolyte balances in ageing, 1163
Stewart G. Albert

97 The pituitary gland, 1173
James F. Lamb and John E. Morley

98 Thyroid disorders, 1183
Ligia J. Dominguez, Mario Belvedere and Mario Barbagallo

99 Ovarian function and menopause, 1199
Nicola Pluchino, Tommaso Simoncini and Andrea R. Genazzani

100 Testicular function, 1211
Nazem Bassil

101 Diabetes mellitus, 1225
Alan J. Sinclair and Graydon S. Meneilly

102 New therapies for diabetes mellitus, 1241
George T. Griffing

Section 11 Urogenital Disorders

103 Gynaecology and the older patient, 1261
Radha Indusekhar, Fidelma O'Mahony and P.M Shaughn O'Brien

104 The ageing bladder, 1271
James M. Cummings and Kimberly C. Berni

105 Prostate diseases, 1281
Clement Gaudin, Nicolas Doumerc, Loic Mourey, Stephane Gerard and Laurent Balardy

106 Urinary incontinence, 1299
Ramzi R. Hajjar

107 Geriatric nephrology, 1309
Carlos G. Musso and Dimitrios G. Oreopoulos

Section 12 Cancer

108 Cancer and ageing, 1319
Tanya M. Wildes

109 Oncological emergencies, 1333
Chantal Bernard-Marty, Clement Gaudin, Stephane Gerard and Laurent Balardy

110 Breast cancer, 1345
Robert E. Mansel and Bedanta P. Baruah

111 Maintaining functional status, 1355
Miriam B. Rodin

Section 13 Functional Disorders and Rehabilitation

112 Multidimensional geriatric assessment, 1377
Laurence Z. Rubenstein and Andreas E. Stuck

113 Frailty, 1387
John E. Morley

114 Rehabilitation, 1395
Michael Watts and Paul Finucane

Section 14 Iatrogenic Infections

115 Tuberculosis, 1415
Shobita Rajagopalan and Thomas T. Yoshikawa

116 Valvular heart disease and infective endocarditis, 1425
Aneil Malhotra, Sam Dawkins and Bernard D. Prendergast

117 Infections of the central nervous system, 1447
Michael Blank and Allan R. Tunkel

Section 15 Special Issues

I Abuse and older people

118 Elder abuse: a UK perspective, 1467
Claudia Cooper and Gill Livingston

119 Good quality care: abuse, 1473
Jean-Pierre Aquino and Geneviève Ruault

120 Alcohol consumption and cognition, 1479
Luc Letenneur and Jean-François Dartigues

121 Drug misuse and the older person: a contradiction in terms?, 1483
Antoine Piau and Fatima Nourhashemi

122 The use and abuse of prescribed medicines, 1495
Abdi Sanati and Mohammed T. Abou-Saleh

II Emerging themes

123 Transportation, driving and older adults, 1503
Desmond O'Neill and David Carr

124 Smart homes, 1513
Roger Orpwood

III Dermatology

125 Skin disorders, 1525
Robert A. Norman and Jaffer Babaa

126 The prevention and management of pressure ulcers, 1531
David R. Thomas

IV Surgical themes

127 Perioperative and postoperative medical assessment, 1545
Milta Oyola Little

128 Anaesthesia, 1557
Suzanne Crowe

V Ageing themes and ethical issues

129 Health issues in the ageing female, 1569
Carolyn D. Philpot

130 Antiageing strategies, 1575
Ligia J. Dominguez and Mario Barbagallo

131 Ethics in geriatric medicine, 1589
François Blanchard

132 Participation of older people in clinical trials, 1595
Nicola Coley and Sandrine Andrieu

133 Restraints and immobility, 1607
Elizabeth A. Capezuti, Laura M. Wagner and Kathleen C. Reid

134 Centenarians, 1621
Thomas T. Perls

VI End-of-life care

135 End-of-life and palliative care, 1631
Rachelle E. Bernacki, Ryan Westhoff and Miguel A. Paniagua

136 End-of-life care: special issues, 1641
Victoria J. Wheatley and Ilora G. Finlay

Part 3 | Global Healthcare Systems

137 Improving quality of care, 1653
Julie K. Gammack and Carolyn D. Philpot

138 Clinical audit of healthcare, 1673
Rhona Buckingham, Jonathan Potter and Adrian Wagg

139 Carers and the role of the family, 1687
Jo Moriarty

140 Nursing home care, 1697
David R. Thomas, Yves Rolland and John E. Morley

141 Geriatric occupational therapy: achieving quality in daily living, 1709
Karen F. Barney

142 Geriatric medicine education in Europe and the United States, 1719
Antonio Cherubini, Philippe Huber, Jean-Pierre Michel and Miguel A. Paniagua

143 Systems of healthcare: the United States, 1725
Julie K. Gammack

144 Systems of healthcare: Australia, 1735
Gideon A. Caplan

145 Systems of healthcare: the United Kingdom, 1741
Simon Conroy

146 Geriatric medicine in China, 1747
Leung-Wing Chu

147 Ageing in developing countries, 1761
Renato Maia Guimarães

148 Geriatric medicine in the European Union: towards unification of diversity, 1765
Alfonso J. Cruz-Jentoft

Appendix Function assessment scales, i
John E. Morley

About the Editors

Alan Sinclair

Alan Sinclair is Dean and Professor of Medicine at the Bedfordshire & Hertfordshire Postgraduate Medical School at the University of Bedfordshire, UK. He was a founding member and Academic Director of the European Union Geriatric Medicine Society (EUGMS) and previously Charles Hayward Professor of Geriatric Medicine at the University of Birmingham, UK. His principle research interests are in the areas of diabetes, older people, nutrition and frailty. He is the recipient of both national and international research awards. Alan recently established the Institute of Diabetes for Older People (IDOP), which is the first institute of its kind to be solely dedicated to the enhancement of quality diabetes care in older people.

John Morley

John Morley is the Dammert Professor of Gerontology, Director, Division of Geriatric Medicine and Director, Endocrinology at Saint Louis University Medical Center. Dr Morley is the Editor-in-Chief of the *Journal of the American Medical Directors Association*.

Bruno Vellas

Bruno Vellas is Professor of Internal Medicine and Geriatrics, Chair of the Gérontopôle in Toulouse, France, including the Alzheimer's Disease Research and Clinical Centre. Professor Vellas is President of the IAGG (International Association of Gerontology and Geriatrics) and Editor-in-Chief of the *Journal of Nutrition, Health and Aging*.

Preface to the Fourth Edition

> ''I offer no apology for the publication of this volume. The subject is one of the highest importance, and yet it has been strangely overlooked during the last half-century by the physicians of all countries.''
>
> –George Edward Day
> (1815–1872)

George Day's introduction to his textbook *Disease of Advanced Life*, published in 1848, regrettably remains appropriate for textbooks published over 150 years later. Modern physicians can still fail to recognize the differences in disease presentation and management between middle-aged and older adults. It is our hope that this Fourth Edition of ''Principles and Practice of Geriatric Medicine'' will help increase the awareness of geriatric principles and improve the treatment of older individuals. John Pathy's original vision for the first edition was to provide, in a single volume, a comprehensive reference source for all those involved in the medicine of old age. We have endeavored to adhere to this vision, but inevitably the size of the textbook has grown. While in any text of this size some overlap with general texts of medicine will occur, the emphasis is on those assessments and disorders that are particularly of relevance to older persons.

Over the seven years since the last edition of this text was published, there have been dramatic advances in our understanding of the pathophysiology of disease as it interacts with the physiological processes of aging. There has been a continuing validation of assessment tools for older persons and the development of some new ones. Large-scale studies of the efficacy of various geriatric systems such as Acute Care for the Elderly Units, Geriatric Evaluation and Management Units, and Home Care Systems have been carried out. All of these have demonstrated the value and cost-effectiveness of the geriatric specialist approach to managing older people. In comparison, most studies assessing Coronary Care Units and Intensive Care Units have failed to come close to demonstrating the effectiveness that has been shown for geriatric units. Despite this, all major hospitals have highly expensive critical care units, while fewer have developed geriatric units. The last decade has also seen an increased awareness of the need to enhance the quality of long-term care. This increase in geriatric knowledge has been recognized by the addition of nearly 40 new chapters in this edition. In addition, many of the previous chapters have been totally rewritten to allow the recognition of the changes that have occurred in our understanding of the care of older persons.

Previous editions of this textbook were edited by a single person, John Pathy. With the rapid increase in geriatric knowledge and John's desire for the Fourth Edition to reflect the input of other academic minds, he has added two new editors to share the burden with him, namely, Alan Sinclair and John Morley. This has allowed a more even distribution of the editing tasks, though John Pathy has continued to carry the lion's share. In recognition of the globalization of the world, in general, and geriatrics, in particular, one of the new editors, John Morley, is from the United States, while Alan Sinclair draws on his European experiences. In addition, a major effort has been made at the end of the text to recognize the differences (as well as the similarities) of geriatrics as it is practiced around the world. The enormous good fortune the editors had in recruiting a stellar class of contributors from around the world has, we hope, allowed this text to be truly representative of a global view of geriatric medicine. From the beginning, John Pathy has made this a goal of his text, and the editors feel that this edition has truly achieved an international view of old-age medicine as originally developed by Marjorie Warren and her colleagues in the United Kingdom.

The general outline of the text still follows that of the first edition. The first sections provide a general perspective of old age, the processes of aging, and social and community perspectives. The chapter on preventive medicine now focuses on issues of particular importance to older persons. In Part III ''Medicine in Old Age'', the section ''Eating Disorders and Nutritional Health'' has been increased to recognize the increased importance and understanding of nutrition in old age. Chapters on frailty, sarcopenia,

palliative care, and women's health have been added to recognize the increasing importance of these issues in older persons. The final part on ''Health Care Systems'' focuses first on the emergence of continuous quality improvement, geriatric systems and evidence-based medicine as the foundation of high-quality geriatric medicine. The development of novel education systems is discussed. Finally, unique aspects of geriatric care around the world are examined.

In an attempt to improve the readability of the text, we have asked the authors to make liberal use of tables and figures, and key points have been added at the end of each chapter. References have been limited, and at the beginning of the reference list, authors identify a few key references to allow for further reading. The new editors have tried to keep the easy reading style of the previous editions, but, as can be imagined, this has been a difficult task as we have increased the number of contributors from around the world.

Overall, we hope our readers enjoy and learn from this textbook; for the three of us, it has been a true labor of love. We particularly would like to thank our contributors for the excellent job they have done. We would also like to thank Layla Paggetti from John Wiley & Sons for her tireless efforts in making sure this book came to fruition. Finally, we would like to thank our families for their forbearance. This book is dedicated to all those who care for older persons.

M.S. John Pathy, Alan J. Sinclair, John E. Morley
December 2005

Preface to the Fifth Edition

The Fifth Edition of this widely known international textbook incorporates the latest evidence of research into the often complex management of common clinical problems in older people. We as Editors embarked on this edition with the knowledge that John Pathy would be there to guide us with all his wisdom and incredible grasp of the discipline of Geriatric Medicine. His untimely departure from this world left a major gap for us, but we have worked very closely as an editorial team, supported by Wiley-Blackwell, and hope that this edition fulfils all the expectations and objectives that were set when we originally sat down with John Pathy to discuss the textbook. We pay tribute to John Pathy as a tremendous role model for aspiring geriatricians all over the world and hope that his textbook will continue to educate all those who seek enlightenment in caring for older people.

We have used, wherever possible, an evidence-based approach to developing each chapter and asked all authors to think hard on what are the key messages. Chapters that have been revised and updated were edited closely to ensure that the clinical pathway is still highly relevant and that the references also reflected an in-depth revision process. A new layout of chapters will be apparent and is based on grouping chapters with similar clinical relevance and where similar pathophysiological mechanisms may be operating. In a majority of chapters, we have leading international authors who are experts in the field.

Wide clinical experience is the hallmark of a sound geriatrician or other healthcare specialist who claims expertise in managing older people who are hospitalized or who have clinically deteriorated in the community. This may take many years of training, although at an early stage of their careers, recognition of the varying nature of illness in old age and how both simple and focused interventions can lead to health gain are prerequisites for enhancing clinical care. This textbook should complement these activities irrespective of the status of the practitioner but, as always, reading a book and acquiring knowledge must be accompanied by a practical clinical care approach aligned with compassion and understanding of the critical issues affecting older people.

Professor Alan Sinclair would like to thank Caroline Sinclair, and Professor John Morley would like to thank Susan Brooks, for their tremendous assistance in helping them to complete their editorial tasks, and the Editors would like to express their appreciation of the incredible patience and support from Gill Whitley and Robyn Lyons at Wiley-Blackwell.

Foreword

One of my earliest memories is of my father at work in his small study: he would be surrounded by what, to a child's eye, appeared to be a chaotic mass of books, journals, papers and slides. He never seemed to rest. The time not occupied by professional work was filled with hard labour in the garden or, with the constant support of his devoted wife Norma, in bringing up five children.

One of the results of the drive and determination in that time spent in his study was the first edition of *Principles and Practice of Geriatric Medicine* in 1985. I had become a medical student by that time, and remember the work involved in the production of that first edition. Twenty-five years on, I wonder at how my father managed to find the time, after completion of all his clinical and teaching tasks, even to contemplate such a *magnum opus* – however, many distinguished contributors may have been ready to assist.

The success of the first edition led to a request for a second, enlarged, edition, and then to a third edition. It was during the production of the third edition that my father himself required in-patient treatment. During this stay in hospital I called in to visit him, but found that he was not in bed but in the ward office on the telephone to a consultant at the hospital who was a contributor to the book, simply confirming that the contribution would be received by the deadline.

My father died before he could begin work himself on the fifth edition. Although by then he was no longer as physically fit as he would have wished, particularly for gardening, he remained mentally sharp, alert and energetic. Medicine remained his passion. He continued to be involved in research and remained abreast of the latest developments in professional literature. His private study, where he continued to beaver away energetically, remained as chaotic as ever.

Dr Damian Pathy FRCP

FIFTH EDITION

Volume 1

Introduction: Historical perspectives

Michael J. Denham[1] and John E. Morley[2]

[1]Wellcome Trust Centre for the History of Medicine at UCL, London, UK
[2]Saint Louis University Medical Center and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

The broad subject of old age has attracted the attention of writers and philosophers for many centuries. It contains the interrelated topics of the theories of ageing, how to increase longevity, and the medical management of sick elderly people. Initially, the first two themes attracted most attention. It was not until the twentieth century that literature relating to medical care came to the fore.

The earlier writers on old age

Early writers such as Hippocrates, Cicero, Galen, Roger Bacon and Francis Bacon discussed old age in general terms pointing to features such as skin changes, reduction in physical strength and deteriorating memory, sight and hearing. None were sure of the cause(s) of old age. Theories ranged from incorrect diet, through loss of heat to loss of moisture. Although the basis of growing old was unclear, several philosophers thought that a healthy old age could be promoted by keeping active, eating sensibly and exercising regularly.

Later, British writers of the eighteenth and nineteenth centuries, such as Sir John Floyer, Sir John Hill, Sir Anthony Carlisle, Professor George Day and Sir John Sinclair, wrote about old age and how life might be prolonged, but devoted limited attention to medical management of disease in older people. They generally considered it impossible to turn an elderly man into a young person, but agreed that much could be done to make later life healthy. Lifestyle was important. They recommended wise eating of easily digestible foods taken at regular intervals, exercising regularly, ensuring good sleep, keeping clean, wearing warm clothing and avoiding constipation. In 1863, Dr Daniel Maclachlan, medical superintendent at the Royal Hospital Chelsea, criticized the lack of English literature relating to old age and pointed out that precise diagnosis could be difficult in older people because several diseases could exist simultaneously. In 1882, the English translation of Jean Martin Charcot's *Clinical Lectures of the Diseases of Old Age* was published, which described an extensive range of subjects including the overt signs of old age, rheumatism, gout, arthritis, fever and its feeble response in older people, respiratory infections, cerebral haemorrhage and cerebral softening. However, his contribution to treatment and management was limited. The early twentieth-century English writers such as Sir Henry Weber, Dr Robert Saundby, G. Stanley Hall and Sir Humphry Rolleston continued to describe old age, but again medical management received little attention. Maurice Ernest's writing in 1938 pointed out that until the nineteenth century only superficial knowledge existed of how the body worked.

The birth of modern geriatric medicine

Modern geriatric medicine commenced in the United States. Although American writers in the nineteenth century, such as Dr Benjamin Rush, had published on the subject of old age, the real impetus for advance came later when a young medical student, Ignatz Nascher (1863–1944), an immigrant to America from Vienna, was taken to an almshouse to see some interesting cases. An old woman hobbled up to the medical teacher with a complaint. The class was told that she was suffering from old age and that nothing could be done for her. This remark impressed him so strongly that after qualification he took up the study of the diseases of old age. His lifetime work on the subject resulted in his becoming known as the 'father of geriatric medicine'. His publication of *Geriatrics* in 1916 was followed by others, including Dr Malford Thewlis, who published the first edition of his book, *Geriatrics*, in 1919, Dr Edmund Cowdry, whose *Problems of Aging* appeared in 1939 and Dr Alfred Worcester, who published a series of lectures in 1940 called *The Care of the Aged, the Dying, and the Dead*. Dr Nathaniel Shock, in 1951, published the first edition of his classification of geriatrics and gerontology but pointed to

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

the scarcity of material. In 1942, the American Geriatrics Society was formed with a membership of physicians, and in 1945 the Gerontological Society of America was created with a multidisciplinary membership. Each of the societies produced its own journal in 1946. Unfortunately, this momentum for change was not sustained, partly because physicians saw little attraction in the subject. Interest was not reignited until the 1960s, when Medicare and Medicaid were introduced.

Thus it was that leadership and instruction in modern geriatric medicine in the post-war era passed to the United Kingdom, where the achievements of a handful of pioneers were becoming known.

British developments

Health care in the United Kingdom goes back to that provided by the monasteries until they were dissolved in 1536. After the dissolution, many of the aged and infirm, who could not be managed at home with the help of family members, were left uncared for. The Poor Law Relief Act of 1601 attempted to remedy these problems. Parishes levied a rate on all occupiers of property to provide work for the unemployed and accommodation for the lame, old and blind. Workhouses were built for these purposes, but were made as unpleasant as possible to discourage people from entering them. Infirmaries were established to look after sick inmates of the workhouses. Outdoor relief was available for the poor, but this was curtailed in 1832.

Hospitals did not become central to health care until the nineteenth–twentieth centuries, by which time two different types of hospitals were evolving: the voluntary hospitals and the workhouse/municipal infirmaries.[1] Voluntary hospitals, some of which dated back to the tenth century, were financed from endowments, subscriptions, fees and fund raising. They had a high reputation, with good nursing and medical staff, and acted as a base for clinical teaching of medical students. They were reluctant to admit the chronic sick, fearing that their beds could become blocked because these patients were slower in improving and there could be social problems preventing their discharge. An important consequence was that medical students rarely saw them and, therefore, were not taught about the diseases of old age or how to manage the mixture of medical and social problems they would meet after qualification.

Workhouse infirmaries were funded by local rates. They gradually became long-stay institutions for the chronic sick. Examples of unsatisfactory conditions and poor care in workhouses and infirmaries surfaced in the 1860s and resulted in visits by the *Lancet* commissioners and the inspectors of the Poor Law Board. The 1869 report of the *Lancet* Sanitary Commission was damning, stating, 'The fate of the ''infirm'' inmates of crowded workhouses is lamentable in the extreme; they lead a life which would be like that of a vegetable, were it not that it preserves the doubtful privilege of sensibility to pain and mental misery'.[2]

In 1929, the Local Government Act came into force, which aimed to correct the existing bipartite system of health care of 'one part for the pauper and the other part for the non-pauper'. However, Charles Webster concluded that health services between the two world wars were ramshackle and uncoordinated, with hostility between sections of the service, increasingly chaotic funding and with a hospital service which was unevenly distributed and limited in rural areas.[3]

Further reform came in 1948 with the creation of the National Health Service (NHS), which rearranged British health care into a tripartite system. First, there was the hospital service, which was formed by the nationalization of 1143 voluntary and 1545 municipal hospitals. It became the dominant partner in the Service. Second, there were the general practitioner and the ophthalmic, pharmaceutical and dental services. The third arm, which was managed by the local authorities, included health centres, health visitors and ambulance services. Their immensely valuable home help and meals-on-wheels services did not really 'take off' until some years later. Importantly, health care for all became free of charge.

Voluntary and charitable organizations made important contributions to the care of the older person and research into old age. In 1943, the Nuffield Foundation was created, one of whose objectives was the care of the aged and the poor. This support led to the formation of the National Corporation for the Care of Old People in 1947. The Foundation also stimulated major research into the causes of old age (gerontology). These moves to assist older people became increasingly important as the proportion of older people in the population steadily increased. In 1841, the over-65-year-old people comprised 4.5% of the population, which rose to 4.7% by 1901, 7.8% by 1921, 9.6% by 1931 and 10.5% in 1947.

An overview of early geriatric medicine in the United Kingdom

Modern geriatric medicine in the United Kingdom dates from 1926, when Dr Marjorie Warren was appointed to the West Middlesex Hospital, where her interests were initially surgical. However, in 1935 the Hospital took over control of the adjacent old Poor Law institution and Warren was put in charge of 874 patients. The situation she found was described in the first of her many articles on the modern treatment of the chronic sick.[4] At about the same time, three other British doctors were also keen to improve the medical care of the elderly: Dr Eric Brooke, Mr Lionel Cosin and Dr Trevor Howell. Like her, they, too, applied classification, diagnosis and treatment to their elderly patients, which had

previously been missing. After the war, a further wave of enthusiasts, such as Lord Amulree, Drs John Agate, Charles Andrews, Ferguson Anderson (later Professor), Bill Davison, Hugo Droller, Norman Exton-Smith (later Professor), Tom Wilson and Lyn Woodford-Williams, began to make their mark with many publications.

These newly appointed post-war consultants in geriatric medicine had to embark on a steep learning curve. In the early days, they had the responsibility for very large numbers of inpatients, sometimes many hundreds, who were often kept in bed for no discernible medical reason, which could ultimately lead to a totally bedridden state. Generally there was a massive waiting list for admission, often precipitated by the death or illness of the carer or the person's inability to prepare meals for him/herself. These new consultants learnt that illness and the presentation of disease in the older person differed from those in younger people, that more time was required to recover, that prescribing drug therapy required great care, that extensive teamwork was needed for successful rehabilitation and that local social service support was usually essential to provide alternative accommodation or domiciliary support services. They had to provide a service although they lacked adequate resources and staffs, had poor ward accommodation, inadequate investigative/treatment facilities, and were not always based on the main hospital site. They had to fight antagonism and resistance from their fellow consultants and some hospital management committees. One chairman of such a committee refused a consultant geriatrician the use of empty beds in general medical wards: 'Over my dead body', he said. When he died, the geriatrician got the beds. Another consultant had to fight for proper washing facilities in the wards and for curtains to be placed around the beds of elderly patients. Yet others had to struggle to get heating installed in the wards and repairs made to the leaking ward roofs.

Important studies of the elderly living at home or in residential homes appeared shortly after the war. Dr Joseph Sheldon, a general physician, published *The Social Medicine of Old Age* in 1948, which was the result of his research into the health of the elderly living in the community in Wolverhampton. In 1955, Professor William Hobson and Dr John Pemberton published *The Health of the Elderly at Home*, which was a study of older people living at home in Sheffield. In 1962, Professor Peter Townsend published *The Last Refuge*, a seminal study of old people living in residential homes.

The British Ministry of Health, which was created in 1919, and its medical officers supported the newly emerging style of medical care of the sick elderly patient with official circulars, memoranda, meetings and documents. These highlighted its firm belief in modern management of elderly patients and the drive to establish a geriatric unit in every health district. The Ministry organized surveys of hospitals in England and Wales, which were to be the basis of the forthcoming NHS. The reports, published in 1945, were generally very critical of services and accommodation for the chronic sick. 'The worst and oldest buildings were set aside for the chronic sick'.[5] 'The buildings are old, dark, devoid of modern sanitary conveniences, death traps in the case of ''fire'', and unfit for the nursing of the chronic sick'.[6] 'The first essential is that every patient should be thoroughly examined and treated with a view to restoring a maximum degree of activity'.[7] Later, Lord Amulree and Dr Edwin Sturdee, both medical officers of the Ministry, presented a paper on the care of the chronic sick to the Parliamentary Medical Committee in 1946.[8] In it they stated, 'Not only is the problem of the treatment of the chronic sick not being met, but also most people do not realize there is a problem'. In 1957, Dr Christopher Boucher, a Principal Medical Officer at the Ministry, published the result of an important survey of services available to the chronic sick and elderly.[9] However, the Ministry realized that it could not force change, but could only use persuasion to improve proper medical services for older people.[10] Perhaps this was why that, even in 1978, 42 health districts in England still lacked geriatric beds in general hospitals.

The British Medical Association played its part in planning the medical care of older people with a series of very specific reports. A coordinated geriatric service was recommended to the newly created Regional Health Authorities, supported by a wide range of domiciliary services, which would be needed by the infirm elderly to enable them to stay at home for as long as possible.[11–13]

However, commentators looked back to the old Poor Law and the new NHS with mixed feelings.[14–17] They pointed out that whereas the old Poor Law system had given a coordinated personal service to its clients, the tripartite structure of the NHS service led to lack of cooperation and coordination between the arms of the service. Chronic and mental services received a smaller share of capital and revenue, and clear guidelines for the treatment of old people were lacking. The political will to produce a nationwide effective geriatric service was lacking. On the other hand, the new service did provide the less well off with forms of care to which previously they had only limited entrée, and the elderly now had access to consultant services.

The early pioneers in geriatric medicine

In 1935, *Dr Marjorie Winsome Warren*, CBE, MB (1897–1960), was placed in charge of 874 patients from the adjacent Public Assistance Institution. These included 16 maternity patients and about 144 'mental observation' patients, who were subsequently transferred to their appropriate departments. She assessed and examined the remainder. She described the situation as follows: 'Having lost all hope of recovery, with the knowledge that independence has

gone, and with a feeling of helplessness and frustration, the patient rapidly loses morale and self-respect and develops an apathetic . . . temperament, which leads to laziness and faulty habits, with or without incontinence. Lack of interest in the surroundings, confinement to bed . . . soon produces pressure sores . . . inevitable loss of muscle tone make for a completely bedridden state . . . [leading to] disuse atrophy of the lower limbs, with postural deformities, stiffness of joints, and contractures . . . in this miserable state, dull, apathetic, helpless, and hopeless, life lingers on, sometimes for years' (Warren, 1946).[18]

She criticized the medical profession: 'It is surprising that [it] has been so long awakening to its responsibilities towards the chronic sick and aged, and that the country at large should have been content to do so little for this section of the community'.[18]

She recognized the importance of the environment in helping patients recover. She improved ward lighting, arranged repainting of the wards from the previous drab colour to cream, replaced old-fashioned beds, provided modern bedside lockers, bed tables and headphones, and also bright red top blankets, light-coloured bedspreads and patterned screen curtains. Wards were equipped with handrails attached to the walls, and suitable armchairs provided. Floors were no longer highly polished and steps were avoided. Special chairs and walking sticks and frames were provided for arthritic and heart patients. Some equipment that she designed herself is still used today. She was the first British geriatrician to publish admission, death and discharge data. By 1948, Warren reported that the general medical staff acknowledged that their 'chronic' elderly patients actually did better in the geriatric unit than in their own wards.

Mr Lionel Zelick Cosin, FRCS (1910–1993), came from a surgical background to the care of the elderly chronic sick.[19] At the outbreak of war, he was drafted to Orsett Lodge Hospital in Essex, which had been upgraded to an Emergency Medical Service Hospital in 1939. He became responsible for 300 chronic sick patients in addition to his surgical commitments. He found that they were fed and kept clean but no other treatment was given. When ordinary admissions restarted in 1944, he admitted elderly women with fractured femurs, successfully operated on them, gave them rehabilitation and discharged them home.

In 1950, he was invited to establish a geriatric unit at Cowley Road Hospital in Oxford, where he became its first clinical director and established the first day hospital in the United Kingdom. He classified, diagnosed, and treated his elderly patients. He reorganized inpatient accommodation, creating an acute geriatric ward for investigation, treatment and physiotherapy, and also a long-stay annex ward for the permanently bedfast, long-stay wards for the frail ambulant, and 'residential home' type of accommodation for the more robust patients. These methods resulted in the average length of stay falling from 286 to 51 days. The proportion remaining in hospital longer than 180 days declined from 20 to 7%. Admissions increased from 200 to 1200 per year through the same number of beds. The average age of the patients increased from 68 to 75 years. Approximately 10% of his patients became permanently bedfast.[20]

Dr Eric Barrington Brooke, FRCP (1896–1957), became the first medical superintendent of the newly built, 800-bed, St Helier Hospital in Carshalton. The building was hit several times by enemy bombs, his superintendent's house was destroyed by a flying bomb in 1944, and he was severely wounded and lost an eye, but he returned to duty in due course. In 1953, he was appointed consultant physician to the Southampton group of hospitals.

His approach to his long waiting list for admissions was different from others because he had few hospital beds. He devised a scheme of managing patients at home with a domiciliary 'inpatient service' supplemented by increased use of the outpatient department. The process began with a home visit made by a member of the hospital-based geriatric team. These revealed that only one in three of the patients on the list required admission on a short-term basis for investigation and treatment, terminal care or to provide holiday relief for caring relatives. Where appropriate, he arranged for a coordinated home-based service with district nurses, home helps, domiciliary occupational therapists, a laundry service, and the Red Cross library. The local Women's Voluntary Service set up a hot 'meals-on-wheels' domiciliary service. He viewed the general practitioner as the key member of the whole support scheme.

Dr Trevor Henry Howell, FRCP Ed. (1909–1988), first encountered elderly patients when he was a general practitioner before the war. What puzzled him was what represented 'normal' for age and what represented disease. After his war service, he established a geriatric research unit at Battersea Hospital in London before becoming medical superintendent at Queen's Hospital, Croydon. He kept meticulous records of his patients, which formed the basis of over 300 papers and four books that he wrote. He kept a handwritten record of every book he read, every patient he saw, and every postmortem held on his patients. Like his colleagues, he firmly supported teaching medical students. He and Sturdee were the driving force behind the creation in 1948 of the Medical Society for the Care of the Elderly, which later became the British Geriatrics Society. Howell was its secretary for many years.

The second wave of geriatricians

These were led by *Lord Amulree*, KBE, MD, FRCP (1900–1983), who, prior to his appointment as geriatric physician to University College Hospital and St Pancras Hospital in London in 1949, had worked at the Ministry of Health on aspects of care of the older person. This

had brought him in touch with all the early pioneers. His appointment in geriatric medicine was, for a long time, the only one at a London teaching hospital. He and his staff classified, diagnosed and treated elderly inpatients. Assessment visits were made to old people who were on the waiting list for admission. This ensured either appropriate placement of patients in hospital or that the necessary home support was arranged to enable the person to continue to stay at home. The result was a considerable shortening of the average inpatient length of stay, increased patient/bed turnover and a reduced waiting list.

Amulree was unique amongst geriatricians in having a 'wide-angled' view of the care of elderly people. This resulted from his experience as a clinician, as a medical officer of the Ministry of Health and as a Liberal peer in the House of Lords, where he spoke on matters relevant to the care of the elderly. He wrote extensively and his work included one of the first comprehensive articles on care of the elderly.[21] He is possibly best remembered for his maxim 'Adding Life to Years', in addition to his stature, wisdom and willingness to help colleagues. He was President of the British Geriatrics Society for 25 years. When all his achievements are taken into account, there is a case for calling him 'the father of British geriatric medicine'.

Professor Norman Exton-Smith, CBE, FRCP (1920–1990), was based at the Withington Hospital in London, before moving to University College Hospital and St Pancras Hospital when Lord Amulree retired. Like others, he made detailed assessments of his clinical management of sick elderly people. His style of medical management of inpatient care increased patient turnover and reduced their length of stay. He adapted progressive patient care to fit the needs of geriatric medicine. He led and/or encouraged research work, imbuing enthusiasm in his research team, registrars and colleagues. He established a research unit at St Pancras Hospital and supported work in subjects such as thermoregulation, control of the autonomic nervous system, falls, osteoporosis, osteomalacia, fractures of the femur, nursing of the elderly patient, pressure sores, nutrition of the older person, meals-on-wheels, terminal care, predicting mortality and cognitive assessment. He wrote many papers and a substantive textbook on geriatric medicine and co-authored several books.

Exton-Smith considered the components of an effective geriatric department that included having a sufficient number of beds, both in total and in the District General Hospital, practicing progressive patient care, having adequate medical and nurse staffing, consulting with other consultant colleagues, making home visits, having a day hospital and having good coordination with primary care and local authority services to produce a successful planned discharge. He thought that approximately half to two-thirds of all geriatric beds should be in the main hospital where the main diagnostic and treatment facilities were based, and the remainder should be in smaller units near the patients' home.

Professor Sir William Ferguson Anderson, OBE, FRCP (Glasgow, Edinburgh and London) (1914–2001), was a strong advocate on behalf of older people. In 1965, he was appointed David Cargill Professor of Geriatric Medicine in the University of Glasgow. He firmly believed in the speciality as an academic discipline and the need to teach medical students about old age. He took geriatric medicine into the community, notably in Rutherglen, where he established health centres for the elderly. He wrote extensively, and his textbook *Practical Management of the Elderly* went into five editions. He lectured in many countries, spreading the message of the achievements of British geriatric medicine, was a visiting professor in many countries, a major advisor to several medical charities for the elderly and a superb charismatic ambassador for the specialty.

Geriatrics in the United States

The development of modern geriatrics in strongly based on the Veterans Administration and private foundations, such as the Josiah Macy Jr Foundation, the John A. Hartford Foundation and the Donald W. Reynold Foundation. The Veterans Administration developed the Geriatric Research, Education and Clinical Center in 1976. These institutions have been the leaders in developing geriatric faculty, science and education at major universities in the United States. They also played a leadership role in developing palliative care and the teaching nursing home concept. In 1940, the Unit of Aging was started by the National Institutes of Health. In 1958, under the leadership of Nathan Shock and Reuben Andres, this became the Baltimore Longitudinal Study of Aging. The National Institute on Aging was established in 1974. Robert Butler was its first director.

There are three major geriatrics and gerontological societies in the United States. Each sponsors a yearly meeting and has its own journal. The Club for Research in Aging was founded in 1939 and it evolved into the Gerontological Society of America in 1945. The *Journal of Gerontology* was first published the following year. The Joseph T. Freeman Award was first given in 1980 to Robert Butler and its awardees read like a modern Who's Who in American Geriatrics (Table 1).

The American Geriatrics Society was formed in 1942 by Malford W. Thewlis. *The Journal of the American Geriatrics Society* was launched in 1953.

The American Medical Directors Association was founded in 1978, with William Dodd being its first president. Its journal is called the *Journal of the American Medical Directors Association*. Table 2 provides the impact factor for the major geriatric and gerontology journals.

Leslie Libow created the first fellowship in geriatric medicine at City Hospital Center, New York (a Mount Sinai School of Medicine affiliate) in 1966. The following year he created the first teaching nursing home in the United States. In 1982, the first Department of Geriatrics was formed at Mount Sinai Medical School. Dr Robert Butler was its first chairperson.

The first certifying examination in geriatrics was given in 1988. At the same time, 2-year geriatric fellowship programs were certified. In 1995, the fellowship requirement was lowered to 1 year. As of March 2010 there were 7029 board certified geriatrics and 1705 board certified psychiatrists in the United States. In 2008–2009 there were 470 geriatric medicine fellowship slots, of which only 62% were filled. Over two-thirds of the slots were filled by International Medical Graduates. At present there is one geriatrician for every 2699 persons aged 75 years or older in the United States. At the present rate of recruitment into geriatrics, this will decrease to one for every 5549 older Americans by 2030. Physicians working in nursing homes can be certified separately by becoming a Certified Medical Director, which is offered by the American Medical Directors Association.

Over the last 30 years, the United States has taken the lead in developing the scientific base of modern geriatrics. Unfortunately, the lack of interest by young physicians in geriatrics is likely to erode this over the next decade.

Geriatrics in the rest of the world

The first geriatrics society in France was formed in 1939 under the leadership of A. Baudouin. In the modern era, Professor Bruno Vellas, whose father developed the University of the Third Age, has revolutionized the approach to geriatrics in France. He founded the *Journal of Nutrition Health Aging* as the premier ageing journal in Europe. He developed the Mini Nutritional Assessment. His centre at the University of Toulouse has become a leader in modern research in nutrition, Alzheimer's disease and nursing homes.

In Italy, 'Recover' (old people's homes) was established by the Catholic Church in the mediaeval period. At the start of the twentieth century, hospital departments for the care of older persons and the disabled were formed. By the middle of the twentieth century, there were long stay hospital units ('lungodegenza'), rehabilitation units ('infermeria') and rest homes ('casa di riposo'). The Geriatric Society in Italy was formed in 1949. M. Ascoli was the first chair. Italy has two longitudinal studies on ageing, namely the Italian Longitudinal Study on Aging (ILSA) and the InCHIANTI (Invecchiare in Chianti).

In Sweden, the first chairs of geriatrics were established in Uppsala University and Göteborg (Gothenburg) University. Under the leadership of Alvar Svanborg and Bertel Steen, the longitudinal population study of persons over 70 years of age was established in Gothenburg in 1970–1971. The work of Torben Gill at the Old People's Town in Copenhagen from 1936 led to Denmark establishing a specialty of long-term care. In 1972, the Danish Society of Geriatric Medicine was founded.

The Spanish Society of Geriatry and Gerontology was started in 1948. A. Baudouin was the first chairperson. Geriatrics has been a recognized medical specialty since 1978, with a 4-year training program. Switzerland played a major role in the development of geriatric psychiatry under the leadership of Professor J.-.P Junod, who became the first Professor of Geriatrics in 1962. The University of Geneva has developed a Department of Geriatrics. Jean-Pierre Michel developed the European Academy for Medicine of Ageing (EAMA) in Sion, a centre for training young geriatric faculty.

The leader in geriatrics in Japan is the Tokyo Metropolitan Institute of Gerontology, which was founded in 1972. It is

associated with a 700-bed geriatric hospital. The National Institute of Longevity Science was established in 1995.

The first International Congress of Gerontology was held in Liège, Belgium, in 1950. In 1952, the second congress held in St Louis led to the formation of the International Association of Gerontology. This has recently been renamed the International Association of Gerontology and Geriatrics (IAGG). In conjunction with the World Health Organization (WHO) and under the leadership of Professor Vellas, the society has become more active. As a result, they have recently published guidelines developed by a task force chaired by John Morley and Yves Rolland, to enhance care in nursing homes (Table 3).

Teaching geriatric medicine

The teaching of medical students about the medical care of sick elderly people had long been recommended, but it was not until 1949 that Lord Amulree was appointed to University College Hospital, a London teaching hospital. Further advance had to wait until 1965, when Sir Ferguson Anderson became the first UK Professor of Geriatric Medicine. After this, progress was slow but by 1998 almost all the London teaching hospitals had a professorial chair in the specialty, and increasing numbers of chairs in geriatric medicine have been made in the country as a whole. These academic departments were usually based on an active geriatric unit with good community links. The curricula vary but could include biological and sociological gerontology in addition to clinical geriatric medicine. Postgraduate research courses leading to the degrees of MSc and PhD have been set up. Some universities have a cluster of associated chairs, such as the University of Manchester with two chairs in geriatric medicine and one each in cognitive gerontology, old-age psychiatry, gerontology, biological gerontology and social gerontology.

However, research on attitudes of medical students toward the elderly has shown that they tend to lose their initial interest and empathy for older people as they train and qualify. A survey of their attitudes before qualification showed that they had empathy for, and a 'bedside interest in', the elderly, which disappeared after graduation when the doctors considered their career prospects.[22] Parkhouse and McLaughlin[23] found that no doctor who had graduated in 1974 wished to enter geriatric medicine. Lambert *et al*.[24] showed that little had changed in a review of career preferences among newly qualified doctors: preferences for geriatric medicine remained very low at 0.9%, well below general medicine and surgery, although above genetics. Factors blamed included the prejudice of medical teachers against geriatric medicine, poor image/role of the geriatrician and mediocre working conditions. As a result, recruitment of medical staff into the specialty was poor. The Royal College of Physicians responded in 1972 and 1977 with a range of recommendations, including integration of geriatric medicine with general medicine, appointment of consultant physicians with a special interest in geriatric medicine and rotation of junior training posts between the two specialties.[25,26] The College also introduced the

Table 3 The IAGG Task Force recommends the following.

No.	Recommendation
Recommendation 1	Effective leadership structures are established, that where possible, include an expert physician (medical director), and an expert registered nurse (nursing director) and skilled administrator
Recommendation 2	An international alliance is formed to develop nursing home leadership capacity and capabilities
Recommendation 3	To showcase international exemplars of excellence in nursing home practice to raise awareness of the demonstrable benefits for older people and high standards achieved through expert practice
Recommendation 4	To create positive working conditions for nursing home practitioners with attractive career development opportunities, recognition and similar rewards enjoyed by health care workers in comparable roles within the acute care services
Recommendation 5	That nursing home quality indicators are developed that are sensitive to clinical and care needs and the right of older people to care that is dignified and respectful
Recommendation 6	The use of physical and chemical restraints should be reduced to those that are absolutely indispensable
Recommendations 7	That 'meaningful activities' be offered to residents to provide physical and mental exercise and opportunities to participate within the nursing home and in community life, enhancing personal autonomy, social relationships (including intergenerational relationships), and social support
Recommendation 8	That evidence-informed pain assessment and management programmes are introduced into all nursing homes
Recommendation 9	That evidence-informed end of life and palliative care programmes are introduced into all nursing homes
Recommendation 10	National drug approval agencies consider requiring drug trials that are age appropriate and inclusive of nursing home residents before they are approved
Recommendation 11	IAGG develop international certification courses for nursing (care) home health professionals
Recommendation 12	Pilot the use of 'Community of Practice Models' as a practice improvement method for nursing homes, utilizing both face-to-face interdisciplinary training and virtual team support
Recommendation 13	A universal ethical approach to obtaining informed consent and monitoring the appropriateness of research is developed
Recommendation 14	Develop nursing home research capacity in developing nations
Recommendation 15	An investment is made in research priorities that address major public health problems and inequalities that affect older people receiving long-term care. Research priorities for which a high need is recognized include: a A worldwide survey of different models of care, nursing home structure and issues in improving quality of care is undertaken b A worldwide survey of older persons and their families is undertaken to determine their preferences for long-term care c A cross-national, prospective epidemiological study measuring function and quality of life in nursing homes d Development of culturally appropriate standardized assessment instruments including those involving social participatory methods e A function-focused approach of the prevalence of geriatric syndromes, their impact on function and development of strategies to improve care for these syndromes needs to be developed f Research that evaluates the impact of different models of care against trajectories of physical and cognitive function

Diploma of Geriatric Medicine in 1986 to encourage general practitioners to gain interest in the care of older people.

Achievements of geriatric medicine

Gerontology: the science of the ageing process

Interest in gerontology in the United Kingdom was stimulated by the support of charitable foundations and the enthusiasm of a few individuals. The Nuffield Foundation created a medical and biological Research Committee, which gave grants to Howell for his research, to Dr Alex Comfort to work with Sir Peter Medawar at Birmingham, and later at University College London, and to Professor Sir Frederick Bartlett at the University of Cambridge to establish a research unit to investigate the psychological aspects of ageing. The Nuffield and the Ciba Foundations supported Vladimir Korenchevsky (1880–1959), a Russian biologist, who had studied under Pavlov and Metchnikoff. His enthusiasm for the science of ageing culminated in his becoming director of the Oxford Gerontological Institute. He was a driving force behind the creation of the International Association of Gerontology (IAG). The Ciba Foundation supported the IAG, which held its first meeting in 1950 in Liège, Belgium. The first meeting of the clinical

section of the IAG was held in Sunderland in the United Kingdom in 1958 and was chaired by Dr Oscar Olbrich. A later meeting was held in Manchester in 1974, which was organized by Professor Brocklehurst. The Ciba Foundation maintained its interest in old age by establishing a series of special colloquia in London, which were attended by many international experts on ageing, and supported the British Society for the Research in Ageing, which was founded by Korenchevsky.

As the new-style treatment methods were applied to the previously neglected chronic sick, clear evidence emerged of its effectiveness, particularly in hospitals. Official health data sources, such as Hospital In Patient Enquiry (HIPE) data collection, the Office of Health Economics and Health and Personal Social Services Statistics for England, showed that the number of deaths and discharges of elderly people and patient turnover from geriatric wards steadily increased while the average and median lengths of stay decreased. In 1980, the Chief Medical Officer for England and Wales was able to report 'the average length of stay for patients in hospital departments of geriatric medicine is steadily diminishing – more so than in any other hospital specialty. Only 10% remain in hospital for more than 6 months; the median length of stay is only 21.7 days'.[27] Progress was such that in 1984, the Nuffield Provincial Hospital Trust was able to comment, 'It [geriatric medicine] has established its expertise and has had notable success in developing and raising the standards of services for the old'.[28] Concomitant with these developments, individual geriatricians began to create differing styles of practice: whereas some did not take emergency admissions, others took increasing numbers of acutely ill patients, and still others reintegrated with general medicine, taking part in unselected acute medical intake and joint ward rounds with their general physician colleagues.

Problem areas

The birth of geriatric medicine in the United Kingdom was hampered by the indifference of the medical profession to elderly patients for many reasons. The care of the aged and infirm lacked the dramatic appeal of acute illness in the young. Physicians questioned why elderly people should be put through extensive rehabilitation when they had only a few years to live. Complete recovery was rarely possible and the result was often disproportionate to the effort required. Chronic sick patients were often accommodated in poorly equipped and staffed hospitals. General physicians feared 'bed blocking' if they admitted elderly patients, appeared uninterested in deciding what was normal or abnormal in this age group and in learning what treatment could achieve, were displeased at the diversion of resources from general medicine to geriatric medicine and were unenthusiastic about the considerable social/non-medical components of geriatric medicine. Geriatricians were viewed as 'second-rate' physicians.

Another concern was the quality of care given to the elderly in hospital. This culminated in the publication in 1967 of *Sans Everything: a Case to Answer*, which alleged inappropriate care in hospitals for the elderly and mentally ill. Official investigations found that the complaints were inaccurate, vague, lacking in substance, misinterpretations or over-emotional.[29] Following yet another allegation of improper care in a unit for the mentally subnormal in 1967, the Secretary of State for Health created the Hospital Advisory Service (HAS) in 1969, which was to act as his 'eyes and ears'. It was to be responsible only to him and was to be independent of the Department of Health. Visits to hospitals for the elderly and mentally ill started in 1970 and were carried out by teams of 'in-post' professionals: consultant geriatricians or psychiatrists, senior nurses, paramedical staff, administrators, and later social workers. It is best considered as a form of 'peer review'. Later its remit was extended to cover community services, at which time it was renamed the Health Advisory Service.

The development of specialist service for the elderly mentally ill lagged behind that of the physically ill. Not infrequently, these patients were inappropriately admitted to geriatric wards, where staff had limited experience in managing them. Sometimes they were admitted to large general mental hospitals where the general psychiatrists did not welcome them. The Ministry was aware of the problems presented by these patients and published advisory documents.[30,31] Eventually, guidelines were introduced to ensure admission to an appropriate ward: assessment by a multidisciplinary team was recommended. Joint assessment units with input from the local authority, psychiatrists, and the geriatrician were set up, although they tended to silt up owing to the failure to move the patients on to suitable wards or accommodation. Psychogeriatric day hospitals were opened, which provided a useful community function. Local authority residential homes were encouraged to take more mentally ill patients. However, it was not until the 1970s that consultant psychogeriatricians were appointed.

Another source of debate was the term *geriatrics* and allied words. The word *gerocomy*, attributed to Galen, was used for the medical care of the elderly and was adapted to *geroncology* for their sociological aspects. In 1903, Metchnikoff invented the word *gerontology* for the biological study of the ageing process. Nascher is generally credited with coining the word *geriatrics*.[32] 'The term was . . . derived from the Greek, *geron*, old man and *iatrikos*, medical treatment. The etymological construction is faulty but euphony and mnemonic expediency were considered of more importance than correct grammatical construction'. Howell pointed out

at least one author who had confused *gerontology* (the science of old age) and *geriatrics* (the care of the aged). The word *gerontology* has been attacked as a barbarous misspelling and the word *geratology*, the study of old age, has been suggested instead. The founders of the Medical Society for the Care of the Elderly did not use the word *geriatrics* since it was, in 1940s, almost unknown. Many United Kingdom hospital geriatric units, aware of the public's perception of *geriatrics* as being apparently synonymous with *senility*, now call themselves 'Department for the Medical Care of the Elderly' or 'Care of the Elderly Department'.

Key points

- In spite of interest in old age, enlightened medical treatment of the elderly sick patient did not start until the twentieth century.
- Classification of patients and modern treatment methods showed that the majority of those admitted to elderly care wards could be discharged.
- Community studies found unreported minor illness in older people, which could have a major impact on the quality of life if left untreated.
- University authorities were slow to implement the education of medical students about the medical and social aspects of illness in the older person.
- Powerful charitable foundations supported research into the causes of ageing.

PART 1

Ageing: Biological, Social and Community Perspectives

CHAPTER 1

A biological perspective of ageing

H. James Armbrecht

St Louis Veterans' Affairs Medical Center and Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

This chapter provides an introduction to the 'principles and practice of geriatric medicine', the topic of this textbook. Underlying the need for geriatric medicine are the biological changes with time that we call ageing. The purpose of this chapter is to summarize what we know about these changes, how they relate to the diseases and conditions that require medical intervention and why they even occur at all.

This chapter develops several themes. Biological ageing progresses differently in different cells, tissues and organisms. Age theories focusing on one concept are common, for example, free radical, genetic, neuroendocrine, and immune, but they are incomplete in themselves. And finally, there are multiple gaps in our knowledge concerning the causes of ageing.

Ageing populations

In talking about biological ageing, it is useful to talk about the ageing of whole populations. Although the age at death of an individual varies widely, the survival of whole populations is fairly predictable, and the curves have a similar shape across species. Figure 1.1 shows human survival curves for people in the United States. Each curve represents survival data (percentage surviving) at each age for the calendar years indicated. The survival curves are sigmoidal, and they are characterized by very few deaths in the early years, a short period with a large number of deaths and a tail of old survivors. The age at which the number of survivors starts to decrease rapidly is usually referred to as the onset of senescence. The slope of the curve during the decrease is the rate of senescence, and the age where there are no survivors is the maximal lifespan.

In 1900–1902, there was an early drop in survival, due to infant mortality, followed by a somewhat gradual decline, and ending with a steeper decline between age 70 and 90 years. As the calendar years progress from 1900–1902 to 1949–1951 to 2006, there were many more survivors at each age and a delay in the onset of senescence. This is sometimes referred to as the squaring off of the survival curve. Much of the difference between 1949–1951 and 2006 was due to a delay in the onset of senescence with little change in the rate of senescence (the slope of the decline). Also, the maximum lifespan was similar for all curves. The net effect is that the average lifespan has increased largely through a delay in the onset of senescence with little change in the rate of senescence or in maximal lifespan.

The dotted line represents a theoretical population where the onset of senescence has been further delayed but with an increase in maximal lifespan. This is the type of shift that is seen with caloric restriction of animal models.[1] To see such a change in human populations would most likely require a fundamental change in our biological ageing. It would not arise from more effective treatment of the diseases of ageing, which would tend to square off the existing survival curve.[2,3]

Although survival curves are useful, they show only one rather dramatic endpoint – death. As more people live longer, there is greater interest in quality of life rather than just the length of life. This has given rise to the concept of 'functional lifespan', which can be assessed by various clinical measures. One challenge in the biology of ageing is to develop markers that reflect physiological age rather than just chronological age. Such markers could be used for early intervention with the goal of extending functional lifespan.

Why do we grow old?

The question of why we grow old can be answered at many levels – philosophical, religious and biological – and, of course, becomes more relevant personally the older we become. Recent research and thinking form a framework in which to wrestle with the question of why we grow old biologically. This question was proposed as an 'unsolved problem of biology' by Medawar in 1952.[4] However, recent concepts have led two prominent gerontologists to

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

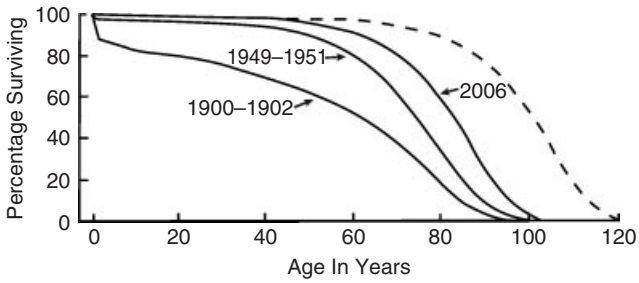

Figure 1.1 Human survival curves. Percentage surviving versus age is plotted for each of the calendar years indicated. Data redrawn from the National Center for Health Statistics (US Bureau of the Census). The dashed line represents a theoretical shift in the data for 2006. The data are shifted such that the age of onset of senescence and maximal lifespan are increased, but there is no change in the rate of senescence.

conclude that 'aging is no longer an unsolved problem in biology'.[2,5] The reason for this change is that since Medawar first posed the question there has been a large amount of descriptive gerontology – a cataloguing of the physiological and biochemical changes that characterize ageing in many different organisms. As a result, within about the last 20 years biologists have begun to look at the big picture of why we age.

The question of why we grow old is really tied into a fundamental characteristic of life itself – reproduction. Simply put, if the purpose of a particular species is to maintain itself through reproduction, there is no reason to invest biological resources in maintaining a member of that species after the birth and nurturing of the next generation. Hence, after reproduction, species generally decline physiologically and eventually die. This broad perspective is usually referred to as 'the evolutionary theory of ageing', and it makes important predictions about the biology of ageing.

The evolutionary perspective of ageing – key concepts

The evolutionary perspective of ageing is made up of three interrelated concepts[3,5] – mutation accumulation, antagonistic pleotrophy and disposable soma (Table 1.1).

Mutation accumulation

The 'mutation accumulation' concept was postulated by Medawar in an attempt to answer his own question about why we age.[4] It states that genes may accumulate that are expressed only after reproduction. These genes may have deleterious effects that contribute to the physiological decline of the organism. These late-acting genes are not selected against because they do not affect reproduction and nurture of the next generation.

Table 1.1 Evolutionary perspective of ageing.

Mutation accumulation	Genes may accumulate that act late in life and contribute to the physiological decline of an organism
Antagonistic pleotrophy	Some genes may have positive effects early in life but then have negative effects later in life after reproduction
Disposable soma	There is a competition for resources between reproductive (germ line) cells and maintenance (somatic) cells, and after reproduction the somatic cells are no longer needed (disposable)

Antagonistic pleotrophy

An extension of the mutation accumulation concept is the idea that these late-acting genes may exist in the gene pool because they have positive effects early in life. Thus, the same gene may have positive effects early in life but negative effects after reproduction. This concept is called 'antagonistic pleotrophy'. An example would be the fact that a particular apolipoprotein (ApoE4), which is a significant risk factor for Alzheimer's disease, maintains itself in the population. Since Alzheimer's disease arises very late in life after reproduction, there is no selective pressure to remove it from the gene pool. The fact that ApoE4 is still found in the gene pool may mean that it gives some positive advantage early in life.

Disposable soma

For a species to survive, it must reach reproductive age and nurture the next generation. Since organisms have only a limited amount of biological resources at their disposal, these resources must be allocated carefully between maintenance and reproduction. This is sometimes looked at as a competition between the cells involved in maintenance (the somatic cells) and the cells involved in reproduction (the germ line cells). In such a competition, the most important thing is for the germ line cells to be passed on to the next generation. The somatic cells (the vast majority of the cells in the body) are only a means to that end. In that sense, somatic cells are 'disposable' after they have supported the organism through reproduction. Hence this concept has been named the 'disposable soma' theory. There is no incentive to maintain the stromal cells past the reproductive age, and a long post-reproductive lifespan could be viewed as wasteful.

Changing concepts in the biology of ageing

The descriptive work and the evolutionary perspective have changed the way in which we look at a number of

Table 1.2 Changing concepts in the biology of ageing.

Older concepts	Newer concepts
There is a genetic programme that controls the ageing process much like there is a developmental programme	Ageing is not the result of a 'programme' but rather the result of 'biological neglect' after reproduction
Biological ageing is a singular process that affects all tissues and organisms equally	Biological ageing has many components that affect tissues and organisms in diverse ways
There is one 'theory of ageing' that explains the ageing process in biological terms	Biological ageing is complex change with time that is described by multiple perspectives (theories) at multiple levels
Ageing is due either to our environment (extrinsic) or to our genes (intrinsic)	Ageing is roughly 25–35% genetic with the rest influenced by our environment and lifestyle
Maximal lifespan is characteristic of an organism and is fixed	Maximal lifespan can vary within limits in response to the nutritional and reproductive needs of the organism
Ageing is the sum of all of the diseases of ageing	Ageing results in an increase in disease, but it is separate from the diseases of old age

important concepts in the biology of ageing. In a sense, the fields of geriatrics and gerontology have been around long enough so that there has been an 'ageing' of the concepts related to biological ageing (Table 1.2)

There is no 'genetic programme' for ageing

Previously, ageing was viewed as a 'process' or even a 'programme'. Much like a developmental programme, it had its own intrinsic clock that moved inexorably towards universal senescence and death. At various times, this clock has been postulated to be hormonal (hypothalamus–pituitary axis), immune (involution of the thymus) or cellular (cell senescence). However, from an evolutionary perspective, ageing is not a genetic program but rather the result of biological neglect (not necessarily benign) that occurs after reproduction is complete.

Biological ageing varies with tissue and organism

Since there is no programme, there is no reason to expect that biological ageing will progress the same in all organs of an individual or in all species. The death certificate of a mouse may look very different from that of a human. For example, laboratory rodents often die of kidney disease, but this is a much lesser cause of mortality in humans.

There is no one 'theory of ageing'

Another result of this lack of post-reproductive maintenance is that different organ systems will fail at different rates across tissues and organisms. That is, biological ageing is probably not due to a single universal deficit in all organisms. Put another way, there is no one mechanism or 'theory of ageing' that explains everything. However, the classical theories of ageing describe important aspects of biological ageing (see below).

Ageing has both genetic and environmental components

Some researchers have made a sharp distinction between ageing due to environmental factors and ageing due to genetic factors.[2] They classified theories of ageing as either extrinsic (environmental) or intrinsic (genetic). It is becoming clearer that ageing is influenced by both environment and genetic makeup, and it is sometimes difficult to untangle the two. There definitely is a genetic component, as the best predictor of lifespan is the lifespan of one's parents. Studies of twins suggest that in humans about 25–35% of ageing is genetic and the rest is environmental. Recently, studies of centenarians have found certain genes that seem to be associated with long life. These are sometimes referred to as 'longevity assurance genes'. The idea is that these genes contribute to long life, but they are not part of a genetic mechanism to regulate lifespan.

Maximal lifespan can vary within limits

The lifespan of a group of genetically related animals (inbred laboratory rodents under laboratory conditions) is remarkably constant, even though it is not directly regulated. This has led to the concept that lifespan, especially in higher organisms, is fixed. Yet the lifespan of lower organisms (worms, flies, yeast) can be markedly altered by a variety of manipulations. These include restricting diet, boosting antioxidant defences and modulating insulin/growth signalling pathways (see below). However, modulating the lifespan of higher organisms such as mammals seemed difficult, except through caloric restriction.[1] Recent studies have suggested that higher organisms have 'longevity assurance pathways' that parallel those in lower organisms.[6] Modifying these pathways in various ways has made it possible to extend life in mice. Thus, even higher organisms have the ability to modulate their lifespan based on reproductive needs and environmental conditions.

Ageing is not the sum of the diseases of ageing

The relationships between ageing and the diseases that accompany ageing are still the subject of some debate.[3] Previously there was a tendency to identify ageing with the diseases of ageing. More recently, the emphasis has been that these diseases may be due to underlying biological changes with age. In other words, increased vulnerability to disease is a characteristic of biological ageing, but ageing is not just the sum of all of the diseases of ageing. The distinction between ageing and the diseases of ageing is very important in terms of research strategies. If ageing is mostly the diseases of ageing, then these diseases will have to be slowly conquered one by one. On the other hand, if there are underlying biological processes driving disease, then understanding and modifying these could possibly reduce the vulnerability to many diseases at once.

The 'theories of ageing'

Although there is no universal 'programme' of ageing, when one looks across species there are common themes as to how organisms age. These have led scientists to propose various 'theories of ageing' over the years based on experimental observations. These theories used to be viewed as rivals, but they are really complementary. They each describe some aspect of biological ageing at some level of organization. Since none of these theories gives a complete picture, it may be more useful to refer to these 'theories of ageing' as 'components' or 'perspectives' of biological ageing.

Over the years, there have been many 'theories of ageing' proposed and many attempts to organize them. In a review paper in 1990, Medvedev identified over 300 theories of ageing.[7] There have been a number of more recent reviews describing the theories of ageing in an organized way.[8–10] In this chapter, we describe some of the major theories that have been helpful in characterizing aspects of the biology of ageing.

One way to organize the theories is according to the level of biological organization that they address.[8,10] Complex biological organisms are composed of multiple organ systems, made up of individual organs, made up of individual cells, made up of subcellular organelles and individual molecules. So we can talk about the subcellular, cellular, and systemic components of ageing (Table 1.3) These components seek to describe *how* we age (increased damage, decreased repair, etc.) whereas the evolutionary concepts (Table 1.1) seek to describe *why* we age.

Subcellular components of ageing

The free radical perspective

One of the most important concepts in the biology of ageing over the last 50 years is the free radical perspective of

Table 1.3 Components of biological ageing.

Components	Type	Description	Ref.
Subcellular components	Free radicals	Free radicals generated by cells produce oxidative damage to proteins, DNA and lipids, impairing cell function	13, 14, 16
	Mitochondria	Energy production by mitochondria generates free radicals that cause local oxidative damage and further degrade mitochondrial function	17, 18
	Gene expression	DNA damage results in altered gene expression and accumulation of non-functional proteins, altering cell function	19–21
Cellular components	Cell senescence	Somatic cells stop dividing due to a programmed limit or due to cellular stress and damage, affecting the surrounding tissue	24, 25
	Stem cells	The capacity of resident stem cells to divide and replace damaged tissue declines with age	26–28
Systemic components	Neuroendocrine system	Multiple changes in hormone secretion, action and feedback result in altered responsiveness to internal and external stressors	31–33, 36
	Immune system	Changes in the number and function of immune cells result in decreased capacity to counter new challenges and respond to vaccines	38, 39

ageing. The importance of free radicals was first proposed by Harmon in 1956.[11] Free radicals are highly reactive chemical species that are formed as a byproduct of certain biochemical reactions. A major source of free radicals is the production of energy by oxidative phosphorylation in the inner mitochondrial membrane. Certain other biochemical processes also produce free radicals, in addition to ionizing radiation and environmental pollutants. These reactive chemical compounds then produce oxidative damage to important cellular molecules such as proteins, DNA and lipids. Such damage can then affect homeostasis at the cellular level, resulting in cell senescence, and/or uncontrolled cell growth (see below). Because the free radical reactions produce oxidative damage, the free radical theory is sometimes referred to as the 'oxidative stress' theory.[12]

One of the important contributions of the free radical perspective is that it makes several experimental predictions, many of which have been borne out. First, in experimental animals, oxidative damage to proteins, DNA and lipids has been shown to increase with age.[13] Second, species that are longer lived are less susceptible to oxidative stress,[14] and they have more efficient repair mechanisms. More free radicals are generated by a high metabolic rate, and a high metabolic rate is associated with a shorter lifespan. Third, caloric restriction of organisms increases their maximal lifespan and tends to increase their antioxidant defences and reduce oxidative damage.[1] Finally, organisms which have their antioxidant defences boosted artificially live longer. This has been demonstrated in fruit flies, roundworms and mice.[15]

An important byproduct of free radical production is an acceleration in the non-enzymatic coupling of glucose with proteins – glycosylation. A common example of this is the high levels of glycosylated haemoglobin in the blood of diabetics. Glycosylation increases with age and may interfere with protein function. Glycation may play a role in the ageing of connective tissue, blood vessels and the lens of the eye.

More recently, the importance of free radicals and oxidative stress in determining maximal lifespan have been called into question. One reason is that a systematic knockout of components of the antioxidant systems in mice has failed to shorten lifespan.[16] However, there may be enough redundancy built into the antioxidant systems that more than one system must be knocked out to see an effect. Second, numerous attempts to extend lifespan through dietary antioxidants have been negative. However, human studies have shown that diets high in antioxidants correlate with positive outcomes. Thus, antioxidants may be used more efficiently in the body when consumed as part of a diet. In addition, although it may be difficult to show an effect of free radical manipulation on lifespan, free radicals may play an important role in some of the morbidities of ageing such as cancer and cataract formation.

The mitochondrial perspective

Since most of the free radicals in cells are generated by mitochondria, it is only a small jump from the free radical perspective to the mitochondrial perspective of ageing. Since free radicals do not travel very far before reacting, this component has focused on local damage to mitochondrial proteins, DNA and lipids. Again, there is experimental evidence to support this concept. It has been shown that oxidative damage to mitochondrial proteins and DNA increases with age.[17] Mitochondrial DNA codes for some of the proteins that are important for mitochondrial energy production. Oxidative damage to mitochondrial proteins and DNA may then lead to inefficient energy production and the release of more free radicals. This downward spiral may account for the fact that mitochondria in older aerobic tissue such as skeletal muscle are fewer in number, have an altered appearance, and are less efficient in energy production. On the other hand, altered expression of mitochondrial antioxidant enzymes does not show a clear effect on lifespan in mice.[18]

The gene expression perspective

A third major subcellular component of ageing is the gene expression perspective. In its broadest sense it relates to changes in information flow between DNA, mRNA and proteins. DNA is subject to strand breaks, covalent modifications and chromosomal rearrangements. This may result in altered gene expression and contribute to the ageing process.[19,20] Much DNA damage is in the form of chromosomal rearrangements. Such rearrangements are usually associated with diseases such as cancer rather than with biological ageing as a whole. With the advent of inexpensive gene arrays, there have been many reports of changes in gene expression in various tissues and in various models of ageing. However, it difficult to know whether the observed changes reflect primary changes that are part of general biological ageing. In many cases, the changes could be in response to age-related disease or to a general increase in oxidative stress.

Since DNA damage ultimately leads to changes in proteins, it has been proposed that the number of abnormal proteins may increase with age. This has been referred to as the 'error catastrophe' theory. Although an increase in abnormal proteins can be detected in some circumstances, there does not appear to be a general increase in dysfunctional proteins. Interestingly, it may be that changes in the turnover of certain proteins with age is important. Protein turnover may play an important role in the development of certain neurological diseases characterized by abnormal protein aggregation.[21]

Cellular components of ageing

The cell senescence perspective

For the number of cells in a tissue to remain constant, there must be tight control over the rate of cell production and cell death. Uncontrolled production by cell division can lead to cancer and uncontrolled cell death can lead to tissue dysfunction and disease. Cell death can take the form of senescence (cells stop dividing), apoptosis (purposeful cell death) or necrosis (cell death usually due to insults). Cell senescence seems to have the most relevance with regard to ageing of the whole organism.

The phenomenon of cell senescence was originally described by Hayflick and Moorehead, who found that human skin fibroblasts divide only a finite number of times (population doublings) even under optimal growth conditions.[22] Initially, the number of population doublings seemed to correlate with donor age (inversely), with the longevity of donor species (directly) and with certain human premature ageing syndromes (decreased). Because of this possible correlation between population doublings and ageing of the whole organism, there was an intense effort to determine what regulated the number of cell divisions at the cellular level. It was finally established that a major determinant of population doublings was the length of telomeres, structures that play a protective role on the tips of chromosomes. Cells that divide indefinitely (germ cells, cancer cells, stem cells) contain an enzyme called telomerase that repairs the telomere shortening after each cell division.[23]

Recently, it has become clear that telomeres and telomerase are not the sole factors regulating cell senescence. Cells can undergo stress-induced senescence in addition to replicative senescence.[24] Cell senescence can also be induced by free radical damage and DNA damage that acts via independent cellular pathways.[25] Thus, cell senescence may be a consequence of the free radical and DNA damage components of ageing described previously. Also, telomere shortening has been difficult to observe in rodents, which nevertheless age in ways analogous to humans. However, telomere length and cell senescence may contribute to the ageing of certain tissues. In particular, it may contribute to the ageing of stem cells (see below). In the big picture, then, cell senescence may function more to prevent uncontrolled cell growth (cancer) rather than as a 'clock' to limit lifespan. Also, some of the original correlations between cell senescence and organismal ageing have been called into question.

The stem cell perspective

The other side of cell loss by cell senescence is the production of new cells via stem cell proliferation. It is now recognized that many tissues have the capacity to renew themselves in response to tissue damage and that this can take place at any age. This renewal capacity is the result of resident adult stem cells that have the capacity to proliferate in response to tissue needs.

The concept that stem cells may play a major role in the ageing of critical organs is fairly new.[26] Many of the concepts have emerged from studies in worms, flies and mice, but more data are being accumulated from humans. The importance of stem cells in the function of proliferating tissue such as the haematopoietic system and the gut epithelium is well known. Recently, stem cells have been found in non-proliferating tissues such as the nervous system and muscle. Because of the ease with which it can be studied, the proliferative capacity of the haematopoietic system, which gives rise to immune cells such as T cells, B cells and macrophages, has been shown to decline with age. This plays a major role in the decline of the immune system (see below). The number of neuronal stem cells in the human brain and the number of satellite stem cells in human muscle have also been reported to decrease with age.[27]

The factors that lead to a decrease in stem cell number and function may be the same ones that contribute to cell senescence. These include free radicals, DNA damage and telomere shortening.[26,27] A current line of research is to determine the contribution of intrinsic ageing and systemic factors to stem cell ageing. The decline in stem cell function may not be completely random but may be regulated. Stem cells seem to have distinct ways of maintaining themselves depending on their age.[28] The result of this is that they proliferate less well in older organs. They are also less susceptible to becoming cancerous, which is perhaps a necessary trade-off in older organisms.

The relationship of stem cell ageing to organismal ageing is still unclear. If ageing stem cells result in organ failure due to lack of repair, then they play a major role. On the other hand, stem cell ageing may simply reflect systemic changes that are taking place in the ageing organism. It may even be protective in terms of limiting the chances of uncontrolled proliferation. In any event, the existence of ageing stem cells in many important tissues raises interesting therapeutic possibilities. The first possibility would be that of enhancing the function of older stem cells *in situ* in order to stimulate the repair of older tissue. The second possibility relates to the fact that it is now possible to reprogramme cells such as fibroblasts so that they act like stem cells in that they can differentiate into multiple cell types.[29] Reprogramming of cells may allow the production of individual, personalized stem-like cells for therapeutic purposes. With regard to ageing, this capability raises the questions of whether cells from old individuals can be successfully reprogrammed and whether old individuals can benefit from stem cells from younger individuals.

Systemic components of ageing

Much of this textbook is organized around age-related changes in the various organ systems and their treatment. For example, there is the Gastrointestinal System (Section 2), the Cardiovascular System (Section 4), the Central Nervous System (Section 6) and so on. Many (but not all) of these changes may be the result of changes at the cellular and subcellular levels. A major area of research in the biology of ageing is to describe (as much as possible) the changes at the organ and system levels in cellular and subcellular terms. However, for many years there has been the concept that certain organ systems actually *drive* the ageing process in higher organisms. These include the growth regulatory system, the stress response system, the immune system and the reproductive system. Although they are not the clocks, the ageing of two systems, the neuroendocrine and immune systems, accounts for many of the features of ageing mammals.

The neuroendocrine perspective

Major functions of the neuroendocrine system are stress response, growth regulation and reproduction. These have all been related to biological ageing.[30,31] The clinical aspects of the ageing neuroendocrine system are covered extensively in other chapters of this textbook [see Eating Disorders (Section 1), CNS Disorders (Section 6), Endocrine Disorders (Section 10), etc.].

In the past, the endocrine contribution to biological ageing has been viewed mainly as hormonal deficiency. With ageing, there is a decrease in dehydroepiandrosterone (DHEA) production (adrenopause), a decrease in growth hormone and IGF-1 (somatopause) and a decrease in estrogen and testosterone (menopause/andropause).[30] These decreases were postulated to be driven by the hypothalamus as a sort of 'pacemaker' of ageing. However, biological ageing is more than a hormone deficiency and the idea of a 'pacemaker' is weakened by evolutionary considerations (see above). Because ageing has been viewed as a hormone deficiency, there have been efforts to supplement with things like growth hormone and DHEA, but with limited success. Recently, it has been shown that biological ageing can be modulated substantially through hormonal (growth) pathways even in mammals. This has sparked renewed interest in the insulin signalling pathways apart from their role in diabetes (see below).

One of the hallmarks of ageing is the decreased ability to adapt to stressors. The classical stress response system comprises the hypothalamic–pituitary–adrenal (HPA) axis. The clinical aspects of the ageing HPA axis are addressed in Chapter 97. As would be expected in such a complex system, there are multiple changes in hormone secretion, hormone action, feedback regulation and so on with age.[32,33] For example, the production of DHEA, an important steroid hormone precursor, declines with age despite normal levels of ACTH and cortisol. In general, the stimulation of the HPA appears to increase with age in humans, although there is much individual variation. This HPA stimulation appears to result from a combination of factors. These include repeated external 'life stressors', decreased end organ responsiveness and decreased feedback inhibition. There has been a particular focus on high cortisol levels and their contribution to altered hippocampal function and neurological diseases in the elderly.[32]

There has been renewed interest in the role of the growth regulatory system, comprising growth hormone, insulin and insulin-like growth factors (IGF), in biological ageing.[33] In particular, the insulin/IGF-1 signalling system and its analogues in lower organisms have been studied extensively with respect to its effects on longevity. Modulating insulin/IGF-1 signalling extends longevity in a number of mouse models.[34] The emerging picture is that there are longevity pathways that are conserved across yeast, worms, flies and mammals.[6] These pathways, which normally promote growth, are blunted in times of nutritional stress. In the case of mammals, this would be food shortages in the wild or experimental caloric restriction in the laboratory. These conserved pathways involve insulin-like signalling and other energy-sensing proteins. Inhibiting these pathways with drugs or through genetic manipulation increases lifespan in mice.[35] These same pathways are activated by caloric restriction, which extends maximal lifespan. The mechanism by which these pathways modulate lifespan is under investigation and may involve antioxidant defences.[36] In support of this, the hormone Klotho has been shown to extend maximal lifespan in mice in part by blunting the insulin signalling pathway.[37] Klotho is made primarily in the kidney and also stimulates antioxidant defences. These endocrine studies demonstrate that mammalian lifespan may be manipulated within limits at the hormonal level.

The immune system perspective

A decline in the immune system has been well documented in humans and animal models of ageing. In humans, this results in increased susceptibility to infection, decreased effectiveness of vaccination and an increase in autoimmune disease and possibly cancer.[38] The clinical implications of this are covered in Chapters 46–47 and 115–117.

The function of the adaptive immune system clearly declines with age, but the effect of age on innate immunity is less clear.[39] T cell production declines with age due to the involution of the thymus. The function of T-helper cells declines with age, including decreased expansion and differentiation into effector cells. On the other hand, there is excessive clonal expansion of some subsets of T cells.

This results in decreased numbers of T cells to fight new infections. With regard to innate immunity, there is a similar pattern of a decrease of naïve B cells and a clonal expansion of memory B cells with age. There is also an increase in auto reactive serum antibodies. As with cell senescence, changes in lymphocyte function have been linked to free radicals, DNA damage and telomere shortening, in addition to repeated exposure to antigens such as cytomegalovirus (CMV).[38] There are conflicting reports regarding functional changes in neutrophils, macrophages and natural killer cells.

In societies with good public health measures, the decline in the immune system seems to play a lesser role in human ageing. Even with the involution of the thymus, there is still T cell production in old age and no decline in total peripheral B cell numbers. However, the decline of the immune system may contribute in more subtle ways to the increase in autoimmune disease, cancer and transplant rejection in the elderly.

The biology of ageing and geriatric medicine

Geriatric medicine, as extensively described in this textbook, is daunting in its scope. However, there is reason for hope. First, ageing is not a program for failure but a result of evolutionary neglect after reproduction. As components fail, there is reasonable optimism that they can be fixed or replaced, as is now being done. In this context, the possibility of using intrinsic or extrinsic stem cells to repair organs is exciting.

Second, there is evidence that biological ageing can be altered in fundamental ways even in mammals. These ways include modulation of insulin/IGF-1 signalling (see above) and caloric restriction. Caloric restriction involves feeding animals less food than they would ordinarily eat.[1] This increases mean and maximal lifespan in worms, flies, yeast, mice and rats. It has beneficial effects on almost every aspect of physiological ageing, so it is not clear exactly how it works. These effects include reducing oxidative damage and modulating the insulin/IGF-1 signalling pathway. A recent study showed that caloric restriction delays disease and mortality in monkeys.[40] This has spurred renewed interest in finding a caloric restriction mimetic for humans that would reduce morbidity and mortality without the drawbacks of a restricted diet.

Third, in the light of an ever larger ageing population, biologists who study ageing have realized there is a greater urgency to consolidate a body of knowledge that will be helpful in clinical care. To that end, the National Institute on Aging recently convened a 'Biology of Aging Summit'.[41] The purpose of the meeting was to summarize what is known, identify gaps in knowledge, identify promising new avenues of research and apply some of these concepts to clinical care.

To answer the questions raised earlier, the manifestations of biological ageing will have to be dealt with one condition at a time from the clinical perspective. The pathologies found in each organ and organ system are different. We do not yet know what the underlying link is or if there is one. Even if science were somehow able to affect the biology of ageing in some fundamental way and shift the survival curve (Figure 1.1), there would still be much for physicians to do. There would still be an age bracket where the population suffers a rapid decrease in survival. It would only occur later in life on average. As summarized by Carnes *et al*.,[3] 'Physicians need not fear that science will put them out of work' (p. 698).

Finally, comparative aspects probably give us the best biological perspective of ageing. In lower organisms there is a close relationship between the loss of reproductive capacity and rapid senescence. In humans this is not the case. Humans have the ability to live many years past the end of their reproductive years. Some have speculated that this is because children develop slowly and need long-term parent (and in some cases grandparent) care. In any event, such a long post-reproductive lifespan is unusual, and its length is increasing. From the standpoint of biology, it is a gift – a gift that raises the questions, 'Why do we live as long as we do?' and 'What will we do with the extra time?'.

Key points

- There is no genetic program for ageing.
- Biological ageing varies with tissue and organism.
- There is no one theory of ageing.
- Ageing has both genetic and environmental components.
- Ageing is not the sum of the diseases of ageing.
- Maximal lifespan can vary within limits.
- At the present time, we provide care mostly at the level of the diseases of ageing.

CHAPTER 2

The demography of ageing

Kenneth G. Manton[1] and John E. Morley[2]

[1]Duke University, Durham, NC, USA

[2]Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

We examine several dimensions of past, current and future demographic changes and the health dynamics of ageing in the USA and other developed countries. Models of the demographic and health dynamics of elderly and oldest-old populations require updating as information about the characteristics of those populations accumulates from (a) demographic sources (e.g. population censuses and vital statistics), (b) specialized longitudinal surveys of elderly populations, (c) epidemiological and clinical studies of elderly subgroups and (d) integrating multiple data sources in comprehensive models of health, ageing and mortality.[1] This last approach will increase in importance with time as the linkage of biomolecular mechanisms with population dynamics becomes increasingly important in assessing the macro/population influences of accumulated knowledge from epidemiological, clinical and basic science studies. This is neither meta-analysis (statistical study of multiple clinical data sets) nor bioinformatics (analyses of laboratory studies to find common patterns). It is a new scientific discipline born of the mathematical integration of medicine, mathematics and biodemography. When populations are successfully modelled at micro (biomolecular), meso (organ systems and individuals) and macro (population) levels, the models can be applied to economic and policy studies – in both government and commercial service (to optimize the effects of medicine and medical research on population health). To understand how these models will evolve, we start with a discussion of the application of basic demographic techniques.

Probably the most basic view of the demography of ageing is that a trio of forces, each driven by multiple social and physiological processes, determines the current and future growth of the elderly and oldest-old populations in the USA and other developed countries. Two of these are the larger size of recent birth cohorts who will become the elderly in the near future and decreases in mortality at earlier ages allowing larger proportions of birth cohorts to survive to ages 65+ years. The third factor, discussed separately, is mortality declines at late ages and their age variable relation to, and interaction with, changes in health and functioning.

The first two forces are now well understood – although their magnitude is not appreciated. In the USA (as elsewhere), the oldest-old (aged 85+ years) population in 2005 was composed of persons born in 1920 or earlier. From the 1920 US birth cohort, 18.6% of males and 35.1% of females or 796 100 persons, were expected to reach age 85 years. Since life expectancy (LE) at age 85 years for this cohort is roughly 5.3 (males) to 6.6 (females) years, this implies a US population aged 85+ in 2005 of 4.9 million persons.

The largest US 'baby boom' cohort (1961) was 4.3 million persons. If 1920 male and female survival rates were applied to the 1961 birth cohort, then 1 154 550 persons would survive to 85 years – or 45% more persons than from the smaller 1920 birth cohort. US survival improved from 1920 to 1960. Of persons born in 1960, 34.4% of males and 49.9% of females are expected to reach 85 years. Applying these proportions to the 1961 birth cohort implies 1 812 450 persons would reach 85 years – an increase of 57.0% over the number surviving to that age from the 1961 birth cohort than if 1920 mortality rates had not changed. Increased birth cohort size and reduced early mortality increases the number of persons passing 85 years by 127.7%.

If all cohorts were similar in size, these two forces would imply (assuming that life expectancy at 85 years increases to 7.5 years) 13.5 million persons aged 85+ years – increases of 2.7 million persons due to larger cohort sizes and 5.9 million due to mortality declines. This increase would take 42+ years to realize, that is, the birth cohort of 1961 passes 85 years in 2046. These simple calculations, using actuarial survival statistics and population counts, gives a sense of the relative contributions of birth cohort size and improved early mortality to increases in the size of future elderly

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

populations. Uncertainty about exact changes in the size and composition of the elderly population is largely due to uncertainty about mortality declines at late ages. Some projections envision larger populations reaching ages 85+ years, for example, 40+ million persons might reach ages 85+ years in 2050 if significant progress in improving known risk factors is assumed.[1]

Thus, if US social, economic and health conditions remain stable, the potential for large increases in the elderly and oldest-old population exists in the birth cohorts comprising the current US population and their early health and mortality experiences. Looking at the situation in reverse, the elderly and oldest-old populations currently being examined epidemiologically, clinically and physiologically come from cohorts born long ago [e.g. in 1915, pre-World War I (WWI) and 1930, the beginning of the great depression], which were relatively small at birth and which experienced what today would be extraordinary, and excessive, mortality risks and adverse early health experiences (e.g. exposures to many childhood diseases which are now prevented by vaccination or for which there are effective medical treatments; for many European countries, there are also the effects of injuries suffered by combatant males in WWI and WWII).

This brings us to the third force, that is, mortality experienced at late ages (e.g. ages 85, 95 and 100+ years) and antecedent health conditions. Late age mortality interacts with antecedent health and disability conditions (e.g. by mortality selection), which have dramatically changed across current elderly, and near elderly, cohorts. An understanding of the demography of ageing requires appreciating the health dynamics, current and historical, characterizing cohorts forming the elderly population.

Models of chronic disease and mortality trends

The idea that mortality and other age-related health conditions are mutable to late ages (i.e. age 85+ years) is relatively new. The idea that function can be regenerated and the physiological clock run backwards is even newer. In the USA, mortality was thought to have reached irreducible levels by the late 1950s or early 1960s because male survival decreased in that period – although female survival continued to improve. Social Security actuaries assumed that ultimate life expectancy limits would be reached in the United States in 2000 in Social Security Trust fund projections made in 1974. In 2011, the life expectancies of 75.9 and 80.9 years for males and females, respectively, were already 6.3 and 3.8 years above this 'ultimate' limit to life expectancy.

In Table 2.1, we present data on total, male and female life expectancy in 2011.

For the small country Monaco, the total life expectancy of 89.3 years and the female life expectancy of 93.4 years cause one to think the posited ultimate limit to life expectancy of 85 years mentioned above is far too low. The female life expectancy of 85.7 years in Japan and the total life expectancy of 82.3 years also suggest that one should be sceptical about 'ultimate' lifespan limit estimates.

Other authors suggested that US stagnant male mortality conditions in 1954–1968 reflected increased chronic disease risks due to the nature of industrial societies. Why risks might be elevated for cardiovascular diseases was discussed and a model was posited of the stages of the epidemiological transition of which the third, and end, stage characterized economically developed societies as having a high prevalence of chronic degenerative and man-made diseases with static life expectancy. Much of this pessimism was due, however, to congenital disorders, such as Down syndrome, where life expectancy could increase past reproductive ages, generating a 'pandemic,' or cascade, of chronic degenerative disease.

Analyses of mortality to late ages suggest why human life expectancy limits are difficult to estimate. First, human lifespans are long (e.g. it will take 120–130 years for a recent, large birth cohort to die out at current mortality levels in Japan, France and other developed countries, making it difficult to acquire reliable data on the full mortality experience of a birth cohort (let alone for multiple birth cohorts). Second, human populations are free living and cannot be studied in experimentally controlled environments. Hence the proportion of human life expectancy potential realized in any population is a smaller, and less certain, proportion of their biological potential than can be observed in animal

Table 2.1 Life expectancy for selected countries in 2011.

	Life at birth (years)						
	Japan	**Monaco**	**Germany**	**France**	**Sweden**	**Canada**	**USA**
Total	82.25	89.73	80.07	81.19	81.07	81.38	78.37
Male	78.96	85.77	77.82	78.02	78.78	78.81	75.92
Female	85.72	93.84	82.44	85.54	83.51	84.1	81.43

models under experimental conditions. Third, for much of human history, fertility was a more dynamic factor than mortality in controlling population growth and shaping population structure. Thus, after large increases in US life expectancy at birth from 1900 to 1950 (i.e. from 47.3 years in 1900 to 68.2 years in 1950, an increase of 20.9 years or 0.42 years of life per calendar year) the rate of increase in life expectancy at birth slowed (e.g. from 68.2 to 70.8 years for 1950 to 1970 or 0.13 years of age increase per calendar year). From 1970 to 2000, life expectancy increased from 70.8 to 77.0 (6.2 years) or 0.21 years per calendar year (a 50% acceleration over the 1950–1970 period), with recent increases accelerating owing to declines in cancer mortality. In the subsequent 11 years, life expectancy increased by only 0.12 years per calendar year, returning to the rate of the 1950–1970 period.

For certain periods, US male life expectancy declined. From 1954 to 1968, male mortality rates increased by 0.2% per year; they declined by 0.8% per year for females. From 1970 to 2001, life expectancy at age 65 years for males and females combined increased (i.e. from 15.2 years in 1970 to 18.1 years in 2001 or 0.1 years of age per calendar year) and represented a larger proportion (45%) of the gain in life expectancy at birth (6.4 years) than before 1970. Gains were achieved, in part, by reducing mortality in 'uncharted' territory, that is, ages 85+ years. The first well-documented reports of centenarians occurred in about 1800. The first reliably documented report of a survivor to 110 years (a 'super' centenarian) was in 1931. The first documented survivor to 120 years (eventually dying at age 122 years) was recorded in 1995. It may be that a 130-year-old is alive but not yet discovered.

For the last 30 years, the centenarian population in the USA and several other developed countries has grown by 7% per year. As higher proportions of larger, more recent birth cohorts survive to late ages, reductions in mortality at those ages will contribute proportionately more to life expectancy gains.

What was observed about health changes in the 1982–1999 National Long Term Care Survey (NLTCS) was remarkable – and contrary to most models of human ageing. In Figure 2.1, we show changes in (a) life expectancy and (b) active life expectancy (ALE) (i.e. period lived free from serious disabilities[2] in 1982 and 1999).

The change in life expectancy was 4.5 years and the change in ALE was 3.8 years. Thus, most (84%) of the gain in life expectancy was in healthy years of life. Figure 2.2 shows the acceleration of the improvement of functioning from age 65 to 100 years.

In Figure 2.2, we can examine rates of change in the difference between ALE and LE in 1982 and 1999. We see that the differences between LE and ALE were similar in 1982 and 1999, never being much higher than 20% (left axis) – although the 1999 differences shifted to the right by

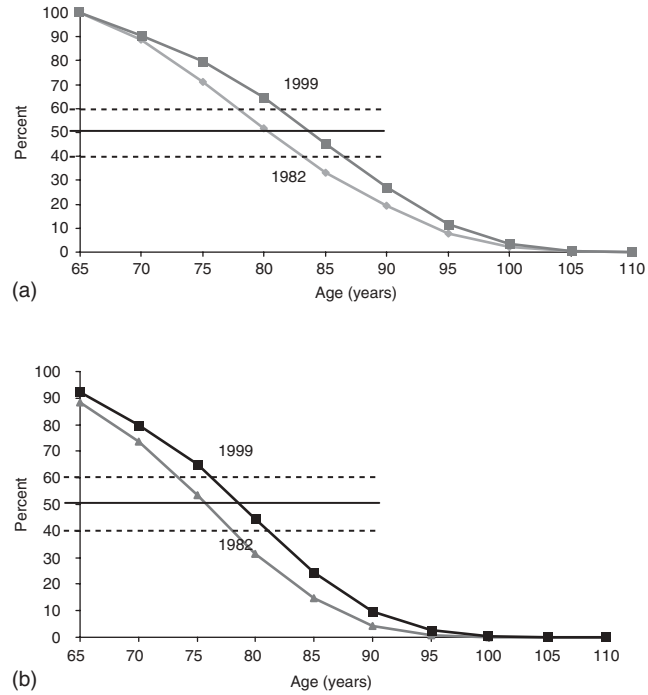

Figure 2.1 (a) 1982 and 1999 life expectancy estimates; (b) 1982 and 1999 active life expectancy estimates.

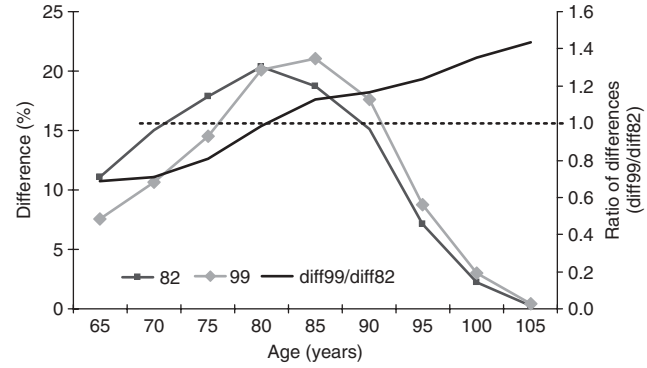

Figure 2.2 Difference between LE and ALE.

about 5 years at age 85 years. Despite higher life expectancy at all ages above 65 years, the difference at age 85 years is only slightly higher than (at age 80 years) in 1982. After age 85 years, the ratio of ALE and LE differences over age suggest a small difference and stable rates of change from 1982 to 1999, up to age 105 years. This is why we can expect future declines in disability and increases in ALE, that is, improvements are manifest to age 105 years.

Further complicating factors in efforts to predict life expectancy are gender and cause-specific differences in mortality. From 1950 to 1970, male life expectancy at 65 years increased by 0.3 years (i.e. from 12.8 to 13.1

years) with life expectancy declining from 1954 to 1968. Female life expectancy increases were 2.0 years from 1950 to 1970 (i.e. from 15.0 to 17.0 years). From 1970 to 2001, life expectancy at 65 years for both US males (13.1 years) and females (17.0 years) increased by 3.3 and 2.4 years – to 16.4 and 19.4 years, respectively. There were larger changes in cause-specific mortality. US age-standardized heart disease mortality declined by 57.8% and stroke mortality by 68.0% from 1950 to 2001. Age-standardized cancer mortality increased by 11.4% up to 1990 but from 1990 to 2001 it declined by over 9%. This decline was due to both social (smoking cessation) and treatment innovation – despite the criticism of the 'war on cancer'. It was suggested that application of 'drug efficiency testing' at the individual level could improve the efficacy of chemotherapy by 20:1.

An area recalcitrant to treatment until recently was neurodegenerative disorders, for example, Alzheimer's disease. Recent analyses of the 1982–1999 NLTCS show large declines in severe cognitive impairment. In 1994 and 1999, severe cognitive impairment was found to map to four ICD9 (Ninth Revision of the International Classification of Diseases) codes. Of these codes, those representing dementia due to circulatory disease (e.g. sequalae of stroke) or mixed processes showed most of the declines, that is, Alzheimer's disease alone was stable.[3,4]

The nature of medical conditions evolved as more persons survived to late ages, for example, up to the 1940s and 1950s much concern was directed to effects of rheumatic fever or syphilis on the heart, hypertension and stroke.[5] In the 1950s and 1960s, hypertensive heart disease declined whereas atherosclerotic heart disease increased. The mean age at which hip fractures occurred in Britain from 1944 to 1990 increased from 67 to 79 years – a 12 years of age increase in 46 years. Concurrently, the nature of hip fractures shifted from intra- to extracapsular fractures. The nature of osteoporosis, the process underlying most US hip fractures, differs from ages 55 to 74 years, where it depends on postmenopausal change in estrogen levels, to ages 75+ years where it is related to age-related effects in the vitamin D endocrine system.

Clearly, more basic physiological processes were at work and over a longer period of time than anticipated by efforts to estimate life expectancy limits based on total and cause-specific mortality trends and by efforts to relate changes to significant, but recent, changes in 'standard' chronic disease risk factors. One study suggested that US stroke mortality started to decline by 1925.[6] Fogel[7] showed that US declines in chronic diseases may be even more long lived. He compared the prevalence of chronic diseases in Civil War veterans age 65–84 years applying for pensions in 1910 (US birth cohorts of 1825–1844) with the prevalence of chronic diseases for WWII veterans over 65 years assessed in the 1985–1988 National Health Interview Surveys (i.e. 1905–1924 cohorts). He found chronic disease prevalence at 65+ years declined by 6% per decade between 1910 and 1985–1988. The prevalence of heart diseases was 2.9 times higher in Civil War veterans aged 65+ years in 1910 than in WWII veterans aged 65+ years in 1985–1988. Declines in chronic diseases set the stage for subsequent declines in mortality up to several decades later.

Fogel[7] attributed changes in chronic morbidity to economic and productive factors affecting early nutrition which increased stature and body mass index (BMI) over time. Many changes between Civil War and WWII veterans predate documented US increases in cholesterol and fat consumption – estimated to have peaked in 1959. One possible explanation of the effects of nutrition on health was the impact of protein, micronutrient and caloric deficiency on fetal development. This was attributed to effects of maternal nutritional deficiencies on the fetal development of organs such that a physiological priority was assumed to exist which dictated which organs received adequate nutrition under conditions of protein and caloric deprivation. If the central nervous system received the highest priority for nutrients, organs such as the liver (affecting cholesterol metabolism and thrombotic factors) and pancreas (affecting glucose metabolism) might be susceptible to developmental restrictions that became manifest in chronic disease risks at later ages. There is evidence for this in studies relating the ratio of placental to birth weight and of weight at 1 year of age to chronic disease at later ages. Higher weight at 1 year was found to be inversely related to ischaemic heart disease, systolic blood pressure and impaired glucose tolerance in adults and possibly to fibrinogen levels in men aged 59–70 years. The relation of systolic blood pressure to placental weight for women and men aged 46–56 years was direct.

Others have suggested that nutritional deficiencies affect persons most at ages where the most rapid physical growth occurs with the highest protein, caloric and other nutrient needs. This is consistent with Fogel's use of the Waaler curve to plot changes in BMI and chronic disease risks.[7] It is also consistent with results that found Japanese male cohorts born 15 years before WWII (i.e. birth cohorts of the early Shāwa period 1925–1939, aged 5–20 years during WWII when there were nutritional shortages in Japan) had elevated mortality from diabetes mellitus, ischaemic heart disease, peptic ulcer, cirrhosis and suicide. These cohort differences in male cause-specific mortality are probably due to poor nutrition during early, critical stages of adolescent male growth spurts. Deficiencies involved gross energy (caloric), proteins and micronutrients; for example, in periods of rapid skeletal growth vitamin D serum levels are highest and vitamin C (affecting collagen formation) and B (affecting methionine metabolism and growth hormone release) needs are elevated.[8]

Two other models may help explain why chronic disease and mortality risks in specific birth cohorts may be related

to nutritional and hygienic factors over long periods of time. One suggests that the effect of viral and bacterial infections on chronic disease has changed over time (in addition to the natural history of the chronic diseases) due to changes in food processing and hygiene. Such arguments have been used to explain why some diseases have strong geographic patterns, for example, association of multiple sclerosis with temperate climates. For atherosclerosis, there is evidence to relate its initiation (i.e. injury to arterial endothelium starting inflammatory and wound-building activity stimulated by dietary cofactors such as serum cholesterol and aggravating conditions such as hypertension) to viral and bacterial insults. This model derives support from evidence that atherosclerotic plaques have a monoclonal origin, suggesting that a somatic mutation is involved in plaque initiation.[9] Various infectious agents have been found in plaques or in circulating immunological complexes in cases with circulatory disease versus controls. Among agents implicated are *Chlamydia pneumoniae*, CMV (cytomegalovirus)[10] and other herpes viruses. One mechanism that could be involved in infectious agent damage to arterial endothelium involves platelet-derived growth factor (PDGF). PDGF may play a central role in atherogenesis because it is both a mitogen and a chemoattractant. There is a striking homology (87%) between the amino acid sequence of PDGF and a protein from an oncogene (v-sis) in the simian sarcoma virus. This homology suggests that PDGF is important in the proliferation of cells transformed by a virus. Cells transformed by retrovirus, DNA viruses and cells with somatic mutations appear to secrete PDGF molecules. Cells virally transformed appear to express a previously repressed cellular gene (c-sis) for PDGF. An immunological factor identified as raising the risk of myocardial infarctions, especially for males, is null allele C4B*Q0. There is evidence to suggest that immune mechanisms are involved in hypertension, with some data pointing to predisposing genes in the major histocompatability complex, either secondary to hypertension-induced vascular damage (causing positive feedback in plaque growth) or as a primary abnormality. However involved, reductions in infectious disease exposures might reduce hypertension prevalence in recent cohorts.

Data from Hiroshima suggest that ionizing radiation is another exogenous stressor involved in hypertension and cardiovascular disease. In Hiroshima, there was acute γ-radiation. In Chernobyl, the most damaging radiation was β (electrons) due to biological incorporation of ^{90}Sr in bone and ^{137}Cs in soft tissue. The radiation flux of these isotopes is relatively high although they have a long half-life of about 30 years. With this type of radiation, there appears to be an acceleration of basic age processes[3] consistent with the well-known free radical theory of ageing. This syndrome involves cataracts, stroke, circulatory diseases and neurodegeneration. Effects on neurodegeneration originally were not viewed as plausible because it was believed neurons seldom divided. There is now evidence that neuronal regeneration occurs in several areas of the brain (e.g. in the hippocampus and the substanta nigra), as the brain is an area of high metabolic activity where baseline free radical production is high and where protein formation in synaptic gaps is sensitive to even very low doses of radiation.

The evidence suggests that atherosclerotic circulatory diseases and their catastrophic manifestations are thrombotic, occlusive events leading to ischaemia in critical organ systems, due to a multistage pathological process where initial damage to the arterial intima stimulates inflammatory and immunological responses, where LDL (low-density lipoprotein) cholesterol becomes oxidized, forming foam cells from monocytes/macrophages drawn to the site of the injury, which are then integrated in plaque. Involved in plaque elaboration are complex processes of autocrine and paracrine mechanisms of vascular response to injury. Other stages of the process involve intracellular absorption of calcium leading to calcification of plaques and inflammatory responses leading to plaque rupture. Immunological responses to infectious agents directly stimulating plaque ruptures (and subsequent thrombotic events) are also suggested by the antiphospholipid syndrome.

To explain how infectious disease involvement with atherosclerosis relates to long-term population health and mortality changes, Mozar *et al*.[10] suggested that changes in circulatory disease risk can be traced back at least to 1910, when 8% of US deaths were attributed to heart disease. This proportion rose to 30% by 1945 and to 54% by 1968. A similar trend occurred in the UK. with diseases of the heart and blood vessels responsible for 11.4% of all deaths in 1910, rising to 36.3% in 1959. In the USA, the peak heart disease risk was reached in 1968. A caution is that death certificates are notoriously inaccurate as to the cause of death. Mozar *et al*.[10] suggested that this was due to ingestion of atherogenic viruses during the pre-War period (i.e. initial injuries led to processes with lengthy latency times; autopsy studies found that fatty streaks and plaque development began at early ages, possibly as early as age 3 years in the aorta, even in less developed countries where heart disease risks do not increase late in life), which interacted with increased fat consumption and other risk factors (e.g. the methionine–homocysteine model of atherogenesis) up to 1970.

The nutritional (hygienic) factor argued by Mozar *et al*.[10] to be associated with declines in heart disease risk was commercial food processing – initiated before the turn of the century. The use of commercial food processing accelerated after WWII as economic conditions improved, large proportions of the US population moved from rural to urban areas and efforts to control livestock infections such as vesicular xanthema (a viral disease of swine discovered in 1932) were started, for example, in California in 1945–1949. An

outbreak of vesicular xanthema in 1952 mandated thermal preparation of food fed to swine. A hog cholera eradication programme began in 1962. The Swine Health Protection Act was passed in 1980.

New genetic and molecular evaluation and assay techniques allow the identification of viruses and other infectious agents causing several types of cancer. Epstein-Barr virus is implicated in the aetiology of human lymphoid and epithelial malignancies. *Helicobacter pylori*, a causative agent in peptic ulcers, is associated with gastric cancer and possibly other malignancies (e.g. liver cancer). Both Rb and P53, growth-regulating genes whose normal function is to arrest cell growth when mutations are detected, can be disturbed by viral infections allowing malignant growth. *H. pylori* is of interest in that its infection rate is related to water quality. Thus, long-term improvements in water quality may be responsible for US cohort-specific declines in gastric cancer. Elevation of gastric cancer risks in the upper midwest of the USA may be due to the use of well water in rural areas (*H. pylori* grows well in still water in wells or cisterns). *H. pylori* remains highly prevalent in developing countries (e.g. West Africa) and has a high seroprevalence in elderly US cohorts.

Hence long-term trends in both circulatory and neoplastic disease and mortality appear to depend partly on viral and bacterial infections as initiating events or cofactors and may depend in the future on radioecological events. Reductions in standard chronic disease risk factors can only be documented, in the US population, from the early 1960s (e.g. smoking declines, reduction in unhealthy fat consumption). Reductions in hypertension were first documented in the National Health and Nutrition Examination Surveys in 1960–1962. As genetic and molecular biological assays become more sensitive, we may find many other chronic diseases are dependent on a variety of infectious and other environmental agents. Changes in the human environment (e.g. improvement in water quality reducing *H. pylori* infection) or in food processing (e.g. elimination of viral infections in livestock or thermal processing of food) may be partly responsible for large cohort-related declines in circulatory diseases in the USA.

Cancer risks are now decreasing in the USA. It has been proposed that common processes underlie both cancer and ageing. Warner *et al*.[11] related these processes to effects of caloric restriction (CR) on programmed cell death (PCD). They suggest that CR upregulates the expression of antioxidant genes and attenuates the formation of reactive oxygen species – and possibly DNA and mitochondrial damage caused during ageing. The emphasis on effects of antioxidants on ageing and cancer leads to a third model of changes in chronic disease risks and their contribution to late-age health changes.

Another hypothesis is that long-term changes in micronutrients alter chronic disease risk. Antioxidant vitamins A, C and E seem to affect cardiovascular disease by lowering the potential for LDL cholesterol to become oxidized, consumed by macrophages and trapped in atherosclerotic plaques as foam cells. Vitamins A and E are redifferentiating agents that repair some genetic damage and antioxidants preventing certain chemical reactions from causing somatic mutations or other cell damage. However, it is vitamins and antioxidants as components of food that produce this effect, not as drug supplements.

Vitamin D, a vitamin/enzyme/hormone, has powerful effects on bone metabolism; especially in late-onset (i.e. at ages 75+ years) osteoporosis (type II) in females. This may interact with cardiovascular diseases by affecting cellular calcium metabolism, parathyroid hormone activity and hypertension. It may interact with iron and magnesium metabolism and is a powerful cellular differentiating agent. As such, it (or its antagonists) might prevent strontium-90 uptake in radioecological disasters such as Chernobyl.

Vitamin D supplementation in milk and other foodstuffs has been adopted for a long time in the USA and Canada. One strategy to examine its effects on chronic disease is to trace the epidemic of atherosclerosis and ischaemic heart disease and the ratio of male to female deaths. In the USA, this ratio was ~1 until the mid- 1920s, then the male predominance in ischaemic heart disease increased steadily until 1968. Curative effects of cod liver oil on rickets were documented in 1917. In 1923, the USA imported 0.5 million gallons of fish liver oil and in 1930, 2.8 million gallons. UV-irradiated milk was introduced in the USA in 1924. Manufacture of vitamins D_2 and D_3 increased from 35 lb in 1948 to 14 000 lb in 1972. By 1970, vitamin D_2 was added to many food products. There was a concurrent decline in Mg in the US diet. Mg mediates effects of vitamin D on cellular calcium absorption. Vitamin D hypervitaminatosis interferes with Mg absorption. Oversupplementation of vitamin D aggravated Mg deficiencies in the US diet. Mg deficiency may have additional effects on circulatory disease because it appears to stimulate renin release through the elevation of prostaglandins; and suppress aldosterone production by mobilizing intracellular calcium.

In the late 1960s, the US Food and Drug Administration (FDA) began considering limiting vitamin D supplementation. Regulations restricting vitamin D supplementation were implemented in 1972 – coincident with the beginning of the decline in heart disease.

The sex ratio of femoral neck fractures was used to trace the origins of the US osteoporosis epidemic. This ratio suggests (based on Rochester, MN, data) that osteoporosis began its upsurge in the late 1920s – about the same time as ischaemic heart disease began to increase. Vitamin D intake, its increase from 1920 to 1970 and its subsequent decrease could explain the interaction of atherosclerosis and osteoporosis for females and their joint trajectories. This is further aggravated by the use of sunblock, leading to a

decrease in endogenous vitamin D production. Vitamin D increases Fe absorption, which may lead to increased free radical generation and oxidation of LDL cholesterol. This might explain the rapid increase in atherogenesis in females postmenopausally, that is, Fe stores in females increase and, with excess vitamin D, increase calcification of atherosclerotic plaques.

Another model for explaining long-term trends in circulatory diseases is the homocysteine theory.[8] Ingestion of the sulfur-based amino acid methionine (an essential amino acid for mammalian growth) produced, after demethylation, homocysteine. Elevated levels of homocysteine, due to genetic predisposition or dietary deficiency of vitamins B_6 and B_{12}, had toxic effects on arterial endothelium. Lesions created by elevated homocysteine levels showed the characteristic fibrous nature of atherosclerotic plaques – but not with lipid deposition if cholesterol is not elevated. The theory suggests that fibrous plaques are not produced unless vitamin B deficiency allows the accumulation of homocysteine and a toxic metabolite, homocysteine thiolactone. The metabolism of homocysteine is affected by vitamin C. Although ascorbic acid is a potent reducing agent, after oxidative conversion to semidehydroascorbic acid its physiological function is to oxidize the sulfur atom in homocysteine. Three stages for methionine utilization are (a) demethylation and dehydration of methionine to homocysteine thiolactone, (b) oxidation of homocysteine thiolactone to homocysteic acid by semidehydroascorbic acid and (c) reaction of homocysteic acid with ATP (adenosine triphosphate) to form active coenzymes to synthesize sulfate esters of connective tissue proteoglycans.

Methionine deficiency inhibits growth and wound healing – like scurvy. In scurvy, the lack of dehydroascorbic acid inhibits the formation of sulfated proteoglycans. Increased conversion of methionine to homocysteine thiolactone increases the production of sulfated proteoglycans matrix, deposited in atherosclerotic plaques, which accelerates growth and stature in homocystinuria. Age changes in homocysteine hepatic metabolism may explain why children in rapid growth phases are less susceptible to atherogenic effects of homocysteine. Stimulation of growth is due to homocysteic acid, which has a similar effect to somatomedin (the serum polypeptide mediating the effect of pituitary growth hormone on cartilage) on sulfate binding in cultured cartilage fragments – suggesting a relation of homocysteic acid, somatomedin and the action of growth hormone. After normal growth ceases and epiphyses ossify, growth stimulation affects cells of blood vessels (especially smooth muscle cells) rather than chondrocytes and osteocytes in growing bone. The homocysteine model also suggests a basis for the age dependence of osteoarthritic diseases and effects of growth hormone and somatomedin on the ageing of connective tissue. Some evidence suggests that the agent mediating the growth of smooth muscle cells is carried by platelets and released during platelet aggregation and adherence to injured intima. Calcification of fibrous connective tissue is stimulated, as is the disruption of intermolecular cross-linking in newly synthesized collagen fibrils, which may be due to the reaction of homocysteine with allysine to form tetrahydrothiazine adducts. This may interfere with intermolecular cross-linking in collagen and elastin.

The relation of this mechanism to increased heart disease in the twentieth century may be due to an increased dietary ratio of animal to plant protein (dietary intake of methionine is correlated with cholesterol intake). This may explain the relation of increased body size with atherosclerosis. Vitamin B_6 levels decrease through life to the eighth decade because serum glutamine oxaloacetic transaminase activity decreases. When the elderly are treated with pyridoxine, transaminase levels return to levels of younger persons.[12] Also, since pyridoxine is water soluble, as the lipid content of the diet increases, pyridoxine availability may decrease.

To explain US population trends in heart disease, quantities of synthetic pyridoxine hydrochloride were examined.[8] US production increased from 1900 kg in 1944 to 30 000 kg in 1963. Imports increased from 9100 kg in 1963 to 17 700 kg in 1969, to 59 500 kg in 1972 (yielding a threshold consumption of 0.79 mg per day) and to 275 000 kg in 1978 (3.42 mg per day). This increase is consistent with post-1968 declines in coronary heart disease. Since vitamin B_6 supplementation will prevent arterial damage, but not reverse it, the decline in circulatory disease should increase as younger cohorts who had adequate supplementation reach older ages. Supplementation is also necessary because thermal food processing (which may have decreased viral exposures in animal protein) degrades natural pyridoxine. This is controllable by consuming adequate synthetic vitamins B_6 and B_{12}.[12] The problem increases with age due to altered vitamin intake, absorption or metabolism.

Dietary intake of at least two other trace minerals may affect long-term heart disease and stroke mortality trends by affecting blood pressure. One is reduced salt intake, which lowers blood pressure and reduces abnormalities of calcium metabolism, incidence of renal stones and bone demineralization. There is, however, minimal evidence that reduction of salt intake to low levels actually decreases mortality. Potassium, found in many fruits and vegetables, also decreases blood pressure. Increases in fruit consumption may be involved with early reductions in stroke.

New explanations of these processes derive from a better understanding of cellular bioenergetics – especially the function of the mitochondria. This suggests that, in addition to the CR model, they are the effects of thyroid hormone on mitochondrial function. It is known that thyroid hormone administration increases oxygen

consumption by mitochondria. The effect may be both short and long term. The short-term influence (within minutes of the hormone treatment) results in enhanced expression of the mitochondrial genome. Thyroid hormone increases levels of mitochondrial transcription by elevating mRNA synthesis and improving their stability. The long-term influence (after 24 h) involves the stimulation of mitochondriogenesis. This may explain why honey bees, with a nutritional intervention (royal jelly) containing a protein with partial structural similarity to human thyroid hormone, may stimulate the production of cytochrome *c* in mitochondria with lifespan epigenetically increased 30-fold or more despite elevated metabolic rate. Intervention effects were shown in mice where the mitochondrial function of old mice was returned to that of young mice by administration of α-lipoic acid (an antioxidant zwitterion) and L-acetylcarnitine, an agent stimulating fatty acid metabolism.

Historically, deficiencies leading to explicit disease syndromes were prevalent until the role of specific vitamins and minerals in those diseases was identified and supplemental sources sought. At levels less deficient than those causing specific deficiency syndromes (e.g. scurvy, pellagra, osteomalacia, rickets), vitamin deficiencies may have contributed to long-term population changes in chronic disease risks.

To make the ebb and surge of specific chronic diseases over time consistent with the models described above, there had to be changes, not only in mortality at late ages, but also in the nature of age-related chronic disease processes over the past 150 years as nutrition (both macro- and micronutrients), food hygiene (e.g. *H. pylori* infections, toxins due to food spoilage) and viral and bacterial exposures changed. Changes may also affect the expression of genetic diseases by altering gene–environment interactions or by changing the inflammatory response of the host to stress, for example, altering serum levels of IL-6.[13] The average health characteristics of the very elderly population may evolve in the future as different cohorts, with different early health experiences, enter this age group. As the profile of chronic diseases affecting elderly populations changes over their lifespan, one also is aware of long-term changes in age-related chronic disease – and in ageing changes.

Mortality selection and trajectories

Hygiene and nutritional changes caused differences in chronic disease risks across birth cohorts, and these and other factors (e.g. smoking) may have altered age trajectories of cohort mortality. Specifically, many demographic models use a Gompertz function to describe age increases in mortality. However, at late ages the trajectory of human mortality deviates from the Gompertz curve, overpredicting increases in mortality.[14]

One explanation for deviations from the Gompertz curve (beginning about age 85 years) is mortality selection. For example, the prevalence of the B gene of the fourth component of complement (C4B*Q0) is a risk factor, in men, for myocardial infarction. The prevalence of this gene dropped for males in the fifth and sixth decades of life due to adverse affects on longevity. Its prevalence declined at later ages in females. In Italian centenarians there were decreased thyroid autoantibodies compared with persons in their 80s.[15] The prevalence of the ApoE-4 genotype in Finnish centenarians was lower than that at earlier ages. In lung cancer, genetic susceptibility involves the cytochrome P450 enzyme system. The proportion of genetically related lung cancer cases declines sharply between ages 50 and 70 years. In Swedish twins,[16] the relative risk of CHD (congenial heart disease) mortality declined from 14:1 to 15:1 in mid-age to 1:1 above 85 years of age. Thus, many studies of genetically controlled diseases showed change in genotype prevalence due to mortality selection. In clinical examinations of long-lived groups, health at late ages (e.g. 80+ years) is often better than for persons, say, aged 70–79 years.[17]

Effects of mortality selection on the age trajectory of health parameters can be monitored in longitudinal studies where risk factors or disabilities are measured multiple times. In analyses of Framingham Study data (46 year follow-up) and of 18 years of follow-up in a nationally representative study of disabled elderly (1982 to 1999 NLTCS), the mortality selection of persons with adverse risk factor profiles or poor functional status was noted over age. At late ages (e.g. 95+ years), selection was so strong that the prevalence of adverse risk factor profiles or poor functioning started to decrease because mortality rates for very elderly persons with impaired health were greater than the incidence of the adverse health state.[18]

As a consequence of selection, whereas human mortality rates increase by 8–10% per year in middle age, the rate of mortality increase at late ages is slower. In seven studies where mortality was observed up to ages 100+ years, rates increased an average of 3.1% per year between ages 100 and 110 years.[14] For US males, cohort mortality reached a high constant level at ages 100–110 years. US female cohort mortality increased by 3.0% per year of age from 100 to 110 years. The average US cohort mortality rate at age 110 years was 41%; the average for the seven studies was 45%.[14]

The 1982–1999 NLTCS data show this plateau. We examined an alternative model where a plateau is due not only to a genetically heterogeneous population, but also to a balance of degenerative and regenerative physiological processes. This suggests that engineering reliability models, such as the Weibull distribution, are not sufficient in that they describe failure in a homogenous system – not a complex heterogeneous system. It is no longer sufficient to describe a plateau as a genetically determined trait but as a

temporally (absolute clock-time – not simply age) changing equilibrium of decay and repair functions.

In analyses of the actuarial experience of 11 large insurance companies, there was no credible evidence of human mortality rates exceeding 50% at any age. Recently, the level of the plateau was fixed at 40%. Ungraduated insurance data suggest that, above 95 years of age, mortality reaches 25% for both genders and then fluctuates randomly. In animal models, similar phenomena were observed. In large experimental populations, mortality reached a high, constant level after a large proportion (90%) of the population died. This is manifest in the USA by a decline in per capita, per annum Medicare expenditures at late ages, that is, expenditures were several-fold higher at ages 65–70 years than for centenarians.

If human mortality rates increase very slowly at late ages, profound changes will be required in assessing elderly populations. One is that the number of extreme elderly persons will be larger than now anticipated. In developed countries with reliable data, the centenarian population has grown by 7% per year for 30 years. The number of US centenarians of 50 454 in 2000 will increase to 150 000 by 2020 and to 313 000 by 2040 – without assuming large changes in life expectancy or dealing with the large post-WWII baby boom cohorts who will become centenarians after 2047. In Social Security Trust fund projections, mortality rates are assumed to increase by 5–6% per year of age above 100 years – a rate of increase higher than in the data.

From 2035 to 2050, the US centenarian population is expected to grow to 0.6 million persons. The US population aged 95+ years in 2050 would be 3.8 million persons. The population aged 85+ years would be 18.9 million persons – or 4.8% of the US population. The population aged 65+ years would be 20.4% of the total US population. These are 'middle' range projections. Alternative series, assuming greater life expectancy increases, project 2.6 million centenarians in 2050 with 26.4 million persons aged 85+ years and 93.1 million aged 65+ years, or 0.63, 6.4 and 22.7%, respectively of the total US population (i.e. based on life expectancy at birth in 2050 of 83.8 versus 91.1 years for males and females, respectively; the intermediate assumption was 79.7 and 85.6 years for males and females. respectively. in 2050). Second, for individuals at late ages one will have to use different estimates of life expectancy than are available from actuarial estimates.[2] This could change calculations for assessing cost-effectiveness of specific medical interventions at late ages.

Third, the expectation about comorbid conditions and the average health of individuals at specific ages will have to be evaluated taking into account the birth cohorts from which the patient comes and the likely prior health experiences of persons in that cohort who survive. It may be that ageing processes in such persons progress at slower rates than in the population.

Discussion

The evidence suggests that we can expect future elderly cohorts to live longer and to have better health and functioning. This raises the question of how health service systems will deal with this rapidly growing group and their changing health characteristics. What has happened in the USA is that health and long-term care (LTC) services have been redirected towards the community and housing options have been defined to bridge the gap between traditional nursing homes and standard housing. This is reflected in changes in the US healthcare system. Medicare coverage is now often supplemented by private health insurance. Hospitalization rates and lengths of stay are down. What have increased dramatically are Home Health Agency (HHA) and skilled nursing facility use, which, by 1995, constituted 8% of all Medicare expenditures – roughly $14 billion. Concurrently, growth of Medicaid-reimbursed nursing home use declined. Most recently, we have found, despite arguments of some economists that more resources will be required to keep individuals healthy at late ages, that per capita inflation-adjusted Medicare expenditures declined for the non-disabled population and increased for the disabled population.

Efforts to prevent both morbidity and disability among the elderly should be extended. Medicare-based demonstration programmes show that physical activity can be increased. Physical activity (actually the lack) is, itself, a primary risk factor for stroke – and possibly other chronic diseases.

Better evaluations of the efficacy of treatments at late ages are needed. Surgical interventions in patients aged 90–103 years have been shown to have become less hazardous – intraoperative mortality dropped from 30 to 8% over 30 years. As pacemakers increase in sophistication, their use in elderly patients improves outcomes. Dual-chamber, demand-driven pacemakers may be particularly useful for the elderly because of increased reliance with age on atrial function for cardiac output. There are interventions with low mortality that increase the function of elderly persons. Hip and knee replacements are in this category, and also plastic lens implants for cataracts.

Hence the cost–benefit ratios of medical procedures at late ages may be underestimated because the life expectancy of individuals at late ages and the amount of functional capacity that can be regained are underestimated. A reason may be that trends in disability and mortality among populations with particular health characteristics may not be correctly represented in evaluations of patients for the medical and surgical procedures now available for elderly populations. Certain situations, such as long waiting periods for 'elective procedures' in some European healthcare systems, may have more adverse effects at late ages than

in younger populations and operate as a 'self-fulfilling' prophecy about limitations to late-age interventions. Such problems will emerge increasingly in the future as the number of very elderly persons increases and prior health histories evolve. One factor to which recent changes in disability may be related is education. Education has been projected to improve with the proportion of persons aged 85–89 years with less than 8 years of schooling declining from 60+% in 1980 to 10–20% by 2015. A number of health behaviours are associated with education and also the risk of dementia.

The very elderly (aged 95+ years) are a group for which we do not have extensive data from which to extrapolate effects of medical interventions. Studies focusing on the elderly, such as the isolated systolic hypertension intervention programme, often find significant benefits in intervening in disease. Hence the evaluation of both future increases in health service needs for the elderly population, and also evaluating potential gains for elderly individuals with specific health profiles, need to consider the implications of long-term demographic and health changes.

Key points

- Vitality determines mortality and fertility.
- Vitality links birth–death processes.
- Vitality is driven by mitochondrial function under thyroid control.
- Free radical chemistry is central to cellular bioenergetics.

CHAPTER 3

The physiology of ageing

Rafi T. Kevorkian and John E. Morley

Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

In the last century, we have seen a near doubling of life expectancy in humans. Modern medicine has left us with a vast knowledge of information towards the ageing process. A multitude of changes have been known to occur consistently in humans. This chapter examines and focuses on these changes. The organ systems are highlighted with a brief synopsis of each and how they age. The ageing process affects all organ systems and, as such, understanding these changes will allow us to understand better the functional impact that they have on the aged individual.

A multitude of changes occur in each organ and these changes are irrespective of diseases modifying ageing. The rate of age-related decline in organ function varies greatly. Ageing has been defined as a failure to maintain homeostasis under conditions of physiological stress. All species show ageing. Within a normal cell, oxidative stress (free radical theory of ageing) chronically leads to changes in gene expression. This leads to alteration in the phenotype and ageing of tissue. In a different model, 'wear and tear' (somatic mutation, error catastrophe, protein glycosylation) of cells leads to necrosis or apoptosis, which leads to an increase in cell turnover, causing an alteration in the phenotype leading to an aged cell. Senescence is defined as the permanent exit from the cell cycle of cells that would normally be able to undertake division. This may also lead to ageing because it leads to a decline in the growth potential of cell populations, which have undergone turnover. These cells display biochemical features that are distinct from their growing counterparts. The expression of some genes (intrinsic mutagenesis, programmed death) goes up, whereas others go down or are unaffected. Olovnikov proposed that cells might count divisions through the progressive shortening of chromosome ends (telomeres). Telomerases are enzymes that prevent shortening of telomeres. The consequence of this is that a small amount of terminal DNA is not replicated with repeated cell divisions, and this may contribute to senescence. It has been shown that mild oxidative stress may increase the rate of telomere shortening. DNA helicases unwind damaged DNA to allow for repair. Organisms that have greater resistance to DNA damage have conferred longevity. The neuroendocrine theory of ageing stresses the need to regulate the biological clock to maintain homeostasis. The hypothalamo–pituitary–adrenal axis acts as the master regulator to adjust to the physiological needs of the organism during stress. The neuroendocrine-immuno theory of ageing stresses the relation of the endocrine system as it regulates the immune system to fight off infection. As the immune system wanes, the organism becomes susceptible to death due to higher chance of infection, and ageing then would result from a 'decreasing ability to survive stress'. Thus, a multitude of factors can lead to ageing.

Ageing of organs

Ageing of the skin

The skin is the largest organ of the body and has many important functions. It functions as a mechanical barrier, regulates temperature, initiates immunological functions, communicates external stimuli to the body and protects against the effects of ultraviolet light. The skin is composed of three major layers: the outermost layer is the epidermis, followed by the dermis, which leads to the hypodermis. In the epidermis, a multitude of cells exist such as keratinocytes, melanocytes, Langerhans cells and Merkel cells. The basement membrane separates the epidermis from the dermis. The dermis is composed of connective tissue, consisting mainly of collagen fibres, and elastin. The fibroblasts are the major cell type. The hypodermis is composed of the adipocytes, and also the intravascular bundle. The typical signs of ageing include wrinkling and sagging of the skin. Extrinsic ageing is more prominent in the highly vascular retina unlike the lens, and it has six neural cell types organized in 10 layers. The photoreceptor cells (rods and cones), and the retinal pigment epithelium (RPE) are most affected with ageing.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Intrinsically aged skin is thin, pale, and finely wrinkled. Histological staining shows flattening of the dermo–epidermal junction. This form of ageing is felt to be secondary to superoxide free radical formation. Aged skin demonstrates a reduced keratinocyte proliferative capacity. The number of epidermal cell layers remains unaltered during ageing (Table 3.1). A decrease in melanocytes contributes to the paling of the skin.

The dermo-epidermal junction flattens with age due to the retraction of the epidermal papillae (Table 3.2), which leads to a skin structural unit that is less resistant to shear forces than is younger skin. Skin thickness tends to decrease after the seventh decade.[1] Within ageing skin, increased vasoconstrictor responses and decreases in both vasodilators and vasoprotective agents have been demonstrated, and atrophy and hypertrophy of the subcutaneous tissue are common in aged individuals.

The repair of physical damage is an essential day-to-day function of skin. Alteration in wound healing may lead to chronic ulceration and non-healing. The dysfunction of dendritic cells leads to the formation of skin neoplasms. The decrease in the protective effect of the skin leads to further loss of protection from UV light. Sunlight is also felt to lead to the generation of oxygen radicals leading to ageing. It has been shown *in vitro* that keratinocytes and dermal fibroblasts from habitual sun-exposed sites have shorter life spans.

In summary, the skin is the major barrier for our body to protect us within the environment (Table 3.3). As the ageing process ensues, cellular functions are altered, leading to problems with wound healing, immunosurveillance, temperature regulation and general barrier functions.

Table 3.1 General effects of ageing on the cell types resident within the skin.

Cell type	Effect of ageing
Keratinocytes	↓proliferation, ↓ differentiation
Melanocytes	↓density, ↓ proliferation, ↓ biochemical activity
Epidermal lymphocytes	↓antigen presentation, ↓ response to activating factors
Fibroblasts	↓proliferation, ↓ ECM production, ↑ ECM turnover
Endothelial cells	↓proliferation, ↓ response to vasodilators
Inflammatory cells	↓proliferation, ↓ response to mitogens

ECM, extracellular matrix

Table 3.2 General effects of ageing on the function of individual components of the skin.

Skin structure	General effects of ageing
Epidermis	Little change in overall structure and function
Basement membrane	Flattening (loss of rete ridges)
Dermis	↓thickness, ↑ stiffness
Vasculature	↓number of blood vessels, ↓ blood flow
Sebaceous glands	↓secretion of sebum in women
Hypodermis	↓or ↑ dependent on body location
Hair	Greying, hair loss
Nails	↓growth and change in appearance

Table 3.3 Summary of age-associated changes in skin function.

Skin function	General effects of ageing
Wound healing	
(a) Inflammatory response	Dysfunctional and protracted
(b) Re-epithelialization	Slowed and sometimes inhibited
(c) Dermal repair	Impaired granulation tissue formation
(d) Angiogenesis	Reduced
Immunoregulation	Dysfunctional and impaired leading to neoplasm
Thermoregulation	Impaired ability to perceive the cold, decreased sweat response
Barrier function	Decreased with respect to UV protection

Skeletal muscle ageing

Skeletal muscle comprises 40–50% of the human body and is composed of muscle tissue, nerve tissue, blood vessels and connective tissue. Myoblasts are precursor cells, which fuse together forming bundles of muscle fibres. There are two types of individual muscle fibres: type I or slow twitch and type II or fast twitch. Type II has two components: type A are called *fast-oxidative fibres*, and type B are known as *fast-glycolytic fibres*. With ageing, there is a shift towards type I fibres.[2] There are several types of muscle contractions: shortening contractions, isometric contractions and lengthening contractions. Skeletal muscles have developed adaptive responses to the generation of reactive oxygen species to protect themselves from oxidative damage.

These age-related changes in muscle mass are termed *sarcopenia* and lead to an age-related decrease in muscle strength and power. The basal metabolic rate of muscle decreases by 4% per year after the age of 50 years. The synthesis of myosin heavy chains declines with age, whereas the sarcoplasmic protein pool is unchanged.[3,4] The regenerative potential of skeletal muscle, and overall muscle mass, decline with age. There is an increased infiltration of fat into muscle with ageing. Some of the ageing changes are due to the decrease in physical activity that occurs with ageing.

During senescence, there is a loss of motor neurons and muscle fibres. The loss of motor neurons is of primary

importance because it is likely to be the main reason for loss of muscle fibres. Electrophysiological studies have demonstrated a reduced number of motor units in old muscle.[5] The size of the average motor unit increases with age. The loss of strength does not result from failure of the central nervous system to activate motor nerves; however, a reduced rate of firing of motor nerves during maximum voluntary contraction in older subjects may limit the maximum force production in some muscles.[6] During a sustained contraction, central fatigue may be more common in older adults than in younger persons. Age-related fibre atrophy generally is restricted to type II fibres, at least in the muscles of the leg, and this selective atrophy is important functionally because type II fibres can generate more power than type I fibres. It is unclear whether there is impairment in the release of calcium affecting the rate of relaxation and contraction. Welle *et al*. have shown that older human muscle has reduced expression of several mRNA's encoding proteins involved in mitochondrial electron transport and ATP synthesis.[7] An accumulation of DNA deletions is seen in mitochondria of skeletal muscle with age.[8]

With ageing, changes occur with skeletal muscle, affecting size, strength, endurance and functionality in the elderly (Table 3.4).

The ageing eye

Multiple population-based studies have shown a significant increase in the prevalence of impaired vision with advancing age.[9] As such, visual impairment is negatively associated with the independence and functional status of elderly people.[10] In addition, impaired vision may negatively affect cognitive functions among the elderly.[11] The eye suffers age-related disease and is affected by many systemic illnesses (see Chapter 85, Disorders of the eye). The eye consists of the retina, lens, cornea and a neurovasculature. The lens is a transparent, avascular tissue contained within a capsule. The lens cells divide, but are not shed, and as a result, the lens continues to grow throughout life. It has defence mechanisms from reducing compounds that can cause damage. Aggregation of proteins is thought to be responsible for the yellowing of the lens and also the increase in light scattering. Glutathione, a key protecting molecule in the lens, tends to decrease with ageing. Crystallins are proteins that provide the high refractive index of the lens. Alterations in structure and increased aggregation of these proteins are noted with ageing. Cataract formation increases with ageing and a multitude of enzymes have lowered activity in a cataract.

The retina is the light-responsive part of the eye and its density decreases with ageing. There is also loss of ganglion cells and RPE. Lipofuscin is a protein that is formed through many mechanisms and its accumulation can cause cell death in cell culture.[12] Age-related macular degeneration (AMD) is the major cause of non-preventable blindness in Western countries and its prevalence increases with ageing. The molecular pathway leading to AMD has not yet been elucidated. There are also age-related changes to the sclera where it is thinner, yellower and less elastic. Light scattering appears to increase through the cornea with ageing. The vitreous body tends to liquefy with age and collagen fibres concentrate.

Table 3.5 summarizes the changes that occur with ageing affecting the functionality and cognitive capabilities of elders.

The ageing cardiovascular system

Ageing is associated with complex and diversified changes in cardiovascular structure and function. Changes occur at the structural/functional levels and also the molecular/cellular level. The heart becomes slightly hypertrophic and hyperesponsive to sympathetic (but not parasympathetic) stimuli, so that the exercise-induced increases in heart rate and myocardial contractility are blunted in older hearts. The aorta and major elastic arteries become elongated and stiffer, with increased pulse wave velocity, evidence of endothelial dysfunction and biochemical patterns resembling atherosclerosis. These changes are thought to be caused by increased angiotensin II activity in the arterial wall,[13] which leads to endothelial dysfunction, vascular smooth muscle proliferation and an increase in glycation and collagenization. Molecularly these changes are secondary to an increase in transforming growth factor beta-1

Table 3.4 Summary of age-related changes in muscle.

Reduction in muscle mass (30–40%)
Decreased myosin heavy chain synthesis
Decrease in force
Infiltration of fat into muscle tissue
Increased fatigability
Decrease in basal metabolic rate
Decreased innervations
Increased number of myofibril per motor unit
Loss or reduced proliferation of satellite cells
Shift towards type I fibres

Table 3.5 Changes in vision with ageing.

Impaired dark adaptation
Yellowing of lens
Inability to focus on near items (presbyopia)
Decreased contrast sensitivity
Decreased lacrimation
Minimal decrease in static acuity
Profound decrease in dynamic acuity (moving target)

(TGF-β1), matrix metalloproteinase type II, calpain 1 and milk fat globule EGF-8. There is also an increase in reactive oxygen species reactivity, which leads to a decrease in endothelial nitric oxide bioavailability. The arterial baroreflex is altered in ageing, with the baroreceptor of the heart showing greater impairment than the baroreceptor control of peripheral vascular resistance. No conclusive evidence has been shown that alterations in afferent, central neural, efferent and effector organ portions of the reflex arch are altered with ageing. Reflexes arising from cardiopulmonary vagal afferents are blunted in aged individuals.

The changes that occur in the aged heart are outlined in Table 3.6. It is important to clarify that all these changes in cardiovascular function do not imply failure of the system and, in the absence of overt cardiovascular disease, do not result in symptoms.

The ageing immune system

The function of the immune system declines with age (Table 3.7), which leads to an increased frequency of infections, increased prevalence of neoplasms and autoimmune disorders. Thymic involution is a hallmark of ageing, although there are thymic independent pathways for the development of the immune system. Response to vaccines is also decreased. The ability of haematopoietic stem cells to replicate decreases with ageing.[14] There is a decrease in haematopoietic stem cells of the lymphopoietic heritage with progressive predominance of myeloid-biased clones, and this imbalance is responsible for the increase in myelodysplastic syndromes with ageing. All cells are not affected similarly by ageing so, for instance, memory CD4 T cells retain function whereas naive CD4 cells lose function.

There is an age-dependent alteration to antigen-presenting cells. Certain cytokines increase with ageing, such as: (1) interferon γ, (2) TGF-β, (3) tumour necrosis factor (TNF), (4) IL-6 and (5) IL-1, which can lead to dysregulation of haematopoiesis. Most tests of T-cell function are depressed in elderly individuals.[15] They tend to secrete less IL-2 after being stimulated by antigen-presenting cells. Several studies have suggested a positive association between good T-cell function *in vitro* and individual longevity,[16] and between absolute lymphocyte counts and longevity.[17] A high proportion of centenarians have relatively well-preserved immune functions compared with the less elderly.[18]

Monocytes have also been shown to have decreased function with ageing (Tables 3.8 and 3.9). Natural killer cell numbers increase with ageing, but NK cytonicity as measured on a per cell basis decreases. The cytokines produced by activated NK cells (rRANTES and IL-8) also decrease with ageing.[19]

In summary, a multitude of changes occur in the immune system that affect function and survival in the elderly.

The ageing pulmonary system

The ageing lung closely mimics changes in lung tissue that are associated with disease process such as emphysema (Table 3.10). Senile hyperinflation is a well-recognized entity. There is an increase in airspace size, stiffening of the chest wall, loss of respiratory muscle strength, a decrease in intervertebral spaces and a decrease in elastic recoil of the lung tissue. Diaphragmatic strength declines with ageing, which predisposes diaphragmatic fatigue. These changes result in age-related declines in the lung volumes and flow rates affecting the forced expiratory volume (FEV1)

Table 3.6 Effects of normal ageing on the cardiovascular system.

Structural/functional level
Systolic function
No change in maximum capacity of the coronary flow bed
Moderate left ventricular hypertrophy
Maintenance of ability to generate wall tension
Decreased velocity of myocardial shortening
Increased myocardial stiffness
Prolonged duration of (systolic) contraction
Increased left ventricular cavity diameter
No change in stroke volumes, heart rate, cardiac output or ejection fraction at rest
Greater use of the Frank–Starling mechanism
Decline in maximum heart rate and maximum oxygen uptake with exercise
Increased ventricular stiffness
Decreased ventricular relaxation
Diastolic function
Delayed relaxation
Diastolic peak filling rate deceases with age
Decreased peak velocity of early filling while atrial fraction increase with age
Ratio of early peak to atrial peak (E/A ratio) flow velocity decrease with age
Arterial function
Increased arterial stiffness
Decreased endothelial function
Increased systolic blood pressure
Increased pulse pressure
Molecular/cellular level
Increased catecholamine levels
Decrease in β-adrenoceptor-mediated responses
Preservation of β-adrenoceptor number/density but decreased sensitivity
Maintenance of peak amplitude of force generation
Increased duration of the myoplasmic calcium transient during excitation–contraction coupling (in rats)
Prolongation of the ventricular transmembrane action potential (in rats)
Cell dropout and compensatory cellular hypertrophy

Table 3.7 Changes in immune system function with age.

Decreased cell-mediated immunity
Lower affinity antibody production
Increased autoantibodies
Decreased delayed-type hypersensitivity
Decreased cell proliferative response to mitogens
Atrophy of thymus and loss of thymic hormones
Increased IL-6
Decreased IL-2 and IL – 2 responsiveness
Decreased production of B cells by bone marrow
Accumulation of memory T cells (CD-45)
Impaired macrophage function
Facilitated production of anti-idiotype antibodies
Increased NK cell number but decreased cytotoxicity

Table 3.8 Changes in T cells with age.

Decreased	Increased
Number of reactive T cells	Number of memory cells
Number of mitogen-responsive cells	T-cell help for non-specific-antibody production
Proliferative response	
Expression of early activation genes	
Sensitivity to activating signals	
Cytotoxic cell target	
T-cell help for specific antibody production	
Help for generation of cytotoxic cells	

Table 3.9 B cell changes with ageing.

Surface MHC[a]class II molecule expression
Proportion of cells capable of clonal expansion
Number of bone marrow precursors
Number of T cell-dependent antibody-forming cells
Potency
Antibody efficacy

[a]MHC, major compatibility complex.

and the forced vital capacity (FVC).[20] The PaO_2 decreases progressively and linearly, falling from ~95 Torr at age 20 years to about 75 Torr at age 70 years. The alveolar dead space increases whereas the pulmonary diffusing capacity decreases progressively and linearly with age, falling by ~20% over the course of adult life. The ventilatory responses to both hypoxia and hypercapnia have also been shown to decrease with age.

The ability to exercise, as indicated by the maximum oxygen uptake ($VO_{2\,max}$), also decreases linearly and progressively, falling by ~35% between the ages of 20 and 70 tears. The alveolar ducts also enlarge, resulting in decreased surface area. Older persons have a 50% reduction in the response to hypoxia and a 40% reduction in response to hypercarbia.

Table 3.10 Changes of the pulmonary system with ageing.

Decreased FEV1 and FVC
Increased residual volume
Cough less effective
Ciliary action less effective
Ventilation–perfusion mismatching causes PaO_2 to decrease
Trachea and central airways increase in diameter
Decreased lung mass
Decreased respiratory muscle strength
Decreased diffusion of carbon monoxide
Decreased maximum inspiratory and expiratory pressures
Chest wall stiffens
Decreased diaphragmatic strength
Decreased ventilatory response to hypoxia and hypercarbia
Decreased antioxidants

Immunological changes with ageing include an increase in neutrophils and a decline in the percentage of macrophages with ageing in brochoalveolar lavage fluids. IgA and IgM levels also increase and the ratio of CD4+ to CD8+ lymphocytes increases.[21] Older persons have an increased response to bronchial constrictors and a poorer response to beta-receptor agonists, due to a reduction in beta-receptor affinity with ageing. Older persons have a limited response to cysteinyl leukotriene receptor antagonists.

The ageing nervous system

The nervous system is composed of a multitude of cells and layers that control many aspects of function such as memory, speech, verbal and visual function and sensory and motor functions. There are great variations between individuals (Table 3.11).

Both normal senescent age-related changes and late-onset diseases of the brain produce a decline in performance. The number of contacts and the total surface area of the synapses decrease significantly and their average synaptic size increases to different extents according to the brain area taken into account. Pre- and postsynaptic elements thicken with age, whereas vesicle size decreases (Table 3.12). There is failure of the chemical transmission process with ageing.[22]

The regulation of calcium influx is essential to pre- and postsynaptic events. Tanaka *et al*.[23] showed that reduced calcium influx with ageing might cause the reduced acetylcholine release by aged synapses. Brain ageing is also associated with oxidative damage and low energy

Table 3.11 Changes in the central nervous system with ageing.

Small decrease in brain mass
Decreased brain flow and impaired autoregulation of perfusion
Proliferation of astrocytes
Decreased density of dendritic connections
Increased numbers of scattered senile plaques and neurofibrillary tangles
Decreased myelin and total brain lipid
Altered neurotransmitters including dopamine and serotonin
Non-random loss of neurons to modest extent
Increased monoamine oxidase activity
Decrease in hippocampal glucocorticoids receptors
Slowed central processing and reaction time

Table 3.12 Age-related changes in the pre- and postsynaptic markers of the striatal dopamine synapse.[22]

Parameter	Change
Presynaptic markers	
Tyrosine hydroxylase immunoreactivity	↓
Tyrosine hydroxylase activity	↓
Dopamine (DA)	→ / ↓
DA turnover	→ / ↑
Cold stress-induced DA turnover increase	↓
Reserpine-induced DA turnover increase	↓
DA turnover increase induced by training in reaction time	↓
Postsynaptic markers	
D1 receptor levels	↓ / →
D2 receptor levels	↓
D1 receptor turnover	↓
D2 receptor turnover	↓
Adenylate cyclase activity	↓
cAMP-induced phosphorylation	↓
DA/cholecystokinin receptor interaction	↓
D2 denervation supersensitivity	↓

metabolism[24] and nitric oxide has cytotoxic action on neurons.[25] Adrenal glucocorticoids have been shown to accelerate age-related damage in the hippocampus, because of their ability to compromise energy metabolism and make neurons more vulnerable to glutamate excitoxicity.[26]

Autonomic dysfunction increases with ageing. Age-associated changes have been reported in some, but not all, regions of the autonomic nervous system. There are greater age-related changes in the sympathetic system than in the parasympathetic system.

In summary, the ageing nervous system has many features that affect individuals in a wide variety of ways (Table 3.13). For functional changes, such as cognition, these appear to peak before the age of 30 years.

Table 3.13 Age-related changes in the peripheral nervous system.

Loss of spinal motor neurons
Decreased vibratory sensation, especially in feet
Decreased thermal sensitivity
Decreased sensory nerve action potential amplitude
Decreased size of large myelinated fibres
Increased heterogeneity of axon myelin sheaths

Table 3.14 Changes in calcium homeostasis with age.

Parameter	Change
Serum calcium	No change
Intestinal calcium absorption	↓
Serum parathyroid hormone	↑
Serum 1,25(OH)2D	↓or no change
Resorption of calcium from bone	↑
Net calcium balance	↓

The ageing skeleton

Almost everyone loses bone with ageing (Table 3.14). Women have acceleration of bone loss with onset of menopause. Men lose bone more slowly, and lose cortical bone only as they lose tissue in general, not preferentially, as is the case in women. Both men and women lose trabecular and cortical bone. Osteoporosis is a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, which increases the susceptibility to fracture. Remodelling of both cortical and trabecular bone takes place through sequences of activation, resorption (by osteoclasts) and formation (by osteoblasts). A multitude of hormones regulate bone remodelling: (a) calcitriol, (b) parathyroid hormone (PTH), (c) sex steroids, (d) calcitonin and (e) insulin-like growth factors (IGF-1, IGF-2). Vitamin D and PTH maintain serum calcium. Serum calcium levels do not change with age, but the way in which they are maintained changes dramatically.

With increasing age, serum calcium levels are increasingly maintained by resorption of calcium from bone rather than resorption from the diet. The decreased sensitivity of the parathyroids to calcium, decreased responsiveness of the kidney to PTH, and decreased responsiveness of the intestine to calcitriol [1,25-dihydroxycholecalciferol, 1,25(OH)2D] all work together to increase serum PTH levels with age. Calcium supplementation is effective in lowering PTH levels and reducing bone loss in the elderly.[27]

The ageing gastrointestinal tract

The digestive tract maintains much of its normal physiological function during the ageing process. There

are a number of physiological changes that occur with ageing that have the potential to influence drug deposition and metabolism and may influence gastrointestinal (GI) function.

Pharyngo-oesophageal function changes with age, but the clinical significance is unclear. In elderly individuals, a decrease in the number of myenteric ganglion cells per unit area along with a thickening of the smooth muscle layer has been described. Age has no effect on peristaltic velocity, basal lower oesophageal sphincter (LES) pressures or frequency of 'abnormal' double- and triple-peaked waveforms. Gastric emptying for large, but not small, volumes is reduced in the elderly, gastric acid levels are increased, the incidence of peptic ulcer disease is known to increase and gastroduodenal mucosal prostaglandin levels decline with ageing. Changes in small bowel motor patterns with ageing have been described, including relatively minor effects on small bowel manometric patterns with decreased frequency of contractions after eating, reduction in the frequency of the migrating motor complex and reduced frequency of propagated clustered contractions.[28] The physiological and clinical consequences of these changes are uncertain. The absorption of nutrients by the intestinal tract depends on a multitude of factors. Highly lipid-soluble compounds such as vitamin A show increased absorption whereas vitamin D is decreased. Fat absorption is decreased whereas cholesterol is increased. Carbohydrate absorption has been shown to decrease in rats. Numerous studies have assessed sigmoid functioning and colonic transit, and there is little evidence of any alteration in these measures in older adults.[29]

In summary, physiological changes of the GI tract are primarily preserved, although changes do occur that have clinical consequences (Table 3.15). Loss of enteric neurons

Table 3.15 Changes in the GI tract with ageing.

General
Reduced total body mass
Reduced basal metabolic rate
Reduced proportion of body fat
Gastrointestinal
Increased gastric acid production
Reduced gastric emptying rate
Reduced gut motility
Reduced gut blood flow
Reduced absorption surface
Decrease in gut-associated lymphoid tissue
Hepatic–biliary
Reduced liver mass
Reduced liver blood flow
Reduced albumin synthesis
Impaired clearance of drugs that require phase I metabolism

Table 3.16 Changes in the renal system with ageing.

Decreased creatinine clearance and GFR[a] 10 ml per decade
Decrease of 25% in renal mass
Decreased sodium and potassium excretion and conservation
Decreased concentrating and diluting capacity
Decreased serum renin and aldosterone
Accentuated ADH[a] release in response to dehydration
Decreased nitric oxide production
Increased dependence of renal prostaglandins to maintain perfusion
Decreased vitamin D activation
Impaired secretion of acid load

[a] GFR, glomerular filtration rate; ADH, antidiuretic hormone.

Table 3.17 Morphological changes in kidneys with ageing.

Morphological changes
Reduced size and weight
Relative cortical atrophy
Vascular changes
Hyalinosis of arterial walls
Glomerular changes
Increased number of sclerosed glomeruli
Hypertrophy of the remnant glomeruli
Increased thickness of basal membrane
Mesangial matrix expansion
Irregular fusion of foot processes
Tubular changes
Reduction in the number of tubules
Atrophy of the tubular epithelium
Increased thickness of basal membrane
Interstitial changes
Interstitial fibrosis

Table 3.18 Functional changes in aged kidneys.

Renal blood flow
Decreased
Relative increase in medullary blood flow
Glomerulus
Decreased glomerular filtration rate
Increased filtration fraction
Increased permeability to macromolecules
Tubule
Impaired ability for sodium and potassium handling
Deranged tubular transport
Impaired concentration and dilution
Impaired acidification
Other
Decreased synthesis of renin
Decreased $1-\alpha$-hydroxylase activity

Table 3.19 Anatomical changes of endocrine glands with ageing.

Endocrine gland	Structural changes
Pituitary	Increased occurrence of adenomas and empty sellae, proportional decrease in eosinophil cells, increased non-parenchymal cells
Thyroid	Lymphocytic and plasma cell infiltration, fibrosis and increased nodularity
Parathyroid	Increase in oxyphil cells, large oxyphil nodules
Adrenal glands	Fibrotic changes in cortex, accumulation of lipofuscin, mitochondrial fragmentation, increased adenomas and vascular haemorrhage, cellular depletion of zona reticularis
Testis	Germ cell arrest, thinning of germinal epithelium
Ovary	Depletion of oocytes, papillomatous outgrowths, sclerosis of medulla
Pancreas	Loss of compact structure of islet cells, amyloid deposition

Table 3.20 Age-related changes in the degradation of hormones[a].

Increased	Decreased	No change
Epinephrine	Aldosterone	FSH, LH
PTH	Testosterone	GnRH in rats
Cortisol	Dihydrotestosterone	ACTH
	Estradiol	AVP
	Noradrenaline	Glucagon
	Insulin	Calcitriol
	GH	T4, T3
		TSH

[a]FSH, follicle-stimulating hormone; LH, luteinizing hormone; PTH, parathyroid hormone; GnRH, gonadotropin-releasing hormone; ACTH, adenocorticotropic hormone; AVP, arginine vasopressin; GH, growth hormone; TSH, thyroid-stimulating hormone.

in the submucosa and in the myentenic plexuses are key to the functional changes observed with ageing.[30]

The ageing kidney

The ageing kidney maintains its ability to regulate body fluid homeostasis under general conditions (Table 3.16). It becomes progressively limited in its ability to respond to stresses. These changes result from anatomic changes and also from alterations in tubular cell function and responsiveness to hormonal and haemodynamic factors.

The loss of renal mass is mainly due to progressive atrophy of the renal cortex, with relative sparing of the medulla. By age 80 years, between 10 and 30% of the glomeruli are completely sclerosed. The glomeruli of the outer cortex are affected the most (Table 3.17). There are also functional changes in aged kidneys. Renal blood flow decreases by ~10% per decade after a peak in young adulthood, and the renal plasma flow is reduced by 50%.

The cause of age-related changes in the kidney remain unknown.[31] One hypothesis, the hyperfiltration theory due to reduced nephron mass, proposes that a kidney with reduced number of glomeruli, has increased capillary blood flow through each glomerular bed and a corresponding high intracapillary pressure. This high pressure results in local endothelial damage, platelet aggregation and thrombin production, which leads to the release of growth factors from platelets such as (1) platelet-derived growth factor, (2) epidermal growth factor, (3) fibroblast growth factor and (4) tumour necrosis factor alpha (TNF-α). These factors increase fibroblast collagen production and mesangial cell sclerosis. Angiotensin II secretion is then increased due to the disruption of vascular haemodynamics. As glomeruli become sclerosed, the amount of blood flow to each remaining nephron increases, further potentiating the damage. Oxidative stress and telomere shortening are thought to play a role in vascular damage. These changes result in an increase in the filtration function (glomerular filtration rate/renal plasma flow) with ageing.[32]

Functional and morphological changes occur in the aged that affect homeostasis are summarized in Table 3.18.

The ageing of the endocrine system

Ageing is associated with hormonal changes, and with anatomical changes of the endocrine glands as a result of programmed cell death, autoimmune destruction of the gland or neoplastic transformation of glandular tissue. Age-related changes could also occur in hormonal secretion secondary to physiological changes due to circadian and seasonal rhythm or in frequency or height of hormonal pulses. Other changes with ageing include (1) altered bioactivity of hormones, (2) altered transport of hormones to binding receptor sites, (3) altered hormone–receptor interactions or (4) postreceptor changes. Ageing is associated with alterations in plasma membrane properties, intrinsic changes in cellular enzyme activity and changes in calcium mobilization and gene expression. Ageing is associated with important structural changes (Table 3.19).

Changes in hormone secretion are noted with ageing. They are related to altered endocrine cell physiology rather than cellular depletion. Age-related changes in the pituitary

Table 3.21 Changes of organ systems with ageing.

System	Change
Haematopoiesis	Decreased bone marrow reserves in response to high demand
Temperature regulation	Impaired shivering
	Decreased cutaneous vasoconstriction and vasodilatation
	Increased core temperature to start sweating
Smell	Detection decreased by 50%
Thirst	Decreased thirst drive
Balance	Reduced number of organ of Corti hair cells
	Increased threshold vestibular responses
Audition	Bilateral loss of high-frequency tones
	Central processing deficit
Adipose	Decrease in expression and activity of lipoprotein lipase
	Decreased leptin levels in females and increased in males
Genitourinary	Incomplete bladder emptying and increased residuals
	Reduced intensity for orgasm for men and women
	Prolonged refractory period for erections for men

gland are attributed to altered pulsatile pattern of hormone secretion. Desynchronization of various biological rhythms occurs with ageing. Glandular sensitivity to secretagogues is also affected, with some glands having reduced, increased, inhibited or no alteration in response. Finally, clearance of hormones is also altered with ageing. For many hormones, peak function occurs between 20 and 30 years of age and then declines at a constant rate thereafter.

Changes occur in the aged endocrine glands that affect homeostasis greatly (Table 3.20). A decrease in insulin growth factor I receptor is associated with longevity in females. Increased plasma TSH is associated with longevity, which appears to be associated with an alteration in the TSH receptor.[33]

Ageing of other systems

A multitude of changes occur in other systems of the body (Table 3.21). The dysregulation of these systems affect homeostasis in a multitude of ways.

In summary, the aged body, complex yet intricate, adaptive yet reactive, has shown a resolute progression and preservation of function. Although many changes occur leading to decreased reserves, the successful ageing process that some seniors possess confirms the will of humanity to strive for longevity.

Key points

- A multitude of theories have been proposed to explain how the body ages.
- Cytokines play a major role in the ageing process.
- Modulation of cytokines can slow the ageing process.
- The ageing of certain organ systems compounds the ageing affects of other organs.
- The rate of decline among organs varies greatly.

CHAPTER 4

Psychological aspects of ageing

Peggy A. Szwabo
Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

This chapter addresses how adults adapt psychologically as they age. Psychological theories of adult development have been extensively written about in the scientific literature. Several approaches addressing life stage perspective are presented here as it relates to mental vitality in late life.

Psychology is the study of behaviour and the facts and factors that influence behaviour. Psychology of ageing studies behaviour that is organized or disorganized as the adult ages, that is, how the adult adapts or does not adapt to life stresses. These behaviours may be constant throughout life as the person experiences tasks and challenges.

Generally, psychology is viewed as a broad field encompassing personality development, intelligence, memory, motivation, neuropsychological changes, creativity and sensory and motor functioning. Important for the ageing person are information processing, cognition, life satisfaction and personal control. As with all fields, psychology of ageing interrelates with the biological and social aspects of ageing. Psychological processes are constantly intertwined with biological, social and environmental factors. Understanding the psychology of ageing helps the practitioner assess the person's ability to adapt to change, understand and cope with ageing, illness and loss. Furthermore, understanding the older adult's previous or lack of coping and adaptive skills, the practitioner may be able to predict and understand potential problems.

Successful psychological ageing is dependent upon mental vitality. Mental vitality can be described as psychological or intellectual energy. That is, given life's choices, how does the ageing adult face the challenge? What is the individual's mental vigour to cope with changing biopsychosocial changes? What has been their history of adapting and coping throughout life? Studies have found that ill health is related to problems with cognition, learning and motivation, thus challenging the elder's ability to cope.[1,2] In addition, Chou *et al*.[3] found that mood can affect decision-making abilities in the elderly. A happy mood was related to increased risk-taking activities and, conversely, information processing and motivation were affected by the mood of the individual As Kermis[4] so aptly put it, ageing is the greatest challenge.

Mental vitality encompasses present life-style choices, but also one's history of choices. These choices include reducing stress, establishing rest and relaxation, challenging the mind, cultivating satisfying relationships and activities and avoiding known risk factors such as smoking, poor nutrition, weight problems and excessive alcohol consumption. Equally important are the attitudes and beliefs that the older adult has about ageing that reflects how successfully one ages. A mentally vigorous older adult with a positive attitude will be able to cope better with life's challenges and make informed choices. Although cognitive deficits have been extensively written about, it is the positive changes and adaptive abilities that may be more important in daily living skills. Likewise, Reichstadt *et al*.[5] studied the opinions of community-dwelling older adults (60–99 years of age) as to what contributes to successful ageing. Four themes emerged from their focus groups: (1) the importance of having a positive attitude and being adaptable; (2) having security and stability with regard to living situation, finance and support resources; (3) physical health and wellness, but with mixed opinions on whether this is necessary; and (4) a sense of engagement and stimulation, defined as finding meaning in life, being useful with continued involvement in stimulating activities.

Life stage perspective

Here, the focus will be on the emphasis of mental vitality as a life stage approach. This developmental-stage theory emphasizes integration of life experiences. The developmental theorists attempt to describe human development as a sequence of stages or steps. Developmental-stage models

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

hold that changes in the adult personality are results of interaction of the social and biological environment. How the individual interacts with others and integrates that interaction into his/her personality is determined by the developmental tasks that the person performs. These tasks are markers of the individual's movement through the life cycle. Each task combines some aspects of the person's biological, psychological and social functioning. Developmental tasks combine the drive towards growth of the person with the demands, constraints and opportunities of the social environment. These tasks occur for all people in approximately the same sequence, which may overlap each other without a particular onset or termination. Failure and delay in resolving these tasks may affect how successful one will be in resolving future tasks, adjustment and overall mental health. All of these tasks act to move the individual towards optimal psychological function and personal integrity if they are successfully accomplished. Similarly, Atchley[6] proposed the continuity theory of normal ageing, which observes that older adults use strategies reflective of their past experiences and views of self and their world. Change is linked to past perceptions and existing internal structures. Erikson,[7] the most familiar of the developmental-stage theorists, applied his approach to the aged. In his eight stages of development, the person has a conflict with two possible outcomes, adaptive or maladaptive solutions. If an early stage is resolved with a low degree of adaptation, resolving later stages will be more difficult. Erikson's last two stages directly apply to adults and ageing adults. These two stages are broad and cover many years, resulting in other theorists defining more definitive age-specific conflicts.

Havighurst and Peck postulated theories that have particular significance for the elderly; both authors elaborated on Erikson's psychosocial tasks with consideration of tasks of the older adult.[1,7–9] Havighurst[1] described the six tasks of old age as follows:

1 adjusting to declining physical strength and health;
2 adjusting to retirement and reduced income;
3 adjusting to changes in the health of one's spouse or partner;
4 establishing an explicit affiliation with one's age group;
5 adopting and adapting social roles in a flexible way;
6 establishing satisfactory physical living arrangements.

Ageing adults experience a variety of physical, social and psychological losses. These losses can affect mobility both physically and socially, resulting in increasing isolation. There is a chance that the environment will continue to diminish unless the individual takes action. Havighurst's focus was on reorganizing functions and expectations.[1] For example, older adults who do not accept their changing physical and health limitations and adapt may become maladjusted. Partner roles may change if one partner becomes ill. The partner who nurtured may need nurturing care; the healthy partner may have to assume new roles of banker, handyman and decision-maker. Old age is a time of almost constant change. Older adults who do not adapt or adjust flexibly may find themselves increasingly stressed and maladjusted. According to Havighurst,[1] the continued refining roles and expectations to meet environmental demands accomplish the maintenance of identity.

Peck's tasks[9] are summarized into three areas of conflict. The first is ego differentiation versus work–role preoccupation and finding a way to identify and appreciate self without the job or one's career as the marker of success. This includes satisfaction with retirement and children leaving home. The task is to find new ways, activities and passions to define one's self. The second is body transcendence versus body preoccupation, which is understanding the changes in the body and illnesses without being preoccupied with symptoms or illness concerns. The question is, can one live successfully despite age-related changes and disease states? Many older adults cope with illness and live successful lives despite pain or infirmity. Others are preoccupied with their illness, by constantly talking about their symptoms, medication requests and frequent doctor appointments or 'shopping'. Lastly, the third area of conflict is ego transcendence versus ego preoccupation. This process is the coming to terms with the reality of death, putting closure on the past, ensuring the welfare of children and others and leaving a legacy. There is a need to share one's wisdom, knowledge and experience. Conversely, if maladaptive, there is a tendency to treat the world as if it will end with their death. This person may not make wills or plans for the future or for anything that would go on after their death.[9]

In summary, the personality is constantly changing in response to the individual's adaptation throughout life. Life challenges can occur at any time in the life cycle, but older people are more likely to have to confront more challenges simultaneously. Losses, physical and functional changes and cultural expectations stress older adults when their psychological reserves are low and their social supports are diminishing.[4]

What do we know?

In 2011, the first wave of 'baby boomers' (65–74 years old) will be retiring. For the next 20 years, 74 million baby boomers will retire. The 74–95-year-old cohort will steadily increase their numbers and also their life expectancy. As a group, the frail elderly is growing the fastest. In the United States, the 85+ age group will triple to 19 million by 2050.[10] Worldwide, the World Health Organization (WHO) estimates there are 4 million elders over the age of 85 years. Further, since 2007, the global population of all ages of older people has increased to 506 million worldwide.[10,11]

Ageing is not uniform or static. There is differentiation among the ageing, commonly divided into four groupings of the young-old (60–70 years of age), the old (71–74 years of age), the old-old (75–84 years of age) and the frail-old (85 years of age and over).[12–14] Each grouping has different tasks, abilities and issues. For example, the 60–70-year-old groups may still be employed and be more active. They may be dealing with retirement, considering housing options, developing leisure activities and relationship issues.

The 71–74-year-old group may be adjusting to retirement, loss or changes in work–role identity, income changes, friends moving or ill, widowhood and readjusting time management. Neugarten[13,15] noted that chronic illness and role losses were more characteristic of those over the age of 75 years. She further contended that the 55–74-year-olds are similar to the middle-aged who have fairly good health and are as active as they wish.

Riley and Suzman[14] further divided the old-old into the old-old and the frail-old. The old-old group may have more medical conditions, take more medications and may require more support services by either family or agencies or both. There are more losses, more issues with dependency and those related to assisted living situations. For couples, one partner may need more care and placement, resulting in the couple being separated.

This group is primarily female, widowed and more likely to face declining functional ability without a spousal caregiver. The old-old and particularly the frail-old group experience more physiological changes, more comorbid medical conditions, more frailties, higher rates of dementia and loss of connectedness. Connectedness is the desire to feel connected to others, their homes and community. This sense of connectedness is threatened when there are limitations in functioning, necessitating moves to a more secure and assisted living environment, removing the elder form the security of their neighbourhood and their home.[16]

Overall, the frail elder is more likely to be in a supported living setting with more health problems, is more dependent upon others to meet their daily needs and generally takes longer to recover from acute illnesses.[17,18] Many of this population, primarily women, may outlive their financial and health care resources.[18,19] With advancing age they are more likely to live in poverty, have increased risks for health and social problems. There is a corresponding demand for supportive services, long-term care solutions and more money allocated for health care and services.

With each group, there may be a wide range of health or illness states varying from healthy to chronic but stable, acute and acute superimposed with chronic illnesses. Rather than relying totally on age categories alone, it is also important to address health status, adaptive abilities and social characteristics.

Age-related psychological changes

Intelligence

Intelligence is composed of crystallized and fluid intelligence. Crystallized intelligence is the ability to apply past learning to new situations. Crystallized intelligence increases with age, experience and knowledge. Examples of crystallized intelligence are problem-solving activities, mechanical skills, word meanings and understanding social relationships. Fluid intelligence is the ability to improve organization of information and to generate new hypotheses. Fluid intelligence decreases with age. Fluid intelligence consists of reasoning and abstraction, relationships between objects, acquiring new ideas and adapting to change.

IQ increases until the 20s, then levels off and generally remains stable throughout the life cycle. With ageing, there is decreased speed in timed tests. Poor health represents an adverse factor in the older adult's performance. If given more time, the older adult is as accurate as a younger adult is. In general, older adults perform better in everyday practical tasks over laboratory-based tests. Performance on the Wechler Adult Intelligence Scale (WAIS) demonstrates that older adults have an increase in verbal skills, while there is a decrease in tests of performance. Results show that intelligence is stable until the 70s, when there is a decrease in performance countered by an increase in verbal skills.[2] These verbal skills reflect the knowledge and skills acquired over a lifetime.

Ageing influences intellectual functioning. Changes in motor skills and slower decision-making time affect reaction time. Performance is also affected by changes in cerebral cortex functioning and cardiovascular deterioration. When decision-making, older adults have been found to sacrifice speed for accuracy and to reject quick, simplistic solutions to problems, preferring to work slowly and to examine issues from a variety of perspectives before responding. Older persons are more likely to make errors of omission rather than errors of commission, which suggests cautiousness, deliberateness and anxiety.[20] As a compensatory strategy and to avoid embarrassment, many older persons avoid unfamiliar activities and places. This cautiousness may be mistaken for resistance or obstreperousness. In addition, mood and beliefs about ageing affect one's response to testing and evaluation.[3,21,22]

A word of caution is advised, many older adults do not have the advantage of many years of formal education as compared with younger persons and have been years away from the classroom environment.[2] Deliberateness, slower response time and time away from traditional school activities impact tests of intellectual abilities.

Clinicians need to evaluate clearly the impact of physical infirmities, compensatory skills and the older adult's social environment before coming to any conclusions regarding intellectual decline. The impact of the living situation,

lack of stimulation and isolation may constrain intellectual functioning and should not be ignored.[2] If healthy and fit, the older adult's response time is no different from that of less healthy younger people.

Memory

The capacity to learn continues throughout life. Optimal learning involves reading or following instructions on how to organize information, finding tasks meaningful and rewarding and being able to link visual memory with auditory information. There are three phases of information processing – encoding, storage and retrieval. With ageing, more time and effort are required to encode information. Sensory changes can reduce memory efficiency. Because sensory memory lasts less than 10 seconds and with ageing sensory changes, the older adult is less able to encode as well. Short-term memory lasts a few seconds and declines with age.

Recall involves search and retrieval of information from storage. Recognition requires matching information in storage with information obtained in the environment. Recognition abilities remain stable over time.[20] All ages do well in recognition tasks, but recall diminishes over time. It is easier for older adults to do tasks of recognition than recall information.

Long-term memory includes storage of information, a fact learned earlier in life and day-to-day experiences and is relatively permanent. Long-term memory increases from age 20 to 50 years and then is constant into the 70s. Older adults require more time to encode new information. This encoding process is affected not only by sensory losses but also by changes in the environment, such as moves and deaths. These events contribute to memory deficits.

As important is the impact on one's belief that memory loss is inevitable. Lineweaver *et al*.[21] found that these beliefs are pervasive and stereotypical in that study participants rated individuals with positive personality traits as having better memory and less decline than those adults with negative personality traits. For clinicians, a more thorough assessment may be indicated of the older adult's beliefs that may influence their performance in cognitive tasks.

Many older adults adapt fairly well and deficits may not be evident until a traumatic event occurs or is uncovered by a skilled clinician. Using compensatory strategies to augment memory, such as use of calendars and notes, taking time and practicing new material, is indicated. Structure and familiarity also help in improving memory and retention. With slowed recall and physical decline, there is a slower response, which can be misconstrued as more significant memory deficits or resistance.

In summary, older adults retain well-practiced and adaptive skills. Less-practiced tasks and recall requiring a timed response decline.

Sensory

The nervous system is important in receiving, processing and storing information. The senses provide contact with the environment. Changes or decline in senses affects a person's participation in their environment and their quality of life. Losses or changes in vision, hearing, taste, smell and touch influence the individual's functioning, activities, stimuli response and perceptions. Sensory losses can produce alterations in behaviour, independence, confidence and self-esteem. On the other hand, assumptions are made that sensory-impaired elders are senile, stubborn or manipulative. Careful assessment of sensory loss is indicated before assumptions can be made concerning self-care and adaptive capabilities. Spectacles and hearing aids help compensate for sensory losses and allow more independence.

Creativity

Even though creativity is generally not considered a component of psychological functioning, it is an area that is a part of mental vitality and quality of life. There have been many debates about whether creativity is limited to a few and that it declines with age.[23] Research shows that creative thinking is a universal ability that helps adults manage satisfying lives. Creativity is a complex of traits, skills and capacities, including the ability to work independently, curiosity, unconventional thinking, openness to experience and tolerance of ambiguity.[23,24] Cognitive psychologists define creativity as a mental process like imagination and intuition. The newer definition is particularly relevant to the older adult. It is the integration of cognitive processes, knowledge, thinking style, personality, motivation and environment over a lifetime. Creativity is a way to address and resolve dissatisfactions and improve quality of life and can be a response to limits and an uncertain future.[23,24] Older adults appear to experience a decrease in divergent thinking, the ability to generate novel ideas, but this is a qualitative change in the creative process. In contrast, there is an increase in crystallized intelligence and integrative or convergent thinking.[25] Later life may afford more time for reflection, life review and creative pursuits aimed at the development of one's life story and the filling in of gaps and discontinuities. This creative process, which is similar to Butler's life review,[26] is a positive therapeutic process. Adams-Price[23] concluded that late-life creativity reflects aspects of late-life thinking: synthesis, reflection and wisdom.

Implications for practice

Ageing is an adaptive challenge. Mental vitality is the vigour needed to meet this task. As clinicians, continual

evaluation of the older person's understanding of the implication of age-related changes and losses is required. Identifying coping skills and adaptive strategies is also paramount an effective relationship and treatment planning. To incorporate the aforementioned psychological changes into practice, the recommendations are made:

1 Face-to-face education should occur, presenting the information in small increments and supplemented with one-page practical handouts to carry home.

2 Helpful teaching techniques include teaching time, with practice and episodic spot checks to reinforce or to correct, and a telephone phone number and contact person to call if they have questions or concerns.

3 Allow time to complete forms in a setting conducive to writing.

4 Printed materials need to be in larger, boldface type and simplified to adjust for sensory changes. The guidelines of the Americans with Disabilities Act recommend that print be at least 18-point font. Signs should be in large print or symbols with contrasting background of eggshell, matte or non-glare paper for easier reading and to clarify directions.[27]

5 Observe accessibility and visibility issues in the physical environment. Are the directions and locations easy to follow? Lighting should be 100–300 lux to ensure adequate vision and easy reading.[27]

6 Encourage the older person to take notes or write their concerns before their appointment.

7 If necessary or beneficial, suggest that the older person bring someone to assist or take notes.

8 Encourage the older adult's participation in the treatment planning.

9 Allow the older person the opportunity to present concerns, fears or objections to the plan.

10 Allow them time to process information and study their options.

11 Ask how they are coping and what coping strategies they use. For example, 'How do you handle this?', 'You have a lot to deal with', 'How are you holding up?' or 'What helps you?',

12 Encourage innovative or creative solutions. Ask how they would solve a problem.

13 Referral to support group, if it exists, for their medical condition.

14 Referral to a geriatric/gerontology professional for counselling and environmental options.

Conclusion

Not all cognitive changes are negative. The positive cognitive changes include greater experience-based knowledge, increased accuracy, better judgment concerning their abilities and generally an improved ability to handle familiar tasks as compared with their younger counterparts.

Ageing presents psychological and cognitive challenges requiring mental vitality to adapt. An older person who ages 'successfully' has been able to use their accumulated knowledge and wisdom to accomplish most day-to-day living activities well. Rigidity and exaggerated maladaptive behaviours may represent psychological and neurological problems and are not normal ageing and a referral to a specialist is warranted. As with any treatment planning, the older adult's problems may be obvious but treatment interventions are based upon what the person can do.

Key points

- Mental vitality or energy is needed for older adults to cope with life changes.
- Intelligence changes with age. Older persons have increased verbal skills and they demonstrate slowed performance skills. Life-long experience and knowledge are reflected in verbal skills.
- Older adults tend to be more cautious in decision-making activities, pondering their options before responding. This deliberateness should not be mistaken for resistance.
- Memory changes with age. Long-term memory remains fairly constant. It is easier to do tasks of recognition over recall activities.
- Illness, mood, beliefs, social and environmental changes affect learning, memory and creativity. These changes need to be incorporated in treatment planning.
- Creativity is a positive therapeutic process that encourages reflection and development of the older adult's life story.

CHAPTER 5

Ageing of the brain

Jean-François Démonet[1] and Pierre Celsis[2]
[1]Leenaards Memory Centre, CHUV, Lausanne, Switzerland
[2]INSERM Unit 825, Toulouse, France

Even compared with the closest animal species (great apes), the human species is characterized by an exceptionally high brain/body weight ratio and a long lifespan. In this chapter, it is obviously impossible to cover the immense field of both the physiological and evolutionistic features of human brain ageing and the major pathologies that affect, at an increasing rate with age, elderly people. A number of detailed reviews on these issues can easily be found. Here we report some recent research lines that seem relevant for understanding better the 'physiology' of brain ageing and the pathophysiology of major diseases affecting cognition such as Alzheimer's disease, and we review the input of recent brain imaging methods to explore clinically brain function and tissue changes in the elderly.

Increasing human longevity has been a constant trend worldwide over past decades. Improvement of socioeconomic conditions and nutritional resources, together with the prevention and treatment of major pathologies such as infectious, metabolic, vascular and heart diseases, have contributed to a longevity increase from ~60 to ~80 years during the twentieth century in Western countries. Estimations of the prevalence of clinically diagnosed dementia in nonagerians ranges from 20 to 30%, with a higher risk in women;[1] therefore, as age is one of the major risk factors for Alzheimer's disease (AD) and the frequency of vascular lesions also increases with age, one may wonder whether, in the extreme elderly range, a disease-free brain should be regarded as a (desirable) norm or whether it is observed in only a minority of cases.

Is there physiological ageing for the brain?

From an evolutionist point of view, a compelling question is what is the advantage for our species to have a prolonged, senescent period of life in which women cease to be reproductive? Notwithstanding culture-based influences that provide senior members of a group with a protected and honoured social status, it has been proposed that elderly individuals, especially grandmothers, could play a specific role in the transmission of knowledge concerning foraging and other context-dependent hints and strategies crucial to individual and social survival. Therefore, it is conceivable, on biological grounds, that non-reproductive, ageing individuals who can communicate, over a significant period, their experience to junior congeners and participate in the (prolonged) education of children represent an evolutionarily advantage.[2] From a physiological perspective, it should be remarked that the maintenance of the large and complex human brain supporting efficient, long-lived episodic memory implies especially high energy consumption as the brain's energetic needs relative to the total body metabolism is remarkably high in humans (~20% of the body energy consumption). The intimate basis of this enormous energy need probably relates to (i) the considerable membrane surface of most neurons whose dendritic and axonal arborescence extend very far from the cell body and (ii) the energetic cost of molecular trafficking and ionic exchanges throughout membranes of the 'neural tree'. It should be noted that some regions of the consciousness-related 'default mode' network, such as the posterior cingulate cortex, also support high-level autonoetic memory representations. It might not be pure coincidence that this region is also characterized by both a tight coupling between oxidative energy consumption and synaptic firing[3] and heavy binding of amyloid-specific ligands at early stages of AD.[4,5] Further, the effect of constant learning and maintenance of long-term memory during ageing have to relate also to morphological plasticity in the brain. A very slight, non-linear and brain-wide trend to grey matter thinning with preponderance in the parietal and frontal convexity is observed in normal subjects from the second to the eighth decade; this slight frontal atrophy is associated with a decrease in performance on executive and working memory tests.[6] By contrast, the evolution of white matter volume proceeds differently over decades, with a slight growth trend from the third to the sixth decade followed by a rapid decline with further ageing;[7]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

white matter abnormalities in magnetic resonance imaging (MRI), typically small hyperintensities in the periventricular regions, increase with age and represent an independent risk factor for dementia and stroke.[8]

At the microscopic level, the estimation of the reduction in the density of neurons in the cortex has led to controversies; differences between cortical territories might account for these discrepancies, but some moderate, age-related decrease in branching in the dendritic tree and the size of neurons has been more consensually acknowledged (for a review, see Burke and Barnes[9]). Interestingly, normal ageing seems to relate to a shrinkage of cortical mini-columns,[10] although adaptive plasticity may also lead to longer terminal segments dendritic trees[11] in addition to new synapses and neo-neurogenesis[12] that might offset the effects of disappeared connections. At the molecular level, neural plasticity depends on a variety of mechanisms, among which one should note the role of immediate early genes (*CJun, Cfos* and *Zif238*), in addition to a number of other pathways involved in axonal growth, cytoskeletal assembly/transport, signalling and lipogenic/uptake pathways, according to Rowe *et al*.,[13] who also described upregulation in immune/inflammatory, lysosomal, lipid/protein degradation, cholesterol transport, transforming growth factor and cAMP signalling pathways. The influence of education and sustained, challenging cognitive activities on brain structure and functions has been described as the 'cognitive reserve hypothesis' by Stern *et al*.;[14] such an influence of cognition-related neural activities over the lifespan would also elicit brain resilience to pathology. Although the existence of learning-related brain plasticity (from cellular to gyral morphology levels) is beyond dispute,[15] these effects across subject groups differing in education have not been unequivocally confirmed and the protective mechanisms of 'cognitive reserve' against brain pathologies are still poorly understood.

Pathological ageing: proposed cellular and molecular mechanisms

The challenging need for maintenance over decades of high energy consumption in the hugely complex cellular brain architecture has been mentioned above; in the context of such human-specific physiological condition, a number of mechanisms that would be at the origin of ageing-related degenerative diseases have been put forward, especially a lack of clearance of toxic metabolic by-products, oxidative stress and disturbed Ca^{2+} homeostasis. A number of neurodegenerative diseases are associated with the aggregation of misfolded constitutive cellular proteins such as tau, α-synuclein and β-amyloid.[16] The last protein has attracted considerable attention as a consequence of its major implication in the most frequent, age-related degenerative brain disease, AD.

The specific role of the β-amyloid protein in its various monomeric, oligomeric and aggregated or fibrillary forms in the pathophysiology of AD remains to be elucidated, in addition to the mechanistic link between β-amyloid accumulation and pathological accumulation of the hyperphosphorylated form of tau protein in neuronal microtubules. The aggregated, mature form of β-amyloid constitutes the core of senile plaques observed in the brain of AD patients and also in normal elderly subjects, although to a far lesser extent; this typical neuropathological feature probably represents the final state of the pathology process rather than the origin of neuronal death in AD. Oligomeric, soluble β-amyloid has been shown to have toxic effect at the synaptic level via overstabilization of mGlu5 receptors provoking excessive intracellular calcium influx;[17] damage to synapses seems to be one of the earliest lesion stages in pathological ageing with synaptic loss located in key regions such as the mesial temporal cortex.[18] The chronic activation of pro-inflammatory pathways eliciting glial cell activation has been outlined as one of the likely basic mechanisms leading to cell death in neurodegenerative diseases, and even β-amyloid has been related to such inflammatory pathways, putatively activated to fight microbial diseases.[19] One of the only established important genetic risk factors in the late-onset forms of AD is genotype epsilon4/epsilon4 of the ApoE protein, while ApoE3 has protective influence for cardiovascular diseases in ageing. In evolutionistic terms, ApoE4 would be an old form whereas ApoE3 seems to have been selected later, perhaps as a consequence of the changes in the human diet when it went on to involve more and more animal fat. ApoE has a major role in the transport of cholesterol and elevated values of cholesterol blood concentration also represent a risk for AD. A direct binding mechanism has recently been suggested between cholesterol and the C-terminal portion of the amyloid precursor protein.[20]

At the intracellular level, the key role of Ca^{2+} in a number of metabolic processes, from energy production to gene regulation, consists in a transient influx of calcium in the cell, quickly buffered by specific protein transporters and by sequestration in organelles such as mitochondria. Mitochondria play a key role in intracellular energy supply, especially in the neuron synapse regions, and are affected by ageing with changes in their structure and decay of their efficiency, leading to oxidative stress with increase in the cellular concentration of oxygen reactive species (for a review, see Toescu and Verkhratsky[21]). Age-dependent decay of the ionic exchange systems that normally induce rapid calcium elimination from the cytosol relates to various pathogenic pathways that may lead to apoptosis. The various biochemical mechanisms by which excessive calcium concentrations can be alleviated are good examples of the compensatory pathways that can take place in some cell populations to resist pathological ageing. However, it

seems that specific neuron types are more exposed to the toxic effects of increased intracellular calcium concentration or the regulatory mechanisms elicited by this trend. For instance, hippocampal pyramidal cells are characterized by a decrease in the number of NMDA receptors with ageing; this effect may be a way to diminish toxic Ca^{2+} influx but also has the important consequence of a reduced efficiency of memory processes.[22]

Brain tissue depends vitally on a constant supply of oxygen and glucose by blood vessels. Ageing induces a progressive thickening and stiffening of arteries that alter the haemodynamics of cerebral vasculature and the efficiency of the transfer of energy metabolites to glial and neural cells. Hypertension and diabetes are major causes of such changes in the structure of blood vessels.[23] The clinical significance of such vascular changes has already been emphasized above, concerning brain white matter and the periventricular lesions (hyperintensities in MRI) that are observed to increase with age, as a consequence of pathological changes in the small artery system in these deep brain regions (for a review, see Moorhouse and Rockwood[24]). In cohorts of very old patients, neuropathological findings have demonstrated an increasing prevalence of cerebrovascular lesions as a conjoint pathology of typical AD lesions.[25]

Changes in large neuroendocrine systems and in general behaviour during ageing

Although not part of mainstream research, the influence of ageing on the whole neuroendocrine system is compelling. The most obvious example is the fall of ovarian estrogen production at menopause; estrogens, in addition to the cyclic interaction with its hypothalamic control pathways, are known to be involved in the control of mood, memory and cognitive and general behaviour.[26] Akin to this pathway is the stress control system, mainly represented at the hypothalamic level by the corticotropin-releasing hormone (CRH) secreted by the paraventricular nucleus; this system, which undergoes inhibitory control from the hippocampus, is upregulated in depression and to a lesser extent in AD. The implication of the stress system in general behaviour is also compelling when considering that vasopressin secretion co-localizes with that of RCH. Vasopressin is also secreted in a rhythmic way by the supra-chiasmatic nucleus, which is viewed as the biological clock of the brain and is responsible for the circadian changes in the stress system.[27] Ageing affects these neuroendocrine systems and the latter are involved in the major circadian behavioural changes, namely the sleep–wake rhythm (for a review, see Buckley and Schatzberg[28]). Sleep and wake alternations, which result from global brain functioning, underlie consciousness and have major influence on cognitive performance, especially episodic long-term memory (LTM). Non-rapid eye movement sleep (or slow-wave sleep) and the density of spindles in sleep stage 2 have been associated with efficient consolidation of LTM contents;[29] nevertheless, these effects seem specific to episodic memory and rapid eye movement (REM) sleep would also contribute to them in terms of contextual enrichment;[30] consolidation may be supported by the transfer of memory contents from the hippocampal formation to the prefrontal cortex. Age-related changes in sleep consist of a shortening of the successive sleep stages (especially the deepest stage 4), giving rise to an instability of the sleep structure, frequent nocturnal wakening and earliness of morning wakening. The EEG shows that typical events such as delta waves and K complex are less frequent and reduced in amplitude. Decreased performance of episodic memory in elderly healthy subjects relative to young control subjects might be related to the impoverishment of slow-wave sleep in the former. AD affects deeply sleep behaviour including increasing phases of diurnal somnolence and agitation at sunset. Damage to the cholinergic system which is caused by AD is strongly associated with shortened and impaired REM sleep (for a review, see Gagnon *et al*.[31]).

Assessing age-related physiological and pathological changes in brain anatomy and function: the input of brain imaging

Changes in cerebral blood flow and metabolism

Soon after the initial description by David Ingvar of the 'hyperfrontal' pattern of cerebral blood flow (CBF) in resting wakefulness,[32] the effects of age on the so-called 'hyperfrontality' have been reported. Studies agreed on the progressive disappearance of hyperfrontality during the fifth and sixth decades[33,34] and these observations were the first to point to the prominent susceptibility of the frontal cortex to healthy ageing. Since then, numerous metabolic studies using [^{18}F]fluorodeoxyglucose positron emission tomography (^{18}FDG PET) imaging have confirmed the earlier and higher functional vulnerability of the frontal cortex with ageing that may be worth distinguishing from the relative sparing of the mesial temporal and hippocampal cortices, which, opposingly, are early affected by AD.[35] However, other studies have found that, after correction of the ^{18}FDG uptake values for partial volume effects, no cortical region exhibited a significant correlation with age (although moderate, non-significant correlations can still be observed in particular in the frontal cortex), whereas measures of white matter integrity correlated with global and regional cerebral glucose uptake, indicating that white matter degradation may contribute

significantly to the functional changes observed in brain normal ageing.[36] However, a recent study by Chen *et al*.,[37] using arterial spin labelling for measuring cerebral blood flow, showed that the observed age-associated reductions were independent of regional atrophy evaluated by cortical thickness and, very interestingly, that the spatial distribution of CBF decreases spans the regions of the default-mode network.

Changes in brain macrostructure and microstructure

Progress in MRI techniques now allows sensitive and robust measurements of macrostructural and microstructural changes in brain grey and white matters that, combined in a multimodal approach, are substantially improving our knowledge of the impact of normal and pathological (mainly neurodegenerative) ageing on brain structure. These techniques provide, with high spatial resolution, anatomical (macrostructural) information (voxel-based mophometry, cortical thickness) and microstructural information (fractional anisotropy, mean diffusivity, diffusion decay imaging and tractography using diffusion MRI, T1 intensity and T2* relaxation rate for myelination and iron content imaging), each of these measures shedding light on different aspects of the healthy ageing or degenerative processes affecting our brain.

A longitudinal study by Fjell *et al*.[38] showed that the cortical atrophy consecutive to an ageing period as short as 1 year can be readily measured by changes in cortical thickness and volume using MRI. The annual atrophy rate varied across the cortex and was about 0.5% per year on average in a group of healthy subjects aged 60–91 years, the highest annual rate being measured in the hippocampus (–0.84%). Comparatively, the annual atrophy rate was increased in AD patients, with 1% per year change or more, reaching 2.5% in the posterior cingulate/precuneus region and lateral temporal cortex.

Numerous studies using the voxel-based morphometry approach also reported increased cortical atrophy with age, changes often predominating in the frontal cortex.[39] The same authors also reported changes in volume with age in the white matter (WM), especially in the anterior thalamic radiation, the anterior limb of internal capsule and the cerebral peduncle. They also found a negative correlation of fractional anisotropy (FA) with age in most of the WM regions, due to decreased radial anisotropy, and observed a positive correlation between age and mean diffusivity in most of the WM regions, with a relative sparing of the occipital lobes.

Combining cortical thickness, T1-weighted signal intensity and T2* relaxometry in a multimodal study aiming at differentiating maturational from ageing-related changes in the cerebral cortex, Westlye *et al*.[40] demonstrated a non-monotonic relationship of T1-weighted signal intensity with age, with an increase during the maturational phase (up to 30 years), followed by a plateau during middle age and a decrease in senescence that contrasted with the quasi-linear decrease in cortical thickness. They observed that the pattern of maturational development and age-related decline of the signal intensity measures were in agreement with the notion of a posterior–anterior gradient of cerebral maturation but at odds with the early frontal vulnerability reported in metabolic or morphometry studies. Indeed, while the frontal areas were the latest to mature fully as indexed by T1 signal intensity, they were not among the first to decline with advancing age according to this parameter. The authors stressed their observation that cortical grey matter signal intensity alterations were largely independent of concurrent cortical thinning and iron accumulation and possibly reflected alterations in myelination processes and synaptic density.

In addition to the cortex, subcortical nuclei are also affected by age and the corresponding changes can be evidenced by advanced imaging techniques. Measuring atrophy, iron deposition mean diffusivity and fractional anisotropy in seven subcortical structures, Cherubini *et al*.[41] showed that the T2* relaxation time in the putamen combined with the volume and the mean diffusivity of the thalamus accounted for more than 70% of the age variance in a group of 100 healthy subjects aged 20–70 years.

The advanced MRI techniques that contributed to improving our knowledge on the brain correlates of physiological ageing, as exemplified by the studies cited above, have also been applied to the study of the pathological processes that affect the ageing brain, in particular to the main two neurodegenerative diseases where age appears as a major risk factor : Alzheimer's disease (AD) and Parkinson's disease (PD). Cortical thickness in particular has been shown to help in the early diagnosis of AD. For example, using a normalized thickness index, Querbes *et al*.[42] were able to predict correctly, at the individual level, the evolution (or non-evolution) to AD for 76% of subjects with amnestic mild cognitive impairment, as early as 2 years before conversion. The interest in the anatomical measure for AD early diagnosis mainly follows from its immunity against the cognitive reserve which may mask the cognitive decline for many years in highly educated subjects. As another example of the potential of multimodal MRI in the diagnosis of neurodegenerative diseases, Péran *et al*.[43] demonstrated the nigrostriatal signature of PD by combining iron deposition and diffusion measures in the substantia nigra and the putamen. These imaging markers alone provided a 95%, cross-validated global accuracy in discriminating PD patients from controls. This work opens up interesting perspectives for monitoring disease progression and long-term drug impact.

Changes in brain intrinsic connectivity

The study of functional communication between brain regions at rest using MRI, the so-called resting state functional connectivity MRI (rs-fcMRI), has attracted attention in the past few years (for a review, see van den Heuvel and Hulshoff Pol[44]). In particular, one of the networks supporting brain intrinsic connectivity, the default-mode network (DMN),[45] has been shown to be affected by normal ageing and AD. Smaller and slower task-induced deactivation of the DMN has been observed in older healthy subjects[46] and these deactivations were even more reduced in AD patients.[47] Sambataro *et al*.[48] confirmed previously reported results observed in healthy ageing and showed that age-related alterations of the DMN, in particular in the connection between the posterior cingulate (PCC) and the prefrontal cortex (PFC), correlated with the decline in working memory of older subjects. These observations, in line with those of Andrews-Hanna *et al*.[49] on the correlation between decreased PCC–PFC connectivity and decline in executive functions and memory in older adults, may reflect, as suggested by Sambataro *et al*., a deficit in cognitive control and resource allocation possibly related to a decrease in dopaminergic innervation of the PFC in ageing. Interestingly, the intrinsic connectivity between the PCC and the hippocampus has also been shown to predict the performance on an associative memory task in cognitively intact elderly subjects.[50]

The results of the studies cited above suggest that impaired intrinsic connectivity may serve as an imaging biomarker for the early diagnosis of AD. In this perspective, a recent study by Yao *et al*.[51] reported very interesting results. Using a global, graph theoretical approach, they showed that the cortical networks of normal controls, MCI subjects and AD patients all exhibited small-world properties, but that abnormal nodal centrality was detected in MCI and AD, in addition to significant changes in inter-regional correlations. Their findings indicate that a loss of small-world characteristics can be shown early in the progression of disease, the MCI subjects displaying an intermediate pattern between those of controls and AD patients.

Key points

- Grey matter thins slightly with ageing, particularly in the frontal cortex, and this is correlated with the decline in executive function.
- Impoverishment of slow-wave sleep may lead to decreased performance in episodic memory.
- Blood flow decreases with ageing, especially to the frontal cortex.
- Cortical atrophy with a predominance in the frontal cortex occurs with ageing.

CHAPTER 6

Epidemiology of ageing and disability

Lenise A. Cummings-Vaughn

Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Ageing and chronic disease epidemiology

According to the United Nations Department of Economic and Social Affairs' 2002 report, *World Population Ageing: 1950–2050*,[1] the number of older adults has tripled in the last 50 years and is expected to again triple over the next 60 years. This unprecedented population shift is a consequence of steep declines in both fertility and mortality. The percentage of the population aged 60 years and over will equal that of individuals younger than 15 years by 2050 because of the projected decline in birth rates. This population shift is profound. In some developed countries, older persons already far outnumber children. Although the rate of these changes and subgroup proportions vary by region of the world, all regions are experiencing increasing longevity (Figure 6.1). The most rapidly growing group world-wide is those 80 years of age and over. The speed of the demographic transformations is unprecedented. For example, this seminal report[1] has revealed that 66% of the global increase in the world occurred in less developed areas over the last half century. The result of these demographic changes will culminate in four-fifths of the world's older population living in the less developed regions of the world.

In the United States, population projections indicate that one in five people will be aged 65 years or over by 2030.[2] According to these figures, between 2025 and 2030 the population aged over 60 years will be growing 3.5 times more rapidly than the total population. According to figures from the National Service Framework for Older People[3] in England, the number of people over 65 years old has more than doubled since the early 1930s, resulting in one-fifth of the population in England being comprised of persons over 60 years of age. Also, between 1995 and 2025, it is projected that the number of people over the age of 80 years will increase by 50% and the number of people aged over 90 years will double.

The public health significance of these demographic transformations includes the increased burden of chronic disease and disability on health care and socioeconomic impacts on care giving. The focus of health care must be related to reductions in age-specific disability and comorbidities. Current data based on the United States Vital Statistics show that heart disease and cancer are the top two leading causes of death for whites, blacks, American Indians/Alaska Natives, Asian/Pacific Islanders and Hispanics.[4] This is followed by chronic lower respiratory disease, stroke, diabetes, influenza and pneumonia (Table 6.1). However, these rates vary by racial and ethnic group. Life expectancy at the age of 65 years in 2006 was 17 years for men and 19.7 years for women, an increase of 1 and 0.7 years, respectively, since 2000. Diabetes is increasing in prevalence in older men and women. Men have a higher rate of both diagnosed and undiagnosed diabetes at 26% versus 24% for women. In addition, the rate of diabetes among those aged 65 years and over increased over three times faster among non-Hispanic black men. Although the prevalence of heart disease appears unchanged in the last decade, men continue to be diagnosed and suffer from heart attacks at a higher rate than women (Table 6.2). Non-Hispanic white males have the highest prevalence of diagnosed heart disease in the United States.

World Population Ageing: 1950–2050[1] describes the total dependency ratio as a measure of potential social support needs. Therefore, dependency can be used as a proxy for disability in older adults. Dependency ratios offer important information about the relative impact of ageing on the world's population. The ratio between the dependent population (both young and old persons requiring support) is projected to shift, with the older population constituting an almost equal component of dependency with the younger population and even to rise to 63% of the total dependency ratio in developed regions by 2050. The importance of these numbers is that health care needs to address risk factors of disability in the ageing to stem the burden of dependency.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

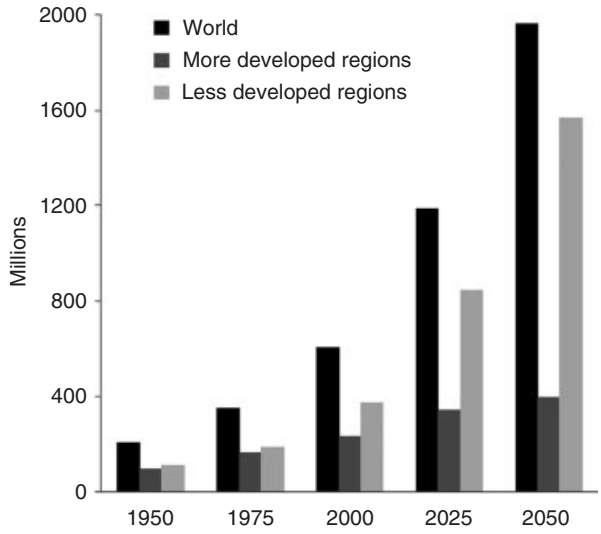

Figure 6.1 Expansion of the population aged 60 years and over: world and development regions, 1950–2050.[1]

Table 6.1 The leading causes of death in the United States in 2006.[41]

1	Heart disease: 631 636
2	Cancer: 559 888
3	Stroke (cerebrovascular diseases): 137 119
4	Chronic lower respiratory diseases: 124 583
5	Accidents (unintentional injuries): 121 599
6	Diabetes: 72 449
7	Alzheimer's disease: 72 432
8	Influenza and pneumonia: 56 326
9	Nephritis, nephrotic syndrome and nephrosis: 45 344
10	Septicaemia: 34 234

Table 6.2 European Union – Eurostat data: circulatory disease/cancer (two-thirds of deaths).

Circulatory diseases (heart attacks, strokes and other circulatory diseases)
41% of all deaths
42% of all deaths for 65–84-year-olds
Cancer
25% of all deaths
Highest cause of mortality for 45–64-year-olds

The response to population ageing needs to focus on the identification of risk factors and the development of effective prevention and treatments for disability. An additional focus is shortening the period of disability in the ageing population. As Hubert *et al*. noted,[5] the approach should be similar to reduction in cardiovascular incidence rates: risk factor models are identified from epidemiologic data and interventions are developed focusing on modifiable or reversible factors. Increased dependency equates to increased care taking and financial burden on families and increased institutionalization of older persons. Therefore, addressing the needs and interventions that accompany disability is rooted in targeted research. Longitudinal studies offer insight into associations of risk factors with disability.

The study of ageing and related diseases has been gradual and has occurred in response to changing population demographics. In the United States, the National Institutes of Health established one of its 27 Institutes and Centers as a National Institute of Ageing in 1974. This signalled interest and support for initiatives in ageing research.[6] In addition, many programs in gerontology and geriatrics were established. The consequence of these developments has been new studies pertaining to various aspects of ageing and geriatric research emerging as an important focus of interest. Population-based health studies around the world have taken initiatives to include older people in data collection and analysis. Prospective longitudinal studies will be important in advancing research and health services for chronic disease and disability that affects older persons. The ultimate goal of these activities is to increase disability-free years and improve quality of life. Therefore, a shift will be necessary to study not only mortality risks, but also risks and modifiable aspects of disability related to disease. Cooperative research that occurs through programs such as EU Public Health Programme and the Survey of Health, Ageing and Retirement in Europe (SHARE) are examples of important sources of data on ageing that can be used to advance aforementioned aims.

Epidemiological research is an important step in developing prevention strategies and creating recommendations and guidelines specific for older adults. In addition to epidemiologic knowledge, clinical studies and judgment along with patient preferences conjointly contribute to evidence-based medicine (see Figure 6.2).

Disability and ageing

Disability types

Because disability often complicates and accompanies ageing, it is an ever-present consideration affecting decision-making in geriatric medicine. Disability can be especially burdensome for women, those residing in poverty and minorities. The ability to distinguish the types or trajectory of disability is an important focus of health sciences research. These issues are also imperative for assessing the need for services and economic appropriation for health care services. Several studies have provided useful data on the prevalence, incidence and changes associated with disability.

Figure 6.2 Practical clinical applications influencing decision-making.

The type of disability most often associated with older persons is physical loss of function. Physical losses are usually measured by the ability to accomplish activities of daily living (ADLs), instrumental activities of daily living (IADLs) and functional limitations. According to the European Health Expectancy Monitoring Unit[7] (EHEMU) calculations from SHARE, women live over half of their projected life expectancy at the age of 65 years with one or two conditions or morbidities. The conditions or morbidities include heart disease, hypertension, high cholesterol, cerebrovascular disease/stroke, diabetes/elevated blood glucose, chronic lung disease, asthma, arthritis, cancer/malignant tumour, stomach/duodenal ulcer, peptic ulcer, Parkinson's disease, cataract and hip fracture. Although this list is long, it is notable for including five of the leading causes of death noted in Table 6.1. Also, these figures should be examined in the light of the longer life expectancy of women. According to the EHEMU's 2006 report,[7] women appear to experience poorer physical functional health than men and spend considerably less time, 27% compared with 45%, after 65 years of age without physical limitations. Also, 20% of expected years at age 65 years, for both men and women, are spent with severe limitations.

The US National Center for Health Statistics[8] analysed data from the 2001–2007 National Health Interview Survey (NHIS) conducted on a non-institutionalized United States population and noted an increasing incidence of age-associated physical limitation. In this sample of 238 018 people aged 50 years and over from the Sample Adult component of the NHIS, persons' physical limitations were assessed by eight separate questions reflecting difficulties with certain activities because of health problems. Individuals aged 80 years and older are 2.5 times more likely to have one or more limitations than individuals aged 50–59 years. Moreover, the percentage of United States adults with three or more physical limitations also increases from 8% to 27% in individuals aged 80 years and older. Sociodemographic differences were found and indicated that the greatest differences in physical limitations exist between non-Hispanic whites and non-Hispanic blacks and men and women. Higher rates are also seen in adults with less than 12 years of education. Overall, these results indicate a significant increase in self-reported disability related to age, race and gender. It is also important to recognize that self-reported disability is important to individual quality of life.

The National Health and Nutrition Examination Survey (NHANES I) and the NHANES I Epidemiologic Follow-up study examined risk factors for disability in 4428 50 to 77-year-old participants.[5] This study showed that the most important baseline predictors of physical disability at 10 year follow-up were age, non-recreational activity level, history of arthritis, education, female gender and weight for height at age 40 years. Similarly, a study of 1741 University of Pennsylvania alumni between the ages of 63 and 72 years showed a postponement of disability by 7.75 years in those who exercised, had a normal body mass index and did not smoke.[9]

A chronic disease associated with multiple forms of disability in older persons is diabetes. Diabetes is a leading cause of death and by its associations with cardiovascular, neurological and ophthalmologic diseases has a significant impact on disability in the elderly. Approximately one-quarter of older men and women had diabetes in the United States in the period 2003–2006.[4] In a study of diabetic individuals aged 60 years and older from the NHANES III study, 32% of women and 15% of men reported physical limitations in walking, climbing stairs and housework compared with 14 and 8% of women and men, respectively, without diabetes.[10] As such, diabetes represents a chronic illness that makes a substantial contribution to disability in older populations.

The Lifestyle and Independence for Elders Pilot Study (LIFE-P),[11] a multicentre randomized clinical trial of individuals with functional limitations, found that adherence to a moderate-intensity physical activity intervention over 12 months showed a significant improvement in the Short Physical Performance Battery when participants performed $\geq$150 min per week of the activity. This trial indicates that physical activity interventions for previously sedentary older adults are possible and do result in measurable improvements in outcomes. This is significant because of the previously noted risks for disability with non-recreational inactivity and exercise specifically indicated in postponement of disability.

The focus of risk assessment and reduction for physical disability should occur in individuals over the age of 80 years, women, non-Caucasians, overweight/obese persons and those with less than 12 years of education. Additionally, preventive measures for disability, such as exercise, should not be limited to those without any disability. Comorbid diseases such as cardiovascular disease and diabetes should be assessed as a contributor to the disability burden in older adults. Prior disability is also significantly associated with the development of disability in activities of daily living.[12]

Mental disability often accompanies physical disability in ageing. Mental disability can be classified as major depression, dementia and vascular-related cognitive disorders. Dementia is the major contributor to mental disability because it is also associated with other mental and behavioural disturbances such as depression, anxiety and psychosis. Stroke, one of the leading causes of death and a significant contributor to the development of vascular dementia, is an important contributor to disability. Risk factors for both stroke and dementia are important targets for interventions that can decrease disability. Longitudinal studies on dementia and stroke are important stepping stones to discovering the impact and interventions. The 1987–1996 Kungsholmen Project is a longitudinal population-based study of 776 home-dwelling subjects aged 75 years and older in Stockholm, Sweden.[13] Thus far, this study has generated findings on the impact of social networks on the development of dementia. Wang *et al*.[13] suggested that frequent participation in mental, social and productive activity is associated with a lower risk of dementia in the elderly.

An unfortunate and all too common result of ageing is the loss of social ties due to death and their own or other's physical or mental disability. In addition, changing dynamics of family structure and migration contribute to this isolation. Social isolation should be recognized as a factor in an individual's overall health and quality of life. Social isolation can be considered a disability that occurs with ageing. This is an important consideration in the institutional placement of the elderly. Deciding whether placement will decrease or increase social isolation is an important consideration. Social isolation speaks of the importance of quality of life in making decisions. For example, placement of an elderly widowed male with multiple medical problems may result in loss of contact with social networks with friends and family, but may also provide a new source of social interactions.

Another type of disability is sensory disability, which includes limitations due to hearing or vision loss. These losses can often lead to deepening social isolation. The limitations can result in increased needs for an individual, medication management, special telephone service and transportation needs. These added needs represent a burden to the patient economically and psychologically. The extent of the disability can be determined by a specialist, audiologist, optometrist, or ophthalmologist. The impact that the disability has on the patient's life is what the medical professionals, for example physicians, nurses, social workers, therapists and transportation specialists, need to determine.

A specific type of sensory disability is presbycusis, sensorineural hearing loss, which can occur among older persons and may go undiagnosed and untreated. This high-frequency hearing loss with difficulty in speech discrimination often leads to further social isolation of older adults. According to the National Institutes of Deafness and Other Communication Disorders (NIDCD), 18% of American adults 45–64 years old, 30% of adults 65–74 years old and 47% of adults 75 years old or older have a hearing impairment. In addition, the NIDCD notes that 12.3% of male and nearly 14% of female adults aged 65 years and older in the United States are affected by tinnitus. Evaluations by both an otolaryngologist and audiologist are useful for determining possible causes of hearing loss and hearing aid utility.

Self-reported hearing loss and deafness have been evaluated in a number of studies. For example, the National Center for Health Statistics in the United States in 2003 found that approximately 600 000 or 0.22% of the population self-report as deaf, with more than half being over the age of 65 years. A study of the prevalence of hearing loss in a cohort of 48–92-year-olds, with an average age of 65.8 years, was 45.9%, with mild hearing loss in 58.1%, moderate loss in 30.6% and marked loss in 11.3%.[14] In addition, the percentage of people reporting a hearing handicap increased with severity of loss. The risk for hearing loss increased by 90% for every 5 years of age and men were almost four times more likely to experience a hearing loss than women. The prevalence of hearing loss among persons over the age of 85 years was 89%. These statistics indicate the vast numbers of older adults are experiencing hearing loss and associated disabilities. Health professionals must be aware of the high prevalence of hearing loss in older adults and perform hearing assessments and self-reported screenings.

Age-related vision changes include presbyopia, cataracts, diabetic retinopathy, glaucoma and macular degeneration. The loss of lens flexibility results in presbyopia. Cataracts result in clouding of the lens. Macular degeneration is the result of deposition of drusen, vascular haemorrhage and scarring. Glaucoma is the result of increased intraocular pressure. Evans and Rowlands[15] found that 20–25% of older adults in the United Kingdom have vision impairment and the majority of the impairments are correctable. This study also found that there was an association with impaired quality of life, impaired ADL performance, depression and accidents. Therefore, vision impairment represents a large

contributor to disability burden in older adults that is amenable to some correction.

Physical, mental, sensory and social disabilities culminate in increased dependence. Many of these disabilities can overlap. For example, diabetes can cause both physical and sensory disability. In addition, any sensory disability can be interpreted, without knowledge and evaluation, as confusion and lead to depression. Health care professionals bear a large responsibility in managing issues related to increased dependence, settings for optimal care and financial burden for dependent conditions. Making decisions in the elderly can be complicated due to the balance of factors that involve limiting risk and quality of life issues.

Several large-scale surveys have been used to assess disability among older adults. Friedman *et al*.[16] performed a systematic review with the aim of investigating the claims of declining disability in older Americans. The review included 16 cross-sectional and cohort survey studies published from January 1990 to May 2002. The results of this review indicated that older American adults had a significant decline in the prevalence of any disability during the 1990s and estimates of the average annual decline ranged from −1.55 to −0.92% per year. In addition, Friedman *et al*. noted that late-life disability declines were concentrated among IADL limitations and basic physical tasks. Estimates of the average annual rate of decline of the IADL limitations ranged from −2.74 to −0.40%. These changes did not include severe cognitive impairment or vision disability. No changes in hearing disability were noted.

Although it appears that increasing disability associated with ageing is being addressed on some levels, the population's continued shift will still pose many challenges. Understanding classifications, risk factors and population trends for disability are not enough. The fluid nature of disability also needs to be addressed. In a study of community-dwelling individuals aged 70 years and over, the concept of disability for ADLs was found to be of a changing and not static nature.[17] Therefore, the measurement of disability may be flawed if studies do not account for this fact. Another study, by Gill and Gahbauer,[18] examined the estimation of chronic disability using different criteria for classification that account for the malleable nature of disability. In this study, data for monthly assessments of disability in ADLs were compared with recall or anticipation of disability for ADLs over 3 months before, during or after a 54 month period. The results are consistent with the observation of a decline in disability and also an overestimation of disability in studies. As such, accounting for the changing nature of disability is important in future estimates. This is important because these estimates will be used for determining the impact of risk modification and preventative treatments on the trajectory of disability.

Interventions

Despite the deleterious effects of chronic diseases on disability and mortality, the leading cause of injury death in older persons is unintentional falls.[19] Gender differences have been found, indicating that older men are 1.5 times more likely to die from an unintentional fall than older women. The World Health Organization (WHO) identified risk factors include increasing age, decreased activity and strength, poor balance, impaired vision, osteoporosis, dementia and multiple medications/illnesses.[20] Many of these risk factors, for example, impaired vision and dementia, are also kinds of disability. In addition, some of the fall risk factors, such as level of activity, are also notable predictors of physical disability. However, many of these falls can be prevented by making changes in the physical environment, such as reducing household hazards, beginning an exercise programme to improve balance and strength and having regular health screenings to monitor medications and changes in vision. Another possibility is to wear protective hip girdles. These are interventions for disability prevention and rehabilitation.

Intervention studies for preventing physical disability are currently under way. For instance, the Lifestyle and Independence for Elders Pilot Study (LIFE-P)[11] is performing a randomized controlled trial on preserving the ability to walk in elders. This study on mobility and health-related quality of life (HRQOL) indicated the need for specific interventions for older adults at risk for disability. Community-dwelling adults with a history of falls or a risk factor for disability participated in a preventative intervention consisting of home exercise, walking exercise, group exercise and self-care exercise.[21] The intervention resulted in a significant improvement in mobility performance compared with controls. In addition, the intervention had improvement in balance performance. These results were limited by the baseline mobility and ADL performance.

Decision-making

There are several factors that are important to decision-making in geriatrics. Decision-making in geriatrics is not only important in end-of-life care but is also critical along the continuum of geriatric care. As noted already, the world population is ageing and health care is dealing with more chronic diseases and disability. The assumptions that may be made about younger patients which guide decision-making may not be applicable to older persons. Therefore, it is important to consider the various preferences that older persons may have and the challenges in providing evidence-based practices that integrate with patient preferences. Life expectancy, risk assessments and Clinical Glidepaths™[22] are useful tools in completing a full

treatment plan. Decision-making regarding risk factors for chronic disease and disability must concentrate on delaying and compressing time of disability while abiding by patient preferences. The decision-making process requires an integration of multiple factors (Figure 6.2).

Patient preferences

In a qualitative study of more than 100 practitioners, Kaufman[23] identified three problems confronted by physicians: the amount of intervention to balance risk reduction and safety and independence, advocacy for patients while demanding medication compliance and assessment of vulnerability and quality of life when making placement decisions. Developing care consistent with an individual's preferences is one facet of decision-making. Preferences may be unrealistic or possibly place an individual at increased risk for harm. How can one abide by patient preferences when these preferences are in conflict with your own or those of other family members? Can you reduce risk for disability in opposition to patient preferences? Health professionals struggle with these questions in the care of older people. Clearly, determining an individual's capacity for decision-making is critical. Do we clearly favour patient autonomy over our perceived reduction of risk? Significant time is spent reducing the perceived risks to patients, but this may not always be an efficient strategy. For example, health professionals speak to patients about decreasing tobacco and alcohol use, using assistive devices and taking medications as required contributions to risk reduction for patients. Are we really treating them or making ourselves feel better about their circumstances? Poor judgment is not the same as poor decision-making capacity. Balancing the need to treat our patients and then advocate for their wishes can be conflicting.[23]

The general definition of decision-making capacity is a patient's ability to communicate a choice and understand and appreciate the consequences of decisions, particularly decisions about medical care.[24] Ganzini *et al*.[25] noted that practitioners need further education in assessment of decision-making in different areas, mental illness and decision-making, dementia and decision-making, evaluation of cognition for determining decisional capacity, emergency treatment for patients without decision-making capacity and negative feelings towards the patient resulting in incorrect determination of decisional capacity. By determining decisional capacity, an individual's true preferences can be determined.

Shared decision-making is the ultimate goal. Unfortunately, because of clinician biases, patient disability or patient perception, older patients are less likely to participate in clinical decision-making. One study of this topic determined factors affecting goal setting, including lack of priority because of time, visits focusing on symptoms, mutual perception of disinterest in goal setting and the presumption that all patients' goals were the same.[26] Ultimately, patients needed to establish a rapport with their clinician before discussing goals. With geriatric populations, goal setting is important in the management of chronic health problems and also acute problems. Multiple studies have found that clinical goal setting is an effective method of care. As Schulman-Green *et al*. pointed out,[26] recognizing goal setting as clinically relevant makes interventions and improving knowledge of patient preferences possible.

Life expectancy and risk assessment

Screening is an important element in guiding decision-making for general medicine. However, the utility of screening among older patients yields conflicting recommendations. For many disease states, older persons have not been significantly represented or represented at all in the studies used to make guidelines. Therefore, many guidelines cannot give any recommendations for older adults, which leads to confusion in decision-making in older adults.[27] An example of this confusion is cancer screening guidelines and recommendations. Walter and Covinsky[27] offered a framework for decision-making in cancer screening that included life expectancy, risk of cancer death and screening outcomes based on published data. This framework may be applied to general risk assessment for geriatric populations. For this, one would take into account life expectancy, risk of death from the condition and outcomes data on the condition. Presumably, many of the outcomes data may not include the geriatric population, but the other elements in the framework can act as a balance in the decision-making process. Although knowing the life expectancy by the top 25th, 50th and lowest 25th percentiles gives very specific information, a general idea of life expectancy is important. For example, the Unites States vital statistics reports for 2005 note that life expectancy for men/women at 70, 75, 80, 85 and 90 years of age is 13.3/15.6, 10.2/12.1, 7.7/9.1, 5.6/6.6 and 4/4.7 years, respectively. Making some determination of a patient's general health and likelihood to live longer or shorter than expected can assist in the decision-making process. This can enhance a clinicians' ability to communicate effectively regarding relative risk assessments and determining an individual treatment plan.

Clinical practice guidelines

As just discussed, clinical practice guidelines (CPGs) or recommendations for older patients can be confusing and conflicting. What is the utility of CPGs in decision-making in the older persons? These guidelines should be based on

the latest published data about the condition. The elderly population is more likely to have multiple comorbid conditions and the practice guidelines are focused on single diseases.[28] Boyd *et al*.[29] reviewed the applicability of CPGs of the 15 most common chronic diseases to the care of the elderly with multiple comorbid diseases. The study found that most guidelines do not account for the multiple comorbidities in older patients. In addition, adherence to each guideline could result in complicated, conflicting and costly pharmaceutical and non-pharmacological treatments. This study again illustrates the complexity of decision-making in the elderly and the need for specific guidelines for the elderly. Therefore, screening recommendations and CPGs used without using specific information regarding life expectancy, patient preferences or comorbid conditions are not useful decision-making tools. CPGs are needed that include these important factors. An assessment of a clinician's quality of care of older individuals cannot be based solely on these guidelines and recommendations.

Some CPGs for non-geriatric syndrome conditions exist. For example, Brown *et al*.[30] published guidelines for older adults with diabetes and complex health status. They take a patient's financial and psychological burden, general health status and preferences into account. These guidelines included geriatric syndromes such as depression, injurious falls, incontinence, cognitive impairment and polypharmacy. Older individuals are to be screened for depression on initial diagnosis because of the increased incidence of major depression. Initial cognitive screening is also recommended because of the impact on self-care, hospitalization and association between diabetes mellitus and cognitive impairment. Screening for urinary incontinence is needed because of the increased risk factors for urinary incontinence in older individuals. A clinician then uses these guidelines in conjunction with other factors, life expectancy, overall health and preferences to reach a decision on an individualized recommendation for treatment. An algorithm[31] is shown in Figure 6.3.

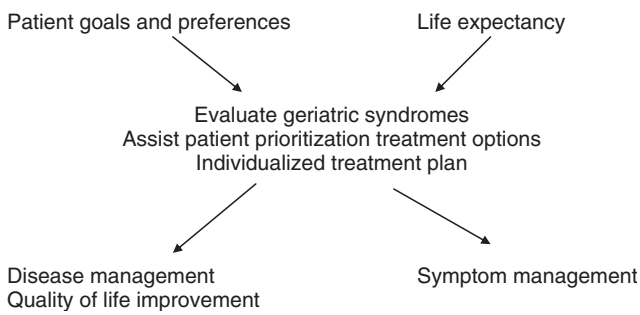

Figure 6.3 Algorithm: integrative approach to decision-making.

Quality of life measures

The WHO defines quality of life as an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns. Incorporating quality of life into clinical assessments can aid in many areas, including prioritizing problems, facilitating communication, screening for potential problems, identifying preferences and monitoring for change or response to treatment.[32] Measuring quality of life was examined in a five-article series in the *British Medical Journal* in 2001. This series examined such topics as quality of life measures, life not worth living, whether measures are patient centred and who should measure quality of life. Ideally, an individual should assess their own quality of life. According to studies, a proxy can provide a good substitute for a person who is impaired and therefore unable to complete an assessment. In general, nurses and lay caregivers can overestimate severity, whereas physicians tend to underestimate.[33] The specific measures considered should be concrete and observable to increase proxy assessments. Part of the understanding of how an individual would rate their quality of life in different situation is to understand that individuals are known to have what Sprangers and Schwartz[34] called a response shift or adaptation to their situation. This shift can result in a higher quality of life rating than would originally have been thought.

Quality of life can also be considered as the discrepancy between our expectations and experience.[35,36] Carr *et al*.[35] considered that an individual's experiences, personal characteristics such as age, social class and gender, timing of assessment and the inherent changing nature of evaluating quality of life exemplify the difficulties that arise with measurement of quality of life. Interestingly, these concepts are important not only to decision-making, but also targets for treatment. As will be discussed, this is part of the importance of the social worker and therapist in the multidisciplinary team.

Quality of life measures can be used as one of the components, representation of a patient's preferences and goals, in decision-making for an individualized disease treatment plan. As noted in Figure 6.1, this comprises part of one-third of the information needed for decision-making. The nature of these measures is flawed because of their inability to capture the full scope of individual experience.[32] Measures used should be valid, appropriate, reliable and responsive to change and interpretability. Additional properties such as simplicity, speed and ease of scoring are also important.[37] As quality of life measures are often used in research, their utility in the clinical setting can be questioned because of the different goals for their use. Existing quality of life measures available for use in clinical practice include the disease repercussion profile support team assessment schedule,

the Edmonton symptom assessment scale, the palliative outcome scale and the measure yourself medical outcome profile (MYMOP). The World Health Organization Quality of Life Instruments (WHOQOL-100 and WHOQOL-BREF) are 100- and 26-item questionnaires developed from determining important aspects of well-being from a diverse cross-section of health care professionals and patients. This measure was tested for reliability and validity in different populations.

The 'disability paradox' demonstrates that persons with significant health or functional problems do not necessarily have low quality of life scores.[35] This is probably due to adjustment of expectations and acceptance of illness. This paradox illustrates that there are individual factors that affect quality of life ratings. Therefore, it is important to decipher and prioritize what areas of life are important to one's patient. There are individualized measures such as the schedule for the evaluation of individualized quality of life (SEIQOL). The SEIQOL requires a patient to choose five areas of life that are important, choose the relative order of importance of the areas and rate their status in each area. The patient-generated index (PGI) requires a patient to identify the five areas of life affected by their current disability or health problem, rate the impact of these areas and then rate the relative importance of the five areas.

Groessl *et al*.[11] describes health-related quality of life for older adults with functional limitations. Using the Quality of Well-Being Scale – Self-Administered (QWBSA) as a measure of HRQOL, this study found that declines in mobility had a possibly greater impact on HRQOL than distinct disease states.

Outpatient Clinical Glidepaths™

The GeriMed Clinical Glidepaths are models for assisting in geriatric decision-making.[22] This concept was developed after discovering the shortfalls of evidence-based medicine clinical practice guidelines and recommendations when applied to the ageing and disabled population. Important to this concept are patient preferences and clinical experience. A dual emphasis provides guidance for providing an individualized care plan for specific disease states. Twenty-four peer-reviewed and/or evidence-based Glidepaths have been developed in the following areas: cerebrovascular accident/carotid bruit/transient ischemic attack, constipation, chronic obstructive pulmonary disease, cognitive impairment/dementia, congestive heart failure, coronary artery disease, depression, diabetes mellitus, dizziness, dyspepsia/gastroesophageal reflux disease, falls/fall prevention, focal incontinence, health maintenance, incontinence in women/men, insomnia, low back pain, osteoarthritis, osteoporosis, peripheral vascular disease, prostate cancer, syncope and weight loss. This process takes into account life expectancy by making the clinician classify the patient as robust elderly, frail, moderately demented and end of life. The robust elderly are those with a life expectancy $\geq$5 years and functionally independent. The frail have a life expectancy of <5 years or significant functional impairment. The moderately demented have a life expectancy between 2 and 10 years. End-of-life persons have a life expectancy of <2 years. In addition, patient preferences were incorporated by grading decisions as 'Do', 'Discuss', 'Consider' and 'Don't do'. These grades reflect whether the recommendation is a strong recommendation, should be discussed regarding the risk/benefit ratio, should be considered by the clinician without discussion and is not recommended, respectively.

Although the Glidepath concept incorporates many of the concepts important to medical decision-making, there are definite limitations.[22] There is no study that demonstrates improved outcomes. Many of the recommendations do not have evidence-based studies available for incorporation.

The interprofessional care team

The members of the interprofessional or multidisciplinary team are usually from diverse health backgrounds and the team composition often varies according to the clinical setting. These teams often include nurses, physicians, physical therapists, occupational therapists, speech and language therapists, recreational therapists, nutritionist/dieticians, chaplains and pharmacists. Teams exist in various permutations in primary, acute, rehabilitative and long-term care settings. These teams provide an opportunity for sharing specialized information that can aid in identifying risk factors for disability and providing input for medical decision-making. According to the framework in Figure 6.1, the team members can contribute in all three areas. The shared goal in the team should be to reach an individualized treatment plan. As such, each discipline must utilize the best available evidence, clinical judgment and patient goals/preferences to arrive at a decision. The complexity of comorbid disease conditions and disability in the ageing population is especially useful for an interprofessional team approach to decision making. In a study of the multidisciplinary needs of 1324 adult inpatients in England, the percentage of patients with multidisciplinary needs increased with age.[38] According to Hubbard *et al*.,[38] 'multidisciplinary need' was defined as needing assessment or intervention from one or more members of the multidisciplinary team on that day, other than a nurse, doctor or pharmacist. These results reflect the increase in disability with ageing and the increased need for multiple health professionals in assessing an older patient.

What is the evidence that such teams improve health outcomes, such as survival, improved function or improvement in disability or improve patient-centred decision-making? The Program of All-Inclusive Care for the Elderly

(PACE) is a model for community-based care for the frail and chronically ill elderly that utilizes the interprofessional/multidisciplinary team approach. The teams must consist of at least a primary care physician, registered nurse, social worker, physical/occupational therapist, recreational therapist, dietician, home care coordinator, personal care attendant, PACE day care centre coordinator and driver. The program assists patients eligible for nursing home placement to live independently. This program has been studied for its relative success in improving outcomes.[39] In 2009, there were 72 PACE programs in 30 states in the United States. The diversified nature of the team reflects an understanding of each team member's role in contributing to the decision-making process. The teams meet formally weekly regarding a medical crisis or health status update. The meetings are led by a team facilitator who can be from one of the disciplines and guides the thorough assessment of the patients needs. The functionality of the teams has been associated with better functional outcomes, measured by ADLs and urinary incontinence (UI), at 3 and 12 month post-enrolment intervals for patients in the PACE program. The program did not have any significant association with survival. The team functionality was determined from surveys of the team members in the 26 PACE sites included in the study. The relative agreement with seven statements in the survey was measured on a five-point scale. The statements included meeting family member needs, member contribution based on experience and expertise for quality solutions, meeting patient care needs, responding to emergencies, almost always meeting patient care needs, feeling the team's outcomes were good and the team overall functioned well together.

For a team to meet properly some of the tenets expressed in the PACE program study, the team members must possess some shared educational foundation. The Health Professionals Education Summit in 2002[40] produced five core competencies that would be essential for health professionals in meeting future health needs. Theses core competencies describe the educational needs of interprofessional team members: provide patient-centred care, employ evidence-based practice, apply quality improvement, work in interdisciplinary teams and utilize informatics. These competencies acknowledge the importance of each team member's command of their own discipline's knowledge, in addition to the ability to contribute constructively to group decision-making.

Conclusion

The ageing of the population presents unique public health and clinical challenges. However, care in preserving patient autonomy cannot be lost. The balance between our wider concerns and individual needs must be integral in the medical decision-making process. First, identifying and screening for the presence of both disability and risk factors of disability is an important task for all health care professionals. Therefore, it is important to utilize the expertise of interprofessional team members in this process. This enormous task should not be carried out by one individual. In a situation where an interprofessional team is not available, regular screening becomes more important. As noted, the fluid and changing nature of disability makes infrequent assessment inaccurate. Health professional's must be aware of this fact and encourage more frequent assessment. This will entail increased education on how to use and interpret the vast available array of assessment tools. Prevention and rehabilitation of disability should be foremost in medical decisions.

Clearly, continued population-based and basic scientific investigation is needed to elucidate further both the causes and treatment solutions for these disability states. The inclusion of older adults in longitudinal and randomized controlled trials will result in the development of more age-specific guidelines and recommendations. Irrespective of these tools, health professionals must still remember that their decisions on clinical management are for an individual and not a population. The importance of patient autonomy and preferences cannot be overstated. The team approach to decisions and solutions regarding disability can assist in this goal. Training in patient evaluation for decision-making capacity should be extended to interprofessional teams. Information that can assist a patient in participating in decision-making includes relating relevant information about your existing recommendations and guidelines, disease trajectory and life expectancy to the patient. Once a clear discussion of the relevant facts has occurred with a competent patient, decisions can be made. However, incompetent patients present obstacles to our decision-making. Health professionals should have training and comfort in utilizing a legal proxy for decision-making. Although one might look at this scenario as less than perfect, evidence indicates that proxy input is almost as good as that by the individual themselves.

Overall, the burden of disability that will come from the increased number of older adults must be addressed. A measured approach to identifying and reaching a shared decision on prevention and treatment involves the integration of multiple factors. Using the expertise and insight of multiple health professionals is likely to result in improved quality of care and outcomes.

Key points

- Disability associated with ageing.
- Prevention and treatment of disability.
- Patient preferences and goals.
- Quality of life.
- Multidisciplinary approach to decision making.

CHAPTER 7

Social and community aspects of ageing

John E. Morley and Nina Tumosa

Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

The interactions between social and community factors and access to healthcare are extraordinarily complex (Figure 7.1), especially for the older person. It is important for the healthcare professional to be aware of the impact of these factors on the health and wellbeing of the older person.

Demography of ageing

The greying of nations

The greying of nations[1] is a metaphor that describes the demographic changes that have taken place in all industrially developed countries since the beginning of the twentieth century. It describes an increase in both the numbers of older people and the proportion of the population that is older.

Absolute ageing

In both developed and developing nations, there has been a rapid growth in the numbers of older people. This has led to a need to ensure that adequate resources are available to meet the growing needs of older persons. Much effort has been placed in designing programmes that would allow older persons to remain in their own homes, 'to age in place'. These new programmes have included redesigning existing communities to deal with the problems of disability and ageing. The rate at which a nation has aged, its gross domestic product and the political will of the nation to recognize the geriatric imperative are all factors that decide the quality of life for older persons.

The causes of absolute ageing

The increase in numbers of older people is primarily due to their increased survival at younger ages that resulted from improved sanitation and better nutrition, housing and working conditions. More recently, vaccinations of children and older persons, treatment of infectious diseases, improved management of chronic conditions, enhanced neonatal survival and improved care for persons with disabilities have all further increased lifespan.

The number of older persons in a society depends primarily on the number of births 70+ years previously and the subsequent mortality of that cohort over those 70 years.

Relative ageing

The relationship between the numbers of older and younger people in a society is important. Three factors determine the rate of relative ageing: fertility rates, mortality rates and, at a national level, patterns of migration.

As a country develops economically, there is usually a decline in mortality, which increases the numbers of older people. However, it is not until fertility declines, usually about 20 years later, that the relative age of the population begins to increase. This has happened in all the developed countries, except those whose age structure has been significantly affected by immigration.

Rising life expectancy and declining birth rate have noticeable effects on the age structure of a population. The old-age dependency ratio is the number of people aged over 65 years per 100 persons of working age (15–64 years old). Between 2005 and 2050, the old-age dependency ratio will almost double in more developed regions and almost triple in less developed regions. The socioeconomic impact resulting from this increasing old-age dependency ratio is an area of growing research and public debate. The old-age dependency ratio is most useful both for those primarily concerned with the management and planning of staff-intensive caring services and for economists and actuaries trying to forecast the financial consequences of pension policies (Figure 7.2). The demographic trend in many less developed countries has a less dramatic effect on the economic systems than in many industrial countries, primarily because less developed countries usually

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

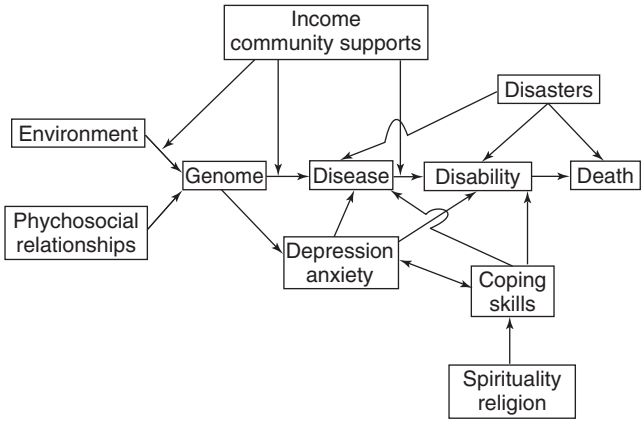

Figure 7.1 An illustration of the complex interrelationship between community/social aspects of ageing, the genome and the progression of disease and disability towards death in the older person.

have no or only rudimentary pension systems. However, the societal implication of the demographic development in these countries remains precarious, as a declining number of young people are available to take care of an increasing number of older people.[2]

Retirement migration

The distribution of old people, and hence their proportion in the population, varies very much from one part of a country to another. Although the main reasons for this range are variations in mortality and fertility rates, the migration of retirees also affects distribution.

In the USA, the general trend has been a migration from colder to milder climate, especially to Florida, South Carolina, Arizona, Nevada and California. Longino[3] described migration patterns of older people in terms of three moves. The first generally occurs at retirement and involves moving for improved amenities (such as weather) and to maintain friendship contacts. The second move is precipitated by moderate functional disabilities, complicated by widowhood, and is often towards the community in which an adult child resides. The third move is due primarily to severe disabilities and is local and towards an institution such as a congregate living or custodial facility (see the section **Housing problems**).

In England, there has also been a southern migration, particularly to the southern coastal areas. People moved soon after retirement for a variety of reasons (Table 7.1). With the development of the European Union, many persons from the UK now migrate upon retirement to southern Europe.

Table 7.1 Main reasons for retirement move.

	Bexhill	Clacton
Sample number	503	487
Reasons for moving		
Better climate; cleaner air; sea air	33	19
Health reasons	11	18
Flat country	1	1
To get away from town or live in a quiet place	16	10
To live in a bungalow	4	9
Having to leave a tied house	5	5
The expense of living in the previous place	5	9
To have a change	7	9
To join friends or relations	10	15

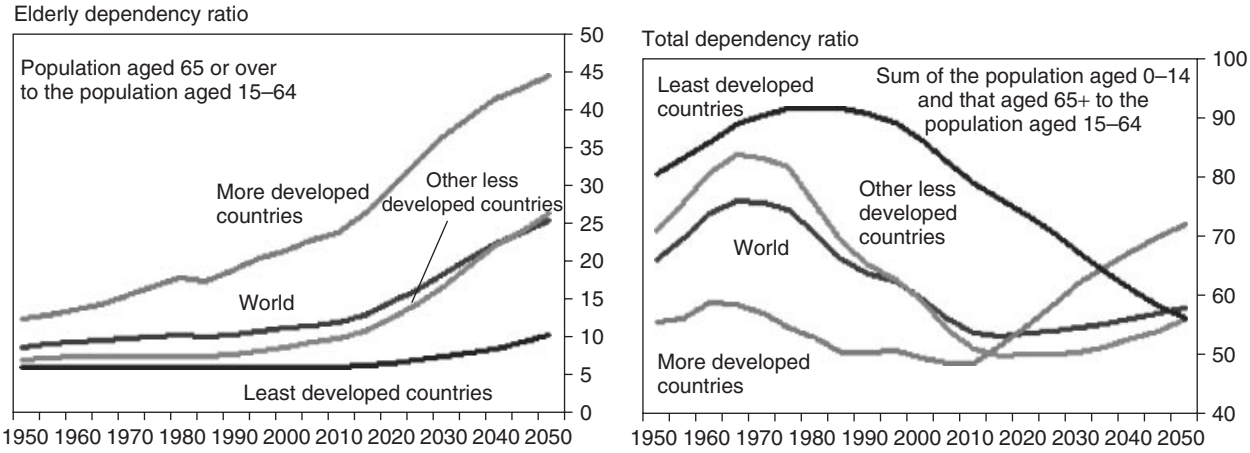

Figure 7.2 Demographic dependency ratio. Source: UN (2004 Revision).

The effect on ageing of these diverse language, cultural and healthcare systems represents a fascinating study for the future. Migration over the lifetime from a poor to a more advantaged community could improve the mortality of the migrants.

Although migration for functional elderly to better climates is on the whole positive, the development of disability often leads to frustration. With ageing and the onset of cognitive and other problems, older persons often require advocates to help them make healthcare decisions and to deal with financial problems. The loss of the ability to drive safely dictates that choosing a place to migrate to must take into account the availability of transportation and the juxtaposition of essential shopping and entertainment facilities. In the USA, case managers often assist adult children who live at a distance to provide care for their older parents who wish to remain in their homes ('to age in place'). The Community Care and Health (Scotland) Act 2002 stimulated changes in community planning for the care of older persons, including personal attendants and free nursing home care.

Effects of immigration

Two forms of immigration can affect the older person: (1) migration as an adult and (2) migration beyond pensionable age. Adult immigrants may have different rates of certain diseases in older age than the population to which they immigrated, for example, immigrants from Yugoslavia and Hungary had a higher stroke incidence than Swedes living in Malmo, Sweden.[5] Alternatively, immigration can lead to altered disease patterns. Japanese immigrants to Brazil have different cancer mortality rates than do Japanese in Japan.[6] Immigrants may or may not adapt to the diet and health practices of their host country. Older Koreans in the USA often continue to utilize traditional Korean medicine (Hanbang). Quality of life may also change. Polish-American ethnic elderly had a significantly better subjective quality of life than Polish-immigrant elderly, who in turn had a better subjective quality of life than Poles in Poland.[7] Studies of Chinese immigrants to Canada and New Zealand have suggested a high rate of depression in older Chinese immigrants compared with the general population and a similar high rate of depression is seen in Hispanic immigrants.[8]

In the USA, by 2003, 11.7% of the population consisted of immigrants. These immigrants were more likely to be poor and, as a group, earned less, had less health insurance and obtained less health promotion testing. Despite this, they live 3–4 years longer based on birth and 1.5 years longer at 65 years.[9]

Immigration has assorted effects on ageing. These may be either beneficial or deleterious. Awareness of health attitudes and health problems specific to older immigrant populations is an essential part of the therapeutic armamentarium of healthcare professionals.

Table 7.2 Expectancy of life in males and females from birth (years) (2009).

Country	Males	Females
Australia	79.2	84.1
Bangladesh	57.6	63.0
Canada	78.7	83.9
France	77.8	84.3
Germany	76.3	82.4
Israel	78.6	83.0
India	67.4	72.6
Japan	75.8	85.6

Swaziland	31.6	32.2
South Africa	49.8	48.1
UK	76.5	81.6
USA	75.6	80.0
Zimbabwe	40.1	42.6

From Wikipedia (http://en.wikipedia.org/wiki/List_of_countries_by_life_expectancy) citing CIA figures of countries by life expectancy.

The male-to-female ratio

The gender ratio of number of men to 100 women in the older age-groups is an aspect of population ageing meriting special mention. The expectation of life at birth (Table 7.2) is about 5 years greater for females in most developed countries than it is for males. In the UK, the difference between the life expectancy at the age of 60 years is about 3.5 years. In the USA, the gender ratio declines by 67% from ages 65–69 to 100+ years (Figure 7.3).

There are biological and social reasons for the differences in life expectancy and also for the fact that there are more older women than older men. Biologically, the high mortality of male fetuses and infants and the inhibitory effect of estrogens on the development of atherosclerosis both play a part. However, social influences appear to be more important. In the early twentieth century, there were more men than women among the elderly so this gender ratio is a relatively recent phenomenon. The change would seem to have been due to the differing lifestyles of men and women. The prevalence of cigarette smoking, high alcohol consumption and exposure to hazards of the workplace have penalized men in comparison with women. In some African nations, such as Niger, South Africa and Zimbabwe, the ratio of older males to females is <1.

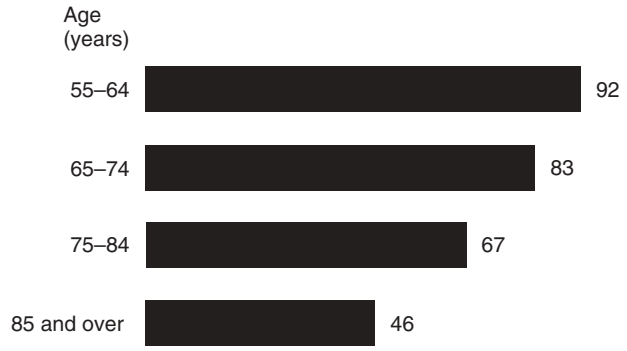

Figure 7.3 Gender ratio of people 55 years and over by age, 2002 (number of men per 100 women). Source: US Bureau of the Census, Annual Demographic Supplement to the March 2002 Current Population Surveys.

A higher death rate of men than women during Wars has also affected the ratio, while higher rates of mortality from homicide and road traffic accidents continue to have an effect during peacetime. This is particularly evident in modern Russia, where there is nearly a 12 year difference between males and females related to societal problems, following the fall of the Soviet Empire. Finally, decreased death rates during pregnancy and decreased number of pregnancies have dramatically decreased female mortality (Table 7.3).

As the lifestyles of men and women become more alike, the gap will probably narrow; changes in female morbidity and mortality associated with increased consumption of alcohol and cigarettes are trends already apparent in younger cohorts.

The changing family

The structure of the modern family in the post-industrialization period has been influenced by increased age at marriage, increased divorce rate (50% in the USA), high geographic mobility, an increasing proportion of women in the labour force and fewer children. In Europe, Asia, North America and Australia, these trends have been exacerbated in the 'baby boomer' generation (those born between 1946 and 1964).

These trends make it difficult for families to look after their elderly relatives when they become dependent. This has created the 'sandwich generation', where the middle-aged person needs to provide care for both dependent children and parents. Nevertheless, there is no evidence that the modern family in the UK or USA cares less for its elders than did the family in the past. In fact, in the USA ~80% of older persons have living children, two-thirds of whom live within 30 min of the elderly parent. Furthermore, ~75% of those over 65 years of age have some contact (personal or by telephone) each day. Support from adult children (transportation, financial and emotional) makes it possible for 95% of people aged over 65 years to live in the community.[11] Most (82%) live independently. Of those who need assistance for functional disabilities, 30% of the needs are met by family members, with the balance being met by a combination of family and formal community agency services.

Only 4.5% of older persons in the USA live in nursing homes, belying myths that families do not provide at least as much support as they did in the past.

Table 7.3 Estimated average number of children to parents born in different years.

Year of birth of parent	Average number of children	Average number of children surviving to age 45 years
1871	4.8	2.7
1881	4.1	2.5
1891	3.3	2.2
1901	2.6	2.0
1911	2.2	1.7
1921	2.0	1.6

Growing older – the social process

Although the distinction is arbitrary, it is useful to try to separate the effects of physical processes affecting people as they grow older from the effects of the social consequences of attaining an advanced chronological age. There are three of these physical processes – ageing, disease and disability – and these overlap with each other and with the social process which is often called *growing old* (Figure 7.4).

In this chapter, we will consider the social problems that occur as a result of growing old.

A life course perspective on age

It is useful to view older people as a product of life course events. Thus, infancy, childhood and adolescence occur in the first two decades of life and involve preparation for a job while living at home as a dependent. Adulthood and middle age bring with them increasing involvement in work, marriage and creating a family in an independent setting. Persons in old age, however, will have experienced departure of grown children, retirement, perhaps death of a spouse, family and friends and increasing dependency, especially from functional health limitations.

From a social psychological perspective, the transition from youth to adulthood may be seen as increasing

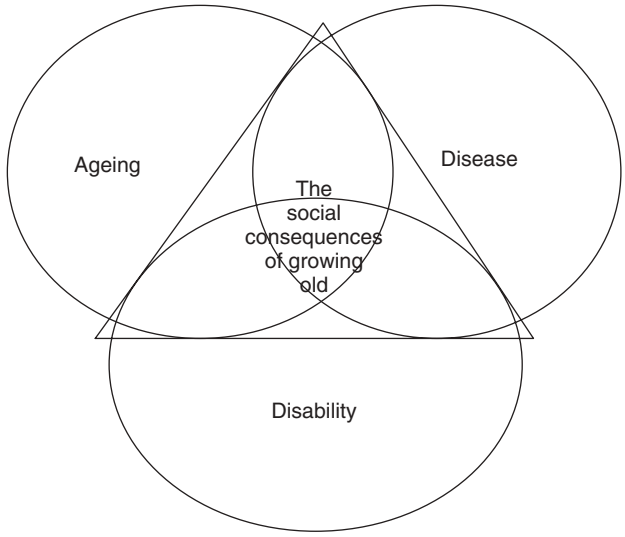

Figure 7.4 Ageing, disease, disability and the social consequences of growing old.

attachment to one's social groups through meaningful and productive roles. Likewise, the transition from adulthood to old age may be seen as detachment from one's social groups as these meaningful and productive roles are given up. This may help account for the reports that the very old are, or at least perceive themselves to be, isolated, a 'burden to society' and to have feelings of unworthiness. In fact, clinical depression is a common problem for older people, which could be exacerbated by these perceptions.

Social problems

When people talk about the social problems of older persons, they are usually referring to certain practical problems that occur more frequently among older people, principally poverty, housing problems, difficulties with transportation and isolation.

The reasons why older people suffer from certain types of social problems more frequently than younger people are outlined below.

Poverty

Many of the problems of older people are simply due to the inability to purchase needed services to maintain an acceptable quality of life.

Immobility

The high prevalence of disabling chronic disease combined with the difficulties that older people have with accessing public transport, compounded by poverty that restricts their use of cars and taxis, makes them less mobile than younger people. Immobility is the cause of many social problems.

Attitudes of older people

Because of their upbringing, older people are, in general, less assertive than younger people. Because many were brought up in a culture in which the individual had fewer rights than they have today, many are less inclined to appeal against official decisions, to seek the help of elected representatives or to try to overcome bureaucratic inertia than younger people. In the USA, this is changing rapidly, with older persons becoming much more assertive. This began with the 'grey panther' movement and is expected to become even more prominent as the 'baby boomers' generation reaches retirement age.

Poverty

The word *poverty* is so commonly used that it may seem unnecessary to define it, but the word has two aspects which need to be distinguished – poverty threshold and relative poverty – and this distinction is particularly important at a time when there are rapid fluctuations in prices and wages.

Poverty threshold is defined by comparing a household's income with the level of prices of the basic commodities necessary for life – the subsistence level, sometimes called the '*poverty line*' or '*bread line*'. Those whose incomes are below the minimum level necessary for subsistence are deemed to be living in poverty.

Relative poverty is defined by comparing a household's income with the average level of incomes in their society. Although individuals' incomes may be sufficient to provide themselves and their dependents with the necessities of life, they may find their relative poverty upsetting because it symbolizes their low status. J. K. Galbraith, an American economist, has described the condition of relative poverty eloquently: 'People are poverty stricken when their income, even if it is adequate for survival, falls markedly below that of the community. Then they cannot have what the larger community regards as the minimum necessary for decency and they cannot wholly escape, therefore, the judgement of the larger community that they are indecent. They are degraded, for in the literal sense they live outside the grades or categories which the community regards as acceptable'.

In the USA, the median household income in persons over age 65 years has increased from $16 882 to $23 729 (in 2006 dollars). Since the mid-1960s, poverty rates for persons aged 65 years and older have declined from nearly 30% to under 10%. Older persons now have similar poverty rates to those of working persons. Over the same period, there has been an increase in poverty rates for those under 18 years of age. Between 1984 and 2001, the median net worth of households headed by a person age 65 years or more has increased by 82%. However, older white households have nearly five times the net worth of older black households.

Social security provided 90% of income for one-third of Americans over 65 years of age. Other sources of income reported were assets (55%), private pensions (29%), government pensions (14%) and earnings (22%).

What is hidden by a simple comparison of 'pensioner households' with 'young households' is that there is a very wide range of wealth within the group of pensioner households. In general, older people are poorer.

The wide disparity is not due to a drop in income as people grow older, but to the fact that the proportion of people in each age group who have an occupational pension decreases the older the age group considered. This, in turn, is due to the fact that occupational pensions are a relatively recent innovation and it is therefore only younger retired people, those retiring more recently, who have qualified for them. The difference between the income of different age groups of retired people is accentuated because men die younger than women, on average, so that the older groups consist of relatively more women, many of whom are eligible for neither national insurance nor occupational pensions and depend on a supplementary pension which is set at the lowest social security rate. Poverty is most common, therefore, among elderly women, particularly among those who never married.

Housing problems

Environmental problems

For some older people, the cause of their housing problem is not their dwelling but its environment. Many of those who lived in the city centres when they were first married have seen the neighbourhood change. Some feel that the area has 'gone down', that those who now live there do not have the same standards as they do and that they are now aliens in a hostile environment in which they once felt at home.

There are numerous examples of major differences in lifespan in persons living in different neighbourhoods which are geographically near one another. The most marked example of this is in Scotland, where the life expectancy in Calton, a poor suburb of Glasgow, is 54 years whereas in nearby Lenzie it is 82 years. Another example is that whites living in Montgomery County, MD, have a life expectancy of 80 years compared with blacks in nearby Washington, DC, whose life expectancy is 63 years. In Canada, persons living in poor areas have more arthritis, diabetes, high blood pressure, congestive heart failure, chronic obstructive pulmonary disease and depression than those living in more affluent areas.[12] In older persons, the external appearance of the blocks they lived in and the condition of their houses were closely correlated with lower body functional limitations.[13] Perception of crime in neighbourhoods limits older persons' desire to walk outside of their houses. The problems of elderly people in city centres and areas of urban deprivation are serious and difficult to remedy because often the best remedy is a move to another area in which the person may feel equally alien, although the majority of those who move do settle well and happily.

Structural problems

Often, it is the dwelling itself that is the principal cause of the older person's concern. Common problems and their solutions are presented in Table 7.4.

The services listed are not universally available and, even where such services exist, older people often have difficulty mobilizing them. Every health professional can help by being aware of the range of services available, suggesting ways in which the dwelling can be improved and helping the person to contact the appropriate services.

Difficulties caused by disability

Sometimes the dwelling itself is suitable until the onset of disability and the type of problem that most commonly causes a housing problem is the onset of a disabling disease that affects the older person's ability to climb the stairs, either stairs inside the house leading to the bathroom and toilet or the stairs leading to an apartment. Sometimes the circulation space within the house is too small to allow easy movement from room to room for a person using a wheelchair or walking aid.

The optimum solution to this type of difficulty is adaptations to the dwelling, and the domiciliary occupational therapist is the professional with the skill to do this. Solutions include the installation of ramps and indoor elevators. Adaptation of the kitchen and bathroom and addition of handrails can increase the safety of the house.

Table 7.4 Solutions to housing problems.

Problem	Solution
Lack of toilet, bath or hot water	The provision of grants and loans to help those who do not have the necessary capital
Difficulties with decorating, minor repairs such as broken windows and major repairs such as rewiring	Help from voluntary services with decorating and minor repairs Provisions of grants and loans for major repairs
The cost of rent and rates or property taxes	The provision of financial help with heating costs
Problems caused by disability	Adaptation of the dwelling, e.g. ramps, rails, chair elevation
Difficulty with heating	Installation of more effective and efficient heating Improved insulation

Making a move

The doctor's opinion about housing decisions is often as highly respected as his or her opinion about health decisions, particularly on that difficult decision – 'should I move?'. Although each case is unique, it is possible to list guidelines for decision-making. Tables 7.5 and 7.6 give good and bad reasons for moving. One of us (J.E.M.) uses this analogy: when living alone is no longer as safe as bungee jumping, then it is time to move to a protective environment.

In general, every attempt should be made to solve any housing problem that will remove the need for a move. The move may still happen. Children often want their parents to move before it is necessary and older adults put off the move as long as possible. The development of 'smart homes', lifeline alarms and so on are further delaying the time to when a decision has to be made to move. The decision of whether an older adult should move into a relative's home or to an institutional environment represents one of the hardest decisions associated with ageing for both the older person and the caregiver.

Sheltered or congregate housing in the UK and senior apartment buildings or assisted living facilities in the USA are the types of housing that most people think of when new housing for elderly people is mentioned, although many move to independent flats or bungalows. Congregate housing offers security and reassurance and a well-designed and heated environment to elderly people and thus meets the needs of many frail elderly people, particularly those who are:

- nervous of living alone;
- anxious that they are not able to call anyone if they should fall ill;
- at risk of hypothermia or hyperthermia;
- isolated, although some people feel just as isolated in sheltered housing as in an independent dwelling.

Sheltered housing is not always suitable for the person who has antisocial tendencies or for the very confused person because the caregiver cannot cope with a large number of dependent people or with very dependent people. The fact that the caregiver lives on-site has many benefits, but it also has its drawbacks because they may be called incessantly by a confused person. It may be that the provision of more staff, that is, the creation of 'very sheltered housing', will overcome some of the problems in sheltered housing, but it is always important to remember that the majority of disabled elderly people live and will continue to live in independent dwellings.

Table 7.5 Bad reasons for moving.

- Because of structural problems: the possibility of solving the structural problems should always be explored first
- Because of financial problems: the provision of the full range of financial benefits may solve the problem
- Because of disability: the advice of an occupational therapist should be sought
- To move away from an area in which the old person feels 'no one cares': more people may be assisting than he or she is prepared to recognize

Table 7.6 Good reasons for leaving.

- To move nearer a son, daughter or relative who is willing and able to offer care
- To move away from a dwelling that is impossible to repair, improve or adapt
- To move away from an environment that is causing severe depression or anxiety
- To move to sheltered housing if living alone is no longer safe

Retirement

The concept of retirement was developed by the German Chancellor Otto von Bismarck in the nineteenth century. His generals had asked that at some time they might be allowed to stop leading troops into battle. Bismarck's actuaries calculated the age at which a general was unlikely still to be alive to reach 65 years. He magnanimously told his generals that they would be allowed to retire at 65 years of age with a state pension. He then introduced a national pension scheme to undermine the growing power of the Socialist Democratic Party.

Before World War II, retirement in the UK was primarily for the rich and those who were incapable of keeping a job. In 1901, 60% of men over 65 years of age were in paid work. This number had declined to 48% in 1931 and to 13% by 1980. Following the passage of the Old Age Pensions Act of 1908, the first old age pensions were paid in England to just under half a million people (mainly women) in 1909. Following World War II, there was an increase in occupational pensions and deliberate attempts by employers and the government to force retirement. Technological developments were, in part, responsible for the erosions of the light work jobs often held by older persons. To some extent, the 'structured retirement' of the 1950s and 1960s was partly responsible for the marginalization of older people and their definition as a distinct, dependent social class. Towards the end of the twentieth century, retirement has become more acceptable, with many persons retiring in their early 50 s.

In the USA, retirement became a reality for most older persons with the introduction of Social Security. Although Social Security is the bedrock of American retirement, for many it is their pension from their employer and personal investments that have allowed earlier retirement. At

present, insecurity about the ability of the government to fund social security payments and the government health plans for the old (Medicare) and the poor (Medicaid) is creating numerous schemes on how to alter the retirement system. Some older Americans have, in retirement, been at the forefront of the modern globalization movement by retiring to Mexico or Costa Rica, where they can better leverage the buying power of the dollar.

The 'golden age' myth

Not only are modern societies those in which work is seen to be important, but they are also societies in which wealth is an important determinant of status. The low income of elderly people, therefore, not only symbolizes the low esteem in which they are held but also perpetuates it. There is a myth about old age that states that there was at one time a 'golden age' for elderly people, an age in which it was good to be old and in which elderly people were loved and respected. The myth has become elaborated with time and some people believe that the golden age was destroyed by the industrial revolution because the traditional skills of elderly men and women, which they passed on to the younger generations by the fireside and in the inglenook, were rendered redundant by the speed of change at that time.[14]

Attractive though this myth is, in fact there is no substance for it. There never was a golden age for elderly people. Rich and powerful elderly people were certainly able to hold on to their position of power and respect. Poor elderly people usually finished up in the workhouse and it is important to remember that in many societies the proportion of elderly people living in this situation was higher in times past than it is today and that the quality of care in modern institutions far surpasses that seen even a quarter of a century ago. If ever there was a 'golden age' for older persons, it is today.

Ageism

'Ageism', like 'racism' and 'sexism', is a prejudice. People who hold ageist views believe that all people over the age of 65 years are of declining intelligence, unable to change or learn, rigid, conservative and dull. They assume that any physical or mental change is due to the ageing process and is, therefore, untreatable. They also have a certain set of expectations about the way in which older people should behave, for example, that it is not normal for older people to drink to excess, show an interest in sex or even to argue forcibly with people with whose views they disagree. Many people, both old and young, hold ageist views and assume that all physical and mental changes are due to 'old age', that is, the ageing process.

It is only in the last few decades that health professionals have begun to appreciate the difference between the effects of the ageing process and the effects of disease. It is extremely important to recognize that older persons, like younger persons, show large variability in most characteristics.

The two main effects of ageist beliefs among older persons are:

1 Failure to seek help for treatable medical problems – 'What else can you expect at my age'?

2 Failure to comply with medical advice – 'It was kind of the doctor to give me tablets but there's no point in taking them, it's just old age that's the problem'.

Societal ageist beliefs lead to undervaluing the contributions of older persons and providing inadequate societal resources for them. Political activism is needed to combat ageism. Persons at all levels of the community and health professions often pay lip service to the ageing demographic imperative, but fail to provide the financial benefits needed to overcome ageist policies. Much of the media has recognized 'ageism' as politically incorrect and has tended to overcompensate by making older persons highly functional and cute. Recent realistic movies about persons with Alzheimer's disease have presented a more balanced view.

The effect of social factors on the aging process

George Valiant,[15] in his pioneering studies on ageing in Harvard graduates and inner city persons living in Boston, provided a framework for the effect of social relationships on ageing successfully (Figure 7.5). He found that not smoking, exercising, not drinking alcohol to excess, not being obese and a stable marriage were the factors that predicted successful ageing. Modern studies support the concept that social connection and perceived social support have an effect on health, but mainly in persons facing crises, stressors and/or adversity.[16] In humans, social isolation or perceived lack of social support leads to more diseases and a higher mortality rate.

Allostatic load is an index of wear and tear on the physiological systems of the body. It has been shown in a longitudinal study to be related to heart disease, physical function, cognitive function and death. The degree of allostatic load could be significantly modulated in men with strong emotional supports. This was not true in women. Other studies have demonstrated the importance of perceived control and economic variables in modulating the health effects of the social environment. This has led to the development of the concept of socioeconomic resiliency. An example of these interrelationships was shown by Suda *et al*.,[17] who found that having the person delivering meals-on-wheels sit with the older persons while they ate decreased both their nutritional risk and their dysphoria.

Figure 7.5 Effect of social relationships on ageing successfully.[15]

Thus, the effect of social relationships on an older person developing and coping with disability depends not only on the strength of the relationship but also on the ability for the person to accept the relationship (e.g. are they depressed?; or did they have a lifelong inability to bond with others?) and their innate coping skills, as well as their economic status and the inherent severity of the disease process (Figure 7.6).

Over half of men and women over 65 years of age do not engage in leisure-time physical activities. This is despite the fact that endurance and resistance exercise can modulate disease processes and slow the development of frailty, disability and death. Exercise enhances frontal lobe cognitive function and may slow the development of cerebral atrophy. Therefore, there is a need to increase the awareness of the benefits of physical activity with ageing. It is important that simple ways to improve physical fitness, for example, climbing stairs rather than taking the elevator, can be as effective as organized activities. The importance of balance exercises, such as Tai Chi, to reduce falls also needs to be stressed.

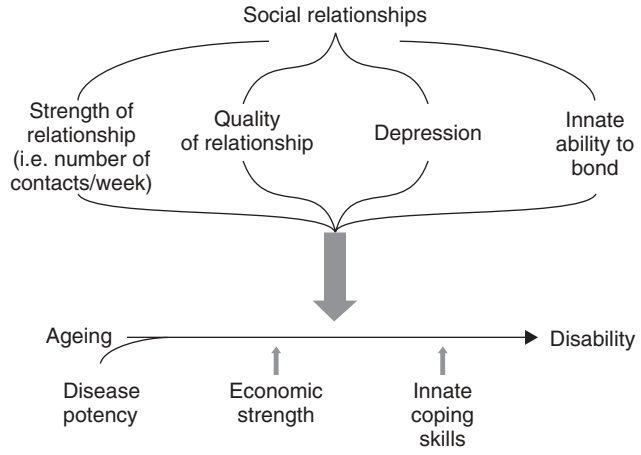

Figure 7.6 Factors modulating the ability of social relationships to modulate the ageing process.

Lifestyle, nutrition and healthy ageing: lessons from the SENECA study

The Survey in Europe on Nutrition and The Elderly: a Concerned Action (SENECA) examined lifestyle and nutrition in 19 towns throughout Europe, from Denmark to Portugal. All participants were born between 1913 and 1918. There was a large variation in lifestyle factors.[18] In Padua, Italy, 78% of older persons drank alcohol on most days compared with Culemborg in The Netherlands where less than 20% drank regularly. Smoking varied from 7% in Vila Franca de Xira in Portugal to 41% in Roskilde, Denmark. The percentage of people who still played sports varied from 4% in Portugal to 32% in Yverdon, Switzerland. Physical activity and smoking habits both predicted death and dependency. However, the relationship varied greatly from town to town, with the highest mortality rate in males being in The Netherlands, whereas the lowest death rate was in Bentanzos, Spain, a city in which the percentage playing sports was only half of that in Culemborg, but alcohol intake was nearly double. Cross-sectional studies such as SENECA represent an important tool to understand how social factors modulate disability and mortality.

Another tool to examine the effects of social factors on ageing is longitudinal studies in populations that are undergoing rapid change in their lifestyle. One such population is in Okinawa in Japan. This area, famous for its centenarians, has undergone rapid change from a calorie-restricted, sweet potato-based diet to a rice and meat diet with more calories and, at the same time, has decreased their energy expenditure. Early reports suggest that these lifestyle changes may be deleterious as males in Okinawa now have a lifespan that has sunk from 1st to 26th among the prefectures in Japan.

In Hertfordshire, England, a longitudinal study found that older persons who do not smoke, have some exercise, eat five fruit and/or vegetable servings per day and drink 1–14 alcohol units per week have a 14 year physiological advantage over persons who do none of these.[19]

Religion and spirituality

Religion and spirituality play an important role in the preservation of the psychological and physical health of older persons. For example, Koenig *et al*.[20] reported that in medical inpatients religiosity correlated with a lower likelihood of feeling downhearted and blue, boredom, loss

of interest, restlessness, feeling hopeless or feeling as if other people were better off. Brown and Gary[21] found that fewer depressive symptoms were associated with religious involvement in a group of urban African-American males. In Israel, religious orthodoxy was found to be protective against death from coronary heart disease, independent of lifestyle correlates. Lack of comfort from religion and failure to participate in church events was associated with an increase in death following heart surgery. In patients with lung cancer, prayer was, in part, responsible for psychological wellbeing.[22] Positive religious coping methods were found to be associated with health improvements. On the other hand, persons who were not at peace with religious issues, or saw God as punishing, had worse outcomes. Spirituality in the UK was shown to be a significant predictor of psychological wellbeing in frail older persons. Spirituality, but not religiosity, was associated with self-appraised good health. Spirituality is associated with a greater ability to deal with grief. In non-Judeo-Christian cultures, the role of spirituality is less clear; a study in Japan showed mixed effects; spirituality was positive in Thais. Religious television or radio was associated with worse physical functioning and greater medical comorbidity.[23] In a meta-analysis, weekly attendance at religious services was slightly more cost-effective than statin use.[24]

Overall, the role of religion and spirituality can be summarized as predominantly improving psychological health with a lesser effect on physical health. There is a small literature suggesting that not all forms of religion are positive. The most parsimonious model for describing the role of religion and spirituality on health is to assume that it increases coping skills and enhances access to support groups.

Healthcare professionals need to be aware of the religious and spiritual affiliations of their patients and, in appropriate cases, be prepared to incorporate them into a holistic model of healthcare. Prayer is a commonly used coping strategy for many older persons dealing with disability or life-threatening illnesses. Involvement of a person's religious leader as part of the team approach to healthcare is important. In some countries, this may stretch to the need to involve the local shaman in the healthcare team.

Anti-ageing medicine

Since the beginning of time, persons have sought the mythical fountain of youth.[25] This has led over the centuries to numerous unscrupulous people selling their version of 'snake oil' to vulnerable older persons. Within recent times, pseudoscientific claims associated with the growth hormone and dehydroepiandrosterone as agents that will 'reverse the ageing process' regularly appear in newspapers, magazines and books. Many of these claims are based on flawed studies originally published in mainstream medical journals. Others are based on hypotheses developed by scientists and published in mainstream literature and then translated as fact by the lay press. A example is the theories of Aubrey de Grey, which are futuristic and not yet ready for 'prime time'.[26] In a 2003 book, Ronald Klatz and Robert Goldman claimed that 'the future of anti-aging medicine promises the elimination of the disability, deformity, pain, disease, suffering and sorrow of old age. In a few decades, the traditional enfeebled, ailing elderly person will be but a grotesque memory of a barbaric past'.[27] Hyperbole such as this is reminiscent of the popular book *The Art of Living Long*, written by the Italian Luigi Comaro in 1550.

The desire for longevity has led to eloquent claims by Linus Pauling that megavitamins will protect the cells from free radical damage. The concept that excess vitamins will rejuvenate remains alive today, despite studies suggesting that instead of prolonging life, they may shorten it.

Within the next decade, we will be faced with the possibility that stem cells can reverse ageing of muscle and cure Alzheimer's disease. This research is accruing at increasing speed in Israel and South Korea, while under embargo in much of the USA. Such social factors will limit the rigour of scientific exploration into the role of stem cells and may eventually limit their use only to the very rich.

From this brief recounting, it is clear that social factors have played, and will continue to play, a major role in the development of anti-ageing medicine. Further, its availability to the general public depends on the decision of regulatory agencies such as the US Food and Drug Administration.

The environment and the genome

There is an increasing literature demonstrating that the environment can modulate gene expression. Two examples of the environment interaction have been found with the APOE4 gene: (1) head injury accelerates Alzheimer's disease in persons who have the APOE4 allele;[28] (2) APOE4 is a risk factor for ischaemic heart disease predominantly in smokers.[29] The interaction of a major life event with a genetic predisposition increases the likelihood of major depression. Physical exercise produces different responses depending on the person's angiotensin-converting enzyme insertion deletion genotype.

Epigenetics represents an emerging area where the environment can alter the genome. Genes can be modulated in response to diet and environmental stressors through DNA methylation, chromatin remodelling, production of double-stranded RNA and prions. These changes continue into old age. There is emerging evidence suggesting that epigenetic changes may be responsible for some forms of mild cognitive impairment.

Similarly, the development of pharmacogenomics has shown that the efficacy and side effects of drugs are associated with specific alleles. For example, persons with the

apolipoprotein E allele have different responses to the antidepressant paroxetine, dependent on the allele.[30] Side effects from paroxetine are related to the number of C alleles of HTR2α.

These simple examples represent only the start of the exploration of gene–environment interactions. As shown by centenarians and other long-lived persons, it is both the genome and the environment that eventually determine the successful ageing potential of a person. The new social science of ageing in the twenty-first century will require the inclusion of the person's genetic background to allow full interpretation of environmental effects.

Elder abuse

Approximately 5% of older persons suffer elder abuse. In most cases, this is not due to physical violence or theft (although such instances are unfortunately not rare), but are more often due to neglect. Thus, poor nutrition or worsening of pressure ulcers is commonly associated with poor care. Even health professionals have practiced elder abuse, ranging from the notorious English physician serial killer Dr Shipman to the use of physical restraints. Overall, persons who abuse older persons are more likely to have been abused when they were young and to have a mental illness. The solutions to elder abuse are complex, ranging from criminal prosecution and separation of the elder from the abuser to psychosocial therapies including such options as daycare, respite for the caregiver and increased home care.

The Internet

Although older persons have traditionally been much less likely to use the Internet than are middle-aged adults or children, this is changing rapidly. Many nursing homes offer Internet facilities for older persons to communicate with family and also to access the news. Older persons are also using the Internet to obtain healthcare information.

With the movement of the 'baby boomers' in the USA into the young-old over the next decade, these uses are expected to increase exponentially. There will also be increased communication between physicians and their patients via the Internet. We can also expect to see an increase in telemedicine as a more technologically adept group of persons join the ageing cohort.

Cultural competency

Shifts in populations have led to the requirement that health professionals acquire cultural competency and that social policy adapts to create more health professionals from ethnic minorities. A dramatic example of the effect of migration has been seen in the UK. In the 1950s, Bethnal Green was a predominantly white, working-class neighbourhood, whereas in the 1990s it had changed its name to Tower Hamlets and become the home of large numbers of Bangladeshi immigrants. Woodford has transformed to the home for many affluent Asians and Wolverhampton now has a substantial population of persons of Caribbean origin. Changes such as these require training programmes for health professionals in the beliefs of different cultures and how they impact the interactions between older persons and their healthcare providers. A new chapter in this edition addresses these issues more fully.

Disasters

The recent spate of earthquakes worldwide in early 2010 served as a reminder of the devastating effects of disasters. In all disasters, older persons are disproportionately affected. Studies in North Africa have shown that older persons are more likely to be left behind when genocide occurs and younger persons flee, creating separation between the generations. Older persons are also more likely to die during migrations from enemy troop areas and during periods of famine. In developed countries, heat waves are the most common disaster causing death. Over 400 older persons per year die from heat-associated death in the USA. Heat waves are often associated with power outages, which lead to air conditioning being unavailable. This has been characterized as a 'disaster within a disaster'. The appropriate measures for preventing heat-related deaths are outlined in Table 7.7.

During disasters, such as hurricanes and earthquakes, one-third of older persons have a worsening of their medical conditions. The disruption of services following these disasters can lead to isolation of the older person, loss of home services and loss of access to prescription medicines. The appropriate contents of a disaster kit for older persons are listed in Table 7.8. Following disasters, there is an increase in myocardial infarctions. For example, the Hanshin–Awaji earthquake in Japan was associated

Table 7.7 Preventing heat-related deaths.

- When available, use home air conditioning
- If no home air conditioning is available, try to go to an air-conditioned mall
- Check frequently on persons at high risk
- Wear lightweight, light-coloured clothing
- Reduce strenuous activities
- Drink plenty of fluids
- Avoid alcohol and caffeine
- Take cool showers or baths frequently
- Municipalities should develop a comprehensive heat emergency response plan, including early warnings, appropriate health messages and transportation to emergency shelters

Table 7.8 Items to be included in a senior disaster preparedness kit.

- Identification bracelet
- Extra pair of glasses/hearing aids
- List of medications
- List of diseases
- Set of emergency prescriptions
- 3 days to 1 week medication supply
- Flashlight
- Extra batteries
- Pet evacuation plan
- Family pictures
- Emergency numbers (including a contact for at least one family member who lives in another geographical area)
- A copy of FEMA's *Are You Ready?* emergency preparedness handbook
- A copy of the Hartford Foundation's *The Calm Before the Storm* for family members of patients with dementia

with a threefold increase in myocardial infarctions. The earthquake in Chengdu, China, was associated with a doubling of the death rate in persons over 90 years of age. Even psychological stressors such as the return of Hong Kong by the British to China increased mortality rates in old men. The reverse is also true, in that, when there is a reduction in environmental stressors such as when East Germany reunited with West Germany there was a marked improvement in longevity in East Germans.

Deaths from fires are common in older persons. Persons living in mobile homes or old homes with faulty electrical systems are at particular risk. Smoking and excessive alcohol use are human behaviours that are often associated with fires. Smoke detectors can save lives.

Terrorism affects many countries. While a bombing incident is easily recognized, there is a need for surveillance techniques to detect outbreaks of disease, as was shown in the slow recognition of the *Salmonella* outbreak by the terrorist cult in Oregon in 1980 and the anthrax outbreak in the USA in 2001. The anthrax outbreak demonstrated that older persons had a greater susceptibility to biological agents and a poorer outcome than young persons. Terrorist attacks may include (1) biological agents, for example, smallpox, ricin, anthrax, plague, *Salmonella*, ebola; (2) chemical agents, for example, vesicants (blistering agents) such as lewisite or mustard gas or cholinesterase inhibitors from the G group (GB-Sarin, GD-Soman) or the V-group (VX); (3) nuclear weapons or attacks on nuclear power plants or nuclear waste transport systems. The symptoms produced by cholinesterase inhibitors are listed in Table 7.9.

It is the responsibility of all to see that older persons are properly prepared for disasters, cared for during disasters and returned to their homes after disasters.

Table 7.9 Symptoms produced by cholinesterase inhibitors.

- Excessive tearing and salivation
- Miosis
- Ptosis
- Nausea
- Vomiting
- Bronchospasm
- Bradycardia
- Muscle fasciculation
- Paralysis
- Restlessness
- Delirium

Key points

- Genome–environmental interactions play an important role in the development of disease and disability with ageing.
- Disasters have a disproportionate effect on older persons.
- Religion and spirituality have positive effects on ageing.
- Immigrants live longer than non-immigrants, despite multiple stressors including a higher level of poverty.

CHAPTER 8

The developmental origins of ageing

Avan Aihie Sayer and Cyrus Cooper
Southampton General Hospital, University of Southampton, Southampton, UK

Introduction

> As soon as we are born we begin to die and the end depends on the beginning.
>
> *Manilius Astronomica*, IV 16

Interest in the connection between development, growth and ageing is not new. Animal studies linking rate of growth and length of life date back to the 1930s. Early findings, however, were conflicting and demonstrated both beneficial and detrimental effects of growth restriction on lifespan. Only later was it understood that timing of the dietary intervention to reduce growth was critical; dietary restriction in later life could slow ageing processes and extend lifespan, whereas a similar intervention instituted in prenatal life was associated with adverse effects.[1]

Human ageing can be studied at a number of levels, from a population approach down to investigation of individuals at a system or cellular and molecular level. The ageing of a population is defined in terms of mortality statistics, but individual ageing may be defined more broadly as the deteriorative changes with time during post-maturational life that underlie an increasing vulnerability to challenges, thereby decreasing the ability to survive. Progress in understanding why ageing occurs has come from the field of evolutionary biology and there is growing support for the concept that failure of repair is central to ageing. Aetiological studies of ageing have traditionally focused on influences operating in later life, but this has been extended to consideration of the role of early environmental factors, particularly on age-related disease and mortality. More recently, there has been research investigating the developmental origins of system ageing and preliminary studies identifying underlying cellular and molecular changes.

The influence of early nutrition on subsequent health and disease has been a focus of dietary manipulation studies in a range of animal models, but human studies have generally utilized birth characteristics such as size at birth or in infancy as markers of early nutrition and related these to subsequent health outcomes. However, there is also some evidence for the direct effects of early nutrition on long-term human health from natural experiments such as the Dutch Famine Study. This chapter introduces the underlying concept of developmental plasticity and presents evidence for links between birth characteristics and mortality, age-related disease, ageing at a system level (illustrated by the musculoskeletal system) and ageing at a cellular and molecular level. The final section proposes a life course approach to ageing and the relevance of this to clinical practice.

Developmental plasticity

A series of epidemiological studies demonstrating the relationship between small size at birth and an increased risk of age-related disease in later life led to the developmental origins of health and disease hypothesis.[2] Initial observations came from geographical studies. For example, Forsdahl reported that the prevalence of arteriosclerotic heart disease correlated with past infant mortality in the 20 counties of Norway and was the first to suggest that a poor standard of living in childhood and adolescence was a risk factor in heart disease.[3] A subsequent study showed that differences in rates of death from coronary heart disease in different parts of England and Wales paralleled previous differences in death rates among newborn babies.[4] This led to the Barker hypothesis that adverse environmental influences *in utero* and during infancy permanently change the body's structure, physiology and metabolism, increasing susceptibility to disease in later life.

The developmental origins of health and disease are thought to be a subset of the broader biological process of developmental plasticity by which organisms adapt to the environment experienced across the life course. Developmental plasticity involves a single genotype producing alternative forms of structure or function in response to environmental conditions, and it appears to have evolved

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

because it is adaptive. It promotes Darwinian fitness by enhancement of survival and reproductive success through enabling a range of phenotypes better suited to both the prevailing environmental conditions and the anticipated future conditions.[5] The biological basis for invoking developmental plasticity as an influence on the risk of disease derives from animal studies in which dietary, endocrine or physical challenges at various times from conception until weaning induce persistent changes in cardiovascular and metabolic function of the offspring. The most commonly used animal models involve a prenatal nutrient imbalance which can be induced by a reduction in overall maternal food intake or by protein restriction in an isocaloric diet. Other models include non-nutritional interventions such as glucocorticoid exposure or placental restriction to impact on early growth and development.

There is growing evidence that epigenetic mechanisms are responsible for tissue-specific gene expression during differentiation and that these mechanisms underlie the processes of developmental plasticity. Examples of epigenetic mechanisms include coordinated changes in the methylation of cytidine–guanosine (CpG) nucleotides in the promoter regions of specific genes, changes in chromatin structure through histone acetylation and methylation and post-transcriptional control by microRNA. Cues for plasticity operate particularly during early development and they may affect a single organ or system, but generally they induce integrated changes in the mature phenotype. In mammals, an adverse intrauterine environment, including suboptimal nutrition, results in an integrated range of responses, suggesting the involvement of a few key regulatory genes that reset the developmental trajectory in expectation of poor postnatal conditions. Mismatch between the anticipated and the actual mature environment exposes the organism to risks of adverse consequences. For humans, it is suggested that prediction is inaccurate for many individuals because of changes in the postnatal environment towards energy-dense nutrition and low energy expenditure, contributing to the epidemic of age-related disease.

Developmental influences and mortality

Geographical studies demonstrated that areas with high infant mortality were also the areas with high mortality from coronary heart disease 70 or more years later. However, it took retrospective cohort studies to demonstrate the link between birth characteristics and adult mortality in individuals. This required identification of men and women with historical records of early size. This could then be related to the later occurrence of age-related disease. The first study of this kind was carried out in the county of Hertfordshire, UK. From 1911 onwards, all births were attended by a midwife who measured birth weight. Subsequently, a health visitor went to the baby's home at intervals throughout infancy and the weight at 1 year was also determined. This information was meticulously recorded in ledgers (Figure 8.1). Many years later, the individuals in these records were traced, enabling the relationship between size at birth or infancy and subsequent health to be investigated.

The associations between birth weight and a range of mortality outcomes have been considered in the Hertfordshire Cohort Study.[6] This included 37 615 men and women born in Hertfordshire, UK, between 1911 and 1939, of whom 7916 had died by the end of 1999. For men, lower birth weight was associated with increased risk of mortality from circulatory disease [hazard ratio per standard deviation decrease in birth weight 1.08, 95% confidence interval (CI), 1.04–1.11] and from accidental falls, but with decreased risk of mortality from cancer (hazard ratio per standard deviation decrease in birth weight 0.94, 95% CI, 0.90–0.98). For women, lower birth weight was associated with a significantly ($p < 0.05$) increased risk of mortality from circulatory disease, injury, musculoskeletal disease, pneumonia and diabetes. Overall, the beneficial effects of an increase in birth weight outweighed the detrimental effects, such that a one standard deviation increase in birth weight reduced all-cause mortality risk by age 75 years by 0.86% for both men and women.

It has been postulated that suboptimal early nutrition underlies the association between low birth weight and increased mortality in adult life. Evidence from the few animal studies that have investigated the effect of dietary restriction during prenatal or early postnatal life, as opposed to post-maturational life, supports this. For example one study of mice dating back to 1920 showed that alteration of diet shortly after birth, sufficient to slow growth, resulted in a shorter lifespan. More recent work using a rat model investigated the effect of a maternal low protein diet on mortality of the offspring. Rat dams were fed either a control diet or a low protein diet from conception until the end of pregnancy. The average lifespan of the female rats exposed to a low protein diet in utero was reduced by 11%[7]. There was a similar but non-significant trend in the males. Two subsequent studies using rat models also found that that prenatal dietary restriction was associated with a shorter lifespan.

Developmental influences and age-related disease

The epidemiological studies demonstrating links between weight at birth and adult coronary heart disease mortality have been followed up by cohort studies of survivors where

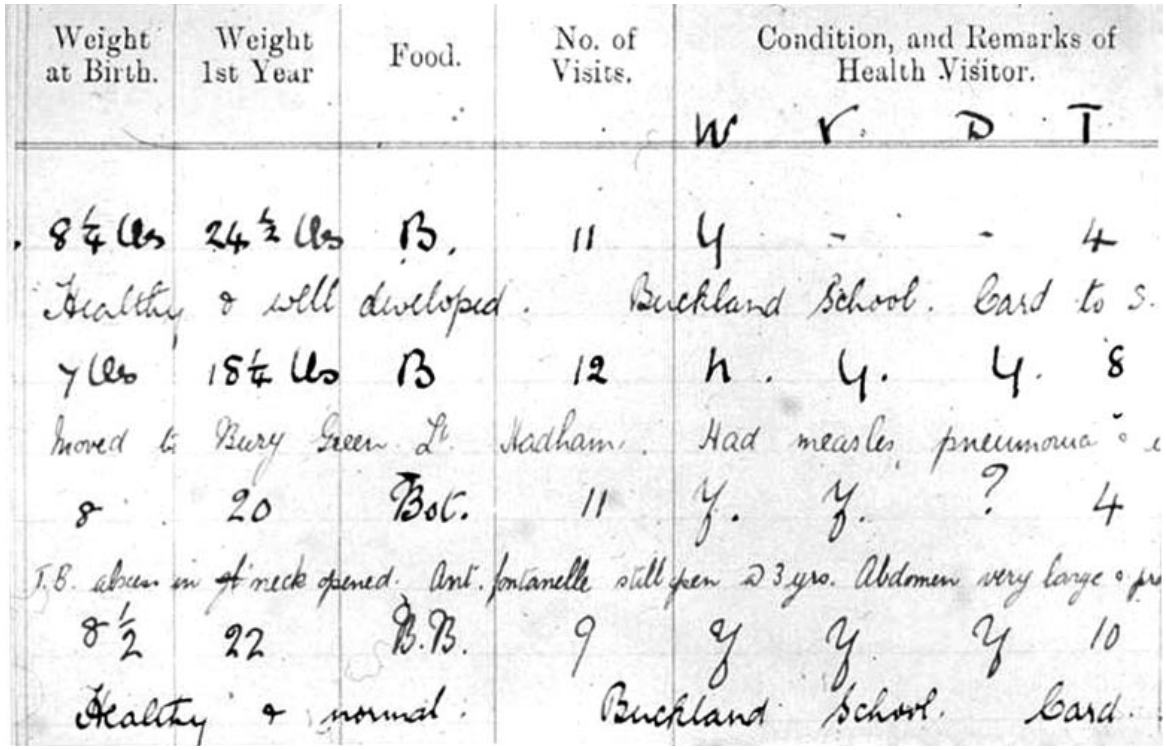

Figure 8.1 Historical ledger from Hertfordshire, UK.

the prevalence of heart disease as well as its risk factors could be identified. Low birth weight has consistently been shown as a risk factor for coronary heart disease and stroke in studies from different populations in Europe, North America and India. The relationship is not limited to the extremes but is graded and linear, operating across the range of normal birth weights. There is some evidence that prematurity is associated with at least some of the risk factors for heart disease but most of the population-attributable risk is thought to be due to reduced fetal growth independent of gestation. Furthermore it appears that the important developmental phases affecting long-term cardiovascular health extend into infancy and childhood.

The association of low birth weight and higher blood pressure is modest, approximately 2 mmHg per kilogram birth weight, whereas the association with frank hypertension is stronger and has been attributed in part to the number of nephrons or the amount of elastin in blood vessel walls, which are lower in individuals born small. There is also evidence that the shape and size of the placenta are important for the subsequent development of hypertension and cardiovascular disease. For example, in the Helsinki Birth Cohort, a small placental surface area was associated with the later development of hypertension in shorter mothers.[8] It has been suggested that the effects of placental area on hypertension depend on the mother's nutritional state. Poor maternal nutrition may compound the adverse effects of small placental size. In better nourished mothers, the placental surface may expand to compensate for fetal undernutrition. They may also reflect effects of the mother's body size on the transport of nutrients across the placenta.

Small size at birth, in terms of both thinness and low birth weight, has been consistently associated with type 2 diabetes and impaired glucose tolerance. However, in some studies, an inverse J-shaped association has been shown with rates again increasing at the highest birth weights. It has been suggested that gestational diabetes, which is associated with high birth weight, may itself programme long-term adverse health outcomes. Insulin resistance is thought to be a consequence of the term changes in body composition associated with low birth weight, in particular the combination of low lean mass with high fat mass. The relationship between low birth weight and plasma lipids is relatively small: two recent meta-analyses have reported an overall association of approximately $0.04\,\text{mmol}\,\text{l}^{-1}$ higher total cholesterol per kilogram lower birth weight. However, birth weight is only a crude indicator of adverse environmental conditions such as suboptimal nutrition. For example, the Dutch Famine Study showed that famine during early gestation was associated with an atherogenic lipid profile despite being unrelated to birth weight.

Developmental influences and ageing of the musculoskeletal system

Musculoskeletal ageing is a key contributor to the development of physical frailty, disability and dependency in later life. Most aetiological research has focused on identifying adult influences on ageing in the different components of the musculoskeletal system, but recent attention has focused on the contribution of developmental plasticity to ageing in skeletal muscle and bone.

Skeletal muscle ageing

Skeletal muscle makes up 40–50% of the human body. It consists of longitudinally arranged muscle fibres broadly classified into two main groups illustrated in Figure 8.2. Type I myofibres have a high capacity for oxidative phosphorylation with high myoglobin levels and mitochondrial density. They are used for endurance activities and are characterized by a slow contraction time and relative resistance to fatigue. Type II myofibres have a greater reliance on glycolytic enzymes. They are used for short, powerful bursts of movement and typically have a fast contraction time but tend to fatigue rapidly. There are multiple changes in muscle with age. Macroscopically there is a reduction in muscle mass with infiltration of adipose and connective tissue. Microscopically there is a reduction in the myofibre number and cross-sectional area, particularly affecting the type II fibres. At the molecular and cellular level, there is decreased muscle protein synthesis with evidence of reduced mitochondrial activity and increased oxidative stress.

The loss of muscle mass and function with age is called sarcopenia and there is increasing recognition of its adverse consequences in terms of increased disability, morbidity, mortality and health care costs. Adult determinants of sarcopenia, including age, gender, size and level of physical activity, have been well described and the beneficial effect of resistance exercise to slow the age-related loss of muscle has been well documented. Twin studies suggest a heritable component and a recent genome-wide association study identified *TRHR* as an important gene for lean body mass. Nevertheless, there remains considerable unexplained variation in muscle mass and strength between older people which may reflect not only the current rate of loss but also the peak attained earlier in life. Early growth and development of muscle are important determinants of peak muscle mass and strength which are achieved in early adulthood and generally remain stable until the fifth decade. Over the age of 50 years, muscle mass is lost at a rate of 1–2% per year and strength at 1.5–3.0% per year.

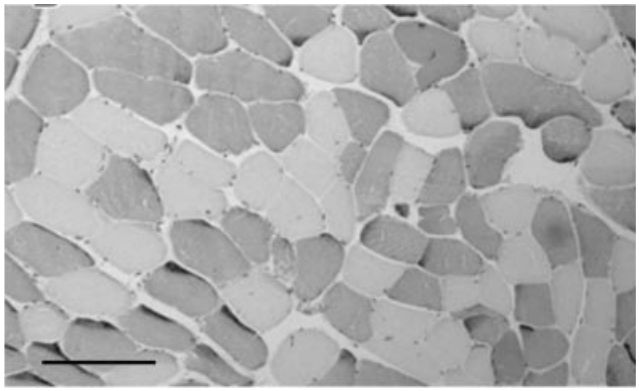

Figure 8.2 Cross-section through muscle fibres.

Evidence for developmental influences on ageing muscle has come from a series of observational epidemiological studies linking low birth weight with reduced muscle strength, mass and size in later life. The association between low birth weight and reduced muscle strength was first reported in the Hertfordshire Ageing Study, a retrospective birth cohort study of men and women born in Hertfordshire, UK, between 1920 and 1930 and still living there 60–70 years later.[9] They had historical health visitor records of weight at birth and age 1 year and were traced through the National Health Service Central Registry in Southport, UK. Following a home interview, 717 men and women attended a local clinic for measurement of current size and markers of ageing in different body systems, including grip strength measured using hand-held dynamometry (Figure 8.3). Lower birth weight and weight at 1 year were significantly associated with lower grip strength in later life. These relationships remained significant although attenuated after allowing for adult height, suggesting that an adverse early environment may have an effect on both muscle quality and quantity.

The association between birth weight and adult grip strength has been replicated in a younger group of Hertfordshire men and women born in 1931–1939 and participating in the Hertfordshire Cohort Study and in a British birth cohort of middle-aged men and women born in 1946 and taking part in the National Survey of Health and Development. More recent work has demonstrated a similar effect of size of birth weight on adult muscle strength in young women aged 20–34 years taking part in the prospective Southampton Women's Survey, suggesting that the association may be between birth weight and peak muscle strength rather than decline. Using a meta-analysis approach, it has been possible to compare the findings from published epidemiological studies investigating the relationship between lower birth weight and reduced grip strength in later life. These show remarkable homogeneity of association with a pooled effect size estimate of a 2.06 kg increase in grip strength per kilogram increase in birth weight. Adult height typically attenuated, but did not

Figure 8.3 Grip strength measured using hand-held dynamometry.

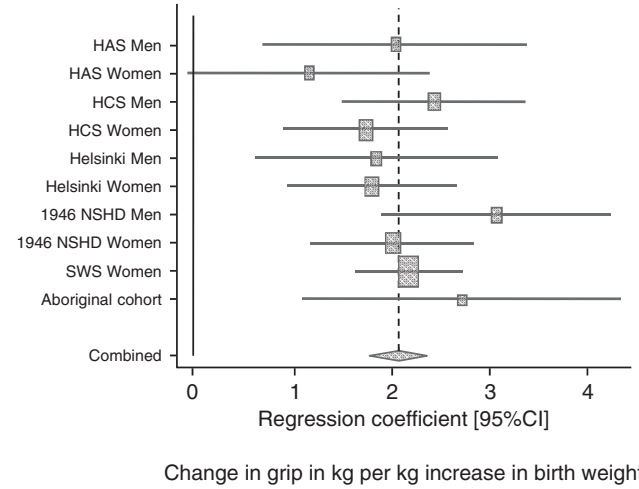

Figure 8.4 Meta-analysis of the association between birth weight and grip strength. Reproduced from Sayer *et al.*,[10] with permission from Springer Science + Business Media.

remove, the birth weight versus grip strength relationship (Figure 8.4).[10]

Studies investigating the relationship between growth in early life and muscle mass have demonstrated consistent findings linking low birth weight with reduced muscle mass. A study of older men participating in the Hertfordshire Cohort Study showed that birth weight was strongly positively associated with fat-free mass but showed only weak positive associations with measures of adult total fat mass. In contrast, weight at the age of 1 year was strongly associated with fat-free mass and adult fat mass estimated using anthropometry. Similar findings were observed in studies of men and women using urinary creatinine excretion and dual X-ray absorptiometry to estimate muscle mass. A study in the Helsinki Birth Cohort has replicated the relationships between small size at birth, lower muscle mass and reduced grip strength in adults. More recent work using peripheral quantitative computed tomography to measure muscle size directly has shown that birth weight is positively associated with forearm and calf muscle area in older men and women, suggesting tracking of relative muscle size throughout life.

There is considerable interest in which early environmental influences are important in these epidemiological associations. Few retrospective cohort studies have sufficiently detailed data on pre- and postnatal environmental influences to assess specific effects on long-term muscle mass and strength. However, the prospective cohort design of the Southampton Women's Survey will allow these questions to be addressed.[11] This study has recruited over 12 500 women living in the city of Southampton, UK, and interviewed them to assess general health, body composition, lifestyle and diet. The women have been followed up during pregnancy and their offspring studied through childhood, with the aim of identifying prospectively the influence of the preconceptional and antenatal environment on the growth and development of the fetus and child. Using data from 448 mother–offspring pairs in this cohort, it was possible to examine maternal influences on neonatal body composition ascertained by dual X-ray absorptiometry.[12] Taller women and those with higher parity had offspring with increased birth weight, fat and lean mass, whereas women who smoked during pregnancy had lower birth weight babies, with reduced fat and lean mass. Maternal walking speed as a marker of maternal physical activity was negatively associated with birth weight and maternal fat mass positively predicted neonatal relative fat but was negatively correlated with proportionate lean mass.

Bone ageing

Close relationships between muscle and bone mass have been documented at different stages of life and a number of studies have considered this association during musculoskeletal ageing. A Finnish study of peri- and post-menopausal women demonstrated that women who experienced an improvement in grip strength over a 5 year

period had significantly lower rates of bone loss at the femoral neck and lumbar spine compared with those whose grip strength remained unchanged or decreased.[13] A study utilizing the Framingham Heart Study Cohort of 504 women and 285 men aged 72–93 years reported that among men, muscle mass and not percentage fat was positively associated with bone mineral density; among women, bone mineral density increased with both increasing muscle and fat mass.[14] There is considerable interest in what might underlie the relationship between ageing bone and skeletal muscle. There is some evidence for muscle contraction as an important mechanical stress for increasing bone density, but the role of shared developmental influences remains to be explored.

Ageing is associated with bone loss and osteoporosis, which is a skeletal disorder characterized by low bone mass and microarchitectural deterioration. Osteoporosis is a major cause of morbidity and mortality through its association with age-related fracture. The worldwide direct and indirect annual costs of hip fracture in 1990 were estimated at US$34.8 million and are expected to rise substantially over the next 50 years. These fractures typically occur at the hip, spine and distal forearm. The frequency of fracture at all three sites increases with age and fracture pathogenesis depends upon both bone strength and propensity to trauma. Bone strength is directly related to bone mass; the bone mass of an individual in later life depends upon the peak attained during skeletal growth and the subsequent rate of bone loss. Although there is evidence to suggest that peak bone mass is inherited, current genetic markers are unable to explain more than a small proportion of the variance in individual bone mass and determinants of bone loss are incompletely understood. However, evidence is accumulating that early environmental influences also modulate peak bone mass and fracture risk.[15]

Several epidemiological studies have addressed the relationship between birth weight, weight in infancy and bone mass in adulthood. In the first of these, 153 women born in Bath, UK during 1968–1969 were followed up at age 21 years; data on childhood growth were obtained from linked birth and school records. Statistically significant associations were documented between weight at 1 year and bone mineral content, but not density, at the lumbar spine and femoral neck. These relationships were independent of adult body mass index. The findings were replicated in an older cohort of 238 men and 201 women aged 60–75 years in Hertfordshire, UK. Again, the relationship remained after adjustment for later environmental determinants of bone loss such as physical activity, dietary calcium intake, cigarette smoking, alcohol consumption and age at menopause among women. These studies have also provided evidence that the early environment might interact with the genome in influencing bone mass. Thus, polymorphism in the gene for the vitamin D receptor was shown to relate to bone mineral density in opposite directions among individuals of varying birth weight. Among individuals with the 'BB' genotype, lumbar spine bone mineral density was increased in those of lower birth weight but reduced in those of higher birth weight. Such findings suggest that genetic influences on adult bone size and mineral density may be modified by understanding early growth and development.

Confirmation of these observations in the United States, Scandinavia and Australia allowed the data relating growth in infancy with adult bone mass to be brought together.[16] This demonstrated that the strongest association was between weight in infancy and adult bone mass, with around 50% of this relationship observable by birth. However, the clinically important consequence of reduced bone mass is fracture and there are also data directly linking growth rates in childhood and adolescence with the risk of later hip fracture.[17] A study in the Helsinki Birth Cohort allowed linkage of birth and growth data to later hospital discharge records for hip fracture in 7000 men and women born in 1924–1933. The two main determinants of hip fracture risk were tall maternal stature and low rate of weight gain between age 7 and 15 years. In addition, those with fracture were found to be shorter at birth but of average height by age 7 years, suggesting that hip fracture risk might be particularly elevated among children in whom growth of the skeletal envelope was forced ahead of the capacity to mineralize. Extrapolation from the epidemiological studies of bone mass to those of hip fracture suggest that developmental plasticity of bone mass alone would be insufficient to explain the hip fracture risk. It is likely that developmental influences on muscle mass and strength are also involved and that ageing of the musculoskeletal system as a whole needs to be considered in the aetiology of fracture in older people.

The associations between birth characteristics and musculoskeletal ageing have been clearly demonstrated. However, the causal pathways are only just starting to be investigated. Detailed physiological studies have been used to investigate hormonal influences and the role of the hypothalamic–pituitary–adrenal axis. Profiles of circulating cortisol and growth hormone were obtained in groups of men and women and related to both size in early life and adult bone density. These studies showed that low birth weight predicted increased adult cortisol levels and low weight in infancy was associated with decreased growth hormone levels in later life. The levels of these two skeletally active hormones were also found to be determinants of prospective bone loss. The data are compatible with the hypothesis that environmental stressors, such as undernutrition, occurring during intrauterine or early postnatal life, may alter the sensitivity of the growth plate to cortisol and growth hormone. The consequence of this endocrine programming would be to reduce peak

skeletal size and perhaps also mineral density, and also to predispose individuals to accelerated rates of bone loss during later life. The role of the resetting of endocrine axes in linking birth characteristics with muscle ageing remains to be established.

Developmental influences and ageing at the cellular and molecular level

Cellular and molecular ageing mechanisms

There is growing acceptance for the disposable soma theory of ageing,[18] which comes from the field of evolutionary biology. This proposes that our survival mechanisms, which evolved to cater for the shorter lifespans of our evolutionary ancestors, are insufficient to prevent damage from accumulating over the longer term. Ageing is therefore caused by the lifelong accumulation of subtle cellular and molecular faults – a process that might begin *in utero*. Multiple mechanisms are likely to contribute to the accumulation of damage that causes ageing and conversely there are multiple maintenance and repair systems in place to counteract them. It has been proposed that the genetic setting of the maintenance and repair systems explains the genetic contribution to human ageing.

There is considerable interest in understanding the specific cellular and molecular mechanisms underlying the process of ageing in both stem and non-stem cells and much of the focus of current research is on the role of nutrient sensing pathways,[19] reactive oxygen species (ROS) production[20] and DNA damage and repair.[21] ROS are byproducts of energy-generating mitochondria and cause damage to both mitochondrial and nuclear DNA, including telomeres. Telomeres are non-coding DNA repeat sequences at the ends of chromosomes that decrease in length during each cell division. When they become critically short, the cell is no longer able to replicate and enters cellular senescence. Telomere shortening is accelerated by oxidative damage and has been proposed as a biomarker of human ageing. Sirtuins may link nutrient sensing, ROS production and DNA damage/repair. They are intracellular proteins that have an important role in nutrient sensing pathways and may also be involved in DNA repair. Caloric restriction, the only intervention to prolong lifespan consistently across species, is associated with increased levels of sirtuins and a number of studies have investigated the effects of giving resveratrol, found in red grapes, as it mimics sirtuin activity.

Increasingly studies of ageing at the molecular and cellular level are being linked to ageing at the system level. In ageing muscle there has been considerable investigation of the role of nutrient sensing, ROS production and DNA damage/repair at the molecular level and also study of the loss of muscle fibres and stem cells at the cellular level.[22] It has been proposed that the decline in muscle mass and strength with age is associated with impaired insulin signalling, decreased protein synthesis and aberrant ROS generation. In bone, there have been several studies investigating the relationship between telomere length and bone ageing. One recent study found a significant association between telomere shortening and reduced bone density in female twins. However two subsequent studies failed to replicate these findings. A study of organ-specific telomere shortening in a rat model demonstrated age-dependent shortening in the kidney, liver, pancreas and lung but not the brain; muscle and bone were not studied. A study using a mouse mesenchymal cell line considered the role of sirtuins and demonstrated that a sirtuin was expressed in stem cells and furthermore that resveratrol, which activates Sirt1, led to increased expression of osteoblast markers and increased mineralization.

Developmental influences on general mechanisms of ageing

Understanding of developmental influences on cellular and molecular ageing mechanisms is only just emerging. Indeed, there has been scepticism that early environmental influences could be detected in rates of ageing[23] and a call for integration of work in human populations with multidisciplinary studies of ageing in different model species subjected to nutritional and other challenges during preadult development. This approach has been taken in a series of studies by Ozanne and colleagues in Cambridge investigating the influences of an adverse early environment on a range of cellular and molecular ageing processes.[24] Using a rodent model of maternal protein restriction, they demonstrated that in the offspring, longevity can be influenced by early growth patterns and that underlying this may be changes in insulin metabolism, expression of antioxidant defence systems and levels of oxidative damage (including telomere attrition).

Another study showed that a murine model of a human syndrome linked to defective DNA repair resulted in animals with premature ageing but that the accumulation of DNA damage was restricted mainly to the embryonic period. This might be compatible with the high initial damage load hypothesis, which proposes that early development of living organisms produces an exceptionally high load of initial damage, comparable to the amount of subsequent ageing-related deterioration accumulated during the rest of life.[25] This hypothesis predicts that even small progress in optimizing early developmental processes could potentially result in major benefits in terms of slower ageing, prevention or postponement of age-related diseases and extension of healthy lifespan. Others have sought to summarize the evidence that telomere attrition might underlie the developmental origins of cardiovascular

disease in human ageing and found that most published studies to date were based on *in vitro* experiments or on tissue specimens collected at a single age so that individual variation in the rate of telomere attrition and how this might relate to growth rate and the rate of decline in vascular endothelial and metabolic function in individuals remain unknown.

Developmental influences on cellular and molecular ageing in muscle and bone

Muscle fibre number is a critical determinant of muscle mass and strength at all stages of life. It appears that fibre number is set at 24 weeks of human gestation and fibres are incapable of replication thereafter. Hence subsequent growth, maintenance and repair are believed to occur through muscle fibre hypertrophy rather than hyperplasia achieved by recruitment of myoblasts, derived from embryonic stem cells, at approximately 6 weeks of gestation in the human embryo. These observations suggest that key periods during gestation may influence the formation of myofibres and recruitment of myoblasts with long-term consequences for muscle mass and strength. The neonatal period appears to be particularly important for muscle growth through fibre hypertrophy.[26] Skeletal muscle is the fastest growing protein mass in neonates due to accelerated rates of protein synthesis accompanied by the rapid accumulation of muscle nuclei. Feeding profoundly stimulates muscle protein synthesis in neonates and the response decreases with age. The feeding-induced stimulation of muscle protein synthesis is modulated by enhanced sensitivity to the postprandial rise in insulin and amino acids. This capacity is further supported by enhanced myoblast proliferation, but how these two processes are linked remains to be established.

There is good evidence from animal models to support the concept of developmental plasticity of muscle. This is exploited in farming, where manipulation of the diet of livestock is routinely used to maximize muscle growth and therefore meat yield. Indeed, a recent study showed that peri-implantation and late-gestation maternal undernutrition differentially affected skeletal muscle development in fetal sheep.[27] There was evidence of reduced slow-twitch myofibre and capillary density in the fetal triceps but not the soleus with undernutrition at both time points. This reduction in fibre density, which may have been a consequence of decreased capillary density, was associated with higher insulin receptor, GLUT-4 and type 1 insulin-like growth factor receptor mRNA levels, suggesting a redistribution of resources at the expense of specific peripheral tissues as a consequence of undernutrition. Furthermore, there is evidence that the changes in insulin signalling due to *in utero* growth restriction may go on to result in altered trajectories of postnatal growth. Other studies involving experimental manipulation of early nutrition have similarly shown that prenatal maternal diet restriction is associated with reduced neonatal muscle weight in a range of mammalian models. In particular, maternal undernutrition appears to have a predominant effect on the growth and development of secondary fibres whereas the major influence on primary fibre number appears to be genetic, and there is evidence that these effects on muscle persist.[28]

Successful prenatal development depends on nutritional supply, utilization and hormonal regulation, and the maternal somatotropic axis plays a significant role in the control of myogenesis. For example, the infusion of growth hormone into pregnant sows up until mid-gestation results in overall increases in both birth weight and fibre numbers in the smallest littermates. This suggests an important role for cross-talk between nutrient availability, the growth hormone–insulin-like growth factor (GH–IGF) axis and regulation of fibre number with long-term consequences for muscle form, function and ageing in later life. These investigations have been taken further using the spontaneous differential fetal growth of pigs to investigate the mechanisms underpinning the link between fetal size and muscle development. The development of the longissimus muscle in small fetuses and their average-sized littermates was investigated on days 45, 65 and 100 of gestation, where term was 113–116 days. Small fetuses were reported to have significantly lower body weight at all time points and significantly reduced secondary to primary muscle fibre ratios on day 100 compared with littermates. The expression of the IGF-1 receptor and IGF binding protein (IGFBP)-3 were significantly higher at day 65 in the longissimus muscle of the small compared with the average-sized fetuses. IGF-1 receptor expression remained elevated at day 100 and was accompanied by significantly increased expression of the IGF-2 receptor and of IGFBP-5. These data suggest that reduced fetal muscle development is associated with increased expression of several genes of the IGF system in mid to late gestation, which may be compensatory to poor growth.[29]

The GH–IGF axis remains very important in neonatal growth and development and a study in rodents found that muscle from small neonatal rats secreted significantly more IGFBPs and less IGF than average-sized littermates. This differential expression, if maintained postnatally, could account for the persistence of small muscle size throughout life and have consequences for lifelong muscle function. Animal models have further demonstrated that efficiency of nutrient utilization is reduced in neonates, with intrauterine growth restriction suggesting altered function of the major organs involved in the digestion, absorption and metabolism of dietary nutrients. For example, proteomic analyses of the gastrocnemeus from small and normal weight newborn piglets demonstrated major adaptations in 13 proteins which were associated with reduced muscle size

at birth. These proteins related primarily to macronutrient metabolism, particularly protein synthesis and degradation, antioxidant function and immune response, and also to cellular structure. The postnatal consequences of reduced birth weight in lambs include slowed postnatal engagement of the GH–IGF system. When small lambs are reared in an optimum environment, they grow at rates comparable to average-weight lambs. However, they lay down more fat as a consequence of high energy intakes, low maintenance requirements and limited capacity for muscle and bone growth.

Akt is a protein kinase essential for metabolism and survival which acts downstream of both the IGF-1 and insulin receptors. Signalling through Akt, following the binding of IGF-1 to its receptor, is associated positively with muscle protein synthesis. Myofibre contraction has also recently been demonstrated to stimulate Akt signalling and GLUT4 translocation, both central regulators of glucose homeostasis. Among the intracellular mechanisms controlling protein synthesis, signalling via Akt appears to regulate gene transcription through inactivation of Forkhead box Os (FOXOs), which are associated with E3 ubiquitin ligase expression. mTOR is another important protein kinase. It regulates translation and its expression increases with increase in muscle hypertrophy and vice versa, suggesting an important role in determining muscle mass. Nutrition, insulin and IGF-1 all activate the Akt/mTOR pathway and it could therefore be postulated that older adults who had reduced birth weight and then developed insulin resistance in later life might have reduced mTOR concentrations or down-regulation of its activation.

Sirtuins may also be important. There is evidence that SIRT1 is central to the ability of adult skeletal muscle fibres to sense and react to nutrient availability, and it has been postulated that sirtuin expression might also be affected by nutrient restriction *in utero* or early childhood.

Studies identifying mechanisms for developmental influences on bone have also utilized animal models. A study of rats demonstrated that the experience of a low protein diet in prenatal life was associated with subsequent reduction in bone area and bone mineral content and also alteration in growth plate morphology in adulthood. There was also evidence of down-regulation of proliferation and differentiation of bone marrow stromal cells as assessed by fibroblast colony formation at 4 and 8 weeks. Subsequent work considered the effect of early undernutrition on the osteogenic environment and demonstrated changes in IGF-1, osteocalcin and vitamin D levels associated with alteration in skeletal structure which persisted into late adulthood.

There has been less work linking early environmental influences with changes in human muscle or bone at a molecular or cellular level. One small study involving 27 adult women looked at the relationship between size at birth and skeletal muscle morphology but did not find significant associations. In contrast, a more recent study focused on a group of 40 young men and showed that those with low birth weight had altered skeletal muscle fibre composition and also specific changes in muscle insulin-signalling protein expression. Most recently, the same group investigated mitochondrial function in the skeletal muscle of young men born with low birth weight and abnormal glucose metabolism in adult life. However they did not demonstrate underlying mitochondrial dysfunction. This cellular and molecular work now needs to be taken forward in studies of older adults to investigate mechanisms underlying the developmental origins of sarcopenia and osteoporosis. Of course, one of the main challenges is collecting tissue to carry out this type of basic science research, but interestingly a recent study demonstrated that it was both feasible and acceptable to carry out muscle biopsy in older men already taking part in an established epidemiological study.[30]

A life course approach to ageing and its relevance to clinical practice

Most research into human ageing focuses on influences operating in later life. However, there is considerable unexplained variation in markers of ageing and age-related disease between individuals of a similar age. A life course approach to ageing suggests that this is partly explained by the fact that manifestation of ageing in later life reflects not only the rate of decline experienced at that stage but also the peak attained earlier in life. This is illustrated with regard to musculoskeletal ageing in Figure 8.5. Thus the determinants of peak structure and function attained in early adulthood become an important focus, in particular influences on early growth and development. Understanding the role of developmental influences in ageing is relevant

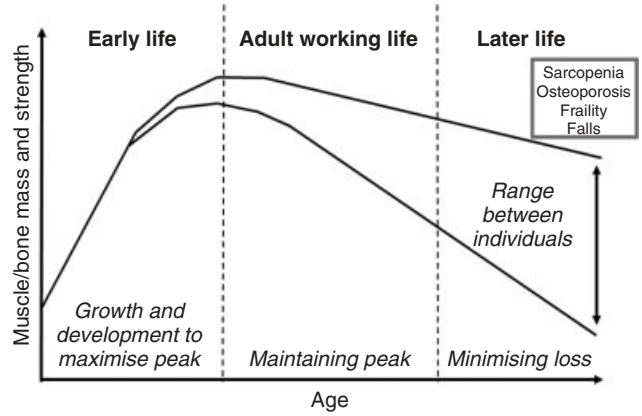

Figure 8.5 A life course approach to musculoskeletal ageing.

to clinical practice for several reasons. For example, it provides an opportunity to identify individuals at risk of accelerated ageing earlier in the life course. It also suggests that the window for instituting beneficial interventions should be widened to include all stages of life. Furthermore, knowledge of underlying mechanisms, particularly at the cellular and molecular level, has the potential to inform the development of novel therapeutic agents to minimize the detrimental effects of ageing.

Key points

- There is increasing recognition that developmental influences are relevant to human ageing.
- Small size at birth has been associated with increased mortality and morbidity from a number of age-related conditions, including cardiovascular disease, type 2 diabetes, sarcopenia and osteoporosis.
- Understanding the role of developmental influences in ageing has clinical relevance in terms of predicting accelerated ageing, widening the window for interventions and informing the development of novel therapeutic agents.

CHAPTER 9

Sexuality and ageing

John E. Morley[1] and Debbie T. Tolson[2]

Introduction

Sexuality remains an important component of quality of life throughout the lifespan. Sexuality is much more than the physical act of sex and encompasses intimate feelings, sensuality and the way we view ourselves or others see us as men and women. Relationships are influenced by sexuality and cultural codes of behaviour set the boundaries of what is considered to be acceptable or unacceptable behaviours in given contexts such as a nursing home. Myths and prejudice abound in terms of societal and professional expectations about the sexual activity and behaviours of older people and their needs in this area can easily be over looked. Cultural norms and values are changing and it is likely that future generations of older people will be more assertive in terms of seeking health care advice and interventions. However, it is important to recognize that current prejudices and myths about celibacy dominate western views of sexuality and sexual activity in later life, and this may inhibit older people from seeking help with sexual performance, sexual health and relationships.

The spectrum of sexuality and ageing is outlined in Table 9.1. The full expression of sexuality is dependent on biological, psychological and social factors. Testosterone is a driver of sexuality in both sexes, but its effect is modulated by psychological and social factors. The effects of ageing on sexuality can create major anxiety but, with adequate education, sexuality can remain enjoyable throughout life. There is much misinformation about sexuality. Although open discussion of sexuality has become much more common in the last 40 years, many older persons come from a generation where sexuality remains a taboo subject. This chapter explores both the biology of sexuality and ageing, and also the emergence of the special needs of a substantial cohort of older gays and their unique needs. The role of disease in the sexuality of older persons is addressed and, finally, the problems faced by older persons who have had lifelong paraphilias are considered.

In the United States, a survey of males and females aged 57–85 years found that 73% of persons 57–64 years of age were sexually active.[1] This prevalence declined to 26% of persons 75–85 years of age. Women at all ages were less sexually active than men. Sexual problems existed in half of the population but only 38% of men and 22% of women had discussed their sexual problems with a physician. Women reported a low desire (43%), poor vaginal lubrication (39%) and failure to climax (37%) as their main problems. About 37% of men had erectile dysfunction. Of these men, only 14% had used medications to improve their function. In a study of persons 75–85 years of age, 38.9% of men and 16.8% of women were sexually active.[2] Good health was the major factor predicting a healthy sex life.

Sexual health

It is essential that older people are informed and equipped to enjoy sexual activity safely. Older people are increasingly at risk at of sexually transmitted disease and they tend to delay seeking help longer than younger people from the onset of symptoms.[3] Access to age-sensitive information and health promotion is important; sexually transmitted diseases are not a prerogative of the young. It is important for health professionals to recognize that many of the older people who consult with them today have not benefited from health education programmes and may be unaware of the protection provided by condoms.[4]

Sexuality and the older woman

Many women associate menstruation with femininity, fertility and youth, which is in sharp contrast to the symbolism of menopause, which signals biological ageing triggering a new dynamic in self identity and sexuality. In the medical literature, the view that menopause is a deficient state is prolific, which some would argue is a social construction

of ageing based on the medicalization of menopause and failure to recognize this as a natural life transition.[5] These debates aside, menopause is an individual experience derived from the interplay of physiological, psychological and other factors. Natural menopause occurs in women with an average age of 52 years. Epidemiological studies have suggested that the older a woman is at menopause, the longer she will survive following menopause. Smoking is a major cause of an early menopause.

Numerous studies of ageing and menopausal transition demonstrate multiple health-related changes, alterations to sexual response and impacts on intimate relationships that may lead a woman to seek support through either traditional or alternative medicine.[6] The major symptoms of menopause are hot flushes and night sweats. These occur in approximately 85% of women at the time of menopause. Although in most women hot flushes last less than 5 years, a few women continue to have them into their 80s. Environmental factors such as spicy foods, alcohol, caffeine and hot weather and psychological factors, for example, stress, can be precipitants of hot flushes. Hormone replacement therapy is commonly prescribed to treat menopausal symptoms and to prevent post-menopausal bone loss. A concern of some women is that such treatment will result in weight gain; as shown by a recent systematic review of 28 randomized controlled trials with 28 559 women, there is no evidence of an effect of unopposed estrogen or combined estrogen with progestogen on body weight.[7] It seems that body mass index increase is normal and associated with the onset of menopause that can be addressed by changes in life style, including diet and exercise. There is currently insufficient evidence to determine the role of exercise in the management of vasomotor menopausal symptoms.[8] Menopause is not necessarily associated with a decline in libido. Some women find the cessation of menses liberating. Use of estrogen is declining following the results of the Women's Health Initiative and the HERS study. These studies showed that both estrogen alone and estrogen plus progesterone were associated with an increase in myocardial infarction, stroke, pulmonary embolism and breast cancer.[9,10] This was balanced by a decrease in hip fracture and colon cancer. Unfortunately, estrogen also appears to accelerate the onset of cognitive impairment in older women.[11]

Testosterone levels decline rapidly between the ages of 20–40 years in women.[12] There is then a slight increase in testosterone levels in women between the ages of 60 and 80 years. Testosterone, tibolone (an estrogen–progestagen–testosterone) and dehydroepiandrosterone (DHEA) all improve libido in older women. In addition to increasing libido, testosterone has also been reported to improve general well-being, decrease mastalgia, decrease headaches and increase bone mineral density and muscle mass (Table 9.2). The testosterone products available for women are listed in Table 9.3. A number of studies have shown positive effects of testosterone patches in women with female sexual desire disorder.[13]

Female hypoactive sexual desire disorder is defined as persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. This must cause marked distress or interpersonal difficulty. The condition cannot be better ascribed to another psychiatric condition, for example, depression or to the effects of a substance, for

example, medication or a general medical condition. The approach to the management of sexual dysfunction in older women is given in Table 9.4.

It is important to recognize that for many older women, intimacy and 'cuddling' are more important than intercourse. The sensitive clinician needs to recognize the specific needs of the individual and then work with her to obtain her goals. Some women will choose to use complementary therapies such as black cohosh or dong quai soy. It is important to recognize that there are no long-term data on their efficacy or safety. At present, the use of estrogen in women over 60 years of age should be avoided whenever possible. There is a clear need for increased research on sexuality in older women.

The major sexual problems reported by older women include lack of orgasm, lack of sexual interest, a decline in lubrication, failure to find an appropriate partner, dyspareunia, problems with safe sex and sexual intercourse decline from 30–78% at 60–70 years to 8–43% at 80 years. Most older persons who are still sexually active have intercourse an average of once per week. Approximately 45% of older women masturbate. Of those still having intercourse, 73% enjoy intercourse and the rest tolerate it. Only 21% of women over the age of 75 years still have a partner. Most studies have shown that the majority of physicians do not include sexual concerns and questions as part of their general history taking. Figure 9.1 provides the spectrum of sexuality and the older female.

A number of diseases have a major impact on sexuality in women. The disease that most alters a woman's self-image is breast cancer. Up to 40% of women with breast cancer have a reduction in their sexual activity.[14] The effect of breast cancer on sexuality is highly dependent on the relationship that the woman has with her partner. Urinary incontinence can modify sexual interactions in up to one-third of women. Severe incontinence may lead to the need for separate beds. Uterine prolapse is more likely than incontinence to alter sexual relationships. Urogenital atrophy, due to estrogen deficiency, leads to vaginal dryness, vaginal bleeding, urge incontinence, urinary frequency and dysuria, irritation and pruritus of the labia and mons, dyspareunia and urinary tract infections. All of these changes can lead to sexual dysfunction. A number of lubricants are now available to allow women to overcome vaginal dryness. Estrogen creams, tablets and rings

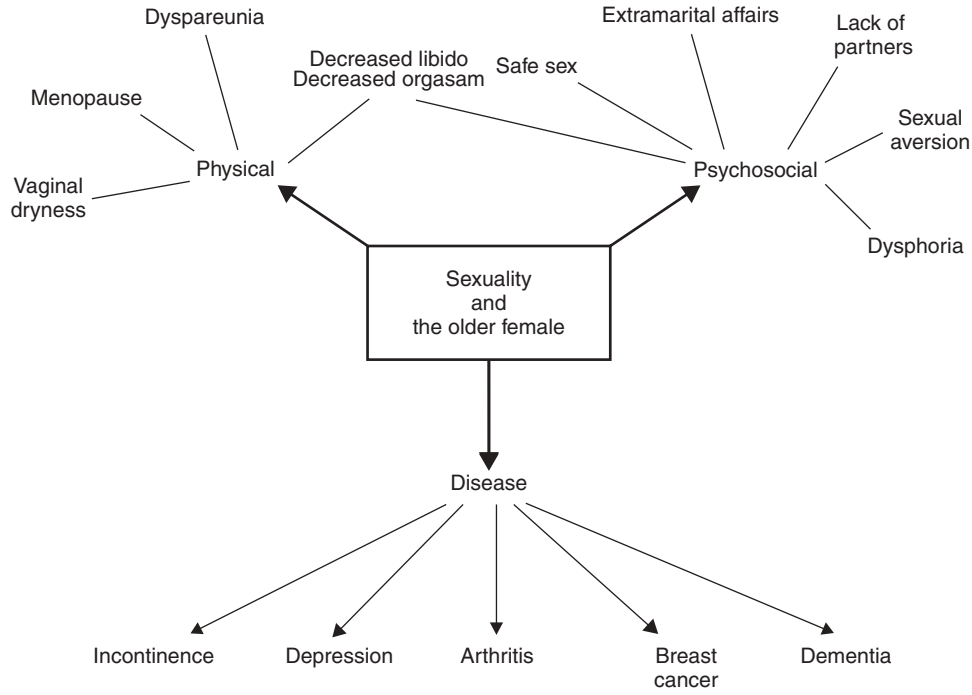

Figure 9.1 Sexuality and the older female.

may also be useful in the management of severe vaginal dryness. However, it must be remembered that vaginal estrogen is absorbed and may have all the effects of oral or parenteral estrogen.

Erectile dysfunction

Erectile dysfunction is defined as the inability to attain or maintain a penile erection sufficient for sexual performance on at least two-thirds of occasions.[15] Physiologically, older males have an increased time for development of erection and less full erections with a decreased pre-ejaculatory secretion. During orgasm, there is a decline in expulsive force and urethral contractions. Following ejaculation, there is a rapid tumescence with rapid testicular descent. The refractory period is markedly prolonged.

A number of older males have an active sex life.[16] However, studies in Germany and South America has found that 53% of men aged 70–80 years have some degree of erectile dysfunction.[17] The Massachusetts Male Aging Study showed that at 40 years of age, severe erectile dysfunction was present in 5.1% and moderate erectile dysfunction in 17%.[18] By the age of 70 years, 15% had severe dysfunction and 34% moderate dysfunction. In the Olmsted County Study, 30% of men over 70 years of age had no erections and only 10% had intercourse more than once per week.[19] The major risk factors for developing erectile dysfunction are heart disease, diabetes mellitus and hypertension.

Erections occur when the smooth muscle of the corpora cavernosa relaxes, allowing pooling of blood. Figure 9.2 demonstrates the different neurotransmitters involved in producing penile erection.

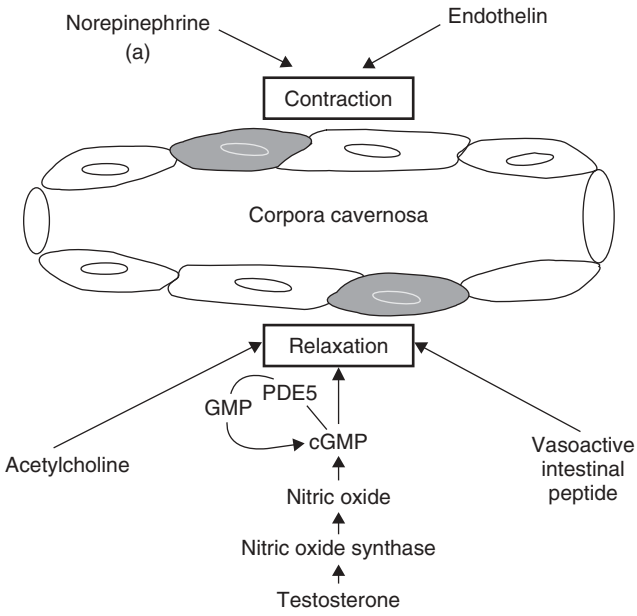

Figure 9.2 Neurotransmitters involved in producing a penile erection.

Approximately half the males with erectile dysfunction are found to have vascular disease as a cause. Other causes include medications, psychogenic causes, neuropathy, diabetes mellitus, thyroid disease and hyperprolactinaemia. Thiazide diuretics are the main medication-associated cause of erectile dysfunction worldwide. Tobacco use is associated with increased erectile function. In dogs, nicotine decreased cavernous nerve stimulation and increased erections. In humans, smoking two cigarettes decreases the quality of papaverine-induced erections.

While low testosterone levels decrease the production of nitric oxide synthase, most studies have failed to show that hypogonadism is a major cause of erectile dysfunction.[20] Nevertheless, persons with low testosterone have poor-quality erections. Testosterone treatment improves the quality of erections produced by phosphodiesterase-5 inhibitors.

Table 9.5 lists the causes of erectile dysfunction and Table 9.6 lists the available management strategies for it.

The most common treatment for erectile dysfunction is a phosphodiesterase-5 inhibitor. This works by blocking the breakdown of cyclic GMP that has been generated by nitric oxide. There are three phosphodiesterase inhibitors in general use: sildenafil, vardenafil and tadalafil. The pharmacokinetics of these drugs is given in Table 9.7. The major side effects of phosphodiesterase-5 inhibitors are headache, flushing, dyspepsia, rhinitis, visual disturbances, hypotension and death (Table 9.8). Persons on nitrates and α-adrenergic blockers should avoid phosphodiesterase-5 inhibitors. With ageing, all phosphodiesterase-5 inhibitors

have increased plasma concentration or area under the curve.

Vacuum tumescence devices are useful for older persons who wish to have intercourse rarely, for example, once per month. Intracavernosal injections with vasoactive agents can produce a response rate as high as 74% in older males.

A number of complementary medicines claim to improve erections, such as cantharidin and ginsenosides. These do not work and can produce haematuria.

Overall, modern medicine will allow the majority of older males to obtain an erection (Table 9.6). It is important to include the partner in decisions concerning which approach is best. It is important not to assume that an older male's partner is his spouse.

Andropause

It is now recognized that testosterone levels decline at the rate of 1% per year.[21] This decline leads to 3–5% of persons 40–50 years of age and 30–50% of persons over 70 years of age having biochemical hypogonadism. Other estimates suggest that 20% of persons 40–70 years of age are hypogonadal. When testosterone levels fall below the normal level for men 20–40 years of age and this is accompanied by symptoms such as a decline in libido or fatigue, the person is recognized as having andropause or androgen deficiency in ageing males (ADAM). Other terms that have been used historically, for example, climacteric or male menopause, are no longer considered acceptable. Two symptom-screening tests have been developed to screen for males with andropause. These are the ageing male symptom (AMS) and the ADAM questionnaires[22] (Tables 9.9 and 9.10). Both have excellent ability to detect males with biochemical hypogonadism but also are answered positively by a large number of males who are not hypogonadal, for example, older persons with depression.

The cause of the fall in testosterone with ageing is multifactorial (Table 9.11). Although levels of luteinizing hormone are slightly higher in hypogonadal older males, it is rarely out of the normal range. Hence these males are considered to have secondary (hypothalamic–pituitary) hypogonadism. The major cause of this seems to be irregular (chaotic) secretion of gonadotrophin-releasing hormone from the hypothalamus. There is also an increase in negative feedback of testosterone at the pituitary level. A decline in testosterone response to human chorionic gonadotrophin is present in older men. There is a decrease in Leydig cell number.

With ageing, there is an increase in sex hormone-binding globulin (SHBG). This leads to less testosterone being available to the tissues. Therefore, the tissue-available testosterone can either be measured directly using a free testosterone value by dialysis or a bioavailable testosterone (ammonium sulfate precipitation technique). Alternatively, tissue-available testosterone can be calculated using an SHBG, total testosterone and albumin by utilizing the

Table 9.9 ADAM questionnaire[a].

Yes	No	1	Do you have a decrease in libido (sex drive)?
Yes	No	2	Do you have a lack of energy?
Yes	No	3	Do you have a decrease in strength and/or endurance?
Yes	No	4	Have you lost height?
Yes	No	5	Have you noticed a decreased enjoyment of life?
Yes	No	6	Are you sad and/or grumpy?
Yes	No	7	Are your erections less strong?
Yes	No	8	Have you noticed a recent deterioration in your ability to play sports?
Yes	No	9	Are you falling asleep after dinner?
Yes	No	10	Has there been a recent deterioration in your work performance?

[a]A positive answer represents yes to 1 or 7 or any three other questions (circle one).

Have you got any other major symptoms? If Yes, please describe:	Yes	☐	No	☐	

program available at www.issam.ch. Most experts feel that some measure of tissue-available testosterone is preferable to measuring a total testosterone in making the diagnosis of andropause.[12]

It is essential to recognize that the response to testosterone depends on the ability of testosterone once it is in the cell to translocate to the nucleus and bind to the receptor and the receptor responsiveness. The binding capacity of the receptor depends on the number of CAG repeats in the receptor. The lower the number of CAG repeats, the better is the binding capacity of the receptor. The effect of ageing on the intracellular trafficking of testosterone, the ability of testosterone to bind to the receptor and receptor responsiveness is just starting to be explored.

The symptomatic concept of andropause has been recognized since the time of the Chinese Text of Internal Medicine. The major symptom of andropause is a decline in libido. A decline in libido may also be due to depression, illness or death of a spouse. Testosterone replacement restores libido in 70–80% of persons. Testosterone is also essential for the production of nitric oxide synthase. Production of nitric oxide is essential for firmness of the erection.

Table 9.11 Age-related changes in testosterone regulation.

Loss of circadian rhythm
Asynchronous production of GnRH
Increased inhibitory effect of T at pituitary
Reduced GnRH release of LH
Decreased T response to HCG
Altered receptor and post-receptor effects

Improved erectile function
Increased haematocrit
Increased muscle mass
Increased muscle strength
Increased IGF-1
Decreased fat mass
Decreased leptin
Increased bone mineral density
Decreased LDL and HDL cholesterol
Increased brachial artery flow
Decreased ST depression and angina
Enhanced spatial cognition

Thus, low testosterone levels can lead to soft erections or failure of phosphodiesterase-5 inhibitors to produce an erection. Low testosterone levels are associated with a low ejaculatory volume.

The effects of testosterone in older males are listed in Table 9.12. Testosterone increases muscle mass and strength. Testosterone stimulates the stem cells to produce satellite cells (these are responsible for repair of skeletal muscle) and also increase protein synthesis in skeletal muscle and inhibit the ubiquitin–proteasome system, which is responsible for muscle breakdown. Testosterone inhibits adipocyte precursor cells, resulting in a loss of fat mass. Testosterone may improve function, but at present there are limited data in this regard. Testosterone increases bone mineral density in the lumbar spine and the hip, improves visuospatial cognition and increases the haematocrit. Testosterone may have beneficial effects on the cardiovascular system. Testosterone's negative effects include gynaecomastia, water retention and possibly sleep apnea. The effects of testosterone on the prostate are uncertain. Testosterone cannot be given to persons with active prostate cancer.

The history of testosterone replacement stretches from the end of the nineteenth century when Brown-Sequard injected himself with an animal extract of testosterone. During the early twentieth century, 'monkey gland', goat testicle and even human testicular transplants were done on the rich in an attempt to rejuvenate them. The available and experimental forms of modern testosterone replacement are listed in Table 9.13. At present, most men with andropause choose to use the testosterone gel forms of treatment. After the gel, the next most popular form of treatment is testosterone injections. Selective androgen receptor molecules (SARMs) have been developed to avoid the sexual stimulant properties of testosterone and enhance the anabolic features of testosterone replacement. These can be steroids, for example, nandrolone or oxandrolone, or a series of non-steroid molecules that can be ingested orally.

Libido represents an important component of sexuality in older men. The treatment of depression and where appropriate testosterone replacement can markedly enhance libido in older men.

Sexuality and disease

Disease can greatly alter the sexuality of an individual. Pain and disability can interfere with sexual intercourse. Fatigue reduces libido. Negative self-image is commonly associated with diseases. Depression, with or without other systemic diseases, can lead to a decline in libido or erectile function. Many systemic diseases reduce testosterone, leading to a decrease in libido.[23]

Diabetes mellitus causes early onset of erectile dysfunction and a decreased libido. Males with diabetes mellitus have low testosterone. Women with diabetes mellitus have clitoral damage. Women with diabetes have a decline in libido and vaginal lubrication, but minimal change in the ability to attain orgasm. Amputations and dysphoria can further alter sexuality in persons with diabetes.

Hip arthritis causes both stiffness and pain, which interfere with sexual intercourse. Judicious use of pain medication prior to intercourse, alterations in positions for intercourse and positioning of pillows can all enhance the sexual experience for persons with arthritis.

Persons with left cerebrovascular hemisphere strokes have a marked decrease in libido. Coital frequency is markedly decreased in two-thirds of persons following a stroke. Persons with a stroke can often have hemineglect and their partners need to be aware of this problem.

Table 9.14 Instructions for patients and their spouses after myocardial infarction.

- Sexual activity may be resumed as soon as you can bring your heart rate to 120 beats per minute without occasioning chest pain or shortness of breath, the equivalent of climbing two flights of stairs rapidly.
- If chest pain develops during intercourse, take a nitroglycerine. If the pain does not subside within 15 min, consider that an emergency.
- If chest pain regularly develops during sexual intercourse, take a nitroglycerine 10 min before attempting sex.
- No sexual position is the best or is prohibited. Some patients may find one position preferable for their needs.
- Altered desire after a heart attack is usually due to psychological factors, such as fear of another attack. Please discuss these problems with your physician.
- Altered ability to obtain an erection after a heart attack may be due to medications or to vascular disease of the penis. These are both treatable. Please discuss this with your physician.
- If the female has decreased vaginal lubrication or pain during intercourse, ask your physician to prescribe a lubricant or, in some cases, you may need estrogen replacement.
- There is no time of day during which we know that sex is safer or more dangerous. Please be advised that sexual activity in a novel situation, for example, with a partner other than your spouse, appears to be associated with increased problems.
- Discuss your sexual needs and concerns frankly with your spouse.
- Any questions or concerns you have should be brought to the attention of your physician or nurse. It is best that both you and your spouse read these instructions. Feel free to have your spouse discuss his or her problems with the health professional team.

Sexual activity can be restored in male patients with normal pressure hydrocephalus after shunt placement.[24] Men and women with Parkinson's disease have a high prevalence of sexual dysfunction. Very low testosterone levels have been reported in men with Parkinson's disease. Pelvic organ prolapse when severe is associated with a decrease in sexual activity.[25]

Death during sexual intercourse in persons with cardiovascular disease is extremely rare, with an estimated rate of 0.2 per 100 000 being reported in males.[26] Cardiovascular disease and hypertension are major risk factors for erectile dysfunction. Persons with two- or three-vessel disease have softer erections and more erectile dysfunctions than those with one-vessel disease. In females, heart disease is associated with decreased libido, vaginal dryness, dyspareunia, orgasmic difficulty and decreased genital sensation. Saint Louis University has developed a series of instructions for patients for resuming coitus following myocardial infarction (Table 9.14).

The older homosexual

There are approximately 3 million older gays in the United States. It is estimated that approximately 4% of older women are lesbian and/or bisexual. Older gays tend to have a higher use of alcohol and tobacco. The Women's Health Initiative found a slightly greater rate of obesity and dysphoria in older lesbians.[27] Breast cancer was more common in lesbians.

Nearly one-quarter of AIDS cases in developed nations occur in persons over the age of 65 years.[28] By 2015, 50% of HIV-infected males in the United States will be over 50 years of age. The rate of CD4+ all cell loss is more rapid in older males. Older persons are less likely to be screened for HIV. There has been a marked increase in males over 50 years of age looking for sex on the Internet.[29] Condom use is extremely rare in gays over 50 years of age. HIV testing is rare in older gays.

Homophobia leads to many older gays not identifying themselves to health care providers. Many physicians assume that their older patients are heterosexual. Unmarried homosexual partners are often poor as they grow old as they are ineligible, in the United States, for social benefits such as Social Security. A major issue occurs when the partner becomes sick, as the homosexual partner often has no rights to make health care decisions for their ill partner. It is important that older gays have a durable power of attorney for health, designating their partner as the decision-maker. There are numerous unmet health and social service needs of gay and lesbian elders.[30]

Paraphilias

Paraphilias are unusual sexual behaviours. The advent of the Internet has greatly increased awareness of persons indulging in these behaviours. The most common paraphilia is erotic talk on the telephone or the Internet. Substantial numbers of persons practice exhibitionism, voyeurism, sadomasochism, sexual bondage, anal eroticism and fetishes. Many of these practices are still indulged in by older persons. Some become exaggerated as the older person develops dementia and loses the normal social sensibilities. The physician needs to be aware that many of these are variants of normal sexuality and may be able to help the older person.

Paedophilia is sexual abuse of a child by an adult. In one series of 261 cases, the child abuser was the grandfather in 16 cases.[31] Paedophilia needs to be reported to the appropriate authorities.

Sexuality in the nursing home

Sexuality does not necessarily cease on entry into a nursing home. However, within the nursing home there are multiple barriers to sexuality.[32] These include lack of privacy,

lack of a partner, staff and resident attitude and knowledge concerning sexuality and family attitudes. Special ethical problems arise when two demented patients form a romantic liaison. Most ethicists feel that older persons should retain their right to continue appropriate sexual behaviour in the nursing home. It has been suggested that older persons may wish to develop an advanced directive for sexual behaviour.

From the facility point of view, it is essential that staff are educated and taught to be accepting of sexual behaviour. Residents of nursing homes are entitled to privacy and, where wanted, conjugal visits. Unfortunately, sexual abuse of residents, including rape, is also a problem in nursing homes. Maintenance of a healthy sexual environment in the nursing home is often extremely difficult. Society needs to come to terms with the sexual needs of older persons in nursing homes.

Sexual disinhibition is not uncommon, with a prevalence of about 2% in the community and as high as 25% in nursing homes.[33] No randomized control trials exist for the pharmacological treatment of sexual aggression. The use of behavioural management whenever possible is recommended. Use of antiandrogens and estrogens in males is associated with an increase in side effects and therefore cannot be recommended.

Conclusion

Awareness of the sexual needs of older persons is an important quality of life issue. Health care providers need to be open to discussing the sexual needs of older persons and providing treatment where appropriate. Education of society and increased awareness of sexuality in elders are key components of sexual health in the future.

Key points

- Sexuality is important throughout the lifespan.
- Erectile dysfunction is the major problem in older males.
- In older women, the major problems are reduced libido, poor lubrication and failure to climax.
- There are biological, psychological and social components of sexuality.
- Alternative sexual lifestyles are not unusual in older persons.

Introduction

The interaction of physical activity, exercise and physical fitness with health and ageing is complex and multifaceted. Although many questions remain about mechanisms of effect and dose–response curves, a synthesis of the literature indicates many potentially positive effects of participation in physical activity on the ageing process. Most recent position stands and policy recommendations include physical activity prescriptions for health promotion and disease prevention and also chronic disease treatment in older adults. However, there is still scepticism among some clinicians and investigators as to the actual potency of exercise for disease and/or disability prevention and treatment, particularly in already frail or near frail adults. Exercise has not become fully integrated into usual geriatric medicine practice and is still virtually absent from the core training of most geriatric medicine physicians and healthcare professionals. Therefore, this chapter attempts to provide a rationale for the use of exercise and physical activity for health promotion and disease prevention in older adults. Exercise is discussed in terms of the specific modalities and doses that have been studied in randomized controlled trials for their role in the physiological changes of ageing, disease prevention and treatment of older persons with chronic disease and disability. Recommendations will be offered to address gaps in knowledge and also clinical implementation needs in this field.

What is exercise?

Any discussion of these issues must begin with definitions of the terminology. Physical activity has traditionally been defined as any bodily movement produced by contraction of skeletal muscle that significantly increases energy expenditure, although the intensity and duration can vary substantially. It should be noted that some forms of physical activity which may have particular relevance to an ageing population (e.g. balance training) may not conform to this standard definition. This activity may be performed in leisure or occupational hours and surveys for the older adult should capture both paid and unpaid (volunteer) work. Exercise is a subcategory of leisure time physical activity in which planned, structured, repetitive bodily movements are performed, with or without the explicit intent of improving one or more components of physical fitness.

Recently, efforts have been focused on merging these formerly distinct entities in order to promote 'lifestyle integration' of exercise as a means to enhance long-term adherence. For example, taking the stairs instead of the elevator, standing on one leg while doing the dishes or slowly standing and sitting without use of the arms represent ways of incorporating aerobic, balance and strengthening exercises, respectively, into everyday activities. Current investigations are exploring whether such prescriptive techniques are superior to standard approaches for the promotion of behavioural change in older adults.

Physical fitness, by contrast, is defined as a set of attributes that contribute to the ability to perform physical work (e.g. cardiorespiratory endurance, muscle power, balance, flexibility and body composition) or influence health status. 'Metabolic fitness' has been advanced more recently as a term that encompasses a range of biologically important traits (increased insulin sensitivity, lipoprotein lipase activity, endothelial cell reactivity, heart rate variability, etc.) which may contribute to health status, but do not directly affect exercise capacity. Both genetic predisposition and lifestyle factors contribute to physical and metabolic fitness and the extent to which they are modifiable with exercise training.

Dose–response relationships between changes in fitness and better health outcomes have been defined for some, but certainly not for all, diseases and syndromes. Some modalities or doses of exercise that are promoted for older

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

adults (mild calisthenics, slow-paced walking) have little or no discernible effects on physical fitness, but may possibly yield benefits in some domains. This area of investigation is critical for defining *threshold and optimal* levels of activity that are necessary for health promotion and disease management. It should be recognized that what is suitable for prevention may be entirely inadequate for treatment, as is also the case with pharmacological management of chronic diseases. For example, aspirin may reduce the risk of ischaemic heart disease, but a host of potent agents may be required once coronary occlusive disease is present and symptomatic.

Does exercise increase life expectancy?

The effects of exercise on total mortality are unlikely ever to be substantiated via randomized controlled clinical trials, given the impossibility of random assignment to various physical activity regimens over many decades. However, there is clear evidence of an inverse, linear dose–response relationship between the volume of physical activity reported in epidemiological studies (with sample sizes ranging from less than 500 to over 2.5 million individuals) and all-cause mortality rates. These relationships are demonstrable for both men and women and for both older and younger adults. Volumes of energy expenditure during exercise of at least 1000 kcal per week reduce mortality by about 30%, whereas reductions of 50% or more are seen with volumes closer to 2000 kcal per week, when more precise measures or estimates of physical activity participation incorporating fitness assessments are utilized instead of surveys. These changes in all-cause and cardiovascular mortality translate to an increase in life expectancy of ~2 years for those exercising at such volumes. Despite the consistency of the data from well-designed observational studies, many questions still remain regarding the minimum threshold for efficacy, the effect of exercise intensity, duration and frequency (apart from contributions to overall volume), the effect of non-aerobic modalities of exercise and the mechanism of benefit. From a public health perspective, if small, effective doses of moderate-intensity activity are found to be as beneficial as longer bouts of vigorous activity, adoption of mortality-reducing physical activity recommendations by sedentary middle-aged and older adults may be more successful. Of particular relevance to the geriatric exercise prescription are studies which have demonstrated that a change from a sedentary to more active lifestyle in midlife or beyond is associated with a reduction in mortality. In the sections that follow, the focus is on changes in physical fitness and body composition, quality of life and disease burden, rather than on changes in longevity itself. It is in these domains that the centrality of physical activity patterns to optimal ageing is perhaps most relevant to the concerns of the healthcare professional and the older individual.

Preserving exercise capacity with age via an active lifestyle

There is a great similarity between the physiological changes attributable to disuse and those which have been typically observed in ageing populations, leading to the speculation that the way in which we age may be modulated with attention to activity levels.[1] The most important physiological changes associated with ageing or disuse that impact upon exercise capacity are presented in Tables 10.1–10.4. In most physiological systems, the normal

Table 10.1 Changes in exercise capacity due to ageing or disuse potentially modifiable by physical activity.

Component of exercise capacity	Effect of ageing or disuse
Maximum aerobic capacity	Decrease
Tissue elasticity	Decrease
Muscle strength, power, endurance, mass	Decrease
Oxidative and glycolytic enzyme capacity, mitochondrial volume density	Decrease
Gait speed, step length, cadence, gait stability	Decrease

Table 10.2 Changes in cardiorespiratory function due to ageing or disuse potentially modifiable by physical activity.

Cardiorespiratory function	Effect of ageing or disuse
Heart rate and blood pressure response to submaximum exercise	Increase
Maximum heart rate[a]	Decrease
Resting heart rate	No change
Maximum cardiac output, stroke volume	Decrease
Endothelial cell reactivity	Decrease
Heart rate variability	Decrease
Maximum skeletal muscle blood flow	Decrease
Capillary density	Decrease
Arterial distensibility	Decrease
Vascular insulin sensitivity	Decrease
Plasma volume, haematocrit	No change, decrease
Postural hypotension in response to stressors	Increase
Total lung capacity, vital capacity[a]	Decrease
Maximum pulmonary flow rates[a]	Decrease

[a]No evidence yet that exercise can prevent or reverse these changes of ageing.

Table 10.3 Changes in metabolism and body composition due to ageing or disuse potentially modifiable by physical activity.

Metabolic/body composition change	Effect of ageing or disuse
Resting metabolic rate	Decrease
Total energy expenditure	Decrease
Thermic effect of meals	Decrease, no change
Total body water	Decrease
Total body potassium, nitrogen, calcium	Decrease
Protein synthesis rate, amino acid uptake into skeletal muscle, nitrogen retention, protein turnover	Decrease
Gastrointestinal transit time	Increase
Appetite, energy intake	Decrease, no change
Glycogen storage capacity, glycogen synthase, GLUT-4 transporter protein content, translocation to membrane	Decrease
Lipoprotein lipase activity	Decrease
Total cholesterol, LDL[a]cholesterol	Increase
HDL[a]cholesterol	Decrease, no change
Hormonal and sympathetic nervous system response to stress	Increase
Growth hormone, IGF-1[b]	Decrease
Heat and cold tolerance, temperature regulatory ability	Decrease

[a]LDL, low-density lipoprotein; HDL, high-density lipoprotein.
[b]Most training studies show no change in growth hormone or circulating IGF-1 although tissue levels of IGF-1 may increase.

Table 10.4 Changes in central and peripheral nervous system due to ageing or disuse potentially modifiable by physical activity.

Function	Effect of ageing or disuse
REM[a]and slow-wave sleep duration	Decrease
Cognitive processing speed, accuracy	Decrease, no change
Attention span	Decrease, no change
Memory	No change, decrease
Executive function	Decrease, no change
Motor coordination, force control	Decrease
Neural reaction time, neural recruitment	Decrease
Autonomic nervous system function	Decrease

[a]REM, rapid eye movement.

ageing processes do not result in significant impairment or dysfunction in the absence of pathology and under resting conditions. However, in response to a stress or significant disuse, the age-related reduction in physiological reserves ('homeostenosis') may result in difficulty in completing a task requiring near-maximum effort.

Although changes in maximum work capacity (aerobic fitness or maximum oxygen consumption) will be immediately noticeable and disastrous for an elite athlete, they may accrue insidiously in non-athletic populations because most sedentary individuals rarely call upon themselves to exert maximum effort in daily life. Women are particularly susceptible here, because their initial reserve of muscle mass is so much lower than that of men, owing to gender differences in anabolic hormonal milieu and also lifestyle/occupational factors. They will therefore cross this threshold where losses of musculoskeletal capacity impact on functional status at least 10 years before men do on average.

Another important consequence of age-related changes in physiological capacity is the increased perception of effort associated with submaximum work (a lowering of the anaerobic threshold or the approximate level at which significant dyspnoea occurs). This changing physical capacity has the unfortunate negative side effect of increasing the tendency to avoid stressful activity. Such behavioural change compounds the sedentariness caused by changing job requirements or retirement, societal roles and expectations and other psychosocial influences. Thus, a vicious cycle is set up: 'usual' ageing leading to decreasing exercise capacity, resulting in an elevated perception of effort, subsequently causing avoidance of activity and finally feeding back to exacerbation of the age-related declines themselves secondary to the superimposition of disuse on biological ageing.

Many studies suggest that chronic adaptation to physical activity can markedly attenuate decrements in exercise capacity that would otherwise occur with ageing (see Tables 10.1–10.4), with the notable exception of maximum heart rate (due to declining sensitivity to β-adrenergic stimulation in the ageing heart).[2] Although the peak exercise workload achievable is therefore always lower in aged individuals, the cardiovascular and musculoskeletal adaptations to chronic aerobic exercise enable the trained individual to sustain higher submaximum workloads with less of a cardiorespiratory response (heart rate, blood pressure and dyspnoea), and also less overall and musculoskeletal fatigue.

Musculoskeletal function (strength, power, muscle endurance) in ageing is dictated largely by the size of the muscle mass which is contracting and to a lesser extent by changes in surrounding connective tissue in the joint (cartilage, tendons and ligaments) and neural recruitment, conduction velocities, glycolytic and oxidative enzyme capacities and fatigue patterns. Sedentary individuals lose large amounts of muscle mass over the course of adult life (20–40%) and this process, termed *sarcopenia*, plays a major role in the similarly large losses in muscle strength observed in both cross-sectional and longitudinal studies.[3] However, unlike many other changes which impact on exercise capacity, muscle mass cannot usually be maintained into old age even with regular aerobic

activities in either general populations or master athletes. Only overloading of muscle with weight-lifting exercise (resistance training) has been shown largely to avert losses of muscle mass (and also strength) in older individuals. For example, Klitgaard *et al*.[4] found that elderly men who swam or ran had similar measures of muscle size, strength and metabolism as their sedentary peers, whereas the muscle of older men who had been weight-lifting for 12–17 years was almost indistinguishable, and even superior in some aspects, to that of healthy men 40–50 years younger than them.

Clearly, habitual exercise has the potential to lessen the impact of biological ageing on two of the major elements of exercise capacity: aerobic fitness and muscle strength. Similarly, there is evidence that balance training and flexibility training[5] induce adaptations in associated declines in these areas.

Optimization of body composition with ageing

'Usual ageing' is associated with significant losses of bone and muscle (lean mass) and increases in adipose tissue, along with central and visceral shifts in the regional distribution of adipose tissue stores. The extent to which these changes occur in an individual depends upon a combination of genetic-, lifestyle- and disease-related factors that are all interrelated. All of these body composition changes may impact negatively upon metabolic, cardiovascular and musculoskeletal function,[6] even in the absence of overt disease, and therefore it is important to anticipate them and optimize lifestyle choices and other treatments which can counteract the negative effects of ageing and/or disease on body composition. As detailed in the sections that follow and outlined in Table 10.5, one of the most potent pathways from physical activity to health status involves the modulation of these age-related shifts in body composition by habitual exercise patterns.

Role of exercise and physical activity in bone health and fracture risk

Age-related changes in bone

Bone mass begins to decrease well before the menopause in women (as early as the 20s in the femur of sedentary women) and accelerates in the perimenopausal years, with

Table 10.5 Exercise recommendations targeting optimal body composition for older adults.

Exercise recommendations	Decreased adipose tissue mass and visceral deposition	Increased muscle mass and strength	Increased bone mass, density and reduced fracture risk
Modality	Aerobic or resistance training	Resistance training	• Resistance training or aerobic training[a] • High-impact activities (jumping using weighted vest during exercise) if tolerated by joints • Balance training
Frequency	Aerobic: 3–7 days/week Resistance: 3 days/week	3 days/week	• Resistance or aerobic training: 3 days/week • Balance training: up to 7 days/week
Volume	Aerobic: 30–60 min/session Resistance: 2–3 sets of 8–10 repetitions of 6–8 muscle groups	2–3 sets of 8–10 repetitions of 6–8 muscle groups	• 30–60 min of aerobic training • 2–3 sets of 8–10 repetitions of 6–8 muscle groups • 50 jumps per session for high impact[b] • 2–3 repetitions of 5–10 different static and dynamic balance postures
Intensity	Aerobic: 60–75% of maximum exercise capacity ($VO_{2\ max}$ or maximum heart rate) or 13–14 on the Borg Scale of perceived exertion Resistance: 60–80% of maximum strength (one repetition maximum) exertion	60–80% of maximum capacity (one repetition maximum)	• 60–80% of maximum capacity (one repetition maximum) as load • 5–10% of body weight in vest during jumps; jumps or steps of progressive height • Practice most difficult balance posture not yet mastered

[a]Aerobic exercise should be weight-bearing modalities of exercise with high ground-reaction forces (e.g. walking, jogging, running, stepping, rather than swimming or cycling).
[b]Thus far proven only in premenopausal women.

continued declines into late old age. Similar patterns are seen in men, without the acceleration related to loss of ovarian function seen in women. As with losses of muscle tissue (sarcopenia), many genetic-, lifestyle-, nutritional- and disease- and medication-related factors enter into the prediction of bone density at a given age.

Physical activity and bone health

A wealth of animal and human data provide evidence for a relationship between physical activity and bone health at all ages. Mechanical loading of the skeleton generally leads to favourable site-specific changes in bone density, morphology or strength, whereas unloading (in the form of bed rest, immobilization, casting, spinal cord injury or space travel) produces rapid and sometimes dramatic resorption of bone, increased biochemical markers of bone turnover, changes in morphology such as increased osteoclast surfaces and increased susceptibility to fracture.

Comparative studies of athletic and non-athletic populations usually demonstrate significantly higher bone density in the active cohorts, ranging from 5 to 30% higher, depending on the type, intensity and duration of exercise training undertaken and the characteristics of the athletes studied. Exceptions occur with non-weight-bearing activities such as swimming or amenorrhoeic or competitive distance runners, who appear similar to controls. Similarly, on a smaller scale, differences are often observed between habitually active and sedentary non-athletic individuals.

Experimental evidence in animal models and also some human data suggest that changes in bone strength not directly correlated with density may contribute to the overall benefits of mechanical loading for skeletal integrity and resistance to fracture (e.g. increased bone volume or altered trabecular morphology), so that evaluating bone density changes alone likely underestimates the skeletal effects of loading.

Consistent with bone density findings noted above, hip fracture incidence has been observed to be as much as 30–50% lower in older adults with a history of higher levels of physical activity in daily life, compared with age-matched, less active individuals. For example, in the prospective epidemiology of osteoporosis study (EPIDOS) study of 6901 white women over the age of 75 years followed for 3.6 years, investigators found that a low level of physical activity increased the risk for proximal humerus fracture by more than twofold. The relative risk of fracture in sedentary women (RR = 2.2) was greater than that attributable to low bone density (RR = 1.4), maternal history of hip fracture (RR = 1.8) or impaired balance (RR = 1.8). The interaction of these risk factors is indicated by the fracture rate, which rose from about 5 per 1000 woman-years in individuals with either bone fragility or high fall risk to 12 per 1000 woman-years for women with both types of risk factors. Such data suggest the great potential utility of multifactorial prevention programmes for osteoporotic fracture that can address both bone density and fall risk (sedentary behaviour, sarcopenia, muscle weakness, poor balance, polypharmacy, etc.) simultaneously.

Exercise intervention trials in postmenopausal women and older men

Significant changes in the femur, lumbar spine and radius have been seen following aerobic training, resistance training and combined programmes of aerobic and resistive exercise. Unlike results obtained in younger women, isolated high-impact training (jumping, skipping, heel drops) has not yet been found to be effective in studies of postmenopausal women. High dropout rates (30–50%) are problematic in these trials, raising the issue of generalizability and sustainability of the outcomes observed. This is particularly relevant to fracture prevention efficacy of exercise, as several studies have shown complete or partial reversal of gains in bone mineral density (BMD) after the cessation of training.

For older men and women, a combination of decreased anabolic hormones (estrogen, testosterone, growth hormone), increased catabolic milieu (higher leptin and cortisol associated with visceral adipose tissue), the emergence of musculoskeletal and other diseases, retirement and reduced recreational activities have a major negative impact on both bone and muscle tissue. The majority of studies demonstrating the efficacy of aerobic or resistive exercise on bone density have been conducted in women between 50 and 70 years of age and it is not yet known if efficacy would be similar in older women with multiple comorbidities, who have usually been excluded from such trials. Both types of exercise have approximately equivalent effects on bone health in postmenopausal women of about 1–1.5% per year between exercisers and non-exercisers in meta-analyses of well-designed trials.

Optimal exercise modality and intensity for bone health

The predominant exercise training factor that influences bony adaptation is the intensity and novelty of the load, rather than the number of repetitions, sets or days per week or even total duration of the programme. This observation is also true for animal models of mechanical loading, in which bone is most sensitive to short periods of loading characterized by unusual strain distribution, high strain magnitudes and rapid rate of loading.

The relative efficacy of aerobic versus resistive exercise regimens for postmenopausal women may perhaps be best assessed via studies that have directly compared various intensities of these two exercise modalities in randomized subjects. Kohrt *et al*.[7] found that both aerobic activities with high ground-reaction forces (walking, jogging, stair climbing) and exercises with high joint-reaction forces (weight-lifting, rowing) significantly increased the BMD of the whole body, lumbar spine and Ward's triangle,

whereas only the ground-reaction group increased BMD at the femoral neck.[7] The weight-lifting group preserved femoral-neck BMD relative to controls, as has been seen in other resistance training studies. However, lean mass and muscle strength increased only in the weight-lifting group, leaving overall benefits of these two types of exercise for ultimate fall and fracture prevention still unresolved. Kerr *et al*.[8] randomized 126 postmenopausal women to 2 years of high-intensity weight-lifting exercise, moderate-intensity aerobic training (circuit training and stationary cycling) or sedentary control condition. Total hip and intertrochanteric BMD was improved only by strength training and was significantly different from aerobic training or control groups (+3.2% at 2 years). As most comparative studies other than those of Kohrt *et al*.[7] and Kerr *et al*.[8] have not sought to optimize both modalities, it is still not possible to choose definitively one best modality for all bone sites. In general, the older the individual, the more favourable the resistance training appears, due to its broader benefits on muscle, bone, balance and fall risk, relative to aerobic training. If aerobic training is chosen, however, activities that are weight bearing and higher impact have a greater efficacy than non-weight-bearing or low-impact aerobic activities.

It is important to consider not only the optimal modality of exercise, but also the relative intensity, as the skeletal adaptation is critically linked to the *intensity* of the loading (whether due to increased amount of weight lifted during resistance training or higher ground-reaction forces during aerobic/jumping activities). Interesting results have been reported by Cussler *et al*.[9] in a randomized trial of 140 postmenopausal women participating in a multimodal exercise programme (high-intensity resistance training and a weight-bearing circuit of moderate-impact activities including walking/jogging, skipping, hopping, stair climbing/stepping with weighted vests). Bone density improvements at the femoral trochanter were significantly and linearly related to total weight lifted during the 12 months, and also total weight lifted in leg press, squats and military press exercises, but not to volume or quality of the non-resistance training components of the programme. High-intensity resistance training is also more beneficial than low-intensity training for muscle strength gains and muscle hypertrophy, in addition to associated gait disorders, functional impairments and disability, making it ideal as a multiple risk factor intervention strategy for injurious falls in osteopenic women.

Exercise in the treatment of osteoporotic fracture

In older men and women who have already sustained an osteoporotic fracture, exercise is still extremely important to assist in recovery of function and also prevent recurrent injurious falls. Progressive resistance training has been shown to be superior to standard physical therapy during the recovery from hip fracture in elderly patients. In addition, resistance training has been shown to be a potent treatment for depression in the elderly and may thus be able to substitute for antidepressant medications, which are known to increase the risk of falls and hip fracture. A combination of resistance training and balance training may offer the best approach to rehabilitation in this setting, as it optimally targets several of the remediable physiological risk factors for falls, fractures and disability in this cohort. Additional studies are needed to define the effects of training in this clinical setting on bone density and strength itself, and also the optimal timing and duration of such interventions in the post-fracture recovery period.

Role of exercise and physical activity in adipose tissue accretion and distribution

The rising epidemic of obesity is now recognized internationally in both younger and older cohorts and is projected, if it continues, to lead to major changes in related diseases such as diabetes, and also life expectancy itself. Prevention of excess adiposity is both protective, and in some cases therapeutic, for many common chronic diseases, offering significant risk reduction in the case of osteoarthritis, cardiovascular disease, gall bladder disease, type 2 diabetes, breast, colon and endometrial cancer, hypertension, stroke and vascular impotence, for example. Although generalized obesity is associated with excess mortality, cardiovascular disease, osteoarthritis, mobility impairment and disability, it is predominantly excess visceral fat that is associated with the derangements of dyslipidaemia, elevated fibrinogen, hyperinsulinaemia, glucose intolerance or diabetes, vascular insulin resistance, hypertension and cardiovascular disease known as *metabolic syndrome* or *insulin resistance syndrome*. Reductions in visceral fat have been shown to improve glucose tolerance and insulin sensitivity in non-diabetic and type 2 diabetic subjects and changes in trunk fat correlate with improved glycaemic control in type 2 diabetics.[10] Hence the potential for exercise to impact favourably on the accretion and distribution of adipose tissue, as reviewed below, has enormous significance in that it may reduce the burden of disease expressed in the ageing population.

Cross-sectional studies of physical activity and fat mass

Numerous cross-sectional analyses have confirmed an inverse relationship between physical activity and abdominal fat. Master athletes compared with age- and BMI-matched controls have lower waist circumference and physically active women have lower waist-to-hip ratios than inactive women. It has been determined that the higher the intensity of activity independent of energy expenditure, the lower are the abdominal fat estimates for men and women. In a study of monozygotic and

dizygotic female twins, physical activity was the strongest predictor of central obesity after controlling for genetic and environmental factors and this persisted for those with a genetic predisposition to obesity.

Experimental studies of the influence of physical activity on abdominal fat

In the last few years, there has been accumulating evidence from well-designed studies supporting the benefit of physical activity in reducing total abdominal fat. There is no evidence that age limits abdominal fat loss secondary to exercise. In fact, most studies have included middle to older aged populations who have higher accumulation of abdominal and visceral fat than younger adults. They are more likely to demonstrate a greater magnitude of change than subjects who have lower abdominal fat mass at baseline. Furthermore, the potential for physical activity to attenuate the gain in visceral fat is evident in the obese as early as childhood.

Decreases in both total adipose tissue accumulation and its abdominal (visceral) deposition are achievable by both aerobic and resistive training, with significant changes in total body fat usually only in conjunction with an energy-restricted diet or very large volumes of exercise (7 h per week). Preferential visceral fat mobilization is often seen in response to exercise and dietary intervention, which means that small amounts of total body weight or fat mass (5%) may be associated with substantial changes in visceral fat (25% or more), with important metabolic implications for the prevention or treatment of the insulin resistance syndrome.

Exercise and diet in combination are the most effective non-surgical treatment for obesity and this approach is uniformly advocated by international consensus panels. The advantages of adding exercise to diet alone include greater weight loss, preservation of fat-free mass and resting metabolic rate, improved fitness levels, correction of metabolic abnormalities associated with visceral obesity and better long-term adherence to dietary modifications producing sustained weight maintenance. Therefore, robust exercise plus diet appear to represent an optimal evidence-based treatment for obesity.

Relationship between exercise intensity and changes in body fat

In general, weight loss parallels energy expenditure via exercise, whether achieved by greater volumes, intensities or durations of the exercise prescription. There is no evidence yet from well-designed studies that low-intensity exercise is effective for reducing abdominal fat. Most robustly designed studies have used moderate- to high-intensity aerobic interventions. An overall higher intensity stimulus can be delivered via intermittent intensities with resistance or interval training, a prescription which may be effective and more easily tolerated by 'at-risk' populations than sustained, intense exercise.

Relationship between exercise modality and changes in body fat

There is no evidence that aerobic training is better than resistance training for reducing abdominal fat. Both resistance and aerobic exercise, at doses resulting in a sustained negative energy balance for several months, will generally result in significant reductions in fat mass when sensitive measurement techniques (generally not anthropometrics) are used. Resistance exercise may be more suitable as a fat reduction strategy for older obese individuals who have cardiovascular disease, arthritis, osteoporosis or mobility disorders, who may not tolerate moderate- to high-intensity aerobic training or who may need the added benefits of resistance training for maintenance of muscle and bone mass. Importantly, energy restriction results in significant losses of muscle and bone and the addition of resistance training to hypocaloric dieting has been shown to prevent such adverse body composition changes,[11] whereas aerobic exercise alone does not. Combined aerobic and resistance training has demonstrated a superior effect to aerobic training alone on trunk fat for older men. More well-designed studies are needed, particularly in overweight older adults, to explore the relative benefits of these modes of exercise for optimizing body composition.

Role of exercise in muscle mass preservation with age

An increase in muscle mass, in contrast to changes in fat and bone, is only achievable to a significant degree with progressive resistance training or generalized weight gain from extra energy and protein consumption and has a potential role in prevention of diabetes,[12] functional dependency and falls and fractures, in addition to being important in the treatment of chronic diseases and disabilities which are accompanied by disuse, catabolism and sarcopenia. For some diseases, such as type 2 diabetes mellitus, there are potential advantages to both minimizing fat tissue and maximizing muscle tissue, since these compartments have opposite and likely independent effects on insulin resistance in the elderly. Resistance exercise coupled with a leucine-enriched essential amino acid diet is recommended for the treatment of sarcopenia.[13] Muscle wasting or atrophy from any cause will exacerbate problems related to the extent and rate of the peripheral disposal of glucose into skeletal muscle, which is essential for maintenance of euglycaemia in response to normal metabolism, meals or other stressors. There is evidence from a variety of epidemiological and experimental studies that muscle weakness, decreased muscle mass, decreased activation of glycogen synthase and alterations in numbers of type IIb skeletal

muscle fibres are related to, and may precede, insulin resistance, glucose intolerance and type 2 diabetes expression. Thus, the typical alterations in body composition with ageing (decreased muscle mass and increased visceral adiposity) are potentially independently related to the development of impaired glucose homeostasis in older adults.

Exercise to maintain or increase muscle mass

Appropriate progressive resistance training programmes of 3–6 months' duration can be shown to increase muscle strength by an average of 40–150%, depending on the subject's characteristics and intensity of the programme and to increase total body lean mass by 1–3 kg or muscle fibre area by 10–30%.[14] Thus, even if some of the neural control of muscle and absolute number of motor units remaining is not affected by exercise, the adaptation to muscle loading, even in very old age,[15] causes neural, metabolic and structural changes in muscle which can compensate for the strength losses, and in some cases the atrophy, of ageing. Generally, strength gains after exercise far exceed, and are not directly correlated with, changes in muscle size, due to the importance of neural adaptation in this process.

Predictors of muscle hypertrophy after exercise

There is some controversy as to whether or not there are significant gender differences in the functional or hypertrophic response to resistance training in the elderly. Some studies have found women to have smaller gains in muscle strength and power or hypertrophic response to training, whereas others have found no differences or even greater gains in women. It is likely that differences in training regimens (particularly related to intensity) and measurement techniques used to assess muscle mass, cross-sectional area or volume may explain some of these discrepant results. Malnutrition, impaired protein synthesis rates, inflammatory cytokines and depression are other factors that have been identified as detrimental to robust anabolic adaptations to resistance training in some studies.

High-velocity resistance training

A relatively recent area of investigation is that of power training (high-velocity resistance training), which has been proposed as a better way to target the selective fast-twitch fibre atrophy characteristic of ageing muscle, and also the earlier and more precipitous decline in muscle power and its associated disability, relative to muscle strength in older men and particularly women. Power training has been shown to be effective in both healthy[16] and frail elders[17] and results in muscle hypertrophy, strength and power gains and improvements in balance and functional performance. Optimal training regimens for maximization of muscle power are still being defined.

Promotion of psychological well-being

Psychological well-being is vital to optimal ageing and is dependent on a host of factors, including genetic traits, social support systems, personality types and the presence of positive and negative psychological constructs such as happiness, optimism, morale, depression, anxiety, self-esteem, self-efficacy and vigour. Physical activity participation has been shown to be associated with more positive psychological attributes and a lower prevalence and incidence of depressive symptoms in cross-sectional and prospective epidemiological studies and experimental trials.[18,19] It is notable that effects are most significant in those with comorbid illness, such as cardiovascular or pulmonary disease or major depression,[18,20] attesting to the clinical relevance of this exercise adaptation.

The experimental evidence for exercise as an isolated intervention for the treatment of clinical depression in both younger and older cohorts is robust and consistent. Both aerobic and resistance training exercise produce clinically meaningful improvements in depression in such patients, with response rates ranging from 25 to 88%. In the studies that have addressed the issue of exercise modality, resistance training was found to be equivalent to aerobic training in young adults with depression and yoga as effective as aerobic exercise. Blumenthal *et al*. directly compared high-intensity aerobic exercise with antidepressant medications in older adults with major depression and found the two approaches to be equipotent, with no added benefit of combined exercise and medication.[20] Singh *et al*. compared high- and low-intensity progressive resistance training to GP referral and care in older adults with major depression and found that a clinical response (50% reduction in Hamilton Rating Scale for depression) was achieved in 61% of high-intensity training, 29% of low-intensity training and 21% of the GP care group.[19] Similarly, low-intensity aerobic training in older adults with depression has been shown to be similar in efficacy to social contact, reducing depression scores by only 30%. Thus, the literature on exercise and depression suggests that it is effective in young and old, it is approximately as effective as antidepressants in clinical cohorts, that both aerobic and resistance modalities appear equally beneficial and that optimal responses are seen with higher intensities of training.

Exercise and cognitive function

There is a growing body of observational data and experimental evidence that physical activity can exert significant influences on a wide range of cognitive functions.[21] The earliest lines of evidence were provided by cross-sectional studies of athletes or physically active individuals versus sedentary controls, with active or fit individuals demonstrating superior performance in tests of reaction

time, motor control and visual–spatial tasks. Changes in executive-control processes and also changes in brain structures and functions most closely related to these processes are disproportionately affected by ageing and exercise in some studies.[21,22] This has led to speculation that age-related cognitive dysfunction might be partially mediated by suboptimal and diminishing participation in physical activity across the lifespan. Virtually all of these studies have focused on cardiorespiratory fitness (maximum oxygen consumption) or aerobic exercise as the putative protective factor. However, ~50% of the variance in maximum oxygen consumption in children and adults is thought to be mediated by genetic factors rather than physical activity patterns,[23] raising the possibility that shared predisposition to low fitness, vascular risk factors and cognitive decline may explain these associations, rather than adaptation to an active lifestyle. In addition, changes in maximum oxygen consumption with ageing are explained as much by losses of muscle mass (sarcopenia) as they are by losses of cardiovascular reserve, suggesting that non-aerobic activities could be just as important as aerobic activities for the prevention of cognitive decline.

More recently, well-designed prospective cohort studies that have controlled for many known risk factors for cognitive dysfunction have in large part supported cross-sectional associations between physical activity patterns and risk of dementia.[24] For example, in the Honolulu–Asia Aging Study,[25] 2257 physically capable, cognitively intact men aged 71–93 years were followed for 7 years for incident dementia. Walking significantly reduced the risk of dementia in a dose-dependent fashion, with a 1.8-fold increased risk for those who walked less than 0.25 miles per day compared with >2 miles per day, controlling for other possible risk factors.

Acute exposure to even one bout of aerobic exercise may result in improved cognitive test performance, and also reduced depressive symptoms and anxiety. It is not known how long such acute bout effects persist, whether weight-lifting exercise has similar acute effects on cognition or what proportion, if any, of the chronic exercise effects are explained by cumulative acute bout effects. Animal data demonstrate that voluntary wheel running (not stressful forced swimming) is a powerful means to enhance neural plasticity and function, improving learning and memory, in addition to increasing the availability of brain-derived neurotrophic factor (BDNF), formation of new neurons and synaptic transmission in the hippocampus. Exercise also protects against the neurotoxicity of ageing, stress, cortisol or estrogen withdrawal in these animal models and potentiates the beneficial effect of estrogen and antidepressants on hippocampal volume and metabolism.

A recent meta-analysis found that physical exercise protected against physical decline with an effect size of 0.62.[26] Exercise also slows decline in persons with Alzheimer's disease.[27] Aman and Thomas[28] found that supervised exercised reduced agitation in nursing homes.

Potential mechanisms by which exercise could improve cognitive function include changes in fitness, increased cerebral blood flow, reduction in depression, increase in presence or activity of neurotrophic factors [BDNF, insulin-like growth factor-1 (IGF-1)], downregulation of neurotoxic factors [C-reactive protein, cortisol, interleukin-6 (IL-6)] and other inflammatory cytokines and prevention or better control of chronic disease (e.g. stroke, diabetes, cardiovascular disease). Considering the non-robust nature of most of the interventions reported in Heyn *et al*.' s meta-analysis of cognitively impaired elders,[29] it does not appear that increases in aerobic capacity are required for cognitive benefits to accrue, as was previously thought. Cognitive benefits seen after non-aerobic exercise also cast doubt on a central role for aerobic capacity. The other mechanisms noted above appear more likely at this time. Exercise does increase cerebral blood flow acutely, as do cognitive tasks, and increased frontal cortex capillary density has been observed in animal models after exercise training, suggesting a possible common pathway for improved brain oxygenation and, thereby, function. Many of the most promising mechanisms in animal models have yet to be confirmed in human studies. Further exploration of the potential mechanisms of benefit in this crucial domain of health and function is needed, including studies linking changes in cerebral blood flow, depressive symptoms, physical fitness or burden of chronic disease and disability to cognitive changes associated with exercise participation.

Disease prevention through exercise

Both healthy and chronically ill older adults are candidates for preventive strategies that will lessen the burden of comorbidity, disability and premature death caused by incident disease. Physical activity patterns may be influenced by ageing and genotype and physical activity in turn may influence physiological capacity, psychological health, dietary intake, other adverse behaviours or risk factors for chronic disease. All of these are potential pathways by which exercise could ultimately influence the prevalence of chronic disease in a population. Other than genetic factors and environmental insults (pollution, asbestos, heavy metals, infectious agents, etc.), most of the major contributors to the development or severity of chronic diseases are in some way related to habitual levels of physical activity. Examples include cardiovascular disease, stroke, type 2 diabetes,[12] obesity, hypertension, osteoarthritis, depression[20] and osteoporosis. A notable exception to these patterns is the diseases of the central nervous system (CNS) (e.g. Parkinson's disease, other degenerative neurological diseases) that have not been substantively linked aetiologically with exercise or physical activity.

Although appropriate levels of physical activity may optimize such risk factor profiles, on the other hand, the presence of risk factors may lead to reduced physical activity and thus heightened risk of disease. For example, inactivity may lead to sarcopenia, followed by muscle weakness and further restriction in activity levels, subsequently contributing to the development of osteopenia and gait abnormalities and finally hip fracture.

Although observational studies can never completely separate the effects of physical activity from genotype or other unmeasured characteristics of individuals who self-select an active lifestyle, the best studies attempt to control for demographic differences and other known risk factors for the incident disease and eliminate early or occult disease at baseline if possible prior to analysis. Thus, for example, exercise reduces the risk of cardiovascular disease by ~50%, even after controlling for such risk factors as smoking, obesity, hypertension and dyslipidaemia.

Longitudinal cohort studies have generally confirmed the cross-sectional data linking exercise to reduced disease risk. Of particular interest are studies in which middle-aged sedentary adults with low fitness levels have become fit at follow-up and have markedly reduced cardiovascular mortality compared with those remaining unfit or inactive. These findings suggest that preventive exercise prescriptions instituted in middle age or beyond may be as important as those initiated at younger ages.

Randomized clinical trial data are available for the prevention of some disease states (cardiovascular disease, diabetes mellitus and falls) but are not yet available for others (stroke, osteoporotic fracture, depression). Diabetes is clearly preventable in high-risk obese adults with impaired glucose tolerance randomized to exercise and diet, as shown in the Finnish Diabetes Study[12] and the Diabetes Prevention Program (DPP).[30] Similarly to Finnish subjects, DPP participants randomly assigned to the intensive lifestyle intervention of diet and exercise reduced their risk of incident type 2 diabetes by 58% by 3 years. Of particular interest is the finding that those over the age of 60 years responded best, with a 71% reduction in incident diabetes in this time frame.

The major diseases and syndromes for which exercise may be beneficial as a preventive strategy are listed in Table 10.6, along with the postulated mechanisms of exercise benefit and the specific modality of exercise most relevant for these outcomes.

Evidence for the role of exercise in the treatment of disease

Mechanisms of benefit

There are many ways to conceptualize the integration of exercise into the treatment of established disease. For example, traditional medical interventions do not typically address disuse syndromes accompanying chronic disease, which may be responsible for much of their associated disability. Exercise is particularly good at targeting syndromes of disuse and may thus impact significantly on disability without altering the underlying disease itself in any primary way. Examples include Parkinson's disease, chronic obstructive pulmonary disease and chronic renal failure. Exercise may also lower the risk for recurrences of a disease, such as secondary events in patients with cardiovascular disease or prevention of recurrent injurious falls in an individual after a hip fracture. Some pathophysiological aberrations that are central to a disease are specifically addressed by exercise, which may therefore serve as an adjunct to standard care. For example, losses of visceral fat achieved through resistive or aerobic training improve insulin resistance and complement dietary and pharmacological management of type 2 diabetes in the older adult with central obesity.

Exercises designed to stimulate skeletal muscle hypertrophy in congestive heart failure provide benefit that counteracts the catabolic effects of circulating cytokines in this disease and is not achievable with cardiac medications alone. Functional improvements in individuals with arthritis who are given quadriceps exercises improve joint stability and may thus add to the benefits of anti-inflammatory and analgesic medications. It is not possible in this chapter to review every disease in which exercise has beneficial effects and therefore we will use type 2 diabetes as one example of the diseases outlined in Table 10.7.

Exercise in the treatment of type 2 diabetes

The prevalence of type 2 diabetes appears to be rising precipitously, linked to the rise in obesity throughout the world. Most of the individuals concerned have scope for lifestyle modification, in particular for suboptimal levels of physical activity. Cardiovascular disease accounts for half of the mortality in older type 2 diabetics,[31] emphasizing the complex clinical syndrome represented by this cohort.

The value of tight regulation of glucose in type 2 diabetics has been convincingly demonstrated in the UK Prospective Diabetes Study, among others.[32] This is particularly important in the elderly, who may have glucose intolerance and then diabetes for many decades and are therefore at extremely high risk for end organ damage due to glycosylation of body proteins. Although glycaemic control has been proven to be highly effective in controlling diabetes, the deleterious effects of central obesity and lack of exercise can undo the benefits of proper medical management and therefore may hasten the emergence of disease complications in susceptible individuals with insulin resistance. Weight loss diets are clearly central to the management plan of obese type 2 diabetics and may be aided by the use

Table 10.6 Potential mechanisms by which exercise can prevent disease.

Disease or syndrome	Postulated mechanisms of exercise effect	Recommended exercise modality
Arthritis	• Decreased body weight • Maintenance of cartilage integrity • Maintenance of muscle and tendon strength	Aerobic exercise[a] Resistance exercise[a]
Cancer (breast, colon, prostate)	• Decreased body fat • Decreased estrogen levels • Altered dietary intake • Decrease in gastrointestinal transit time • Increased prostaglandin F2	Aerobic exercise
Chronic renal failure	• Reduced risk of hypertension • Reduced risk of type 2 diabetes mellitus	Aerobic exercise Resistance exercise[a]
Congestive heart failure	• Decreased risk of ischaemic heart disease • Decreased risk of hypertension • Decreased risk of type 2 diabetes mellitus	Aerobic exercise[a] Resistance exercise[a]
Coronary artery disease	• Decreased blood pressure • Decreased LDL cholesterol • Increased HDL cholesterol • Decreased fibrinogen • Decreased total body fat, visceral fat • Decreased insulin resistance, hyperinsulinaemia • Decreased cortisol levels, inflammatory cytokines • Increased adherence to smoking cessation, dietary behaviours • Decreased depression, anxiety • Improved endothelial cell function	Aerobic exercise Resistance exercise
Dementia	• Improved cerebral blood flow • Increased neurotrophic factors in CNS • Hippocampal neurogenesis	Aerobic exercise
Depression	• Increased self-efficacy, mastery • Internalized locus of control • Decreased anxiety • Improved sleep • Increased self-esteem • Increased social engagement; decreased isolation • Decreased need for drugs associated with depression (beta-blockers, alpha-blockers, sedative hypnotics) • Decreased body fat, improved body image	Aerobic exercise Resistance exercise[a]
Osteoporotic fracture	• Increased bone density • Increased tensile strength • Increased muscle mass • Improved gait stability and balance • Improved nutritional intake (energy, protein, calcium, vitamin D) • Reduced fear of falling, improved self-efficacy • Increased overall activity levels, mobility • Decreased need for drugs associated with postural hypotension, falls, hip fractures (antidepressants, anti-hypertensives, sedative-hypnotics)	Resistance exercise[a] Aerobic exercise[a] Balance exercise[a]

(*continued overleaf*)

Table 10.6 (*continued*).

Disease or syndrome	Postulated mechanisms of exercise effect	Recommended exercise modality
Stroke	• Decreased obesity • Decreased blood pressure • Decreased cholesterol	Aerobic exercise Resistance exercise[a]
Type 2 diabetes mellitus	• Improved insulin sensitivity • Increased GLUT-4 protein and translocation to membrane sites • Reduced visceral fat mass • Decreased cortisol response to stress • Improved dyslipidaemia • Decreased blood pressure • Increased muscle mass	Aerobic exercise Resistance exercise (combined with diet and aerobic exercise)

[a]Indicates that the modality of exercise has been shown to affect the postulated mechanistic factors, but not yet shown to prevent the distal disease outcome.

of metformin as an appetite suppressant or acarbose as a means to decrease the extent of carbohydrate absorption. However, the difficulty of long-term weight management via dietary restriction is well known in the clinical setting, due to a variety of factors that impede such behavioural change in older adults. In addition, weight cycling due to repetitive attempts at sustained weight loss leads to losses of lean tissue (muscle and bone) and decreases in metabolic rate, thus worsening the energy balance equation in the end and making dietary management more and more difficult. Therefore, the standard care of obese type 2 diabetics leaves the majority of them suboptimally managed in relation to their primary metabolic derangement: *insensitivity to the action of insulin*.

All consensus panels recommend aerobic exercise as part of the management plan in type 2 diabetes. Moderate- or high-intensity aerobic exercise of 3–4 h per week results in improved insulin sensitivity and glucose homeostasis, assists in attainment or maintenance of lower body weight, reduces visceral fat depots, modestly improves blood pressure and lipids and lowers the risk of cardiovascular morbidity and mortality.

However, the clinical management of the obese elderly patient with this disease is often complicated by increasing insulin resistance and resultant polypharmacy, in addition to multiple other comorbid health conditions that impede compliance with both diet and aerobic exercise and reduce quality of life. For example, it would not be unusual for an older diabetic to present with obesity, osteoarthritis, ischaemic heart disease, hypertension, gout, hyperlipidaemia, peripheral vascular disease, sleep apnoea, peripheral neuropathy, a gait and balance disorder, functional impairment, renal disease, postural hypotension, bladder dysfunction, retinal disease and depression. Such *disease clustering* makes the application of standard dietary and exercise recommendations in addition to intense pharmacological management a challenge to practitioner and patient alike. It is not surprising that aerobic exercise recommendations, endorsed by all international consensus panels, are often difficult or impossible to implement in such patients. In particular, obesity, osteoarthritis, amputations, visual impairment, foot problems, fall risk, orthostatic hypotension, peripheral vascular disease and a low threshold for ischaemia may make aerobic exercise at the volumes and/or intensities shown to produce metabolic benefits in clinical trials unrealistic in practice.

An alternative approach to aerobic exercise recommendations for diabetics is the use of progressive resistance training. Insulin resistance is worsened by loss of muscle mass, decreased glucose transport into skeletal muscle and subsequent glycogen storage, catabolic/inflammatory mediators, inactivity, visceral fat and related inflammatory cytokines such as IL-6 and C-reactive protein. The specific indications for resistance training in older diabetics include its ability to combat age and diabetes-related sarcopenia, to prevent loss of muscle and bone mass and reduced resting metabolic rate which otherwise accompanies hypocaloric dieting, to increase glucose uptake and storage in skeletal muscle, to reduce visceral fat depots, to reduce C-reactive protein, as well as its beneficial effects on resting blood pressure, functional status, mobility, sleep and depressive symptoms. The effects on muscle mass are unique to high-intensity resistance training and clearly distinguish it from aerobic exercise. For this reason, some experts are currently recommending its addition to recommendations for aerobic exercise and dietary modification. A review of the randomized controlled trial evidence upon which such recommendations are made is presented in

Table 10.7 Exercise and disease treatment.

Disease state	Exercise of choice	Considerations
Arthritis	Aerobic	Low impact
	Resistance training	Sufficient volume to achieve healthy weight if obese
Chronic insomnia	Aerobic	Exercise 4–6 h before desired bedtime to maximize effects
	Resistance training	
Chronic obstructive pulmonary disease	Aerobic	Resistance training may be more tolerable in severe disease; combined effects complementary if feasible
	Resistance training	Time exercise sessions to coincide with bronchodilator medication peak
		Use oxygen during exercise as needed
Chronic renal failure	Aerobic	Exercise reduces cardiovascular and metabolic risk factors, improves depression
	Resistance training	Resistance training offsets myopathy of chronic renal failure
Congestive heart failure	Aerobic	Resistance training may be more tolerable if dyspnoea severely limits aerobic activity
	Resistance training	Cardiac cachexia targeted by resistance training
Coronary artery disease	Aerobic	Complementary effects on exercise capacity and metabolic profile from combined exercise modalities
	Resistance training	Resistance training may be more tolerable if ischaemic threshold is very low due to lower heart rate response to training
Depression	Aerobic	Moderate- to high-intensity exercise more efficacious than low-intensity exercise in major depression
	Resistance training	Minor depression may respond to wider variety of exercise modalities and intensities
Hypertension	Aerobic	Small–moderate reduction in systolic and diastolic pressures seen
	Resistance training	Larger changes if weight loss occurs
Obesity	Aerobic	Sufficient energy expenditure to induce deficit
	Resistance training	Resistance training maintains lean tissue (muscle and bone) better than aerobic training during weight loss
Osteoporosis	Aerobic	Aerobic exercise should be weight bearing
	Resistance training	High-impact, high-velocity activity (e.g. jumping) potent if tolerable; avoid if osteoarthritis present
	Balance training	Resistance training effects are local to muscles contracted
		Balance training should be added to prevent falls
Peripheral vascular disease	Aerobic	Vascular effect is systemic, upper limb ergometry may be substituted for leg exercise if necessary
		Resistance training has positive but less robust effect on claudication
		Need to exercise to the limits of pain tolerance each session to extend time to claudication
Venous stasis disease	Aerobic	Local muscle contractions stimulate return of fluid via lymphatic system
	Resistance training	Utilize lower body training, elevate legs when possible

Table 10.8. Although there is strong preliminary evidence that weight-lifting exercise improves metabolic control and cardiovascular risk factors in type 2 diabetes, to date there have been only two published randomized controlled trials of resistance training as an *isolated* intervention to augment usual care in type 2 diabetes.

Exercise to counteract iatrogenic disease

Finally, exercise may counteract undesirable side effects of standard medical care, a use of exercise that is just emerging in the literature. Such use of exercise would include resistance training for patients receiving corticosteroid treatment to counteract the associated proximal myopathy and osteopenia, neutralizing the adverse effects of energy-restricted diets in obesity or protein-restricted diets in chronic renal failure,[41] for example.

Osteopenia associated with corticosteroid usage appears to be completely eliminated by concurrent progressive resistance training, which should be recommended for all such patients. Although bisphosphonates have also been shown to be very effective for corticosteroid osteopenia, they do not address the coexisting steroid myopathy, as resistance training does, and are therefore an insufficient antidote for corticosteroid side effects. An excellent target group for such health promotion efforts would be older

Table 10.8 Randomized controlled trials including resistance training in type 2 diabetes.

Study	*N* (average age)	Duration of training (months)	Resistance training intensity	Other additional intervention	Significant improvement in insulin sensitivity or glucose homeostasis
Dunstan *et al.*[33,34]	36 (60–80 years)	2 (6 months supervised)	High	Moderate weight loss programme	Yes, for supervised phase but not home-based, free-weight phase
Balducci *et al.*[35]	120 (60.9 years)	12	Moderate	Aerobic at 40–80% HR	Yes
Baldi and Snowling[36]	18 (46.5 years)	2.5	Moderate	None	Yes
Cuff *et al.*[37]	28 (60.0 years)	4	Low	Aerobic at 60–75% HR	Yes
Loimaala *et al.*[38]	50 (53.3 years)	11	High	Aerobic at 65–75% HR	Yes
Attema *et al.*[39]	85 (age not reported)	6	High	Aerobic at 75% HR	Yes
Castaneda *et al.*[10]	62 (66 years)	4	High	None	Yes
Dunstan *et al.*[40]	27 (51 years)	2	Moderate	Low-intensity cycling between each set	Yes

men with steroid-dependent chronic lung disease, in whom pulmonary cachexia, malnutrition, tobacco use, steroid myopathy and osteoporosis combine to produce profound wasting, osteoporotic fracture and impaired exercise tolerance. Aerobic training will improve functional status in this clinical cohort, but is insufficient to address the musculoskeletal wasting.

Exercise and the prevention and treatment of disability

There are many ways in which physical activity may influence the development and expression of disability in old age. These theoretical relationships are now borne out in many epidemiological investigations and provide the rationale for both the experimental studies and exercise recommendations that are found in many recent reviews of this topic. For example, 1097 participants from the Established Populations for Epidemiological Studies of the Elderly (EPESE) study who were not disabled at baseline were analyzed for factors related to disability-free survival until death in old age. Physically active adults were more likely to survive to age 80 years or beyond and had approximately half the risk of dying with disability compared with their sedentary peers.

The most obvious conclusion from a review of the literature in this area is that there is a great deal of overlap between the identifiable risk factors for disability and the consequences or correlates of habitual inactivity. At the most basic level, shared demographic characteristics between those at risk of disability and those more likely to exhibit sedentary behaviour include advanced age, female gender, non-Caucasian ethnicity and lower educational level and income. Psychosocial features common to both cohorts include social isolation, low self-esteem, low self-efficacy, depressive symptoms and anxiety. Lifestyle choices more prevalent in disabled and/or inactive adults include smoking and excess alcohol consumption. Body composition changes associated with both functional decline and inactivity include sarcopenia, obesity, visceral obesity and osteopenia. Exercise capacity is typically reduced in both conditions in all domains, including aerobic capacity, muscle strength, endurance and power, flexibility and balance. Gait instability and slowness, and also impaired lower extremity function and mobility, characterize both disabled and inactive populations. Since most studies have not assessed the full complement of factors known to be associated with disability and many have made observations at a single point in time, it is not possible to say with certainty how all of these complex relationships fit together, which relationships are causal and which risk factors are independent of each other.

In addition to the associations above, chronic diseases associated with inactivity, such as obesity, osteoarthritis, cardiovascular disease, stroke, osteoporosis, type 2 diabetes, hypertension and depression, are all risk factors for disability as well. In some cases, data linking inactivity to disability-related diseases are available from cross-sectional or prospective cohort studies and also experimental trials [e.g. diabetes, cardiovascular disease and in other cases from epidemiological data alone (colon and breast cancer[42])]. Disability is complex and not fully explained by deficits in physical capacity such as strength and balance and other pathways may be operative, including sensory function, glycaemic control, psychological constructs and other aspects of health status.

Recent prospective and experimental studies have strengthened the hypothesized causal relationship between sedentariness, functional limitations and disability in older adults. Miller *et al*. reported results from 5151 participants in the Longitudinal Study of Aging[43] and showed that physical activity results in a slower

progression of functional limitations and thereby slower progression to ADL/IADL disability at 6 months of follow-up after the intervention ended. In the largest reported randomized controlled trial of exercise and disability to date,[44] 704 residents of nine different nursing homes were randomized into resistive exercise, nursing rehabilitation or control conditions. After 17 months, residents in both intervention homes had significantly less decline in ADL functioning than those in control homes.

Tai chi improves balance, reduces falling and fear of falling and increases walking speed.[45]

A review of studies targeting disability in disease-specific populations such as depression, cardiovascular disease, stroke, chronic lung disease and arthritis is beyond the scope of this review, but there is evidence that exercise is beneficial in all of these conditions as a primary or ancillary treatment. The largest body of data exists for older adults with osteoarthritis, which is the commonest condition related to disability in the elderly. Five of the 11 randomized controlled trials reported up to 1999 demonstrated improvements in disability scores relative to controls in trials from 4 weeks to 18 months in duration. Weight-bearing functional exercises, walking and resistance training were used in various combinations in these studies and there is no clear indication of the superiority of one modality over another in the reduction of pain and disability from osteoarthritis. It is likely that the disability reductions in arthritis are due to the impact of exercise on a variety of factors, including muscle strength, gait and balance, body weight, pain, comorbid disease expression, self-efficacy and depressive symptoms, among others.

Conclusion and directions for future research

There are sufficient data from both epidemiological studies and experimental trials to warrant the training of all physicians, including geriatricians, in the basics of exercise prescription for health-related and quality of life benefits, as outlined in Table 10.9.

Screening for sedentariness should take place at all major encounters with healthcare professionals, given its role as a potent risk factor for all-cause and cardiovascular mortality, obesity, hypertension, insulin resistance, cardiovascular disease, diabetes, stroke, colon cancer, depression, osteoporosis, recurrent falls and disability, among other conditions. Exercise recommendations should be integrated into the mainstream of other healthcare recommendations, rather than being marginalized as at present. Exercise advice should be specific in terms of modality, frequency, duration and intensity, accompanied by practical implementation solutions and behavioural support systems for monitoring progress and providing feedback. Ultimately, the penetration of these recommendations into the most inactive cohorts in the community, who have the most to gain from increases in levels of physical activity and fitness, will depend on a combination of evidence-based guidelines coupled with health professional training and

Table 10.9 Exercise recommendations for optimal ageing and prevention and treatment of disease in older adults.

Modality	Resistance training	Cardiovascular endurance training	Flexibility training	Balance training
Dose				
Frequency (days per week)	2–3	3–7	1–7	1–7
Volume	1–3 sets of 8–12 repetitions, 8–10 major muscle groups	20–60 min per session	Major muscle groups 1 sustained stretch (20 s) of each	1–2 sets of 4–10 different exercises emphasizing dynamic postures[a]
Intensity	15–17 on Borg Scale (70–80% 1RM), 10 s per repetition, 1 min rest between sets	12–13 on Borg Scale (40–60% heart rate reserve or maximum exercise capacity)	Proprioceptive neuromuscular facilitation (PNF) technique[b]	Progressive difficulty as tolerated[c]

[a]Examples of balance-enhancing activities include tai chi movements, standing yoga or ballet movements, tandem walking, standing on one leg, stepping over objects, climbing up and down steps slowly, turning, standing on heels and toes, walking on compliant surface such as foam mattresses, maintaining balance on moving vehicle such as bus or train and so on.

[b]PNF involves stretching as far as possible, then relaxing the involved muscles, then attempting to stretch further and finally holding the maximum stretch position for at least 20 s.

[c]Intensity is increased by decreasing the base of support (e.g. progressing from standing on two feet while holding on to the back of a chair to standing on one foot with no hand support); by decreasing other sensory input (e.g. closing eyes or standing on a foam pillow); or by perturbing the centre of mass (e.g. holding a heavy object out to one side while maintaining balance, standing on one leg while lifting the other leg out behind the body or leaning forwards as far as possible without falling or moving feet).

behavioural programmes tailored to age-specific barriers and motivational factors.

Key points

- The reduction in exercise capacity typical of the older adult is largely explained by reduced muscle mass and function, decreased maximum heart rate and cardiac output and impairment of central and peripheral nervous system processing, recruitment and conduction velocity.
- Ageing and a sedentary lifestyle or disuse syndromes have very similar effects on a multitude of physiological changes attributed to chronological age which reduce exercise capacity.
- Habitual physical activity increases average life expectancy by ~2 years, but the mechanism of this effect is probably multifactorial and not precisely defined.
- Prevention of many of the typical changes attributed to biological ageing is possible with chronic participation in physical activity, particularly alterations in body composition: decreased muscle mass, decreased bone mass and strength, increased adipose tissue mass and its central deposition.
- Prevention and/or treatment of many of the most common chronic diseases which afflict older adults, including obesity, cardiovascular disease, type 2 diabetes, hypertension, osteoarthritis, osteoporosis, stroke, peripheral vascular disease and depression are possible with targeted, robust doses and modalities of exercise.

CHAPTER 11

Health literacy and cultural sensitivity

Nina Tumosa

St Louis Veterans' Affairs Medical Center and Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

Dramatic shifts in population demographics due to migration have led to the requirement that health professionals acquire cultural sensitivity in addition to medical acumen in geriatric health care. A dramatic example of the effects of migration can be seen in the United Kingdom (UK). In the 1950s, Bethnal Green, an area in London, was a predominantly white, working-class neighbourhood, whereas in the 1990s it had changed to Tower Hamlets, the home of large numbers of Bangladeshi immigrants. Wolverhampton, in the West Midlands, UK, has a significant multicultural nature. It has an above-average level of non-Christian religions (13.6% of people, compared with 5.5% for England and Wales). Sikhs account for 7.6% of Wolverhampton's population. The number of Hindus is also higher than the England and Wales average (Wolverhampton 3.9%, England and Wales 1.1%). Leicester is one of the oldest cities in the UK and is also one of the most ethnically diverse. It has small communities of Poles, Irish, Indians from the Indian sub-continent, Kenya and Uganda, Dutch citizens of Somali origin and a significant number of East European migrants. The Commission for Racial Equality (CRE) estimated that by 2011 Leicester will have approximately a 50% ethnic minority population, making it the first city in Britain not to have a white British majority. Changes such as these require training programmes for health professionals in how beliefs of different cultures may impact the interactions between older persons and their health care providers.

The ultimate goal of geriatric care providers is to provide good medical care to all older patients. This goal is made difficult when patients do not possess adequate health literacy, that is, the ability to understand and manage their own health care. Good communication is so critical to improving health literacy. When the cultural characteristics of both patients and providers are so different that communication is compromised, poor health literacy is likely to make it difficult for patients to receive good health care. This chapter presents ideas on how cultural context affects the provision of health care to an ageing, multiethnic population. Collaboration between providers and the patients and their caregivers becomes even more important in these circumstances. This chapter addresses some of the barriers to accomplishing the goal of providing good health care that arise from cultural differences. Suggestions on how to minimize cultural differences in the clinical encounter will be given. Because there is so much cultural diversity worldwide, this chapter will serve as a reminder that the problem must be addressed, rather than provide a laundry list of solutions. A list of resources at the end of the chapter will help guide practitioners in the development of their own strategies to develop and maintain cultural sensitivity with the goal of improving health care to their multicultural patient base.

The importance of health literacy in health care

Health literacy is a relatively recent concept to be discussed in the health care literature. It refers to individuals' ability to understand and manage their personal health care issues. This is of great concern because individuals with limited health literacy have less health knowledge, worse self-management skills, lower use of preventive services, especially for those aged 65 years and older,[1] and higher hospitalization rates. Much research has confirmed that many individuals in the geriatric patient population are at risk of inadequate or marginal health literacy.[2] In the United States, one in three persons has low health literacy.[3] In Australia, depending upon the health literacy assessment tool used, between 7 and 25% of the general population had less than adequate health literacy.[4]

Factors that influence health literacy

Multiple factors influence health literacy (Table 11.1). Factors such as increasing age, less education, lower income, 'blue collar' jobs and poor health status (both mental

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 11.1 Common factors affecting health literacy.

- Cognitive Status
- Gender
- Income
- Race
- Health Status
- Vision
- Hearing

and physical) can all put people at risk for marginal or inadequate health literacy.[5] This risk impacts health outcomes and therefore the cost for caring for older persons. Limited health literacy is associated with low socioeconomic status, comorbidities and poor access to health care, suggesting that it may be an independent risk factor for health disparities in older people.[6] Lower literacy was more common among African Americans, older patients and patients who required medication assistance.[7] Poor health literacy has dire consequences (Table 11.2). Among community-dwelling older adults who had recently enrolled in Medicare, inadequate health literacy was independently associated with poorer physical and mental health.[8] Older patients are particularly affected by health literacy issues because their reading and comprehension abilities are influenced by their cognition and their vision and hearing status. Inadequate health literacy can result in difficulty in accessing health care, following instructions from a physician and taking medication properly. Patients with inadequate health literacy are more likely to be hospitalized than patients with adequate skills.[9]

Functional literacy declines with age.[10] Home interviews conducted with community-dwelling elderly persons (n = 2774) found that a significant decrease in health literacy was associated with every year increase in age, even following adjustments for gender, race, ethnicity, cognitive status and education. Differences in newspaper reading frequency, visual acuity, chronic medical conditions and health status did not explain the lower literacy of older participants. Both health literacy and cognitive abilities independently predict mortality. Interventions to improve patient knowledge and self-management skills should consider both the reading level and cognitive demands of the materials.[11] Memory and verbal fluency are strongly associated with health literacy, independently of education and health status, even in those with subtle cognitive dysfunction. Reducing the cognitive burden of health information might mitigate the detrimental effects of limited health literacy in older adults.[12] In addition, there are age differences in knowledge, as shown by Farrer *et al*.[13] in a study on mental health literacy. In Australia, this study showed that a community's knowledge and beliefs about mental health problems, their risk factors, treatments and sources of help varied as a function of age. Older adults (70+ years) were poorer than younger age groups at correctly recognizing depression and schizophrenia. Older respondents were more likely to believe that schizophrenia could be caused by character weakness.[13]

Table 11.2 Consequences of low health literacy.

- Poorer physical health
- Poorer mental health
- Difficulty accessing health care
- Difficulty following instructions from a physician
- Difficulty taking medications properly
- Increased hospitalisations
- Premature mortality

The role of education in health literacy

Education plays a key role to overcoming the effects of poor health literacy. If health information is shared via spoken instruction, it is best to remember that older patients understand medical information better when spoken to slowly, simple words are used and a restricted amount of information is presented. Often health literacy is addressed using written materials. However, in the United States, many older adults read at an eighth-grade level and 20% of the population reads at or below a fifth-grade level. A study of 177 low-income, community-dwelling, older adults (with no cognitive or visual impairments) was carried out to determine whether they had difficulty in understanding written information provided by clinicians. The subjects' mean reading skills were at fifth-grade level, below those of the general American population. One-quarter of subjects reported difficulty in understanding written information from clinicians.[14] However, most health care materials are written at a tenth-grade level.[5] Health care providers must identify patients with marginal or inadequate health literacy and adjust their health care education strategies to meet these literacy needs. For optimal comprehension and compliance, patient education material should be written at a sixth-grade or lower reading level, preferably including pictures and illustrations.[9] It is also important to provide instruction in the language in which the patient is most fluent. For example, compared with those with adequate and marginal health literacy, women with inadequate functional health literacy in Spanish were significantly less likely to have ever had a Papanicolaou (Pap) test.[15] Of course, having assessment tools translated into the original language does not solve problems with health literacy. In Turkey, in a clinic where 2.7% of patients had inadequate (less than or equal to sixth grade) health literacy, 38.6% had marginal (seventh to eighth grade) and 58.7%

(greater than or equal to ninth grade) had adequate health literacy. Being female, primary school educated, in poor economic condition and older were all risk factors for the lowest level of health literacy.[16] Cordasco *et al*.[17] recruited 399 English- and Spanish-speaking inpatients being evaluated or treated for congestive heart failure or coronary artery disease at a large, urban safety-net teaching hospital in Southern California. They compared by age (aged 65 years or more, 51–64 years and less than 50 years), levels of health literacy, educational attainment, English comprehension and language use and found that the prevalence of inadequate health literacy increased significantly with increasing age. The correlation between older age and lower health literacy persisted when controlling for educational achievement, race, ethnicity, gender and immigration status. Additionally, older patients were more likely to have never learned to read, to have no formal education, to have limited English comprehension and to speak a non-English language at home. This study suggests that in order to meet the chronic disease needs of a growing older, multiethnic patient population and ameliorate the negative health effects of associated low literacy, safety-net hospital leaders and providers need to prioritize the development and implementation of low-literacy educational materials, programmes and services.[17] Finally, differences in mental health literacy across the adult lifespan suggest that more specific, age-appropriate messages about mental health are required for younger and older age groups.[13]

Educational strategies to improve health literacy

Fortunately, proper educational techniques (Table 11.3) can make a difference in health care for persons with low health literacy.[7] Of 111 patients with poorly controlled diabetes, 55% had literacy levels at the sixth grade level or below. Over the 6 month study period, patients with low and high literacy had similar improvements in A1C when they received one-to-one education and medication management for these patients using techniques that did not require high literacy from clinic-based pharmacists. Among community-dwelling Korean older adults, limited health literacy was associated independently with higher rates of chronic medical conditions and lower subjective health status. Nurses were found to be key to providing health education to these older adults[18] to help them maintain their independence. The greatest potential barrier to addressing health literacy is the fact that most patients are often unwilling to admit that they have literacy problems.[9] Indeed, Weiss et al found that 97% of their research subjects, regardless of literacy level, reported that television was their primary source of information.[14]

Table 11.3 Educational techniques to improve health literacy.

- Written material
  - At sixth grade level
  - In primary language of patient
  - Uses simple words
  - Is age appropriate
  - Includes pictures and illustrations
  - Presents a small amount of information
- Auditory material
  - Delivered slowly
  - Is delivered one-on-one
  - Is in the patient's primary language
  - Is delivered by a trusted provider

Cultural sensitivity in geriatrics

The need for cultural sensitivity

Developing strategies to increase awareness of cultural differences and to address them appropriately in the context of providing good health care is difficult because of the various influences on culture (Table 11.4). This goal is further complicated by the fact that culture is fluid and constantly changing. These changes compound misunderstandings between members of different cultural groups. A further complication is the fact that there are cultural differences between the different generations of people who share the same cultural background. Also, cultural differences often seem to be insurmountable between men and women of the same cultural background. Gender differences across cultures can be even more complicated. These differences highlight the complicated and constantly changing nature of culture. Geriatrics requires that the health care providers interact with multiple generations of the same family. Therefore, any general strategies employed to address cultural differences in the clinical setting need to be general and flexible in approach.

When cultures clash

Culture surrounds and defines everyone. Both providers and patients have their own national and ethnic cultures. These cultures include their culture of origin and also those

Table 11.4 Cultural factors that affect health care.

- Age
- Gender
- Ethnicity
- Assimilation
- Generation cohort
- The ever changing nature of culture

cultural values, beliefs, language and skills of the local culture (acculturation) that they have adopted. The patients' cultures will influence when they seek treatment, what their expectation of care will be and whether or not they will comply with the providers' recommendations.[19] Health care providers have the culture of biomedicine in general and that of their specific profession (e.g. medicine, nursing and pharmacy) and specialty (e.g. surgery, geriatrics and rheumatology) in particular. In addition, both providers and patients have cultural ideas and values that relate to their social culture,[20–22] age,[23,24] gender[25,26] and gender identity.[27,28] Finally, health care providers for geriatric patients are almost always younger than their patients. This age difference also has ramifications in compliance based on trust and respect.[29]

Finding a way to communicate effectively is critical to good patient care. Patient satisfaction and the likelihood of compliance with medical instructions[30,31] are linked to patient–provider communication. If cultural differences are not addressed, then poor health outcomes and limited quality of medical decision-making may result.[32] Patient satisfaction with health care is affected by age, race and literacy level. In low-income populations, communication satisfaction may be lower for groups that are traditionally active in doctor–patient interactions (e.g. younger patients, patients with higher literacy skills). Health care providers should be aware that older, non-white, optimistic and literacy deficient patients report greater communication satisfaction than their younger, white, pessimistic and functionally literate peers and are more likely to cope with their illnesses by withdrawing rather than by actively pushing for a higher standard of care.[33] Therefore, health care providers should continuously seek ways to facilitate dialogue with patients who are older, non-white and have poor literacy skills. Thus, cultural sensitivity can help providers improve health care delivery in the clinical encounter. It can lead to better provider–patient communication, more accurate diagnosis, more effective treatment, higher patient satisfaction/compliance and efficient use of medical resources.

For most adults who are not health care providers themselves, navigating the culture of biomedicine is challenging. These challenges are exacerbated for older adults who are handicapped with physical, mental and/or social limitations. Most older adults suffer with chronic diseases in addition to acute diseases. The physical burdens that these chronic diseases put on older persons, especially if they have low health literacy, are often underappreciated by health care providers. For example, community-dwelling Korean older adults with low health literacy often have been reported to have significantly higher rates of arthritis and hypertension. After adjusting for age, education and income, older individuals with low health literacy had higher limitations in activity and lower subjective health. Older individuals with low health literacy were more likely to report lower levels of physical function and subjective health and higher levels of limitations in activity and pain.[18] Nor are the patients themselves the only ones with challenges. The providers have their own challenges when applying their biomedical culture to an ageing population. They were taught '*Primum non nocere*' (or 'First, do no harm', the origins of which are discussed elsewhere[34]), but many cures are harsh. This is because so many cures are designed for younger, robust patients who are experiencing an acute illness, and who have natural reserves that will allow them to overcome any debilitating effects of the 'cure'. This is not true for the frail elderly. For them, multiple pharmaceuticals increase the possibility of lethal drug interactions and/or side effects. Surgery is dangerous and the subsequent recovery can be debilitating. Medical care is expensive and cannot be paid for by everyone. Sometimes the care is available but not always in a timely manner. This waiting period can be particularly problematic for an older person, especially is he/she lacks the cultural understanding of the need for haste or confrontation. Finally, the culture of medicine often emphasizes the quantity of life over the quality of life. However, older patients may insist upon more autonomy than the culture of biomedicine encourages.[35] They do not always follow instructions, especially if they feel that quality of life is preferred over quantity of life. It is not uncommon for family members to decide that an older patient should not be treated of a serious disease such as depression[26] or cancer.[36,37] This makes treatment difficult, if not impossible.

These differences in the approach to the culture of medicine affect care. Being aware of the potential for culture-related problems in the clinical encounter is the first step in developing strategies to deal with those problems when they arise. To address these differences, providers must learn to communicate effectively, to provide evidence-based medicine in a timely manner, to be prepared continually to develop new health services that target older adults' changing medical needs and to consult with the older patient and family as to their preferences for care. The delivery of optimal health care depends upon understanding across all cultures.

Barriers to cultural understanding

There are several barriers to developing successful strategies for the delivery of health care (Table 11.5). First, it is impossible to learn about every cultural or ethnic group that might seek health care. Second, relying on cultural stereotypes for guidance can result in conflict with those patients who show within-culture variations or who have acculturated to the local norms. Third, if culture is viewed as an obstacle to be overcome, rather than incorporated into the care plan, then conflicts cannot be resolved. Finally, if the impact of the culture of biomedicine on provider–patient

- Negative effects of stereotypes
- Complexity of the culture of biomedicine

communication[38] is ignored, then problems with health literacy arise. Any of these barriers may lead to a failure either in compliance or in the application of the best medical solution.

Hence cultural sensitivity is more a process than an outcome. It is as much about acceptance of differences as it is about knowledge of differences. The following section lists a number of common problems that may arise in clinical encounters between people with different cultural experiences. The subsequent section provides general strategies for addressing these problem areas.

Common areas of conflict or misunderstanding in the clinical encounter

There are several areas in which misunderstandings commonly occur during a clinical visit (Table 11.6). Each of these is described below along with suggestions for improvement.

Prior experiences

Both the provider and the patient bring certain expectations to the clinical encounter based on prior experience. Both may be unaware that their own ethnic or professional culture has an influence on the interaction. Problems often arise due to the knowledge and power differential between the patient and the provider.

Patients may distrust their providers based on their own or significant others' previous encounters with biomedicine, such as the American experience with the Tuskegee Syphilis Study. This unfortunate research study exemplifies several factors that have influenced African American's attitudes toward the biomedical community in the United States,[39] although more recent research indicates that these attitudes may have ameliorated over the past two decades.[40] This may be due to acculturation by the younger generation, rather than forgiveness on the part of those who were directly affected.

Table 11.6 Common areas of cultural conflict.

- Mistrust garnered during prior contacts
- Cultural differences in defining who the patient is
- Verbal and non-verbal communication
- Prior misconceptions about cultural norms
- Ageism by both patient and provider

Providers may view the patients' ethnic cultures as an obstacle. For example, because Afghani Muslim women do not seek health care from male practitioners,[26] the woman receives care by proxy. Her husband describes her symptoms to the male practitioner, who then instructs the husband in the recommended treatment plan. Not all practitioners are comfortable in practicing medicine in this manner.

Identifying the patient

In general, Western biomedical culture focuses on the adult individual as the patient. As such, information is gathered from the patient and the patient alone (this is different from practicing Western paediatrics, where the mother and child are often considered to be the 'patient'). In many cultures, however, the family, or even the entire community, plays a major part in managing illness. In cases such as this, it is often best to include the entire family in decision-making,[41] including spouses and/or adult children.

Communication

Communication may be verbal or non-verbal and both are important. When communication is hindered by a lack of a common language, health suffers. Patients not proficient in the local language are unable to take advantage of health promotion programmes.[42,43] The clinician's misunderstanding of the patient's language can lead to inappropriate treatment,[44] ranging from misdiagnosis to ineffective pain control.[23]

Although professional translators may be employed, providers must remember that misinterpretations may occur even when the same language is spoken. Providers tend to mix medical jargon and everyday language when they speak to patients, but a word may mean something different than intended to the patient. For example, a patient may refer to a stomach ache, which is duly interpreted to be a pain in the stomach. The patient may actually mean a pain in the abdominal area. The clinician should be careful when interpreting the symptoms as they are reported. This is particularly true when the interpreter is a child who may not have insight into how important it is to have an accurate description of the symptoms, even if the patient is uncomfortable sharing that information with either the clinician or the child.

A surprising amount of information can be communicated through non-verbal cues. This has led to the successful development of pain assessment tools for demented patients.[45] Research on such tools provides information about which non-verbal assessment tools are most representative of the current state of the science, are most clinically relevant and are practically applicable to integrate into everyday practice and support adherence to regulatory

guidelines. Communication in the clinic is less well studied but certain areas of potential differences should be noted. For example, patients with different cultural backgrounds may have different ways of expressing distress. Some value stoicism whereas others value the open expression of pain. The presence of non-verbal behaviours such as reductions in activity, social withdrawal, self-protective manoeuvres, increased alterations in facial expressions or body postures and observable displays of distress in a stoic patient, who reports no such problems, would assist a provider in diagnosing unreported problems. The lack of these non-verbal behaviours in a patient reporting that their symptoms are severe might identify a patient from a more expressive culture.[46]

Other potentially problematic areas of non-verbal communication between persons with different cultural backgrounds include the pace of conversation, whether interruptions are encouraged, the degree of physical proximity of the provider to the patient during history taking and whether eye contact is appropriate or disrespectful. An interesting unintended consequence of the introduction of the electronic record is the perception on the part of some patients that it is disrespectful of the clinician to interact with the computer screen more than with the patient.[47] It is important to remember that the etiquette of touch, hand gestures and finger pointing varies across cultures. Another area with wide cultural variability is attitudes toward the direct discussion of death and dying, among both clinicians and patients and their families.[48]

Stereotyping

Sometimes a little knowledge is a dangerous thing and can lead to stereotyping.

Instead of trying to memorize what is appropriate for every culture, a brief conversation with the patient or interpreter can clarify what is acceptable and what is not and can clarify major points of potential conflict. Such a conversation would ideally take place during the initial visit of the patient. A special place in the patient record could be the repository of such information, along with a reminder to refer to that note before the patient is seen. Because culture is fluid and changes with social interactions, brief follow-up conversations about potential changes or to confirm previous conclusions would be appropriate at each office visit. It is important to understand that there is variation within cultural groups. There is no substitute for asking the patient what his/her treatment goals are.

Age

Very few health care providers are as old as their older patients. Therefore, there is limited personal experience with or insight into the nature of ageing and the consequences of chronic disease that the provider brings to the provider–patient relationship. Thus, the nature of ageing may be stereotyped by young health care providers. They may exaggerate the meaning/impact of functional differences, the consequences of chronic illnesses and the degree to which disabilities that increase with age affect the patient's quality of life. As a result, there is a risk that providers might fail to recommend lifestyle changes involving smoking cessation, good nutrition and exercise that might help patients to continue to live independently for many more years. Alternatively, older patients may disregard the expert advice of health professionals who are significantly younger than they are (reverse stereotyping) because they feel that the provider does not understand ageing due to a lack of personal experience.

Increasing cultural sensitivity in the clinical encounter

Increase self-awareness

Everyone has a culture. It is important to remember that the provider brings an ethnic and/or national culture to a clinical encounter, in addition to the biomedical culture. Approaching the patient as a cultural equal will reduce conflict between cultures. A sense of humour about small misunderstandings is crucial. Asking for explanations about the patient's culture and offering explanations to the patient about the biomedical culture shows good will and a desire to communicate. None of the cultures involved are problems to be overcome. Rather, they are opportunities for sharing.

Be prepared to address potential cultural differences when they arise. Not all patients identify strongly with their ethnic culture. Educational level, dominant language, religion, gender, year of immigration and even personality may have more of an effect on interactions with health care providers than cultural identity.[49] The best way to find out what influences the patients' cultures have on their health is to ask them directly and listen carefully to what they have to say.

Improve communication

The simple mnemonic ETHNIC(S) (Table 11.7) provides an easily remembered framework for providers to use in providing culturally appropriate geriatric care.[50] ETHNIC(S) can serve as a clinically applicable tool for eliciting and negotiating cultural issues during health care encounters. Geriatrics health care providers need to be aware of the effect that culture has on establishing treatment priorities, influencing adherence and addressing end-of-life care issues for older patients and their caregivers.

Explanation

It is the job of the practitioner to elicit explanations from the patient as to why he/she is seeking care. This may be achieved by asking direct questions about what they think

Table 11.7 ETHNIC(S) mnemonic for improving communication.

Explanation
Treatment
Healers
Negotiate
Intervention
Collaborate
Spirituality/seniors

the symptoms indicate and/or by asking direct questions about what they think family members or other sources may have suggested. It is a rare patient who is unaffected by the television or the Internet. This is a good time to evaluate how well the patient understands the symptoms and what he/she is worried about.

Treatment
Ask what the patient has already tried to alleviate symptoms and specifically mention some commonly used complementary and alternative medicine treatments. All patients have home remedies that are used when a symptom first presents. Sometimes those remedies are helpful and sometimes they are harmful.

Healers
This is an opportunity for providers to indicate to the patient that they understand that they may not be the sole health care provider for the patient. Knowing who the other healers are goes a long way towards knowing who needs to be included in the treatment plan when applying more complicated remedies.

Negotiate
Recovery from an illness requires teamwork, especially with the older patient. Informal caregivers may need to be engaged in the healing process. The provider needs to know how much of a partner the patient intends to be in his/her recovery.

Intervention
The degree to which the patient is willing to participate in the proposed medical interventions must be determined. If compromises must be made based on cultural conditions or if misunderstandings can be resolved, then the planned interventions can be implemented or modified in a timely manner.

Collaborate
Not only do the patient and provider need to work together, but informal caregivers and family members, other healers, other members of the interdisciplinary geriatric health team and community services must also all be included. Continuum of care for older persons is very much a team endeavour. Effective collaboration from the beginning makes the transitions easier.

Spirituality/seniors
Spirituality is an often unappreciated aspect of health care in older persons for both providers and patients. The provider should take the lead in asking whether the patient would like to discuss the role of his/her beliefs in his/her health care. This is particularly important in the case of end-of-life care.

Understand non-verbal cues
Communication goes beyond language and medical jargon. The use of technical terms should be minimized in order to ensure patient understanding. Care must be taken to understand when common terms such as 'stomach' may be used to refer to a different part of the abdominal area. The observation of non-verbal cues such as pointing or guarding of a body area will assist in locating areas of concern even when a common word cannot be found to describe the location of an illness or pain.

Use professional translators when possible
It is usually advisable to engage a professional translator or to use translated written materials for patients who are not fluent in the language commonly spoken in the medical office. Although it may be tempting to ask for help from a young relative who accompanies the patient, this is seldom advisable. Children as translators are especially problematic, especially if the medical topic may be construed as not appropriate for a child. That said, sometimes even minimal communication may be better than none at all. However, care should be taken to understand the social contract between the child and the patient. A particularly sensitive child may wish to protect the patient's dignity, not understanding that the provider–patient relationship relies strongly on honesty. Alternatively, a patient may not be comfortable communicating through a child of the opposite gender, thus leading to more confusion and an underreporting of symptoms. Attention to non-verbal communication becomes particularly important when children are being used as translators.

Promote health
Good nutrition and exercise, and also other lifestyle-related changes such as smoking cessation, are the cornerstones of successful ageing for all patients. Cultural differences in the perception of what is a good diet[51–54] or the proper amount or form of exercise[20,55,56] may be difficult to address, but it will be worth the effort. Lack of physical activity, combined with poor dietary habits, contributes to increased obesity in older persons. Regular exercise and

increased aerobic fitness are associated with a decrease in all-cause mortality and morbidity and are proven to reduce disease and disability and improve quality of life in older persons.

Resources

Health Literacy: http://healthlit.fcm.arizona.edu[3]
Low or inadequate health literacy is a powerful barrier to good health. An excellent resource on health literacy and older adults is readily available.[57] It is an interactive web-based module on health literacy and provides ready access to external special reports, including research projects on older adults and health literacy, assessment instruments to be used in daily practice and other resources, and can be accessed at http://healthlit.fcm.arizona.edu.[3]

Cultural competence in health care

Cultural sensitivity is a powerful strategy that health care providers can use to help reduce the negative impact of cultural differences on health outcomes. The following is a partial list of web-based resources that may be useful. A more complete list can be accessed through search engines using keywords such as Cultural Diversity, Cultural Competence, Explanatory Model, Health Promotion Programmes and Disease Self-Management.

Diversity Rx: http://www.diversityrx.org[58]
This website promotes language and cultural competence to improve the quality of health care for minority, immigrant and ethnically diverse communities. It describes how language and culture affect the delivery of quality services to ethnically diverse populations and provides resources to enable providers to learn about language and cultural competence in health care, design better programmes and policies and network with colleagues and experts. It also provides information on working with interpreters and gives examples of model programmes.

Health Research and Educational Trust Disparities Toolkit: http://www.hretdisparities.org[59]
This web-based toolkit provides guidance on how to collect patient race, ethnicity and primary language data.[60] The free toolkit provides users with resources on how to collect data from patients, how to do staff training and how to address legal and privacy concerns. The toolkit identifies the patient's preferred method of communication, any potential language barriers and the patient's culture. With this information, the provider can enlist any outside assistance needed to ensure proper patient–provider communication. The toolkit is specifically designed to be useful for educating and informing staff about the importance of data collection, how to implement a framework to collect race, ethnicity and primary language data and ultimately how to use these data to improve quality of care for all populations.

EthnoMed: http://www.Ethnomed.org[61]
This website focuses on information about cultural beliefs, medical issues and other related issues pertinent to the health care of recent immigrants to Seattle, WA or to other parts of the United States, many of whom are refugees fleeing war-torn parts of the world. It offers videos in many languages on basic medical history taking with interpreters. Hyperlinks on this site may be useful when provider and patient languages differ. In response to recent earthquake activity worldwide, it has a number of resources that may be useful to international disaster relief workers. An interesting recent addition is a video on culturally competent care in mental health. It has also posted an article on Ethiopian Traditional and Herbal Medications and Their Interactions with Conventional Drugs.[62] The herbs described are used commonly in many world cuisines.

Health promotion programmes

MOVE!: http://www.move.va.gov/[63]
MOVE! is a national weight management programme designed by the Department of Veterans Affairs (VA). This programme is designed to help Veterans lose weight, keep it off and improve their health. The entire programme, from philosophy to handouts, from motivational messages to references, can be found on the Internet and is free. The website has sections for both patients and providers in English and in Spanish. There is a simply stated patient recruitment message about why this programme in important to health and well-being, followed by questionnaires to help patients determine their degree of readiness to participate in the programme. Multiple handouts address barriers that patients may face, such as depression, lack of time and boredom. These handouts offer solutions to those barriers.

There are instructions to providers about how to administer the patient questionnaire and how to run successful group sessions. Reference tools are well labelled and accessible and include discipline-specific information on such topics as nutrition, physical activity, medications and surgery. This programme was originally designed to be promoted by providers to the patients and was so successful that the top administrators of the VA promoted it to all of the employees of the VA nationwide. Now one more layer of promotion has been added that would serve as a model for worldwide success. This programme has been so successful that Michelle Obama, First Lady of the United States, has become a spokesperson for the programme to be used to encourage obese children to be more active and increase their fitness levels.

CDSMP: http://patienteducation.stanford.edu/programs/cdsmp.html[64]

The Chronic Disease Self-Management Program developed at Stanford University is a workshop given 2.5 hours, once per week, for 6 weeks, in community settings such as senior centres, churches, libraries and hospitals. People with different chronic health problems attend together. Workshops are facilitated by two trained leaders, one or both of whom are non-health professionals with a chronic disease themselves. Subjects covered include (1) techniques to deal with problems such as frustration, fatigue, pain and isolation, (2) appropriate exercise for maintaining and improving strength, flexibility and endurance, (3) appropriate use of medications, (4) communicating effectively with family, friends and health professionals, (5) nutrition, and (6) how to evaluate new treatments.

It is the process in which the programme is taught that makes it effective. Classes are highly participative, where mutual support and success build the participants' confidence in their ability to manage their health and maintain active and fulfilling lives. Each participant in the workshop receives a copy of the companion book, *Living a Healthy Life with Chronic Conditions*, 3rd edition, and an audio relaxation tape, *Time for Healing*.

The CDSMP *Leader's Manual* is available in Arabic, Bengali, Chinese, Dutch, German, Hindi, Italian, Japanese, Korean, Norwegian, Somali, Turkish, Vietnamese and Welsh.

Key points

- Individuals with limited health literacy have less health knowledge, worse self-management skills, lower use of preventive services, higher hospitalization rates and more premature mortality than individuals with adequate health literacy.
- Medicine is a culture that is not understood by, and often intimidates, patients.
- Common areas of cultural conflict between provider and patient that negatively affect health care delivery include misunderstandings about the role of the family in the care of the patient, lack of common verbal and non-verbal communication styles, misconceptions about cultural norms and ageism by both the patient and the provider.
- Health literacy in older adults can be improved by using written material that is in the primary language of patient, is written at the sixth grade level, uses pictures and illustration, is age appropriate and presents a limited amount of information.
- Health literacy in older adults can be improved using auditory material that is in the patient's primary language, is spoken slowly and is delivered one-on-one by a trusted individual.
- There are many resources available on the Internet to assist with overcoming language barriers and developing culturally appropriate health promotion programmes.

PART 2

Medicine and Prescribing in Old Age

CHAPTER 12

Preventive geriatrics

Gerald M. Mahon[1], Joseph H. Flaherty[1,2] and Suzanne M. Mahon[3]

[1]Saint Louis University School of Medicine, St Louis, MO, USA
[2]St Louis Veterans' Affairs Medical Center, St Louis, MO, USA
[3]Saint Louis University, St Louis, MO, USA

Introduction

Preventive geriatrics is not an oxymoron. It is, however, a challenging area of medicine for many reasons. (1) How can guidelines for prevention take into account the variability seen among older persons? (2) How can preventive geriatrics balance the dichotomy between the treatment of populations and the treatment of the individual? (3) How can clinicians handle the unclear areas or 'grey zones' of preventive geriatrics? (4) Does early detection or case finding equate with better outcomes?

To deal with these questions, this chapter presents a model of preventive geriatrics called the *Health Maintenance Clinical Glidepath*, which is primarily for office-based practices. It addresses screening for geriatric specific areas (e.g. cognition, gait and balance) and also screening for common medical illnesses and diseases (e.g. certain cancers, heart disease).

Background

Prevention in medicine has traditionally been divided into primary, secondary and tertiary prevention. Primary prevention is the prevention of disease before it actually starts.

The traditional definition of secondary prevention is the detection of disease at an early stage. This can be detection of asymptomatic disease by screening tests or identification of unreported problems by case finding. The following caution needs to be added to the definition. Detection should only be done if detection is likely to improve outcomes such as mortality, morbidity, function or quality of life. The priority and importance of outcomes need to be made based on patient preference.

Tertiary screening, using a comprehensive geriatric assessment approach, allows for identification and intervention of established health conditions such as cognitive impairment, gait and balance disorders, malnutrition and urinary incontinence. The goal of the intervention would be to prevent or minimize a patient's functional decline in order to maintain their independent lifestyle, since functional decline and loss of independence are not inevitable consequences of ageing.

The Health Maintenance Clinical Glidepath

The Health Maintenance Clinical Glidepath answers the first two questions above and addresses the limitations of two types of clinical decision-making tools: practice guidelines and evidence-based medicine (EBM). Although practice guidelines and EBM have been important in raising the standards of healthcare in the past decade, their use in preventive geriatrics is limited. Many guidelines do not include older age groups and, if they do, they are no more specific than 'over 65 years of age'. EBM emphasizes outcomes of populations, whereas clinical practice emphasizes the outcome of the individual. One of the limitations of EBM is the discrepancy between patients in the EBM studies and in clinical practice. For example, many randomized controlled trials of medication interventions for common diseases such as congestive heart failure and osteoporosis exclude patients who are frail, demented or at the end of life.

The older we get, the more unique we become. Chronological age does not equate with physiological or functional age. Guidelines for preventive geriatrics need to take this into account. One approach is to use life expectancy and functional status to help delineate categories of older persons that are more useful than those based on chronological age. Overall health status is a good predictor of life expectancy compared with age alone and functional capacity among older persons has been found to be a predictor of mortality. Four categories can be used to help guide

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

decisions about preventive measures. Although overlap exists and functional status may fluctuate, Gillick proposed the following: Robust (life expectancy of >5 years and functionally independent); Frail (life expectancy of <5e years and significant functional impairment); Moderately Demented (life expectancy 2–10 years and may or may not be functionally impaired); and End of Life (usually a life expectancy of <2 years).[1]

Preventive geriatrics requires making decisions. Healthcare decisions are complex, involving society, healthcare workers and patients. Guidelines for preventive geriatrics need to take into account the following practice principles: (1) patients' expectations and needs, including quality of life, satisfaction and reassurance; (2) physicians' need for diagnostic certainty; (3) physicians' comfort with risk taking and concerns about malpractice; (4) the need for cost-effective medical care; (5) variations in practice patterns, particularly with regard to subspecialty care; and (6) the practical realities of running a practice.[2]

Healthcare decisions are not black and white. Thus, four levels of recommendation were developed to allow for decisions to be made on a 'graded' rather than an 'all or nothing' basis and to allow for better patient involvement in decision-making. The four levels are also based, when available, on the strength or weakness of EBM that exists or does not exist. The four levels are 'Do', 'Discuss', 'Consider' and '* * * *'. 'Do' reflects the strongest recommendation. 'Discuss' reflects a recommendation that the physician discusses the risk–benefit of the decision with the patient. 'Consider' reflects a recommendation that the physician gives consideration, but does not necessarily need to discuss the decision with the patient. '* * * *' reflects that a particular evaluation or management measure is not recommended, based on these principles.

Table 12.1 is a shortened version of the original Health Maintenance Clinical Glidepath which details the recommendations for each area of prevention and for each category of Robust, Frail, Moderately Demented and End of Life. It will be noted in the following sections whether recommendations are based on organizational guidelines, EBM or expert consensus. All areas of the Glidepath underwent a Delphi process.[3]

Office visits

Although there is no direct evidence available on how often Robust elderly versus Frail or Moderately Demented elderly need office visits, because other screening procedures need to be done, the minimum frequency should be once per year. 'Do as needed' is recommended for elderly at the End of Life because of potential limitations or inability on the part of the patient to get to the office.

Blood pressure (BP) including orthostatic measurements

Performing BP measurements in all groups is recommended at each visit. Although this pertains to screening for hypertension in all four categories, it also pertains to hypotension (and associated symptoms) in the Frail, Moderately Demented and End of Life categories. Recommendations for hypertension screening are based on organizational guidelines. Although most organizations agree on the importance of screening for hypertension, they do not agree on how often. For example, the recommendations of the American College of Physicians (ACP) for BP screening for adults range from every 1–2 years to every 2–5 years for normotensive patients. The Seventh Report of the Joint National Committee for Hypertension (JNC 7) and The United States Preventative Services Task Force (USPSTF)[4] recommend BP screening for normotensive patients every 1–2 years and yearly for prehypertensive patients.[5] Note that these organizations do not take into account extreme ages of the elderly (for example, the difference between an 85-year-old and a 65-year-old person). They also set the upper limits of normal fairly low compared with more geriatric-oriented groups. The Assessing Care of Vulnerable Elders (ACOVE) Project recommends screening for systolic hypertension begin at a BP >160 mmHg.

Screening for orthostatic hypotension (OH) is based on evidence that OH is prevalent among older patients (13–30%) and that there is an association between OH and adverse outcomes. JNC 7 recommends screening all patients treated for hypertension for orthostatic hypotension, but the frequency is not specified.

Although no studies have been carried out to show improved outcomes if this screening is done, the cost and risk of the intervention are low enough that postural blood pressure measurements are recommended.

Weight

Weight loss in older patients is associated with increased mortality, morbidity and other unfavourable outcomes (e.g. loss of muscle mass, decreased muscle strength, altered immune function, decreased wound healing). The data on the benefit and outcome of nutrition management are somewhat controversial, but mostly positive. Oral nutritional supplement was shown to improve weight in nursing-home elderly, supplementation was shown to improve weight and reduce falls in frail elderly living in the community and dietary supplementation led to moderate weight gain and improvements in general well-being in homebound elderly.[6–8] A meta-analysis concluded that oral nutritional supplements can improve nutritional status and seem to reduce mortality and complications for undernourished elderly patients in the hospital. Current evidence does not

Table 12.1 The Health Maintenance Clinical Glidepath[a].

Item	Robust elderly Life expectancy >5 years and functionally independent	Frail Life expectancy <5 years or significant functional impairment	Moderately demented Life expectancy 2–10 years	End of life Life expectancy <2 years and functionally non-independent
Office visits	Do 2 times/year	Do 1–4 times/year	Do 1–4 times/year	Do as needed
Blood pressure including orthostatics	Do each visit	Do each visit	Do each visit	Do each visit
Weight	Do each visit. If loss of >5 lb/year perform MNA	Do each visit. If loss of >5 lb/year perform MNA	Do each visit. If loss of >5 lb/year perform MNA	* * * *
Height	Do each visit	Do yearly	* * * *	* * * *
Pain assessment	Do each visit	Do each visit	Do each visit	Do each visit
Medication review including OTCs and herbal medicines	Do each visit	Do each visit	Do each visit	Do each visit
Lifestyle education (exercise, smoking cessation, alcohol and injury prevention)	Do each visit	Do each visit	Discuss periodically with caregiver	* * * *
Maintain awareness of elder abuse	Do each visit	Do each visit	Do each visit	Do each visit
Assess ADLs and IADLs	Do yearly	Do yearly	Do each visit	Do each visit
Visual acuity testing	Consider yearly	Consider yearly	Consider yearly	* * * *
Auditory testing	Consider yearly	Consider yearly	Consider yearly	* * * *
Ask about urinary incontinence	Do yearly	Do yearly	Do yearly	Do yearly
Males: ask about erectile dysfunction and ADAM screen for hypogonadism	Do yearly	Do yearly	Consider yearly	* * * *
Cognitive screening	Do initially; do if symptomatic[b]	Do initially; do if symptomatic	Do initially	Consider if symptomatic
Depression screening	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially; do if symptomatic
Screening for gait and balance	Do initially; Do if symptomatic	Do initially; Do if symptomatic	Do initially; Do if symptomatic	Do if symptomatic
Advance directives	Do yearly and as needed	Do yearly and as needed	Do yearly and as needed	Do yearly and as needed
Influenza vaccine	Do yearly	Do yearly	Do yearly	Do yearly
Pneumococcal vaccine	Do once; consider repeat every 6 years for patients with chronic diseases	Do once	Do once	Consider vaccination once
Tetanus	Do primary series if not vaccinated before and booster every 10 years	Do primary series if not vaccinated before	Do primary series if not vaccinated before	* * * *
Zostavax	Do once	Do once	Do once	Consider
Breast examination	Do yearly	Do yearly	Do yearly	* * * *
Mammography	Do every 1–2 years up to age 80 years	Consider every 1–2 years up to age 75 years	Consider every 1–2 years up to age 70 years	* * * *
Pap smear	Consider 1–3 pap smears if patient has never had one	* * * *	* * * *	* * * *
Faecal occult blood test	Do yearly	Consider yearly	Consider yearly	* * * *
Colonoscopy	Consider every 10 years	* * * *	* * * *	* * * *
PSA	Discuss pros and cons with patient	Discuss pros and cons with patient	Discuss pros and cons with caregiver	* * * *

(*continued overleaf*)

Table 12.1 (*continued*)[a].

Item	Robust elderly Life expectancy >5 years and functionally independent	Frail Life expectancy <5 years or significant functional impairment	Moderately demented Life expectancy 2–10 years	End of life Life expectancy <2 years and functionally non-independent
Osteoporosis	Do at least once; consider every 2 years	Do at least once every 2 years	Do at least once	* * * *
Cholesterol screening	Consider screening for patients aged 65–75 years if they have additional risk factors (e.g. smoking, diabetes, hypertension)	Consider screening for patients aged 65–75 years if they have additional risk factors (e.g. smoking, diabetes, hypertension)	* * * *	* * * *
TSH	Do every 2 years	Do every 2 years	Do every 3 years	Consider
Fasting blood glucose	Do if symptomatic or every 3 years if the patient has risk factors	Do if symptomatic or every 3 years if the patient has risk factors	Do if symptomatic or every 3 years if the patient has risk factors	Consider if symptomatic
Sleep apnea	Do yearly	Do yearly	* * * *	* * * *

[a]MNA, Mini-Nutritional Assessment; OTC, over-the-counter; ADLs, activities of daily living; IADLs, instrumental activities of daily living; ADAM, androgen deficiency in adult males; PSA, prostate-specific antigen; TSH, thyroid-stimulating hormone.
[b]The term 'symptomatic' refers to any complaint given by the patient or caregiver or any problem observed/elicited by the clinician.

support routine supplementation for older people at home or for well -nourished older persons in any setting.[9]

Since screening for weight loss is very low cost and low risk and the benefits of intervention are mostly positive, it should be done for patients in all categories except End of Life. Outpatient screening of unintentional weight loss of 10% or greater in 1 year is indicative of significant malnutrition. Utilizing a validated screening tool, such as the Mini-Nutritional Assessment (MNA), can identify patients who are malnourished or at risk for malnutrition.[10]

Height

Since measuring height is a low-cost screening intervention and as bone loss occurs height may decrease, it may be an effective and economical method to identify early osteoporosis of the spine for Robust and Frail elderly. One study showed a significant association with historical height loss of 1.5 cm and vertebral fractures.[11]

Pain

Pain should now be considered the fifth vital sign and should be assessed at every visit for patients in all categories. Use of Likert scales (e.g. 1–10) or pictorial scale (e.g. facial expressions) can be useful to quantify pain. Even patients with dementia can be evaluated for pain, using such tools as the CNA Pain Assessment Tool (CPAT) and the Pain Assessment in Advanced Dementia Scale (PAINAD-G).[12,13]

Medication review including over-the-counter (OTC) and herbal medicines

The risk of adverse drug events, poor compliance and drug–drug interactions, and even the risk of hospitalization, are most associated with number of drugs, while underlying comorbidities and to some extent age contribute to this risk.[14,15] Patients should maintain an up-to-date medication list including OTC and herbal preparations, to bring in at each office visit or hospitalization. Medication reviews should be performed for patients in all four categories at each office visit, to assess for duplication, drug–drug or drug–disease interactions, adherence, affordability and side effects.

Lifestyle education

Recommendations about areas of lifestyle education in general apply mainly to the Robust and Frail elderly,

with a lower level of recommendation for the Moderately Demented elderly. Activity level should be queried because a low level of activity is a significant predictor of mortality among older adults.[16] In robust elderly, physical activity plays an important role in prevention and reduction of mortality and treatment of various chronic and disabling conditions (e.g. obesity, cardiovascular disease, stroke, diabetes mellitus type 2, hypertension, depression, osteoporosis, osteoarthritis, cognitive decline). Frail elderly undergoing randomized trials of exercise experienced fewer falls, injuries and healthcare utilization. Although the USPSTF does not recommend behavioural counselling of elderly patients by primary care physicians to promote increased physical activity, other professional organizations, such as the ACP, American Heart Association (AHA) and American College of Sports Medicine (ACSM) do support exercise promotion in the elderly. Specific recommended exercises fall into four categories: aerobic, muscle strengthening, flexibility activities and balance training.

Physicians should ask patients about smoking and should clearly and directly advise all smokers to quit. Patients who want to quit should be assisted with self-help materials, encouraged to set a quit date, be referred for behavioural therapy or be advised to try OTC or prescription medications.

Alcohol abuse can initially be screened for by asking what quantity a patient consumes on a regular basis. Men who consume more than four drinks per day and women who consume more than two drinks per day are at risk of alcohol-related problems.[17] A more thorough assessment should include screening tools such as the CAGE questionnaire, MAST or AUDIT. Of these three, the CAGE questionnaire has the best sensitivity and specificity for diagnosing alcohol dependence.[18] Both the USPSTF and the American Geriatrics Society (AGS) recommend that primary care providers screen their older patents for alcohol misuse.

Areas of education for injury prevention include the use car seat belts, alcohol-related risks in relation to driving, home environmental hazards to reduce falls and the restriction of access to firearms and driving with depressed and cognitively impaired patients.[5]

Maintain awareness of elder abuse

Physicians and other healthcare professionals should maintain awareness at all times for patients in all categories. A review of elder abuse screening and assessment instruments have shown that older adults were unlikely to report episodes of elder mistreatment and identification of 70% or more of elder mistreatment comes from third-party observers.[19] Healthcare providers should consider referral to a social service agency for evaluation of mistreatment if elderly patients present with unexplained contusions, burns, bite marks, genital or rectal trauma, pressure ulcers and a BMI of less than 17.5%.

The term 'awareness' is used because no particular standardized evaluation tool for elder abuse has been shown to be better than others.[20]

Assess ADLs and IADLs

Prevention of functional decline is one of the hallmarks of geriatric care. Loss of function among older persons is associated with long-term care placement, morbidity and mortality. Thus, although there is no direct evidence on how often to screen older patients in each of the four categories for functional change, given the importance of this health parameter it is recommended for patients in all categories at the intervals as noted in Table 12.1.

Two commonly used measurements of function are Activities of Daily Living (ADLs) (bathing, dressing, toileting, transferring, continence, feeding) and Instrumental Activities of Daily Living (IADLs) (telephone, shopping, food preparation, housekeeping, transportation in the community, taking medications, handling finances).

Visual acuity and auditory testing

Although both of these are an accepted part of the comprehensive geriatric assessment (CGA), the level of recommendation for testing these areas is 'consider' for patients in all categories. Based on a review of vision screening studies, direct evidence of vision screening in asymptomatic older adults in primary care settings found no effect in improving visual acuity or other clinical outcomes.[21] The USPSTF concluded that evidence is insufficient to determine whether screening older adults for visual impairment improves functional outcomes. However, due to improved treatment of various chronic eye diseases, the National Eye Institute, the American Optometric Association and the American Academy of Ophthalmology do recommend routine comprehensive eye examinations in asymptomatic patients performed by optometrists or ophthalmologists every 1–2 years.

Likewise, although there is evidence that decreased hearing is common and associated with negative outcomes, there is a lack of EBM that screening will improve outcomes.[22] However, use of hearing aids or surgical intervention has a positive effect on quality of life. The ACOVE authors suggest an annual hearing screening by either questionnaire or hand-held audiometry.

Ask about urinary incontinence

The level of recommendation here is the highest for all categories because urinary incontinence is common among women and may occur in men, is easy to screen for (usually one to two questions) and multiple effective treatments are available.

Males: screen for erectile dysfunction (ED) and hypogonadism

It is recommended that this be done for males in robust and frail categories, but should only be considered in males with moderate (not severe) dementia. ED is common, with multiple treatments available.

Male hypogonadism is also common and is associated with muscle weakness and osteoporosis. The ADAM (Androgen Deficiency in Aging Males) screen for hypogonadism has high sensitivity and adequate specificity (see Chapter 111 for details.)

Cognitive screening

Screening for cognitive impairment is part of a CGA and should be done at initial visits for patients in all categories, except for those at End of Life, where it should be considered. The Mini-Mental State examination is a commonly used screening tool, but may have limited utility if the cut-off score is set too high.[23] For elderly with high education levels, the Saint Louis University Mental Status (SLUMS) examination, along with other screening tests, may be used.[24]

Depression screening

Depression screening should be carried out at initial visits for patients in all categories A systematic review concluded that screening for depression can improve outcomes, particularly when screening is coupled with system changes that help ensure adequate treatment and follow-up.[25]

Screening for depression is part of a CGA. There is no strong evidence for one particular screening instrument for depression. The Geriatric Depression Scale (GDS) may be one of the easiest to administer.[26] However, the GDS does not maintain its validity for patients with dementia and the Cornell scale (a 19-item clinician-administered instrument) is recommended.[27]

Screening for gait and balance

The evidence to screen for gait and balance problems at initial visits in all categories except at End of Life is based on the fact that falls are associated with decreased function, increased nursing home admission and increased morbidity and mortality in populations similar to patients in these categories. One of the best 'screeners' for gait and balance problems is to ask patients if they have fallen. The 'Get Up and Go Test' may quantify functional mobility in addition to testing balance and may also be useful in following clinical change over time.[28,29]

Advance directives

Although the evidence is not strong that advance directives make a difference in outcomes (e.g. one study showed that systematic implementation of a programme to increase use of advance directives reduced the utilization of healthcare services without affecting satisfaction or mortality),[30] there are ways to increase discussions and completions of advance directives.[31] Clinicians should take care to assure that underlying depression does not underlie patient preferences or decisions.

Advance directives are especially important for patients in the Frail, Moderately Demented and End of Life categories.

Influenza vaccine

This should be done yearly for patients in all categories. More than 90% of the deaths attributed to pneumonia and influenza during epidemics occurred among persons aged 65 years and older. Influenza vaccination in the elderly has been shown to reduce hospitalization rates, to be cost-effective and to reduce influenza-associated mortality. In the nursing home, although vaccination is only 40% effective in preventing clinical illness, it is more effective in preventing pneumonia, hospitalization and death. Vaccinating more than 80% of nursing home residents has been shown to prevent influenza outbreaks.[32,33]

Pneumococcal vaccine

The recommendations about pneumococcal vaccine are based on some evidence and based on probable life expectancy in various categories. Although pneumococcal vaccination increases antibody levels in older adults to a lesser extent than younger adults and levels decrease more rapidly in the elderly, vaccination has been shown to be effective in reducing the incidence of pneumococcal bacteraemia in older, high-risk patients who have good antibody response to the vaccine.

Most organizations recommend one dose of the 23-valent pneumococcal vaccine to be given for all adults over age 65 years. Older patients who received the earlier 14-valent vaccine should be revaccinated with the 23-valent vaccine if they fall into any of those two groups. If patients have had the 23-valent vaccination before age 65 years, the recommendations for revaccination are controversial.[5] The ACP

reports that there are currently insufficient data on repeated revaccination every 6 years in healthy elderly and most other organizations do not provide specific recommendations for revaccination. However, since older patients with chronic diseases may occasionally be 'Robust' for other reasons, clinicians should '*consider* repeating' every 6 years.

Tetanus

Recommendations regarding adult tetanus/diphtheria vaccination do not vary for older persons from those for younger adults. Over half of the cases of tetanus occur in persons aged 60 years or older. All adults should complete a primary series of tetanus/diphtheria toxoid (Td). If an individual had an incomplete series or an uncertain history, it is recommended that the entire primary series be given. Primary series for adults consists of 0.5 ml of Td intramuscularly as the initial dose and at 2 and 6 months later. Booster doses need to be given every 10 years.[5,34]

Zostavax

Reactivation of latent varicella zoster virus results in a localized eruption known as herpes zoster (shingles). Its incidence increases with age, occurring in up to half of individuals age 85 years or older. Postherpetic neuralgia is a potentially devastating complication, occurring in more than 40% of individuals older than 60 years.[35] In 2006, the FDA approved the use of Zostavax in patients age 60 years or older for prevention of recurrent herpes zoster infection. The Advisory Committee on Immunization Practices (ACIP) recommends a one-time dose of Zostavax for immunocompetent adults age 60 years or older regardless of known prior herpes zoster infection.

Breast cancer screening

There is no evidence for or against the clinician recommending self-examination or the clinician doing the clinical breast examination. Breast self-examination may allow women to detect lesions or breast cancers not seen on mammography or those that develop in between mammography or clinical breast examinations. Clinicians performing breast examinations may find lesions or breast cancers not detected on mammography. Breast examinations should be performed yearly in all categories except for those in the end of life category.

Mammography is the mainstay of breast cancer screening. Research has shown mammography to be effective up to age 80 years.[36] There is lack of agreement among organizations regarding screening with mammography. The American Cancer Society (ACS) recommends yearly mammography in older adults provided that a women is in good health. There are few studies that describe women's decision-making to stop mammography. It appears that some women and their health providers, recognizing that the expected benefit of early detection declines with remaining life expectancy, consciously decide to discontinue screening following a serious health event.[37] The USPSTF recommends biennial screening mammography for women up to age 74 years.

Cervical cancer screening

The low levels of recommendation for Robust ('consider') and 'Don't Do' for the other categories are based on lack of evidence and organizational recommendations. The ACP and the USPSTF recommend no further Papanicolaou (pap) smears for women over age 65 years who have had previous regular screening with consistently normal results. The AGS position statement says that regular pap smear screening at 1–3 year intervals until at least the age of 70 years seems reasonable. Beyond that age, there is little evidence for or against screening women who have been regularly screened in previous years. An older woman of any age who has never had a pap smear may be screened with at least two negative pap smears 1 year apart. The ACS and AGS both recommend that women 70 years and older who have tested positive for HPV DNA should continue screening at the discretion of their healthcare provider.

Colon cancer screening

Regular screening or testing is one of the most effective means of preventing colorectal cancer. This is because most polyps or growths can be found and removed before they have the chance to turn into cancer. The clinician's choice of screening procedure for colon cancer depends on extrinsic factors (e.g. transportation, availability of a gastroenterologist, the patient's willingness to do one procedure over the other and the patient's health status). It is recommended that clinicians consider ordering screening colonoscopies for their robust patients based on current guidelines and based on the number of years it takes for polyps to turn into cancer. Primary care physicians may choose to limit screening in frail individuals or patients with dementia.

The recommendations on the type and frequency of screening procedures vary among different organizations. The USPSTF supports the use of either screening colonoscopy every 10 years, annual screening with a sensitive faecal occult-blood testing (FOBT) or flexible sigmoidoscopy every 5 years with a mid-interval sensitive FBOT. The recommended age of screening is from 50 to 75 years. The ACS lists the following options for colon cancer screening: flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, double-contrast barium enema

every 5 years, virtual colonoscopy (CTC) every 5 years or annual three-sample FBOT. Colonoscopy is a more thorough examination and is the preferred option for screening. Virtual colonoscopy (CTC) is the newest type of screening and should be reserved for patients who cannot undergo a colonoscopy. The ACS does not list an upper age limit on screening.

Prostate cancer screening

The biggest controversy in prostate screening is that some prostate cancers grow slowly and would never cause any problems. Because of an elevated PSA, men may be diagnosed and treated for prostate cancer with either surgery or radiation for lesions that would not cause symptoms or lead to their death. These treatments have side effects that can seriously affect a man's quality of life. No major scientific or medical organization, including the ACS, American Urologic Association (AUA), USPSTF, American Academy of Family Physicians and the American college of Preventive Medicine, support routine testing for prostate cancer at this time. The National Comprehensive Cancer Network (NCCN) guidelines focus on men at an increased risk for developing prostate cancer due especially to family history and race. These organizations emphasize the need for healthcare professionals to discuss, with the male patients, the possible benefits, side effects and questions about early prostate cancer detection. Therefore men, at least 50 years old or younger if at higher risk, can make informed decisions taking into account their own situations.

Osteoporosis

The recommendation to screen at least once for patients in all categories except End of Life is based on studies that show inadequate rates of diagnosis and treatment. However, there is lack of evidence to show that mass screening of all elderly women and men will be cost-effective or improve outcomes related to osteoporosis.[38]

Dual-energy X-ray absorptiometry (DXA) is the current gold standard test for diagnosing osteoporosis in people without a known osteoporotic fracture. It is, however, an imperfect test, diagnosing osteoporosis in less than half of people who progress to have an osteoporotic fracture.[39] Other screening methods have been evaluated to improve the diagnostic accuracy of osteoporosis. These include the WHO fracture risk algorithm (FRAX), which computes the 10 year probability of fractures in men and women from clinical risk fractures: age, gender, previous fracture, femoral neck BMD, body mass index, prior corticosteroid use, history of rheumatoid arthritis, parental history of hip fracture and current smoking and alcohol use.[38,39] The osteoporosis self-assessment screening tool (OST) and calcaneal ultrasound are also both being evaluated in men and women to determine their potential role in better diagnosis of osteoporosis. The USPSTF recommends osteoporosis screening using DXA for routine screening of women at age 65 years and for women at age 60 years with risk factors for osteoporosis. The frequency of screening and the age at which to stop screening are not known. In addition to women, the ACP recommends periodic assessment of men for risk factors for osteoporosis (low body weight, physical inactivity, chronic glucocorticoid use, previous fragility fracture and hypogonadism) and DXA scanning for men at increased risk and who are candidates for drug treatment.

Cholesterol screening

The reason for a low-level recommendation (i.e. 'consider') and a targeted approach (only for the robust and frail with additional risk factors) for cholesterol screening is because there is limited evidence about primary prevention of coronary heart disease using drugs in older populations. However, there are recommendations by organizations for secondary prevention of coronary heart disease in the elderly. The USPSTF does recommend screening individuals age 65 years or older with coronary risk factors because studies have shown a reduction in coronary events on treating patient's with statins compared with placebo. The National Cholesterol Educational Program reaffirms the position that older persons, who are at higher risk and in otherwise good health, are candidates for cholesterol-lowering therapy. The decision to treat should also be based on coexisting disease, social and economic considerations and functional age. There is no upper limit for age of screening and treatment for lipid disorders in the elderly. The recommendations for the frequency of screening are not known.

Thyroid-stimulating hormone (TSH)

TSH screening of all older adults is not currently recommended by the USPSTF on the basis of lack of data. It does recommend screening of symptomatic patients. The ACP suggests office screening of women older than 50 years may be indicated. However, the evidence for treating subclinical thyroid dysfunction is inconclusive.[40] The American Thyroid Association issued guidelines which recommend measuring TSH level starting at age 35 years and every 5 years thereafter. Hypothyroidism may not be associated with adverse outcomes in the oldest individuals when detected by screening alone. A prospective study involving individuals aged 85 years or older did not show an association of elevated TSH levels with reduction in cognitive function, mood or performance of ADLs. Higher TSH

levels were associated with lower all-cause and cardiovascular mortality.[41] Many geriatricians advocate screening high-risk populations such as nursing home populations, frail elderly and patients with dementia.[42] The sensitive TSH assay is probably the screening test of choice.

Fasting blood glucose

This recommendation is based on organizational recommendations only. Although the USPSTF recommends against routine screening for diabetes in asymptomatic individuals, it does endorse screening for patients with a blood pressure of 135/80 or greater. The American Diabetes Association has recommended fasting plasma glucose measurement every 3 years in adults with one or more of a long list of risk factors. It also recommended yearly fasting glucose measurements in patients with pre-diabetes (fasting blood sugar between 100 and 125 mg dl^{-1} or 2 h postprandial blood sugar between 140 and 199 mg dl^{-1}).

Sleep apnea

Because of the low cost of screening (in the form of asking about symptoms of sleep apnea during the routine history and physical or to use a screening questionnaire tool such as the Epworth Sleepiness Scale)[43] and the potential to miss this diagnosis among older patients, it is recommended for robust and frail elderly. Two studies have shown some benefit of treatment of sleep apnea in patients with heart failure and stroke.[44,45]

Abdominal aortic aneurysm

Performing a one-time screening for abdominal aortic aneurysm with abdominal ultrasound has been shown to reduce mortality in men. However, no benefit was shown for similar screening in women.[46,47] The USPSTF and the AHA currently recommend screening in men aged 65–75 years who have ever smoked. They do not recommend screening in women. There is no recommendation for screening men who have never smoked except in individuals who had a first-degree relative who underwent an abdominal aneurysm repair.[5]

Key points

- Health promotion and preventive medicine are key to good outcomes
- Older persons with different levels of function require different approaches
- Vaccinations remain important in older people

CHAPTER 13

Polypharmacy

Oscar A. Cepeda and John E. Morley
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

Geriatric patients are frequently prescribed multiple drugs in complex dosage schedules. In some instances, this is justified because of the presence of multiple chronic medical conditions, the proven efficacy of an increasing number of drugs for these conditions and practice guidelines that recommend their use. In many instances, however, complex drug regimens are unnecessary; they are costly and predispose to non-compliance and adverse drug reactions. Many older patients are prescribed multiple medications, take over-the-counter drugs and are then prescribed additional drugs to treat the side effects of medications they are already taking. Taking over-the-counter drugs, such as vitamins, often leads to non-compliance with therapeutically appropriate drugs.

Although persons aged 65 years and older comprise only about 12% of the US population, they consume one-third of all prescribed drugs and more than half of over-the-counter medicines. Overall, more than 80% of all community-dwelling elders use prescription drugs, with the average older person using between three and eight drugs and 70% of nursing home residents in the USA are receiving more than nine drugs.[1] The devastating consequences of medical errors have been clearly detailed in the book *To Err is Human* by the Institute of Medicine. Medical errors are not uncommon, leading to a number of deaths ranging between 44 000 to 98 000 at a cost of $17–29 billion per year. A Harvard study done in 51 New York hospitals involving 30 000 patients reported that 3.7% had a treatment adverse event and there was a doubling in the number of undesirable treatment effects in persons over 65 years of age. Most errors are preventable; errors of omission are as important as errors of commission.[2]

In addition to concerns about the risks of excessive and inappropriate drug prescribing, there are also concerns about the consequences of underprescribing potentially beneficial drugs. With the increasing numbers of patients surviving to older ages and comprising such a large proportion of drug use, a clear understanding of the risks, benefits and consequences of drug therapy in older patients is needed.

Pharmacokinetics

Pharmacokinetics (the study of the action of a drug in the body over time) changes with age. The physiological changes that accompany ageing alter the pharmacological processes of absorption, distribution, metabolism and elimination. The effects of these age-related changes are variable and difficult to predict. Some of these physiological changes are related solely to ageing, whereas others are most likely caused by the combined effect of age, disease and the environment. Even though increasing age is often accompanied by reductions in the physiological reserve of many organ systems, independent of the effects of disease, these changes are not uniform; substantial variability exists from individual to individual, which makes some older patients more vulnerable than others.

Of the four traditional components of pharmacokinetics – absorption, distribution, metabolism and excretion – only the last three are meaningfully affected by age. In the absence of malabsorptive syndromes, traditional oral formulation of drugs are absorbed as well in old age as in youth; indeed, the well-reported changes in gastric motility and blood flow to the gut with ageing do not appear to alter the efficiency with which medications move (mainly by passive diffusion) from the gastrointestinal tract into the systemic circulation. More important changes occur from the concurrent administration of several medications at the same time. However, some drugs commonly used for older persons require food for optimum absorption, for example, megestrol acetate which is used to stimulate appetite and weight gain has minimal absorption without food (Table 13.1).

Unlike absorption, drug distribution is affected by age in clinically meaningful ways. Serum albumin, the major

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 13.1 Relevant changes in ageing and pharmacology.

Pharmacological parameter	Age-related changes	Clinical effect
Tissue sensitivity	Alterations in: Receptor number and affinity Nuclear responses Second messenger function	Patients are more sensitive or less sensitive to a given medication
Absorption	Decrease in: Splanchnic blood flow Absorptive surface gastrointestinal motility Increased gastric pH	Minimal changes associated with ageing
Distribution	Decrease in: Total body water Serum albumin Lean body mass Increased fat	Higher concentration of drugs Longer elimination half-life of lipid-soluble drugs
Metabolism	Decreased liver blood flow and enzyme activity	Decreased biotransformation and first-pass metabolism
Excretion	Decreased renal perfusion, glomerular filtration rate and tubular secretion	Decreased renal elimination of drugs

drug-binding protein, declines in sick patients due to cytokine excess. Even in healthy patients where there is a small decline, this can substantially increase the amount of free drugs available for action. This effect is of particular relevance for highly protein-bound drugs, especially when they are used simultaneously and compete for protein-binding sites. In long-term care residents, diphenylhydantoin toxicity with low serum levels can occur because the decrease in albumin. Hence measurement of a free dilantin level can be essential in these situations.

The relative increase in body fat and decrease in lean body mass alter drug distribution, such that fat-soluble drugs distribute more widely and water-soluble drugs less widely; this fact can potentially lead the healthcare professional to the wrong decision due to misinterpretation of serum drug levels. Many assays measure the total amount of drug that is present in serum, both protein-bound and unbound (free). The unbound concentration is more clinically relevant than the total concentration because only unbound drug is pharmacologically active.[3] For a patient with hypoalbuminaemia or another deficiency in binding protein, any given serum drug level reflects a greater concentration of unbound drug than the same level would signify in a patient with normal protein-binding capacity. A hypoalbuminaemic patient with a normal total serum drug concentration may actually have an unbound drug concentration that is unacceptably high. By contrast, the same patient with a slightly lower than normal total serum concentration may have an unbound drug concentration that is in reasonable range[3] (Table 13.2).

Table 13.2 Volume of distribution for commonly used medications[a].

Decreased volume	Increased volume
Ethanol	Diazepam
Gentamicin	Oxazepam
Digoxin	Prazocin
Cimetidine	Acetaminophen
Phenytoin	Salicylates
Quinine	Tolbutamide
Theophylline	Chlordiazepoxide
Meperidine	

[a] If the volume of distribution is higher, drug levels are higher.

In evaluating serum drug levels in the older patient, it is also important to recall that the therapeutic range routinely reported in such assays may not be an accurate guide to either efficacy or toxicity in the geriatric patient. Such ranges have typically been defined in non-elderly subjects and cannot take into account pharmacodynamic differences or idiosyncratic aspects of specific agents.[4]

The other important aspect is the drug distribution, which varies considerably with age; the volume of distribution (V_d) is a virtual space in a given patient which a particular drug occupies. Age-related changes in body composition can greatly affect pharmacology by altering V_d; the elimination half-life of a drug varies with the V_d:drug clearance ratio. Thus, even if the same rate of clearance of a drug

is unchanged with age, changes in V_d can affect a drug's half-life and duration of action.

Because the total body water and lean body mass decline with increasing age, drugs that distribute in these compartments, such as antibiotics, digoxin, lithium and alcohol, may have a lower V_d and can, therefore, achieve higher concentrations from given amounts of drugs. On the other hand, drugs that distribute in body fat, such as many of the psychotropic agents, have a high V_d in geriatric patients. The larger V_d will thus cause a prolongation of the half-life unless the clearance increases proportionately, which is unlikely to happen with age.[4]

As an example of the necessary precautions that need to be implemented in elderly patients, warfarin is an excellent candidate because it has been used more often in older persons. Warfarin inhibits the four vitamin K-dependent coagulant proteins, factors II, VII, IX and X, and it is highly protein-bound (97–99%), which could be a problem in malnourished patients, metabolized in the liver and, with a half-life of 42 h, its onset of action is ~36–72 h, with a peak effect within 5–7 days.

Warfarin has been proven to be effective in prophylactic or therapeutic anticoagulation, but the risk of major bleeding with increasing levels of prothrombin time/international normalized ratio (PT/INR) is a major concern; it is increased by the presence of comorbid conditions such as heart failure, liver or kidney failure or cancer. The warfarin dose should be highly individualized and may have to be adjusted several times, based on laboratory test results depending on the target INR for the patient's condition; strict adherence to the prescribed dosage schedule is necessary and patients should be informed not to take or discontinue any other medications, except on the advice of a physician or pharmacist. Checking the pharmacogenomics[5] for all patients when initiating warfarin is recommended. An excellent algorithm for initiating warfarin treatment can be found at www.warfarindosing.org.

In elderly patients, initial doses of warfarin typically are lower and INR monitoring should be performed more frequently and because warfarin possesses numerous drug interactions, some of which increase the effects of warfarin and others that decrease its effects, caution must be observed when any drug, herbal, nutritional supplement or dietary changes are made to existing regimen of a patient receiving warfarin.

Metabolism and drug clearance

The liver represents the major site of metabolism for many medications. Hepatic transformations of drugs are categorized into phase I (preparative) and phase II (synthetic) reactions. Phase I reactions include oxidations (hydroxylation, *N*-dealkylation and sulfoxidation), reductions and hydrolyses. Phase II reactions involve conjugation of the drug molecule to glucuronides, sulfates or acetates. There is evidence of decline in phase I reactions with increasing age and that the decline is more prominent in men than in women. In contrast, the second phase of drug metabolism appears to be less affected by age. There is also evidence that the ability of environmental factors (most importantly smoking) to induce drug-metabolizing enzymes declines with age.[6]

Significant age-related declines in liver size and in liver blood flow have been described; in terms of absolute hepatic blood flow, reductions of 25–47% have been reported in persons between the ages of 25 and 90 years. This decrease is clinically important because hepatic metabolism is the rate-limiting step that determines the clearance of most metabolized drugs. This effect is especially relevant for drugs that undergo rapid hepatic metabolism (e.g. propranolol). Also, drugs that undergo extensive first-pass metabolism are likely to reach higher blood levels if hepatic blood flow is decreased.

The cytochrome P450 (CYP) system, located in the smooth endoplasmic reticulum of hepatocytes, is the main catalyst of phase I reactions. Many isoforms of CYP exist, the most important being CYP3A4, ~60% of CYP enzymes are found in the liver and the remainder are found in the intestine, kidney and brain. Many commonly prescribed medications serve as substrates for these enzyme systems. Phase 1 metabolism often undergoes a substantial decrease in activity in elderly patients as a result of illness or drug interactions; drugs that are metabolized through phase I enzymatic activity will have prolonged half-lives, but there is no easy way to predict the effects of changes in phase I metabolism in an individual patient or to adjust maintenance doses of drugs that undergo this form of metabolism[6] (Table 13.3).

In contrast, phase II hepatic metabolism involves the conjugation of drugs or their metabolites to organic substrates. The elimination of drugs that undergo phase II metabolism by conjugation is generally less altered with age. Thus, drugs that require only phase II metabolism for excretion do not have a prolonged half-life in older people.

Elimination and renal excretion

Unlike the effects of metabolism, those of ageing on renal functions are somewhat more predictable. The tendency for renal function to decline with age can affect the pharmacokinetics of several drugs (and their active metabolites) that are eliminated predominantly by the kidney. Clearance of drugs from the body occurs more slowly, their half-lives are prolonged and there is a tendency to accumulate to higher drug concentrations in the steady state (Table 13.4).

Although blood urea nitrogen (BUN) and serum levels may be useful (albeit crude) markers of renal function, it

Table 13.3 Metabolism of some drugs by the hepatic cytochrome P450 system is altered by ageing.

	Cytochrome P450				
	CYP1A2	**CYP2C9**	**CYP2C19**	**CYP2D6**	**CYP3A4**
Substrates	Olanzapine Theophylline	Phenytoin Warfarin	Diazepam Omeprazole Phenytoin	Codeine Desipramine Haloperidol Metoprolol Paroxetine Risperidone	Alprazolam Nifedipine Terfenadine Triazolam Verapamil
Inducers	Omeprazole Smoking		Rifampin		Phenytoin St John's wort
Inhibitors	Cimetidine Ciprofloxacin		Amiodarone Fluconazole		Erythromycin

Table 13.4 Medications with decreased renal excretion.

Triamterene	Atenolol
Sotalol	Amantadine
Procainamide	Ampicillin
Ranitidine	Cimetidine
Pancuronium	Cephradine
Phenobarbital	Ceftriaxone
Penicillin	Digoxin
Lithium	Furosemide
Kanamycin	Doxycycline
Hydrochlorothiazide	Gentamicin

must be remembered that each is susceptible in its own way to perturbations that can occur with ageing but have nothing to do with renal function itself. For example, BUN reflects the concentration of urea in the blood. However, the origin of much of this urea is ingested protein, so that a malnourished older patient may not consume enough nitrogen to produce an appropriate rise in BUN, even in the face of renal impairment. Similarly, creatinine is produced by muscle and if a patient has a markedly diminished muscle mass, whether because of chronic illness or any other cause, he or she may not produce enough creatinine to reflect a change in the ability of the kidney to excrete this substance. Hence over-reliance on normal-appearing BUN and creatinine in older patients can severely underestimate the degree of renal impairment. Further decrement in renal function is common in the elderly because they frequently have chronic illnesses that affect the kidney such hypertension, diabetes mellitus and atherosclerosis.

Early cross-sectional studies of renal function in ageing suggested that there is a linear decrease in renal function between young adulthood and old age, amounting on average to a reduction in glomerular filtration rate by nearly one- third. The average clearance declines by 50% from age 25 to 85 years, despite the serum concentration that in healthy adults remains unchanged. Because the serum levels tend to overestimate the actual clearance in older persons, the commonly cited equation devised by Cockcroft and Gault may be used to estimate clearance in older adults:

$$\mathrm{CrCl} = \frac{(140 - \mathrm{age}) \times \mathrm{weight(kg)}}{70 \times \mathrm{serum\ Cr}}$$

(for women, multiply by 0.85). However, it should be recognized that this equation represents a poor approximation of renal function in the old-old.

The MDRD (modification of diet in renal disease) equation is a better equation for estimating creatinine clearance in older persons. Cystatin C, which comes from the nucleus and is cleared by the kidney, is the preferred measure for estimating glomerular filtration rate in older persons.

Altered renal clearance leads to two clinically relevant consequences: (1) the half-lives of renally excreted drugs are prolonged and (2) the serum levels are increased. For drugs with large therapeutic indexes (e.g. penicillin), this is of little clinical importance; however, for drugs with a narrower therapeutic index (e.g. digoxin, cimetidine, aminoglycosides), side effects may occur in older patients if a dose reduction is not made. Thus, digoxin is the drug that most often causes side effects in the elderly, especially when doses exceed 0.125 mg per day. To define dose requirements further, therapeutic drug monitoring is useful for doses of drugs with a low therapeutic index.

A common goal of pharmacotherapy in older persons is to achieve and maintain a therapeutic steady-state serum concentration. The steady-state drug concentration is proportional to the medication dosing rate and is inversely proportional to drug clearance. This relationship has a number of important ramifications for the prescriber. Although drug clearance is a biologically determined characteristic of each patient over which the prescriber has no

control, dose and dosing interval are variables that can be modified. To prevent the excessive accumulation of a drug when its clearance is reduced, one can reduce the dose, increase the interval between doses, or both, depending on the situation.

Pharmacodynamics

A proportion of the drug or its active metabolite will eventually reach its site of action. Age-related changes at this point, that is, responsiveness to given drug concentrations (without regard to pharmacokinetic changes) are termed *pharmacodynamic changes*.

Pharmacodynamics has been less extensively studied than pharmacokinetics in older patients. Generalizability is not straightforward; the effect of age on drug sensitivity or the binding of drug to receptor sites varies with the drug studied and the response measured. These differences in sensitivity occur in the absence of marked reductions in the metabolism of the drug and its related compounds.

Older persons are often said to be more sensitive to the effects of drugs. For some drugs, this appears to be true; however, sensitivity to drug effects may decrease rather than increase with age. For example, older persons may be more sensitive to the sedative effects of given blood levels of benzodiazepines but less sensitive to the effect of drugs mediated by β-adrenergic receptors; hence the sensitivity to drug effects may either increase or decrease with age. Other possible explanations offered for these differences are alterations in second messenger function and cellular and nuclear responses.

In general, and because the response of older patients to any given medication is variable, medications should be used with caution to achieve the goal of minimizing risks. This problem could be minimized by knowing the pharmacology of the drugs prescribed, limiting the number of medications used, determining the dosage and preparation on the basis of the characteristics of each individual patient, with downward adjustment for known hepatic or renal illness, and by surveying for side effects (Table 13.5).

Table 13.5 Examples of adverse drug reactions.

Type of drug	Common adverse reaction
Aminoglycosides	Renal failure, hearing loss
Anticholinergics	Dry mouth, delirium, constipation
Narcotics	Constipation, sedation
Diuretics	Dehydration, hyponatraemia, hypokalaemia, incontinence
Sedative-hypnotics	Excessive sedation, delirium, increased risk for falls
Anti-arrhythmics	Diarrhoea, urinary retention
Antipsychotics	Delirium, sedation, extrapyramidal movements

Pharmacogenetics

This novel area of research and development in the medical sciences has been defined as the identification of differences in drug effects that have a genetic basis, but also the development of simple methods by which susceptible individuals can be recognized before the drug is administered.

It has been said that the major concern of pharmacogenetics is related to using information about how the effect of variations in the genetic makeup could affect the clinical efficacy of drugs, the required dose of drugs, the choice of the correct agent and the risk for side effects to drugs.[7]

The fundamental theory of pharmacogenetics states that genotype affects expression of genes resulting in a phenotype and the expression of genes is also modified by agents in the environment. Conversely, the expression of the gene may influence the efficacy of a drug by affecting its metabolism, availability at its site of action and by how the drug binds to its target receptors and achieves a desired pharmacological action. The rapid growth of pharmacogenetics has been helpful in terms of rapid identification and gene sequencing for drug targets, including receptors, transport proteins, ion channels and enzymes that metabolize drugs.

Currently available data on pharmacogenetic research has shown that it will be useful in the near future since the therapeutic–pharmacological approach in many chronic diseases is promising. For example, in chronic conditions or environmental exposures such as nicotine addiction, the response of smokers to drugs for smoking cessation differ according to variations in genes encoding several receptors and enzymes. Genetic variations that affect the function and availability of proteins (dopaminergic DRD2-C32806T receptors and the enzymes dopamine β-hydroxylase DBHG1368A) could increase the efficacy of drugs for smoking cessation.[7]

In the specific case of Alzheimer's disease, several mutations and polymorphisms, including apolipoprotein E4, have been associated with increased risk for this disease. Furthermore, clinical trials have demonstrated that carriers of the ApoE E3 allele respond better to cholinesterase inhibitors than those who lack the allele. There is also evidence that treatment response to non-cholinergic drugs is affected by the ApoE gene and that response to cholinesterase inhibitors is influenced by interactions with other genes involved in drug metabolism.

Another example of how pharmacogenetics is helpful is in the treatment of hyperlipidaemia, where genetic variations at the ApoE locus has been associated with fasting and postprandial plasma lipoprotein concentrations and with cardiovascular disease. The ApoE E2 polymorphism

is associated with an increased lipid-lowering response to statin therapy, whereas E4 polymorphism is associated with a decreased response to therapy. However, testing for this genetic variation is not yet part of routine clinical care.

In the near future, pharmacogenetics will give the chance to provide patients with information about their probability of responding to treatment with a particular medication, given their genotype. Although the discipline is beginning to come of age, only a few pharmacogenetic applications are currently available in clinical settings, but many promise to enter the realm of clinical practice in the next few decades.[7]

Prescribing for geriatric patients

The Beers criteria, a useful consensus for inappropriate medication use in the elderly

The purpose of this initiative was to revise and update criteria for potentially inappropriate medication use in adults aged 65 years and older in the USA. The reviewed criteria covered two types of statements: (1) medications that should be avoided in persons older than 65 years and (2) medications that should *not* be used in persons known to have specific medical conditions.[8]

The Beers criteria identify 48 individual medications or classes of medications to avoid in older adults and their potential concerns and 20 diseases and conditions and medications to be avoided in older adults with these conditions. Adverse drug events have been linked to preventable problems in the elderly patients, such as depression, constipation, falls, immobility, confusion and hip fractures.

The 1997 study on adverse drug reactions found that 35% of ambulatory older adults experienced an adverse drug event and 29% required healthcare services; some nursing facility residents have one of these events over a 4 year period. In summary, these criteria have been extensively used for evaluating and intervening in medication use in older adults over the past decade. However, owing to the continuous arrival of new medications on the market, increased knowledge about older drugs and side effects from the new ones needs to be updated periodically in order to keep physicians updated on how to avoid undesirable medication side effects in the elderly population (Table 13.6).[8]

Clinical strategies

The quality of life for the older patient can be greatly enhanced with the intelligent use of medications and keeping certain key points in mind. A major problem when facing elderly populations is the fact of prescribing multiple and occasionally unnecessary medications with increased risk of significant drug interactions; establishing a diagnosis is critical to avoid treating a symptom with hit or miss drugs versus treating a specific condition. Discussions about geriatric pharmacology are frequently centred around age-related changes in drug pharmacokinetics and pharmacodynamics; nonetheless, non-pharmacological factors can play an even greater role in the safety and effectiveness of drug therapy in the geriatric population.

Frequently, neither the patient nor the healthcare provider has a clear picture of the total drug regimen. New patients undergoing initial geriatric assessment should be asked to empty their medicine cabinets and to bring all bottles to their first appointment. When asking the patient about their medication, it is important to be specific about prescription medications, over-the-counter products, as-needed medications, vitamins, minerals, herbal products and home remedies.

Compliance

Compliance is a major problem in all persons and particularly so in many older persons. Cognitive impairment, depression, decreased hearing and poor vision can all lead to failure to take a drug or for the drug to be taken inappropriately. Instructions on how to take drugs need to be written in large letters with legible handwriting. The healthcare professional needs to check that the patient understands the instructions. Pill boxes need to be set up for older persons having problems remembering to take their medicines.

When choosing the dose of a medication for an older patient, always remember to *start slow, go slow and do not stop too soon*. Initially, doses should be modified on the basis of pharmacokinetic predictions, but actual pharmacodynamic responses to the medication should be used to adjust the dose. If the pharmacokinetic information is not available, doses can be initiated at half the usual adult dose; this can be achieved by splitting tablets or by extending the dosing interval. Minimizing the number of doses per day is easier for the patient and can improve compliance. The use of sustained-release dosage forms or taking advantage of prolonged elimination half-lives in older persons can decrease the number of doses per day.

Cost is a key factor in compliance. Drug costs need to be noted at the time of prescribing, and patients need to be asked if they can afford the drug. It is useful to remember that cheap drugs (e.g. thiazides, β-blockers and reserpine) often perform approximately as well as more expensive drugs. Most pharmaceutical companies have programmes to help persons obtain drugs they cannot afford.

There is an increasing recognition that failure to treat an older person appropriately may be as bad as overtreating. For example, failure to use β-blockers following myocardial infarction would be a clear error of omission. However, it has been shown that atenolol (a cheap once-per-day β-blocker) performs better than the more expensive twice-per-day β-blockers. Most older persons in nursing homes have osteopenia or osteoporosis, yet they do not receive

Table 13.6 Inappropriate medication use in older adults: considering conditions and diagnoses.[a]

Condition	Drug	Comments
Heart failure	Disopyramide, high sodium content drugs (alginate, bicarbonate, phosphate)	Negative inotropic effect. Potential to promote fluid retention and exacerbation of heart failure
Hypertension	Phenylpropanolamine hydrochloride (removed in 2001), pseudoephedrine, diet pills, amphetamines	May produce elevation of blood pressure secondary to sympathomimetic activity
Gastric or duodenal ulcers	NSAIDs and aspirin >325 mg per day	May exacerbate existing ulcers or produce new ones (COX-2 excluded)
Seizures or epilepsy	Clozapine, chlorpromazine, thioridazine	May lower seizure thresholds
Blood clotting disorders or on anticoagulant therapy	Aspirin, NSAIDs, dipyridamole, ticlopidine, clopidogrel	May prolong clotting time and elevate INR values or inhibit platelet aggregation resulting in increased potential for bleeding
Bladder outflow obstruction	Anticholinergics and antihistamines, GI antispasmodics, muscle relaxants, anticholinergics, antidepressants	May decrease urinary flow, leading to urinary retention
Stress incontinence	α-Blockers, anticholinergics, tricyclic antidepressants, long-acting benzodiazepines	May produce polyuria and worsening of incontinence
Arrhythmias	Tricyclic antidepressants	Proarrhythmic effect and ability to produce QT interval syndrome
Insomnia	Decongestants, theophylline, methylphenidate, amphetamines	Concern about CNS stimulant effects
Parkinson's disease	Metoclopramide, conventional antipsychotics	Concern about anticholinergic/dopaminergic effects
Cognitive impairment	Barbiturates, anticholinergics, antispasmodic, muscle relaxants	Concern about CNS-altering-effects
Depression	Long-term benzodiazepine use, sympatholytic agents (methyldopa, reserpine)	May exacerbate depression
Anorexia and malnutrition	CNS stimulants, fluoxetine, methylphenidate	Concern about appetite-suppressing effects
Syncope/falls	Short- to intermediate-acting benzodiazepines, tricyclic antidepressants	May induce ataxia, impaired psychomotor activity
SIADH/hyponatraemia	Fluoxetine, citalopram, fluvoxamine, paroxetine, sertraline	May cause SIADH
Obesity	Olanzapine	May stimulate appetite
COPD	Long-acting benzodiazepines, propranolol	May induce respiratory depression
Chronic constipation	Tricyclic antidepressants, anticholinergics, calcium channel blockers	May exacerbate constipation

[a]NSAIDs, non-steroidal anti-inflammatory drugs; GI, gastrointestinal; CNS, central nervous system; SIADH, syndrome of inappropriate ADH secretion; COPD, chronic obstructive pulmonary disease.
Source: Fick and Cooper.[8]

calcium with vitamin D and bisphosphonates. Many older persons have anaemia and chronic renal failure; despite evidence that treatment with erythropoietin or darbepoetin alfa improves outcomes including quality of life, they are rarely prescribed. However, the other side of the coin is overtreatment of conditions; for example, there is no evidence for treating blood pressure below 160/90 mmHg in older persons and even less for primary prevention of heart disease by lowering cholesterol in octogenarians. When calcium or iron is administered with other drugs they block their absorption, leading to inadequate dosing. Commonly in older persons on multiple medications, an agonist and an antagonist of the same drug class are prescribed for different indications, for example, a cholinesterase inhibitor for Alzheimer's disease and an acetylcholine inhibitor for incontinence. The ridiculousness of this concept is self-evident and leads to multiple side effects.

There are many factors that contribute to the underuse of beneficial therapies in the geriatric patient population. Physicians may fail to prescribe potentially beneficial medications to elderly patients owing to the scarcity of data on which to base pharmacotherapeutic decisions or for fear of causing adverse drug events in patients who are already using multiple medications. While some may consider this practice to represent therapeutic nihilism, others may consider it to be prudent prescribing. A fair and balanced assessment of the issue of undertreatment of elderly patients must give consideration to three important

areas: (1) the lack of high-quality evidence derived from clinical studies with relevance to treating the older patient with multiple chronic medical conditions; (2) the need for systems of care that improve drug safety and enhance adherence in elderly persons on complex medication regimens; and (3) the persistence of financial barriers to access to medications.[2,9]

The Division of Geriatrics at Saint Louis University has developed many different resources to teach both physicians and patients in the field of geriatric medicine. The development of mnemonics, specifically a mnemonic developed towards avoiding polypharmacy, has been very successful:

Guidelines for proper medication prescribing and medication reduction

Alternatives
Vague history or symptoms
OTC (over-the-counter) medications also have side effects
Interactions (drug–drug, drug–disease)
Duration
Therapeutic versus preventive
Once per day versus twice or four times per day
Other doctors
Money
Adverse effects of other drugs
Need
Yes/no (is the person actually taking the medication?)

The use of large numbers of medications will always be a key factor of the medical–scientific care of the growing older population around the world. However, there is always a grey area where there is concern about avoiding the excessive use of drugs and providing access to therapeutic guidelines that might have beneficial effects on morbidity and mortality, function and quality of life. The health system should address this issue, focusing on including more elderly people in clinical trials, especially patients with multiple comorbidities. The implementation of efforts towards the development of interdisciplinary teams to care for elderly patients and the use of information technology to improve medication adherence and safety should be encouraged.

Key points

- Cheap drugs have been around for a long time and, as such, are more likely to have their side effects in people well known.
- Older persons take more medications than their younger counterparts.
- The older body does not accommodate drugs in the same manner as the younger body does.
- There is no such thing as an absolutely safe drug.
- Elderly patients are more likely to experience undesirable side effects from drugs than are younger persons.
- Always 'start slow and go up slow'.

CHAPTER 14

Patient safety

Susannah Long and Charles Vincent
Imperial College London, London, UK

Introduction

History and evolution of the concept of patient safety

The practice of medicine, aptly described by Samuel Johnson as 'the greatest benefit to mankind', has and always will be associated with inherent risks.[1] This has been acknowledged for as long as medicine itself has existed: the Ancient Greeks' words for 'kill' and 'cure' were similar and the Hippocratic Oath contains the promise 'to abstain from doing harm', later adapted by Thomas Sydenham into the famous phrase '*primum non nocere*' or 'first do no harm'.

Perhaps surprisingly, it has only been relatively recently that these risks, their causes and ways to ameliorate them have been subjected to rigorous academic study. One of the earliest specific observations of patient harm was made in the nineteenth century by Florence Nightingale regarding infection in hospitals, a new and devastating problem at the time. In the 1960s, more systematic studies of hospital-associated harm began to be carried out, initially driven by the development of litigation. In more recent times, perhaps triggered by high-profile events such as the Bristol Heart Inquiry and landmark international reports such as *An Organization with a Memory*[2] in the UK and *To Err is Human*[3] in the USA, patient safety has become the focus of much attention. It is now recognized globally as one of the top priorities in healthcare and, as our understanding of healthcare-related harm deepens, so our ability to improve it grows.

In this chapter, we describe some of the current knowledge about patient safety and how this relates to the care of older people.

Definitions

Patient safety may be defined as 'the prevention and amelioration of adverse outcomes or injuries stemming from the process of healthcare'.[4] This definition encompasses not only the avoidance of individual error or harm and the high reliability of healthcare systems, but also the appropriate management of healthcare-associated harm: not just in terms of appropriate immediate medical management, but also in supporting staff, patients and their families.

Patient safety is just one aspect of high-quality care. In the recent UK report *High Quality Care for All*,[5] quality of care, defined from a patient's point of view, encompasses safety, experience and outcomes. In the USA, 'Crossing the quality chasm' similarly described the elements of quality as safety, effectiveness, patient-centredness, timeliness, efficiency and equitableness. Safety has been described as 'the dark side of quality' because of its historical association with litigation and blame, but it is increasingly acknowledged that efforts to learn more about and improve safety are themselves a feature of high-quality healthcare organizations.[1]

Measurement – the scale of harm

There are several ways to measure or estimate the extent of errors or adverse events in healthcare, including analysis of administrative or reporting data, case record review, observations of patient care and active clinical surveillance. Each of these methods has its advantages and disadvantages, in terms of availability of data, cost, reliability, observer bias and clinical relevance. Clearly, the measurement of safety overlaps with the measurement of quality of care, described in Chapters 137 and 138.

An adverse event is defined as an unintended injury caused by medical management rather than the disease process, which is sufficiently serious to lead to prolongation of hospitalization or to temporary or permanent disability or death.[4] This definition is important because it has been traditionally used in studies of the nature and scale of harm, described below.

A critical incident or 'near miss' may be considered to be the next step down from this – incidents which may have caused harm but did not actually do so.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 14.1 International adverse events studies, showing data for older patients.

Study	Year	No. of subjects	No. (proportion, %) of elderly subjects	Definition of elderly (years)	Overall adverse event rate (%)	Incidence in elderly (%)	Incidence in young (%)	Difference
California (Mills)	1977	20 864	3826 (18.34%)	≥65	4.65	7.22 ± 0.82	4.07 ± 0.30	$p < 0.05$
Harvard (Brennan)	1991	30 121	4980 (16.53%)	≥65	3.7	Standardized for DRG 5.7 ± 0.6	2.6 ± 0.2 (16–44 yrs)	$p < 0.0001$
Australia (Wilson)	1995	14 210	3945 (27.76%)	≥65	16.6	23.3	Mean 13.75	Not given
Utah and Colorado (Thomas)	2000	15 000	Not stated	≥65	2.9 ± 0.2	All adverse events 5.29 ± 0.37	All adverse events 2.80 ± 0.18	$p = 0.001$
UK (Vincent)	2001	1014	342 (33.73%)	≥65	10.8	18.13 (62/342)	7.25 (48/662)	$p < 0.001$
New Zealand (Davis)	2002	6579	1967 (29.9%)	≥65	11.2	17.6 (346/1967)	10.93 (504/4612)	Not given
Canada (Ross-Baker)	2004	3745	Not stated	Not stated	7.5	Mean age of patient with adverse events 64.9 (SD 16.7) vs 62.0 (SD 18.4) yrs, $p = 0.016$		
Ottawa (Forster)	2004	502	126 (25.1%)	>72	12.7	22.22 (28/126)	9.57 (36/376)	$p < 0.001$
France (Michel)	2007	8754	Not stated	Not stated	6.6 per 1000 days of hospitalization	Mean age of those experiencing adverse events = 63 yrs, 61.7 yrs for those who did not ($p = 0.5$)		
UK (Sari)	2007	1006	332 (33.0%)	≥75	8.7	13.5 (95% CI 9.8–17.2)	6.2 (95% CI 4.4–8.0)	$p < 0.001$

Over the last 40 years, a number of international adverse event studies have been published, in which retrospective case record review was used to identify adverse events in order to assess the nature and scale of harm in acute hospitals.

A selection of these studies are shown in Table 14.1. Rates of adverse events in most recent studies lie between 8 and 12%, a range now accepted as being typical of advanced healthcare systems. The rate per patient is always slightly higher, as some patients suffer more than one event and about half of adverse events are generally judged to be preventable. United States rates are much lower, Australian seemingly much higher. The lower US rates might reflect better quality care, but most probably reflect the narrower focus on negligent injury rather than the broader quality improvement focus of most other studies.

Studies of errors

There are a number of methods of studying errors and adverse events, each of which has evolved over time and been adapted to different contexts.[6] Each of the methods has particular advantages and disadvantages. Some methods are oriented towards detecting incidence of errors and adverse events (Table 14.2), whereas others address their causes and contributory factors (Table 14.3). There is no perfect way of estimating the incidence of adverse events or of errors. For various reasons, all of them give a partial picture. Any retrospective review is vulnerable to hindsight or outcome, bias, where knowledge that the outcome was bad leads to unjust simplification and criticism of preceding events. Record review is comprehensive and systematic, but by definition is restricted to matters noted in the medical record. Reporting systems are strongly dependent on the willingness of staff to report and are a very imperfect reflection of the underlying rate of errors or adverse events.

Why do adverse events occur?

In order to obtain a true understanding of patient safety, it is not enough just to assess the scale of healthcare-associated harm: we have to look deeper to understand the processes that underlie it. As described later, attempts to understand the causes of adverse events are routinely made within individual organizations in several ways, such as through local morbidity and mortality meetings or through the use of more structured approaches such as root cause analysis.

Learning from other industries

On a more general level, many methods have been employed by patient safety researchers to enhance our knowledge of the causes of adverse events. It is important to appreciate that when an adverse event occurs we may be quick to judge or blame the actions or omissions of individuals, but careful inquiry usually shows us that deficiencies in our systems are also at fault. We have learnt much from other industries in this respect. Investigation of major disasters such as the Chernobyl nuclear explosion, the Space Shuttle Challenger crash and the Paddington rail

Table 14.2 Methods of measuring errors and adverse events.

Study method	Advantages	Disadvantages
Administrative data analysis	Uses readily available data	May rely upon incomplete and inaccurate data
	Inexpensive	The data are divorced from clinical context
Record review/chart review	Uses readily available data	Judgements about adverse events not reliable
	Commonly used	Medical records are incomplete
		Hindsight bias
Review of electronic medical record	Inexpensive after initial investment	Susceptible to programming and/or data entry errors
	Monitors in real time	Expensive to implement
	Integrates multiple data sources	
Observation of patient care	Potentially accurate and precise	Time consuming and expensive
	Provides data otherwise unavailable	Difficult to train reliable observers
	Detects more active errors than other methods	Potential concerns about confidentiality
		Possible to be overwhelmed with information
Active clinical surveillance	Potentially accurate and precise for adverse events	Time consuming and expensive

Source: adapted from Thomas and Petersen.[6]

Table 14.3 Methods of understanding errors and adverse events.

Study method	Advantages	Disadvantages
Morbidity and mortality conferences and autopsy	Can suggest contributory factors	Hindsight bias
	Familiar to healthcare providers	Reporting bias
		Focused on diagnostic errors
		Infrequently used
Case analysis/root cause analysis	Can suggest contributory structured systems approach	Hindsight bias
	Includes recent data from interviews	Tends to focus on severe events
		Insufficiently standardized in practice
Claims analysis	Provides multiple perspectives (patients, providers, lawyers)	Hindsight bias
		Reporting bias
		Non-standardized source of data
Error reporting systems	Provide multiple perspectives over time	Reporting bias
	Can be a part of routine operations	Hindsight bias

Source: adapted from Thomas and Petersen.[6]

accident identified 'violations of procedure' or problems that occurred as the result of actions or omissions by people at the scene. However, further analysis of these events revealed 'latent conditions'[7] further upstream in the process, which allowed these violations to occur and have such a devastating effect. 'Latent conditions' are often a result of gradual and unintentional erosion of safety-enhancing processes because of other pressures, for example, cutting training budgets because of financial costs. Further still in the background are often deeply ingrained cultural and organizational issues, some of which may be elusive and difficult to resolve.

Of course, it is all very well to learn about the underlying causes of these non-healthcare-related disasters, but the question that most clinicians will ask at this stage is what relevance this has to us. Although healthcare is similar to these industries in some respects, such as the high level of inherent risks and the well-meaning and dedication

Table 14.4 Examples of some cognitive biases and heuristics that commonly affect clinical reasoning.

Name	Definition	Example
Availability heuristic	Making judgements based on cases that spring easily to mind	'The last time I saw a patient with fever and a headache it was only flu, so it is likely to be so in this case too' (actually meningitis)
Anchoring heuristic	Sticking with initial impressions	The confused elderly patient who has a 'UTI' on admission (despite a negative MSU), whose severe constipation goes unnoticed
Framing effects	Making a decision based on how the information is presented to you	'A&E referred this patient with fever and haemoptysis as ''pneumonia'' so that is the most likely diagnosis even though the CXR is normal' (actually a PE)
Blind obedience	Showing undue deference to seniority or technology – 'they must be right and I must be wrong'!	'My consultant said that this patient could go home, so I am going to ignore concerns raised by nursing staff' 'The blood results show a normal haemoglobin even though this patient looks clinically anaemic – the blood results must be right'
Premature closure	Being satisfied too easily with an explanation	In a patient with staphylococcal sepsis, assuming the source of sepsis is their cellulitic leg, and missing their underlying endocarditis

Source: adapted from Redelmeier.[10]

of its staff, it is very different in others – such as in its diversity, often non-centralized administration, uncertainty and unpredictability.

Human error

Human error is not easy to define, as boundaries are often blurred between the actions or inactions of individuals and the deficiencies of the systems in which they work. However, it is important to try to define and classify different sorts of error in medicine, largely because this may help us to learn from incidents. We can think about errors in medicine in relation to the clinical processes involved, for example, prescribing errors or diagnostic errors, but perhaps it is also useful to look at the underlying psychological themes. In his analysis of different types of error, Reason[8] divided them into two broad types of error: slips and lapses, which are errors of action and mistakes which are, broadly speaking, errors of knowledge or planning. He also discusses violations that, as distinct from error, are intentional acts which, for one reason or another, deviate from the usual or expected course of action.

Delays and errors in clinical decision-making are particularly critical in medicine and there is an extensive literature about the complexities of medical decision-making.[9] In our daily clinical practice, we use heuristics, which are simple but approximate rules to aid decision-making by simplifying the situation and decision to be made. Particularly at times of fatigue, stress or time pressure, these heuristics can become 'biases', leading to faulty clinical decision-making leading to undesirable consequences.[10] Some of these, with common clinical examples, are given in Table 14.4.

System and organizational factors

Errors and human behaviour cannot be understood in isolation, but only in relation to the context in which people are working. Clinical staff are influenced by the nature of the task they are carrying out, the team they work in, their working environment and the wider organizational context; these are the system factors. The systems in which we work have inbuilt defences and barriers and it is only when these defences are simultaneously breached that adverse events occur. This concept forms the basis of Reason's 'Swiss cheese model', shown in Figure 14.1.

Learning from high-reliability organizations in other industries, which achieve high levels of safety and performance in the face of considerable hazards and operational complexity, is an ongoing challenge to improving safety in healthcare. Important characteristic of these types of organizations are safety culture and leadership: there is

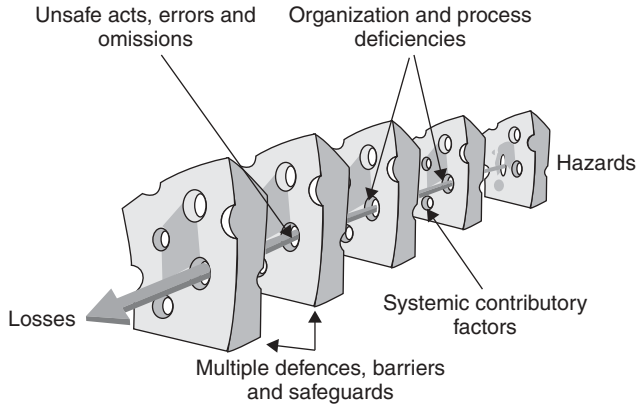

Figure 14.1 Reason's Swiss cheese model.

some evidence that these are related to some measures of safety in healthcare.

Analyses of incidents usually reveal the causes to be a combination of all of the factors described above. This can be summarized by 'the seven-level framework',[11] which conceptualizes the patient, task and technology, staff, team, working environment and organizational and institutional environmental factors that influence clinical practice. This is shown in Table 14.5.

What happens after an adverse event?

Reporting and learning

There are a variety of reporting systems operating at different levels within healthcare systems across the world. Some operate primarily at local level (risk management systems in hospitals), others at regional or national level. Local systems are ideally used as part of an overall safety and quality improvement strategy, but in practice may be dominated by managing claims and complaints. Many different clinical specialities, particularly anaesthesia, have established reporting systems to assist them in improving clinical practice. These systems are designed to provide information on specific clinical issues which can be shared within the professional group. The increasing attention paid to patient safety has led to the establishment of many new reporting and learning systems, most notably, in the UK, the Reporting and Learning System (RLS) established by the National Patient Safety Agency. Other national reporting systems include the wide-ranging Veterans Affairs system in the USA and the Australian Incident Monitoring System (AIMS).

The main purpose of reporting systems is to communicate information about patient safety issues, so that learning and improvement of systems and practice can occur. A secondary benefit of these systems is that we can use them to assess the scale of harm and identify trends.

Table 14.5 The seven-level framework.

Factor types	Contributory influencing factor
Patient factors	Condition (complexity and seriousness)
	Language and communication
	Personality and social factors
Task and technology factors	Task design and clarity of structure
	Availability and use of protocols
	Availability and accuracy of test results
	Decision-making aids
Individual (staff) factors	Knowledge and skills
	Competence
	Physical and mental health
Team factors	Verbal communication
	Written communication
	Supervision and seeking help
	Team leadership
Work environmental factors	Staffing levels and skills mix
	Workload and shift patterns
	Design, availability and maintenance of equipment
	Administrative and managerial support
	Physical environment
Organizational and management factors	Financial resources and constraints
	Organizational structure
	Policy, standards and goals
	Safety culture and priorities
Institutional context factors	Economic and regulatory context
	National health service executive
	Links with external organisations

Source: from Vincent *et al.*[11]

There are inherent problems with all reporting systems in healthcare: most studies have found that reporting systems only detect 7–15% of adverse events,[12] when compared with other methods of detection such as case record review. Some of the common barriers to reporting include a fear of embarrassment, punishment by oneself or others, fear of litigation, lack of feedback and a belief that nothing will be done in response to reporting.

Understanding why things go wrong

The investigation and analysis of cases in which clinical incidents have occurred can be used to illustrate the process of clinical decision-making, the weighing of treatment options and sometimes, particularly when errors are discussed, the personal impact of incidents and mishaps, and critically also includes reflection on the broader healthcare system. There are a number of methods of investigation and analysis used in healthcare, either retrospectively, for example root cause analysis or systems analysis of events, or prospectively, for example failure modes and effects analysis (FMEA).

Caring for patients after an adverse event

Patients and relatives may suffer in two distinct ways from a medical-induced injury: first from the injury itself and second from the way in which the incident is handled afterwards. Many people harmed by their treatment suffer further trauma through the incident being insensitively and incompetently handled. Conversely, when staff come forward, acknowledge the damage and take positive action, the support offered can ameliorate the impact in both the short and long term. Injured patients and their families need open disclosure: an explanation, an apology, or to know that changes have been made to prevent future incidents, and often also need practical and financial help.[13]

Supporting staff

Making an error, particularly if a patient is harmed because of it, may have profound emotional or psychological consequences for the staff involved. This in turn can make future errors more likely and affect teamwork. Factors which may make this more likely include the severity of the error and the reactions of those involved, attitudes to error, beliefs about control and the power of medicine and the impact of litigation. Strategies to minimize the effects of adverse events on staff include wider acknowledgement of the potential for error, having an agreed policy on openness with injured patients, encouraging support from colleagues, education and training and, if necessary, formal support and access to confidential counselling.

Patient safety and older people

The incidence of adverse events in older people in hospital

Re-analysis of the international adverse event studies

There is considerable evidence that older people suffer a higher incidence of adverse events than their younger counterparts in hospital. The landmark, international, adverse event studies described in Table 14.1 investigated the incidence and types of adverse events in hospital inpatients of all ages. This was achieved by two-stage retrospective case record review in the majority of cases. Table 14.1 also shows that if the results of these large studies are re-analysed to consider specifically the effects of age on patterns and frequencies of adverse events, they all show that age is a risk factor for adverse events. However, when this relationship is examined more closely, it emerges that it is co-morbidity, rather than age alone, that appears to be responsible for this association. In addition to experiencing more adverse events, older people also suffer more serious consequences of adverse events in the majority of studies, in terms of morbidity and mortality, increased dependence, increased hospital stay and a greater chance of institutionalization;[14] again, this seems to be related to their physical vulnerability, in terms of frailty and diminished physiological reserve. As might be expected, data from these studies show that older people in hospital tend to experience different types of adverse events than their younger counterparts, such as falls, hospital-acquired infections and drug errors rather than complications related to invasive procedures. In general, it seems that it is controversial as to whether adverse events are more preventable in elderly than in younger patients.

Data from reporting systems

Another way of estimating the incidence of hospital-related harm in older people is to analyse data from local and national reporting systems. The incidents most commonly reported to the NRLS in acute hospitals are patient-related accidents, which in older people are most likely to be falls. These are followed closely by problems related to medication. Data sources such as this are very useful in terms of allowing us to prioritize areas for intervention. However, it is important to bear in mind that many problems go unreported, particularly those which may not be as obvious as falls or drug errors, so the scale and nature of adverse events may not be truly reflected in this way.

Types of adverse events experienced by older people in hospital

The geriatric syndromes

During the hospital stay itself, older people are of course vulnerable to the same adverse events as their younger counterparts, such as hospital-acquired infection, adverse drug events, deep vein thrombosis and procedure-related complications. As described above, there is evidence that the incidence of these types of adverse events is greater in older patients and their consequences are more severe. However, the process and effects of hospitalization in older people, particularly those who are frail with multiple comorbidities, are different to those in younger people; it therefore follows that any analysis of patient safety and adverse events in this vulnerable population should be undertaken in this context. Figure 14.2 illustrates this, in a proposed scheme for the effects of hospitalization in frail older people.

Older people may be admitted to hospital because of an acute illness, acute exacerbation of a chronic disease process, side effects of treatment for these conditions or the development of a new 'geriatric syndrome'. These are similar to the 'geriatric giants' first coined by Isaacs in 1965 (immobility and instability, incontinence and impaired intellect) and are now understood to include delirium, falls, incontinence, pressure sores, depression, undernutrition, constipation and functional decline. Older patients very commonly have one or more of these conditions at the time

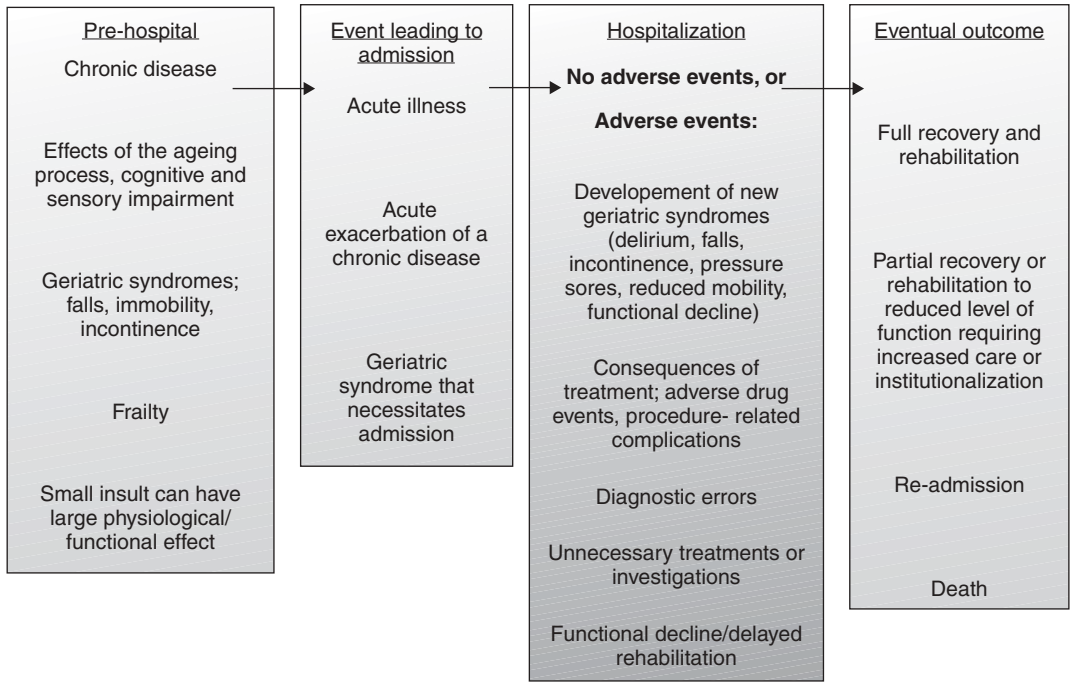

Figure 14.2 A proposed scheme for the effects of hospitalization in frail older people.

they are admitted to hospital, but there is a strong argument that if any of these truly occur *de novo* during the inpatient stay and are not related solely to progression of disease, each should be considered to be an adverse event because of their association with increased mortality and morbidity and the strong evidence that they are largely preventable.[15]

The geriatric syndromes rarely occur in isolation – during the complex, lengthy hospital admissions often experienced by older people, they are often interlinked and may contribute to downward spirals in progress and outcome. They can each contribute or be outcomes of each other; this is illustrated in Figure 14.3, which shows three common

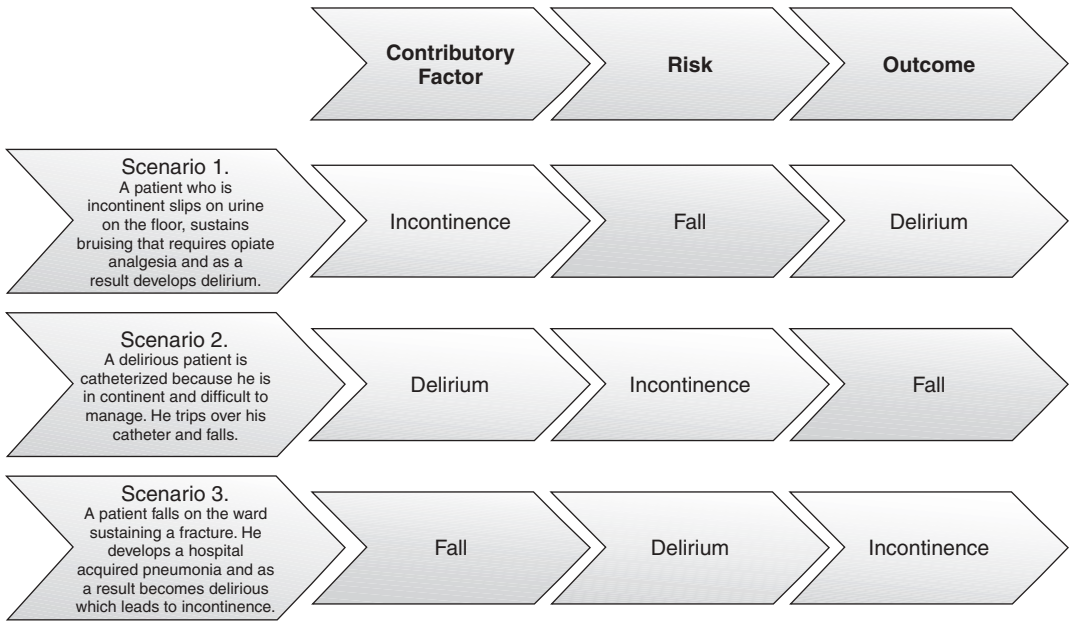

Figure 14.3 Three common clinical scenarios where delirium, incontinence and falls occur in different sequences.

Box 14.1 Adverse events in older people.

The geriatric syndromes, which could be considered to be preventable adverse events if they arise *de novo* in older people in hospital and are not related solely to progression of disease:

- Functional decline
- Loss of mobility
- Urinary or faecal incontinence
- Delirium
- Severe constipation
- Pressure sores
- Falls
- Malnutrition and/or dehydration
- Depression

Other common adverse events in older people:

- Hospital acquired infection (in older patients notably aspiration pneumonia and catheter-associated infections)
- Adverse drug events
- Venous thromboembolism
- Procedure-related complications

clinical scenarios where delirium, incontinence and falls occur in different sequences.

A summary of common adverse events in older people is shown in Box 14.1.

Preventable functional decline as an adverse event

Functional decline, defined as a decrement in physical and/or cognitive functioning which leads to a reduced ability to perform the 'activities of daily living' (ADLs) that are necessary to live independently is a common outcome for older people in hospital, regardless of whether or not any adverse events or geriatric syndromes occur during their stay in hospital. The dangers of believing the misconception that bed rest is good for hospitalized patients was succinctly put by Asher in 1947:[16]

> It is always assumed that the first thing in any illness is to put the patient to bed. Hospital accommodation is always numbered in beds. Illness is measured by the length of time in bed. Doctors are assessed by their bedside manner. Bed is not ordered like a pill or a purge, but is assumed as the basis of all treatment. Yet we should think twice before ordering our patients to bed and realize that beneath the comfort of the blankets there lurks a host of formidable dangers. . . . Teach us to live that we may dread unnecessary time in bed. Get people up and we may save our patients from an early grave.

Unfortunately, older patients are still often confined to bed more than is necessary and functional decline remains an extremely common problem in more modern times; in one study, one-third of elderly patients had lost at least one ADL by the time they left hospital.[17]

Functional decline that occurs during hospitalization can impact on the older person (and the healthcare system) in several ways: it can lead to loss of independence necessitating increased care requirements (and even institutionalization), depression and reduced quality of life. Like the other 'geriatric syndromes', many cases of functional decline are avoidable during a hospital admission if proper measures are taken to prevent it. Once consequence of the diminished reserves associated with frailty and age is that when functional decline occurs, it may be irreversible or require a prolonged period of rehabilitation to achieve partial or complete reversal. When functional decline occurs, the often prolonged hospital stays required for rehabilitation after serious illness, although often unavoidable, bring further risks.

Adverse drug events in older people

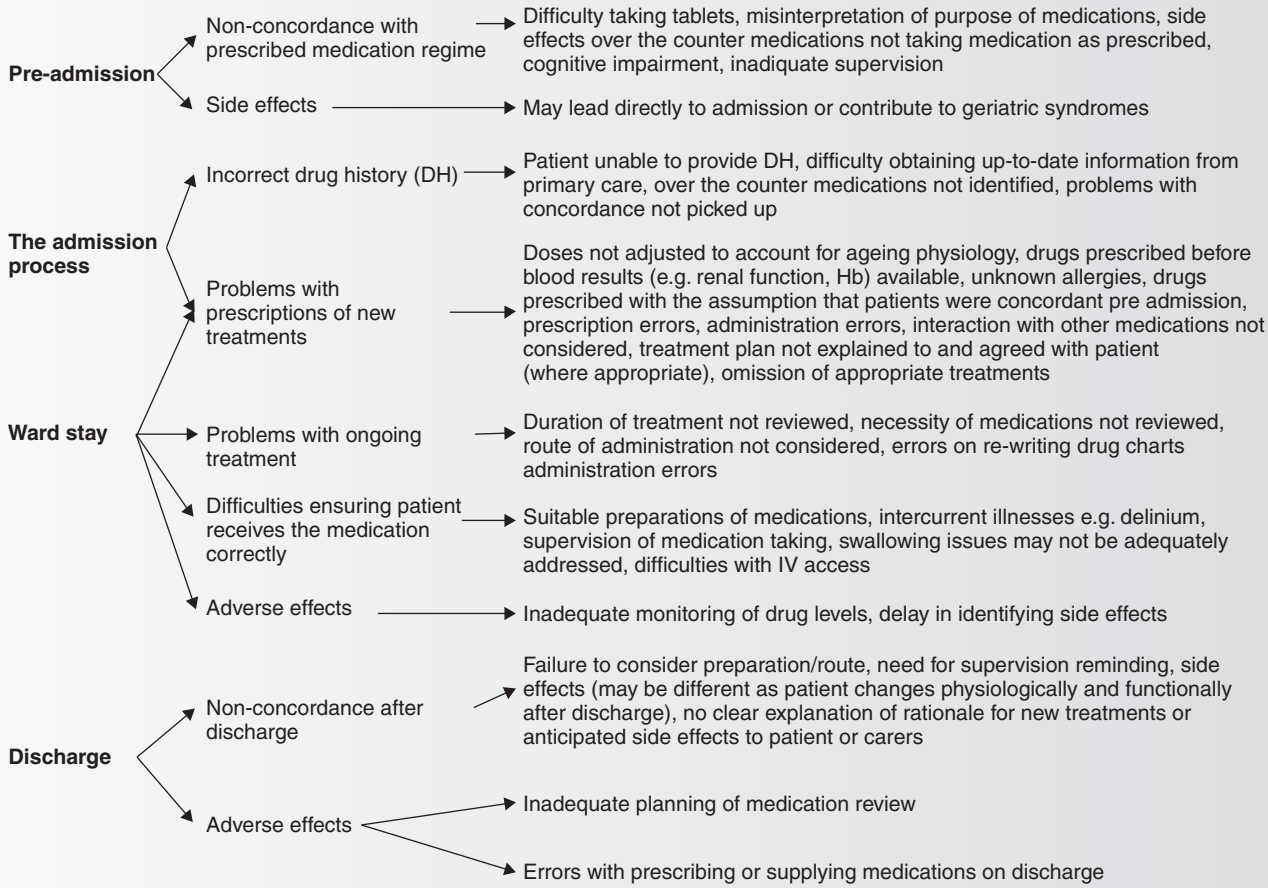
The term 'adverse drug event' covers a wide range of medication-related problems, encompassing the following: errors in prescription, preparation or administration, adverse drug reactions (which may be further subclassified into Type A, predictable, or Type B, bizarre)[18] or problems with concordance. These may occur as a result of appropriate or 'inappropriate' (under-, over- or mis-) prescribing.

As with other adverse events in hospital, at first glance the incidence of adverse drug events seems to increase with age, but there is some evidence that they are actually directly related to complexity and comorbidity rather than age alone. Recent studies have estimated the incidence of adverse drug events in older people in hospital to be between 31.9 and 37%.[19] As with all estimates of hospital-associated risks, this figure depends very much on the definitions and methodologies used. Nevertheless, even when relatively strict definitions are used, adverse drug events are the most common adverse events to affect hospitalized patients of all ages.[20]

The over-60s are the highest users of medications, receiving 59% of dispensed prescriptions in the UK.[21] Polypharmacy is an important issue – one-fifth of people aged over 70 years take five or more medications.[22] Virtually all older patients who are admitted to hospital are given drug treatment of some description. It would be unusual for an older patient not to have been taking any medications prior to admission or for these not to have changed in some way by the time of discharge.

Adverse drug events are also a significant cause of admission to hospital in older people (estimated at 6.5% of admissions, with a median length of stay of 8 days[23]). Furthermore, patients who were admitted because of an adverse

Box 14.2 Common types of medication-related problems in older people in hospital.



drug event go on to have a significant chance (17.7%[24]) of subsequent readmission due to further adverse drug events. Box 14.2 shows the common types of medication-related problems that may occur at different stages of the hospital admission process in an older person.

Outside hospital, the highest users of medications are care home residents. A recent study in the UK showed that the incidence of medication errors in nursing home residents was as high as 69.5%.[25] The categories of error found were similar to those in Box 14.2 – they included prescribing, monitoring, dispensing and administration errors. The underlying causes of the errors both in hospital and in care homes relate to common underlying patient safety themes: system failures, individual errors, communication problems within and between healthcare teams and with the patient and assessment or diagnostic skills and procedures not tailored to the individual.

Certain categories of drugs are more problematic than others for older people, notably anticoagulants, opiates and other centrally acting medications. Several efforts have been made to try to identify groups of medications which pose particular risk, so that they can be more easily avoided in this population, such as those categories of drugs included in the Beers criteria.[26] The fact that common treatments such as oxygen and intravenous fluids should be treated in the same way as other drugs is sometimes forgotten; but these are potentially dangerous treatments (particularly for older patients) and should be treated with due caution. The physiological changes associated with normal ageing and the pathological changes associated with the disease processes which are common among older people in hospital all impact on the risks associated with giving medications to this population. These changes have effects on the pharmacokinetics and pharmacodynamics of virtually all medications.

Frail elderly people are rarely included in large pharmaceutical trials, which in turn may result in harm because findings from clinical trials involving younger patients may be incorrectly extrapolated to older patients. The changes that occur with age also have practical implications, in terms of drug regimens, administration and concordance; for example, swallowing difficulties,

arthritis or cognitive or visual impairment need to be taken into consideration when prescribing and administering drugs to these complex patients.

As with all patient safety issues in older people, adverse drug events do not occur in isolation – they are closely linked to the geriatric syndromes in both cause and effect. The unique characteristics of the frail elderly again play a part here – because of the often non-specific ways in which adverse drug events present in these patients (often in the form of the geriatric syndromes described above, particularly delirium or falls), they often go unrecognized and, rather than stopping causative agents, more medications are added, causing further adverse effects. This can lead to a vicious circle, which is known as the 'prescribing cascade'.[27]

Implications

The undoubtedly higher rate of adverse events in older people has obvious implications financially and for service provision. We must also consider the inescapable implications of the ageing population. By 2025, the number of people in the UK aged over 85 years will have increased by two-thirds; people aged over 65 years account for 60% of acute hospital admissions and 70% of bed days in NHS hospitals. Ensuring patient safety and high-quality care for the growing number of older patients in healthcare systems might be seen as a battle against the inevitable consequences of illness and age, combined with the negative outcomes of preventable geriatric syndromes and adverse effects of treatments and interventions.

Why are older people more susceptible to healthcare-associated harm than younger patients?

The causes of harm to patients are complex and may lie in individual error, process factors, organizational or cultural issues or wider system problems. In this section, we address a number of issues which are particularly critical in the care of older people.

The effects of comorbidity and frailty

As major international studies have shown, adverse events are not associated with age alone, but rather with comorbidity, complexity and frailty. Comorbidity is commonplace among the elderly: 98% of people over the age of 65 years in one primary care population had multiple chronic medical conditions.[28] For patients this leads to complex care needs, interacting medical conditions and polypharmacy – all of which make them more vulnerable to poorer outcomes in general, such as increased mortality and length of hospital stay. In this group, acute illness is usually associated with exacerbations of multiple coexisting chronic diseases, which interplay to produce complex physiological, cognitive and functional consequences. Of course, there is a great deal of inter-individual heterogeneity in the way in which these complexities manifest themselves. It follows that acute illness leading to hospitalization in such individuals is rarely as straightforward as it might be in a younger, fitter patient, hence more healthcare-associated harm can occur.

Frailty can be, but is not always, associated with the latter stages of chronic illnesses. Definitions vary, but frailty is understood to be a clinical syndrome in its own right, which is associated with loss of reserve in multiple organs, associated with a clinical phenotype of generalized weakness, weight loss, exhaustion and immobility.[29] This loss of reserve leads to the frail individual being less able to withstand illness and hospitalization than those without the condition.

The interaction between older people with multiple comorbidities, complexity and frailty with the healthcare system is often complicated by the fact that illness presents in different, often more non-specific ways in this population and may manifest as one of the 'geriatric syndromes' described above.

In addition, cognitive impairment and sensory impairment may make it difficult for these patients to communicate with healthcare staff, which means that they are less able to be involved in their own care than younger people, thus increasing their vulnerability to errors.

Decision-making in the care of older people

Safe and high quality of care for older people requires staff to make complex decisions about medical and non-medical matters, with the involvement of the whole multidisciplinary team and with the aim of meeting patients' best interests. This applies across the entire healthcare system, from decisions relating to the prevention and management of long-term conditions in primary care, deciding when and whether to refer or admit patients to secondary care, to making decisions relating to inpatient care and the complex planning required to maximize their safety on discharge from hospital. The challenge is to make these decisions in the safest possible way, by anticipating and pre-empting potential errors or harm and whilst always acting in the patients best interests.

Very old people, particularly those who are frail and complex, have in the past often been excluded from large clinical and pharmaceutical trials,[30] which have formed the basis of our pharmaceutical approach to treating many common conditions. To a certain extent, this is understandable: the different physiological characteristics, coexisting medical conditions and therapies associated with old age can lead to a variety of responses to drug therapy, both beneficial and adverse; these responses can be difficult to predict,

detect and adjust for accurately in terms of measured outcomes. The consequence of this is that optimal therapeutic decision-making for the individual, for instance in terms of drug dosing or combinations, may be difficult to achieve because of the lack of an appropriate evidence base. Hence a degree of clinical judgement based on the risks and benefits of treatment in the context of elderly, frail physiology needs to be used to make such decisions. Over recent years, it has become more apparent that older people are the target group for many treatments and increasingly trials have been designed with these patients in mind.[31]

Commonly used therapeutic guidelines can also be difficult to generalize to older people, and, particularly when used by those who are not *au fait* with geriatric medicine (such as relatively inexperienced prescribers or prescribers in settings which are more used to dealing with younger or fitter people), this can result in inappropriate treatments being given to frail older people, with adverse consequences which may include over- or under-treatment, for example with opiate analgesia. Even in conditions where strong consensus and clear guidelines for management exist, there is evidence that treatment remains inadequate. This is particularly true of conditions such as delirium, where appropriate management comprises a concerted team effort and a multifaceted approach. There is evidence that such guidelines are not always followed: this demonstrates the fact that if they are to be implemented universally and successfully, concomitant educational and organizational change are needed.[32]

As the needs of each individual within this population are so heterogeneous, care must be taken to tailor decision-making to the individual. Training to develop these difficult decision-making skills is also often lacking and is usually expected to develop with experience. Cognitive biases and failed heuristics[9] are more likely to occur when the information presented to the decision-maker is as complex and of varying quality as is often the case in the care of these patients. Another problem is that whereas younger people might expect and be able to take part in the clinical decision-making process, older people often prefer not to be involved to the same extent[33] or are not able to do so. When making complex decisions such as care planning near the end of life, multiple factors need to be taken into consideration, such as the health status of the patient, their values and individual goals, so that the best interests of the individual are met. All of these factors make decision-making in the frail elderly difficult and any failure in this process can lead to undesirable consequences.

Multidisciplinary team working and communication

The complex needs of elderly patients often require equally complex treatments or interventions, usually involving the combined efforts of a highly skilled multidisciplinary team. Of course, this is in general a highly beneficial way of working because decisions and clinical management are enhanced by the expertise contributed by a variety of professionals; however, teamworking can be associated with its own problems.

If optimal patient outcomes are to occur, the multidisciplinary team needs to communicate effectively. Some of the barriers to effective communication in healthcare teams described in the literature include conflict or ambiguity about individual roles within the team, perceived hierarchical difficulties and interpersonal conflict.[34] There is some evidence that this is compounded by the fact that different professions differ in their ratings of collaboration, perceived barriers to teamwork and beliefs of what the best outcomes for patients might be.[35] In addition, there can be difficulty in ensuring that team members do not work in 'silos' and have a common understanding of goals of care. If multidisciplinary teamwork is ineffective, this can adversely effect communication with patients and carers, in turn causing decisions to be made without adequately involving patients.

Of course, the wider team caring for an older person usually extends across health and social care sectors; here, coordination and continuity of care can be a problem. In particular, poor communication at times of transition of care can cause problems. It has been shown that inadequate communication at discharge from hospital, particularly in relation to medication management and monitoring arrangements, can lead to preventable readmissions in older people.[36] It is also crucial that decisions that have been made with patients about preferred levels of future intervention are adequately communicated at the time of discharge, otherwise they may be subjected to unwanted or unnecessary intervention after discharge.

Attitudes and ageism

Unfortunately, despite standard one of the UK's National Service Framework for Older People in 2001 being 'rooting out age discrimination', there is still evidence that negative attitudes towards older people, including ageism, can result in poor quality of care and problems with patient safety.[37] Ageism describes the act of discrimination against people on the grounds of age alone. Commonly cited consequences of this are that older people may be denied treatment or investigations which may be of benefit to them or that they may be subject to mislabelling or misdiagnosis.[38] For example, there are several studies showing that older people with ischaemic heart disease are less thoroughly investigated and receive less interventional treatment than younger patients, even when it is clinically indicated.[39] This is despite growing evidence that older people are likely to experience substantial benefit in terms of quality and length

of life from appropriate cardiac interventions. This may not occur as a result of overt ageism, but rather may be related to uncertainty about the best and safest clinical practice in this age group, particularly in those who are not specialists in caring for older patients. Of course, one of the unique skills of geriatricians is to be able to strike the correct balance for the individual patient between therapeutic nihilism (the avoidance of treatment entirely) and therapeutic heroism (where all interventions and treatments are given, even when there is unlikely to be any therapeutic benefit).

The care of older people in general can be regarded by some within the healthcare profession as a speciality with very little reward (in terms of clinical outcomes or prestige) for sometimes very 'heavy' physical work. This can lead to staff feeling undervalued and lacking in motivation to implement change. There can also be a negative attitude towards the patients themselves, leading to reduced dignity, loss of patient empowerment and a sense of infantilization. One of the observable manifestations of this is 'elderspeak', where patients, particularly those with cognitive or sensory impairment, are talked down to as if they are children; this lack of meaningful interaction can contribute to depression and cognitive and functional decline.

Systems and processes of care for frail older people

Frailty and comorbidity bring many challenges for healthcare systems, the greatest of which is to ensure integrated care, with seamless communication and transition between services, allowing congruent treatment plans and optimal outcomes. Transitions of care, particularly the interface between primary and secondary care in acute hospitalization (both at admission and discharge), can be particularly problematic.

The goal of care in hospital for a frail person is not just to treat their acute illness, but also to promote maximum functional recovery and independence – in other words, to prevent functional decline. This requires systems in hospital to be set up so that those patients who are frail and at risk of functional decline can be recognized and treated early to prevent adverse outcomes. However, this does not always occur, particularly when older people are admitted (justly) to areas or departments where systems are geared more towards the care of younger, fitter people (such as surgery).

There are several other systems factors that may contribute to adverse events in the care of older people in hospital. These can give rise to poor communication, for example, inadequate procedures for handover for medical and nursing staff, either between themselves when shifts change or between disciplines when decisions are made. Systems factors may also limit good communication – for example, time constraints and pressures of volume of work may not allow healthcare professionals to take the time required to assess an older person thoroughly, decide upon a good management plan, initiate it and communicate all of this effectively to the patient, their relatives and other staff caring for them. This means that even if an individual has good communication and clinical reasoning skills, the system does not always allow these to be realized to their maximum potential in optimizing patient care.

Improving patient safety for older people

Improving the safety of a clinical system requires action at many different levels, combining a focus on generic issues with attention to specific clinical problems. In this section, we first briefly address three issues that are relevant to all healthcare sectors, but particularly critical in the care of older people. These are the education and training of practitioners, improving systems of care and the potential of design and technology to enhance safety. We then consider how specific clinical issues can be tackled, addressing interventions for geriatric syndromes, hospital-acquired infections and medication safety.

Education and skills for individual practitioners

Healthcare professionals caring for older people need to be trained in the clinical reasoning and communication skills necessary to ensure safe and high-quality care in this challenging group of patients. These skills are essential for accurate and thorough initial assessment and, if lacking, may lead to diagnostic errors and subsequent mismanagement, in addition to poor overall quality. Explicit training to develop these difficult skills can be lacking and is often expected to develop with experience. Box 14.3 gives some of the individual skills or behaviours that geriatricians use to maximize patient safety in older people.

The same communication and clinical reasoning skills required for geriatric assessment are also required to detect and manage adverse events in older people once they have occurred during the hospital admission. Successful care of older people requires staff to make complex decisions about medical and non-medical matters, with the involvement of the whole multidisciplinary team and with the aim of meeting patients' best interests. In hospital, this applies to decisions regarding both the inpatient care that elderly patients receive and also the complex planning that is often required to maximize their safety on discharge from hospital. Several educational strategies have been suggested to improve clinical reasoning,[9] such as the introduction of formal critical thinking training, teaching with the use of clinical examples of cognitive biases, encouraging consideration of diagnostic alternatives, developing mental rehearsal for practical skills using simulation

Box 14.3 Some of the individual skills and behaviours that geriatricians use to maximize patient safety in older people.

1. Early detection and prevention where possible of frailty and geriatric syndromes
2. Medication review and reconciliation at every opportunity
3. Ensuring a full collateral history is taken at every available opportunity
4. Maximizing communication at times of transition of care
5. Involving patients in their care as much as possible
6. Working with management to try to improve organisational culture towards older people
7. Ensuring that basic compassionate care is carried out
8. Supporting effective MDT working, sharing goals and information as much as possible
9. Inspiring interest in the care of older people amongst juniors and other colleagues
10. Being aware of cognitive biases in decision making and the use of strategies to overcome these

or using cognitive aids such as guidelines, algorithms or hand-held computer devices.

Medical and nursing curricula should teach the recognition of frail and complex patients, so that interventions for frailty and to prevent the occurrence of the geriatric syndromes can be implemented early. Undergraduate medical education should be designed to allow future practitioners to understand the physiological differences associated with age, informing safe prescribing for older people. Increasing attention is being paid to the teaching of communication skills – these need to be designed with the specific skills required of all healthcare professionals to communicate effectively with older people, such as those with cognitive or sensory impairment.

Keeping patients safe, particularly those with complex and fluctuating conditions, also requires anticipation, awareness of hazards, preparedness, resilience and flexibility, the qualities that those studying high-reliability organizations have sought to capture and articulate. To try to instil these qualities into the next generation of clinicians, patient safety is being incorporated explicitly into both undergraduate and postgraduate training. To aid this endeavour, there has been some work to identify the desirable knowledge, skills, behaviours and attitudes of a safe healthcare practitioner. In surgery and anaesthesia, much work has been done to identify and enhance 'non-technical skills', including communication, stress management, teamwork, decision-making and leadership,[40] which promote patient safety – similar skills are, of course, crucial across all specialities, particularly in the care of older people.

Design (human factors and ergonomics) and technology

Increasingly, design and technology are being used to great effect to improve patient safety, as healthcare learns from the principles of human factors and ergonomics which are so well engrained in other safety-critical industries. These disciplines are concerned with the interaction between humans and the systems in which they work, including perception, cognition, human performance, interaction with technology, teamwork and organizational behaviour. Design of hospital equipment used to be carried out by people at a relative distance from end-users, with feedback occurring only at a late stage or when accidents occurred. Now there tends to be a much more integrated approach, with a substantial and growing literature around evidence-based design. This has led to numerous practical benefits, for example in the re-design of labelling and packaging of medications and anaesthetic and emergency equipment, and in designing hospital environments to reduce the incidence of hospital-acquired infection.[1]

The same principles and ideas can be effective in reducing the incidence of geriatric syndromes in older people in hospital. For example, there is a growing amount of work on the role that design of the hospital environment can play in falls and delirium prevention, in terms of ensuring adequate lighting, noise reduction, orientation boards, suitable hospital beds, appropriate flooring and signage.

Advances in technology can reduce errors by improving communication, providing reminders, making knowledge more readily accessible, prompting for key information, assisting with calculations, monitoring and checking in real time and providing decision support.[41] There are many examples of how technology has helped to counteract the cognitive errors that humans can be prone to making, such as the use of barcodes in blood transfusions. It can also enhance the human qualities of judgement and decision-making, such as with computerized decision support with systems for diagnosis, reminder systems for prevention, systems for disease management and systems for supporting prescribing and drug dosing.[42]

Improving systems of care for older people

Technological advances are also making it possible to redesign systems of care for older people, with the aim of providing more targeted and integrated health and social care. For example, the rapidly growing field of telecare has made it possible for older people with sub-acute problems to be cared for in their own homes, in 'virtual wards', thereby avoiding unnecessary hospital admissions.

In hospital, much effort has been made in recent years to implement new ways of caring for acutely ill elderly patients in order to try to minimize functional

decline during hospitalization and subsequent prolonged rehabilitation. For example, it is now common practice for most hospitals in the UK to have an orthogeriatric service to ensure optimal medical care from admission to discharge of elderly patients who have sustained fractured neck of femurs. Stroke units are another example of how specialist care with focused, immediate rehabilitation and anticipation and swift recognition of complications can improve outcomes and reduce hospital-acquired complications such as functional decline.

In general acute geriatric medicine, it has been shown that providing specialist care environments, with staff who are interested in caring for older people and who have had relevant specialist training, can also prevent the development of the geriatric syndromes in hospital. An example of this are Acute Care of the Elders (ACE) units, in which a prepared environment, interdisciplinary collaborative care, multidimensional assessment, non-pharmacological prescription, medical review, home planning and transitional care all combine to improve a range of outcomes, including improved functional status, lower risk of nursing home placement and higher levels of patient and professional satisfaction with care.[43] This system of care, tailored towards the older person, also leads to a reduction in other errors such as inappropriate prescribing.

Interventions for the geriatric syndromes

There are many well-founded interventions for the prevention and management of geriatric syndromes in hospital.[44] These generally fall into the following categories: risk identification and assessment tools, single- or multicomponent practical interventions, changes to systems of care and educational programmes. Many of these are complemented by, or have been incorporated into, national or international campaigns and guidelines for widespread use. All are most effective if underpinned by strong leadership and robust measurement and reporting systems.

Some examples of commonly used risk assessment tools in the UK are the multitude of available falls risk assessment tools, the Waterlow score for assessing pressure sore risk and the Malnutrition Universal Screening Tool (MUST). There are challenges to the effective use of screening tools such of these: they should be completed by staff who have a sound understanding of the conditions they are assessing and identification of risk must be followed by justifiable actions to prevent the development of the geriatric syndrome.

The best known and most widely used general assessment tool for older people is Comprehensive Geriatric Assessment (CGA). This contains six key elements: assessment of functional ability, cognitive function, physical health, socioeconomic status, nutritional status, mobility and falls risk. Its purpose is to provide a holistic assessment of all issues relevant to a frail patient: it has been shown that if CGA is combined with strong and sustained interventions, better long-term outcomes can be achieved.[45] However, it is unclear whether it has any impact on hospital-acquired complications, although it undoubtedly identifies those who are the most frail and at the highest risk of adverse outcomes.

A good example of a practical intervention designed to prevent the development of a geriatric syndrome in hospital is the multicomponent intervention for delirium tested as part of the Elder Life Program.[46] In this study, six well-known risk factors for delirium (cognitive impairment, visual and hearing impairment, sleep deprivation, immobility and dehydration) were addressed in a comprehensive manner by a trained interdisciplinary team and tested in a controlled clinical trial: the incidence of delirium was reduced from 15% in the 'usual care' group to 9.9% in the intervention group (giving a matched odds ratio of 0.60, with $p = 0.02$). The actual practical methods used in each protocol were simple, commonsense management that it could be argued should form part of 'best practice' and good, empathetic care for all elderly patients. Other multifactorial interventions, when supported by strong leadership and robust measurement and reporting, have been shown to be key to reducing other geriatric syndromes, such as falls.[47]

Hospital-acquired infection

Significant progress has been made in recent years in reducing hospital-acquired infections (HAIs) across all age groups, not just in older people. This has partly been driven by regulatory and public pressure in response to a shift in societal attitudes about acceptable levels of risk, which have made HAIs a major organizational priority and a matter for statutory regulation. HAIs are relatively easy to measure and identify, so the impact of interventions for them can be easily assessed, unlike some of the other hospital-acquired complications common in older people. There are now standard definitions for HAIs, an increasing trend towards mandatory reporting of infections and, in most hospitals, infection control departments which independently monitor and act to reduce HAIs.

The underlying causes of HAIs are complex, ranging from individual actions or inactions, such as failures to follow rules and procedures, through to systemic failures or problems with design and technology. Consequently, many of the interventions which have been successful in tackling HAIs are equally as complex and are increasingly being seen as part of more general quality improvement programmes rather than solutions in isolation. For example, HAIs are one of the major outcome measures of the Safer Patients Initiative,[48] a long-term collaborative programme developed by the Health Foundation in partnership with the US

Institute for Healthcare Improvement and 24 participating UK NHS Trust sites. This ongoing initiative has a focus upon reliability and safety of care through application of continuous quality improvement techniques adapted from process industries and manufacturing.

Some of the other multifaceted interventions which have been shown to reduce the rates of HAIs include the use of care bundles to tackle central line infections and ventilator-associated pneumonias in intensive care units or using combined approaches to improve hand hygiene on general wards. Other effective infection control measures have included advances in treatment, regularly updated antibiotic prescribing guidelines and the use of other precautions such as minimizing ward transfers. Design of the hospital environment has an important part to play, in terms of providing adequate isolation and cleaning facilities and allowing sterile practices to be carried out with minimal contamination. Other innovations include the use of decision support systems in antibiotic prescription or allowing patients to participate in infection control initiatives (although older people may be less willing or able to do this).

Medication safety

Reducing medication error requires a multifaceted approach involving computerized systems, simplification and standardization of clinical processes, education and training and wider cultural and organizational change.[49]

Much work has been carried out to reduce medication error in general. The principles underlying this are common to all successful safety and quality improvement processes: systems must be designed to prevent errors occurring in the first place, then to make errors more visible when they do occur and finally to limit the effects of errors so they do not lead to harm. Standardization of processes, paying particular attention to high-risk medications and involvement and collaboration with both patients and clinicians have all been shown to be successful strategies.

There are several categories of interventions that have been shown to maximize medication safety for older people in particular. Much as for falls or delirium, the first step is to identify and prevent inappropriate prescribing. Assessment instruments such as the Beers criteria, STOPP and START,[50] give lists of drugs to avoid in older patients. These tools are useful for both the prevention and measurement of inappropriate prescribing. The potential drawbacks of such tools are that they may not be internationally useable, they rely on correct usage by prescribers and they may not include all classes of relevant drugs.

A crucial intervention to improve medication safety in older people is medication review and medicines reconciliation, both of which should ideally occur routinely at transitions of care and form a crucial part of specialist geriatric assessment. In primary care, various measures have been shown to improve overall medication safety in older patients, including clinical pharmacist intervention, educational measures and computerized support.[18]

As described earlier, one of the problems in assuring appropriate prescribing for older people is that they have often been excluded from relevant large clinical trials, leading to uncertainty about the safest way to prescribe for them. However, this trend seems to be being reversed of late, with older people being specifically targeted for recruitment into such trials.[31]

Priorities for improving the safety and quality of care for older people

Research priorities

Patient safety in older people across the world

Of course, patient safety is a global priority, of concern to older people and healthcare services all over the world. More research is required to understand the patient safety issues particularly relevant to older people in developing countries.

Improved definitions and measurement

In order to understand and improve safety and quality in older people, particularly those who are frail and complex, it is crucial that we consider further what safety and quality actually mean in this population. As described earlier, existing ways of measuring safety in hospitals, in particular, through case record review or reporting, are not particularly good at detecting the complex geriatric syndromes that are important both to these patients and to the healthcare system. This is not surprising, considering that such measures were not originally developed with the frail older person in mind. Very few adverse events associated with poor clinical reasoning, communication skills or safety awareness are detected by the usual methods of clinical incident reporting.

The complex nature of frail older patients can lead to difficulties when unravelling cause and effect when trying to assess safety in these patients. Another complicating factor is that there are blurred boundaries between adverse outcomes of hospitalization that are not preventable, preventable adverse events and providing a high-quality service.

Current measures of quality of care in older people tend to assess the management of specific clinical problems across healthcare sectors, such as the national audits of stroke, falls and bone health and incontinence in the UK or the ACOVE measures developed in the USA.[51] There is certainly a need to develop generalizable quality indicators for the acutely unwell frail elderly person in hospital, as highlighted recently by the NHS Confederation in the UK.[52]

Patient safety research in non-hospital settings

Much of this chapter has so far concentrated on the hospital environment because that is where the majority of patient safety research has been carried out; of course, although the frailest older people tend to undergo hospitalization the most frequently, they also encounter health services in other settings, most notably in intermediate care, primary care and care homes. Unfortunately, comparatively little research has been carried out on adverse events in older people in these settings, and this needs to be addressed, especially as systems of care are developed to minimize hospital admissions and maximize independence at home for older people. Perhaps the most vulnerable elderly population are those who reside in care homes; here, the patient safety issues are likely to be similar to those encountered in hospital in terms of geriatric syndromes, risks associated with immobility and functional decline and adverse drug events. There are, however, crucial differences likely to affect patient safety in care homes compared with hospital: in this environment things move at a different pace, the majority of patients are frail, responsibilities and expertise amongst staff are different and problems with the management and diagnosis of acute problems will also differ. Although work has been done to look at certain aspects of patient safety in these environments, such as medication safety, there is still much to do.

Key points

- Older people are more vulnerable than younger patients to healthcare-associated harm and its consequences. This tendency is associated with frailty and comorbidity rather than age alone – as our populations age, systems of care need to be designed with this in mind.
- Older people experience a wider range of adverse events than their younger counterparts in hospital – including the geriatric syndromes, yet patient safety in this population is comparatively under-researched.
- There is a need to improve measurement of safety and quality of care in older people and to understand more about patient safety for older people in non-hospital settings.
- Key areas of focus for improving patient safety in older people include the design of safer healthcare systems for older people, the early detection, prevention and management of the geriatric syndromes, providing education to individual clinicians to enhance decision-making, assessment and team working skills and efforts to reduce ageism and negative attitudes towards older people and their care.

Conclusion

In summary, it is clear that although excellent healthcare exists for older people, there are many areas in which further safety and quality improvements can be made for this vulnerable population. As, justly, patient safety and quality of care become the main focus of planners of healthcare services, and with increasing advances in design and technology, it should be possible to make sure that systems of care for older people develop to maximize safety and quality. Continuing attention needs to be paid to the education and training of individual clinicians in respect of the unique decision-making, assessment and team working skills necessary to provide excellent care for older people. We should be particularly mindful of strategies for the early detection, prevention and management of the geriatric syndromes and effective ways of tailoring treatment for the individual. Crucially, safety and quality of care will also be enhanced if the ongoing problems with ageism and attitudes towards older people and their care could be addressed.

SECTION 1

Eating Disorders and Nutritional Health

CHAPTER 15

Epidemiology of nutrition and ageing

Wija A. van Staveren and Lisette C.P.G.M. de Groot
Wageningen University, Wageningen, The Netherlands

Introduction

Population ageing is considered one of humanity's greatest success stories. It is also one of the greatest challenges to cope with in socioeconomic and health policies. Worldwide, the proportion of people aged 60 years and over has risen from 8% in 1950 to 11% in 2007 and is expected to reach 22% in 2050.[1] In addition, it is predicted that decreasing fertility rates and increasing longevity will ensure the continued 'greying' of the world's population. Ageing is a complex process and apart from factors intrinsic to the individual, extrinsic and treatable factors also play a role, such as environmental and lifestyle variables.[2] Since extra years in old age are not always spent in good health, the question often is raised, 'How do I get old healthy?' Analyses of the major causes of death clearly show that the burden of chronic diseases has increased rapidly. Most data come from self-reported (co-)morbidity and medical records confirm this trend. Partly this increase may reflect improved medical knowledge and health service use in elderly people. Such progress leads to a longer period of morbidity, but with an improved functional status.[3] Many of the health risk factors are related to nutrition and inactivity and include high blood pressure, high concentrations of serum cholesterol, low intake of fruits and vegetables, being overweight and alcohol and tobacco use. These factors may lead to, amongst others, cardiovascular disease, type 2 diabetes, certain types of cancer and osteoporosis. These global epidemiological data have prompted the WHO (World Health Organization) and FAO (Food and Agriculture Organization) to set up a Joint WHO/FAO Consultation on Diet Nutrition and the Prevention of Chronic Disease. The report of this group provides dietary recommendations, including the following guidelines:[4]

- limit energy intake from fat and shift consumption away from saturated fats and *trans*-fatty acids towards unsaturated fat;
- increase consumption of fruits and vegetables and also legumes, whole grains and nuts;
- limit the intake of 'free' sugars;
- limit salt (sodium consumption from all sources) and ensure that salt is iodized;
- achieve energy balance for weight control.

The guidelines are evidence based for younger adults and more recent research has shown the potential impact in older adults. In old age, frailty is likely to develop (Figure 15.1) and therefore may expand the role of nutrition from the prevention of diseases to the supply of specific nutrients and the maintenance of food intake. This food intake should be sufficient to combat frailty and to maintain quality of life. Frail is defined here as an age-related physiological vulnerability resulting from impaired homeostatic reserve and reduced capacity of the organism to withstand stress.

In view of the desired adaptation of the dietary guidelines to health priorities in older adults, we discuss in this chapter epidemiological evidence for this age group on:

- body weight, body composition and health;
- dietary intake, dietary patterns, diet scores in relation to mortality: differences within and between populations;
- high-risk nutrients;
- determinants of food choice and vulnerable groups;
- effects of nutrition supplements on health indices;
- dietary guidelines in old age.

Body weight, body composition and health

Body weight change, changes in body composition and usual ageing

In cross-sectional studies, the prevalence of high body weight or obesity [body mass index (BMI) $>30\,kg\,m^{-2}$] increases with age up to about 60 years, remains stable until about 70 years and then declines.[6] Studies indicate that both weight loss and weight gain are associated with adverse health outcomes, such as decreased functional status, institutionalization and increased mortality.[7]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

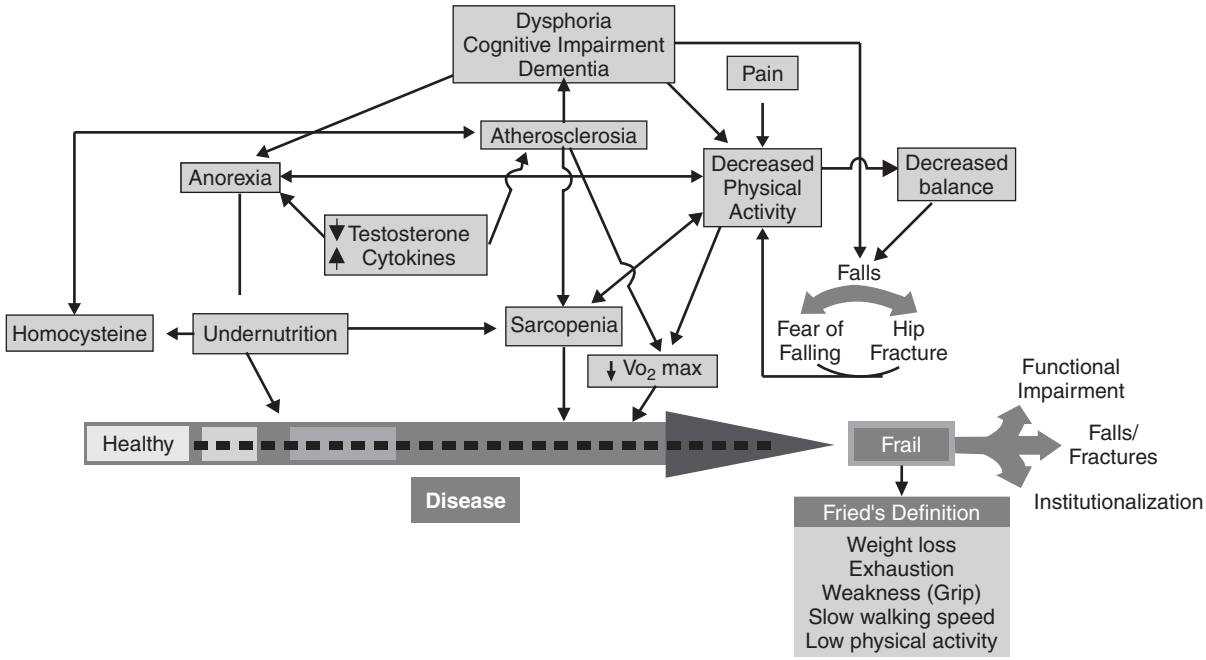

Figure 15.1 The pathophysiology of frailty. (Reproduced with permission from Morley;[5] www.cyberounds.com/conferences/geriatrics/.)

In considering changes in body mass and health, changes in body composition have to be included. A decline in lean body mass occurs in the third decade.[6] This loss in lean body mass, much of which may be due to a sedentary lifestyle, tends to be offset by gains in fat mass that continues until age 65–70 years. At any given BMI, older people will be considerably fatter than younger adults of similar body weight because the fat-free mass diminishes by as much as 70% between the ages of 30 and 70 years. Studies in very healthy elderly people indicate that only very small decreases in weight (0.1–0.2 kg per year) appear to occur in association with normal ageing. Therefore, weight loss should never be dismissed as part of the ageing process.

Most of the studies on BMI in the aged have been conducted in the United States [e.g. the Baltimore Longevity Study, the New Mexico Study and the older age group of NHANES III (National Health and Nutrition Examination Survey)] and in Europe [e.g. SENECA (Survey in Europe on Nutrition and the Elderly – a Concerted Action) and the elderly part of EPIC (European Prospective Investigation into Cancer and Nutrition)]. Available data indicate that demographic changes are even more dramatic in the less developed countries. One study including other demographic groups was the International Union of Nutrition Societies (IUNS) cross-cultural study on 'Food Habits in Later Life'. In this study, people of 70 years and older from communities in Australia, Greece, China, Japan, the Philippines and Sweden were involved. The results showed that on average BMI for Caucasian men and women is about 25 kg m^{-2}, with the highest for Greek women (30 kg m^{-2}). Filipino and Chinese had average BMIs between 20 and 22 kg m^{-2}. The estimated fat mass showed, as expected, a large gender difference with on average 43–50% for women and 25–35% for men, but differences in fat mass between ethnic groups were less striking.[8]

The association between BMI, weight loss and health

Many studies have documented that the relative risks of a high BMI may become less pronounced with ageing. A systematic review and meta-analysis conducted to determine the effect of an elevated BMI on all-cause mortality risk in men and women aged 65 years and over concluded that elderly with overweight (25–29 kg m^{-2}) do not have a significantly increased risk of mortality. A BMI in the obese range (30 kg m^{-2} and over) is associated with only a modest increase in mortality risk regardless of gender, disease status and smoking status.[9] Several explanations for this phenomenon have been put forward, such as selective survival, cohort effects and/or a ceiling effect of mortality rates. The most important explanation might be that BMI is not a good indicator of body composition. The U-shaped relation between BMI and mortality in younger adults may be the result of a positive association between body fat mass and mortality and an inverse linear association between fat-free mass and mortality. As stated above, the ratio between the two compartments (fat and fat-free mass) changes with ageing and the BMI does not measure this. Further, kyphosis in old age makes it difficult to measure height and, therefore,

may result in unreliable estimates of BMI. For this reason, changes in weight (rather than changes in BMI) are a preferable measure, although in the interpretation the possibility of oedema has to be taken into account.[10] As a final reason for the less pronounced relative risk of a high BMI, it is suggested that an excess fat mass is less detrimental in old age. However, recent views on pro-inflammatory factors related to adiposity indicate that fat loss ameliorates some catabolic conditions of ageing since some cytokines may directly affect muscle protein synthesis and breakdown. A voluntary decrease in weight may also ease the mechanical burden on weak joints and muscle, thus improving mobility. Therefore, only weight-loss therapy that minimizes loss in muscle and bone condition is recommended for older obese persons. Especially in the case of sarcopenic obesity, prevention of further loss of muscle mass is urgently required. Sarcopenic obesity is defined as the coexistence of diminished lean mass and increased fat mass).[11]

At the other end of the scale, reflecting body weight, prospective studies have shown that weight loss, a decline in BMI, can be both a marker of and an independent contributor to adverse health outcomes. Involuntary weight loss in elderly subjects is likely to reflect sarcopenia, a loss of lean body mass and particularly muscle mass. Other types of weight loss are cachexia, a disease-related weight loss, and starvation or undereating reflecting loss of mainly fat mass. Weight loss may contribute to the increased mortality, especially if the initial body weight is relatively low. Incidence rates of 5–15% have been reported in studies of involuntary weight loss in community-dwelling older adults.[7] In frail elderly people often dependent on professional care, rates of over 25% up to 40% have been observed. Body weight loss is considered the most important indicator of undernutrition. A loss of 10% in 6 months, 7.5% in 3 months or 5% in 1 month is considered very serious, owing to the direct relationship with morbidity and mortality. Further, nutritional deficits are associated with low energy intake, as is shown in Figure 15.2.[12]

Central adiposity and health

Redistribution of body fat with ageing further limits the applicability of BMI as a risk indicator in older adults. There is evidence in younger adults that those who have the majority of their adipose tissue around their waist (high waist-to-hip ratio) have a higher prevalence of diabetes mellitus, hypertension and coronary artery disease than those who have predominantly hip adiposity. Folsom *et al*.[13] examined the role of body fatness on mortality in a random sample of 31 702 Iowan women aged 55–69 years, followed for 11–12 years. Waist-to-hip ratio was positively correlated with mortality, also after correction for smoking, alcohol and estrogen use. Waist-to-hip ratio is, however, increasingly difficult to interpret with further advancing age. Whereas the waist measures abdominal fatness, hip circumference may also reflect variations in pelvic width and gluteal muscle. In elderly people, narrow hips may reflect peripheral muscle wasting, which may correlate with chronic conditions.

The current literature gives inconsistent answers to the question of how useful it is to measure, in addition to BMI, the waist-to-hip ratio or waist circumference only. So far, except for the oldest age group, the conclusion of Canoy[14] based on current epidemiology may be clinically useful: adipose tissue distribution assessment ideally should provide a single risk estimate that captures the separate effects of abdominal and peripheral adiposity. Although far from perfect, waist-hip ratio or just waist circumference is a simple and inexpensive measure that captures these effects and can help to improve CHD and other chronic disease risk assessments. This conclusion should not stop further research and development of an appropriate protocol for the diagnosis of adipose tissue distribution, including the search into cut-off points for specific ethnic, age and other population groups.

Fluid status and dehydration in the elderly

Older adults are at risk for dehydration because of both reduced fluid intake and increased fluid losses. Even in healthy, successful ageing, there is a reduction in thirst in response to water deprivation, which is evidenced both in a lower self-reported thirst score during dehydration and in ingestion of less water after the dehydration period. Acute weight loss of 3% or more of the body mass or more than 1 kg weight loss per day points to dehydration. It is a common and potentially lethal problem in both institutionalized and community-dwelling elderly people. In hospitals, the mortality rate may be up to 50% in those older adults with dehydration. The most common causes of dehydration are infection, altered level of consciousness, cognitive impairment and use of diuretics. Schols *et al*.[15] concluded that dehydration is a common problem in nursing homes, often due to failures in detection of dehydration and appropriate management. An overload of water and salt is also common and may result in impaired recovery from surgery or perioperative mortality and morbidity. For the elderly, it is advised to take about 1.5 l of fluid per day.

Ageing, bone loss and nutrition

Bone loss commences around the age of 40 years and is on average between 0.5 and 1% per year in men; in women, the rate of bone loss accelerates around the menopause to about 2% per year. When bone density falls below 2.5 SD of the mean bone mineral density (BMD) of young adults, the WHO[16] refers to osteoporosis. The latter is a multifactorial disease and defined also as ‘a systemic skeletal disease

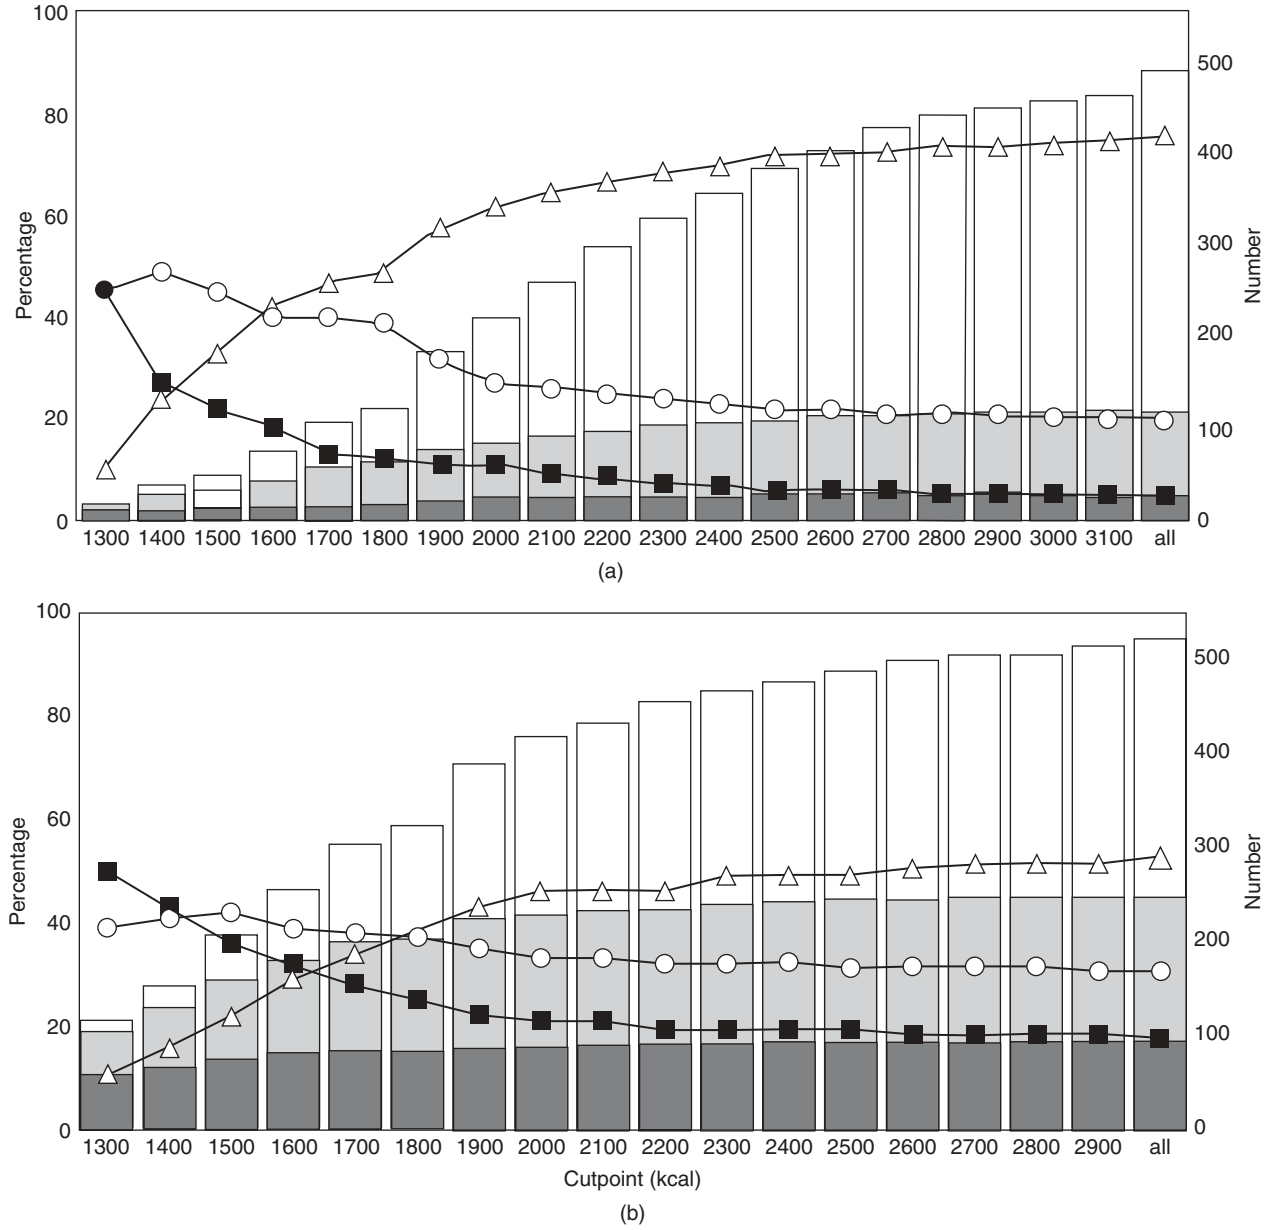

Figure 15.2 Number and percentage of (a) men and (b) women with an inadequate intake of no nutrients (□ and △), one nutrient (□ and ○) and at least two nutrients (■ and □) for groups with energy intakes under different cut points (Reproduced from de Groot *et al.*,[12] by permission of Oxford University Press.)

characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fractures'. Biological, environmental and genetic factors and also lifestyle factors may play an important role in the onset and development of osteoporosis. The incidence of osteoporosis varies widely between countries and between and within ethnic groups. For instance, the NHANES III study[17] showed that low BMD is most common among elderly non-Hispanic white women (21% osteoporosis) and among Mexican American women (20% osteoporosis) and lower in non-Hispanic black women (18%). In Europe it is estimated that 179 000 men and 611 000 women suffer a hip fracture every year and these numbers are expected to double in the next 40 years.[18]

Although a low percentage of the bone mass can be explained by nutritional factors (less than 20%), it can still have a large impact on bone health. The benefits of supplementation of populations at risk for osteoporosis with vitamin D and calcium are well established in studies with endpoints such as effects on BMD, bone turnover and

a reduced risk of fractures without side affects. The vitamin D requirement may be higher in regions where calcium intake is low. Vitamin D also has a beneficial effect on the risk of falling, explained by an improvement of muscle function. Evidence for associations between optimal protein intake and bone mass is diverse, positive, negative and no associations having all been found. Other dietary factors, such as vitamin K, vitamin A, caffeine, fluoride, phosphorus and zinc, are also subjects of current bone research and it is under debate whether they are important and truly associated with bone health.[19]

Dietary intake, dietary patterns, diet scores in relation to mortality: differences within and between populations

Macronutrients as sources of energy

Population-based nutritional surveys have shown a gradual decline in energy intake in old age. Shifts in the percentage of energy coming from various macronutrients while ageing are less clear. Between populations, the macronutrient composition appears to vary considerably. Across studies, intakes range from 12 to 18% energy from protein, from 20 to 42% energy from fat and from 38 to 65% from carbohydrates.[8] In a background paper, Prentice[20] considered the extent to which the development of recommendations for dietary energy needs to account for the macronutrients. He discussed the issue with a view to avoiding undernutrition in addition to obesity. He concluded that 'at the metabolic level, only diets with the most extreme macronutrient composition would have any consequences by exceeding the natural ability to modify fuel selection. However, diets of different macronutrient composition and energy density can have profound implications for innate appetite regulation and hence energy consumption'. The Omni-Heart study,[21] a randomized three-period cross-over feeding trial, studied self-reported appetite and selected fasting hormone levels by comparing the effects of three diets, each rich in a different macronutrient. It was concluded that a diet rich in protein from lean meat and rich in vegetables reduces self-reported appetite when compared with diets rich in carbohydrate and unsaturated fat. The observed pattern of hormone changes, however, did not explain the inverse association between protein intake and appetite.

Proteins

The role of proteins in the diet is currently being extensively studied and discussed, not only because of the satiating effect. Alterations in the ability of cells to regulate homeostasis underlie the pathogenesis of severe human diseases. Even in the absence of disease, deterioration of protein homeostasis likely contributes to different aspects of 'normal ageing'. This makes it difficult to formulate evidence-based requirements for proteins in the diet of (frail) elderly people. There is general agreement on moderately increasing protein intake above 0.8 g kg^{-1} body weight in the elderly (up to 1.5 g kg^{-1}), which may help to reduce progressive loss and stimulate muscle protein anabolism. Current gaps in our understanding of altered protein homeostasis in ageing urgently require further studies.[22]

Dietary patterns and diet scores

In nutritional epidemiology, recently there has been great interest in assessing the relationship between dietary patterns and health, rather than the relation with single nutrients. The reason is that foods and nutrients are interrelated and people do not eat single nutrients, but foods. To investigate dietary patterns, two common methods used are cluster analysis and calculation of diet scores. Cluster analysis explores the categorization of persons into groups on the basis of similarity in food intake (e.g. alcohol drinkers or fish and grain eaters). Diet scores are based on dietary guidelines and are applied to identify groups with good or poor nutritional status. In the United States and Europe, existing measures of overall dietary quality include the Healthy Eating Index (HEI), Mediterranean Diet Score (MDS) and the Healthy Diet Indicator (HDI). These diet scores differ in diet components, scoring rates and definition of cut-off values (Table 15.1).

In spite of these differences, both diet scores and cluster analysis have been shown to be useful tools in identifying groups with different nutritional status. Haveman-Nies *et al*.[23] evaluated the dietary quality of European and American elderly subjects using cluster analysis, the healthy diet indicator and two versions of the MDS. These measures were tested for associations with lifestyle and nutritional status in an elderly population aged 70–77 years from the Framingham study and from the SENECA. Table 15.2 shows food group intake and results of the scores by the five dietary pattern clusters observed.

In general, Southern European centres and Framingham had better mean diet scores than Northern European centres. Cluster analysis revealed that the meat, eggs and fat pattern coincided with significantly lower average dietary quality, as measured with all three scores, compared with all other clusters except the alcohol cluster. The cluster characterized by a relatively high fish and grain intake had a significantly better MDS than all other clusters. High-quality diets were associated with less body fatness, greater physical activity and non-smoking.

Sofi *et al*.[24] (2008) confirmed in a meta-analysis a favourable effect of a Mediterranean type of diet and found a reduction of 9% in overall mortality, mortality from

Table 15.1 Main items in three diet scores: Healthy Eating Index (HEI), the Mediterranean Diet Score (MDS) and the Healthy Diet Index HDI.

HEI[a]	MDS[b,c]	HDI[d]
Grains	Cereals	Complex carbohydrates, dietary fibre, mono- and disaccharides
Vegetables	Vegetables	Vegetables and fruits
Fruits	Fruits and nuts Legumes Alcohol	Pulses, nuts, seeds
Meat, poultry, fish, eggs, dry beans, nuts	Meat and meat products	Protein
Milk	Dairy and dairy products	
Energy: % of: Total fat Saturated fat	Ratio monounsaturated/saturated fat	Ratio saturated/polyunsaturated fat; cholesterol
Salt intake		
Variation score		

[a]For calculations of the index, see http//www.cnpp.usda.gov.
[b]Recently, this score has been changed with alcohol as a separated recommendation and fish introduced in the core pyramid. Also, daily physical activity obtains attention. Oldways Preservation and Exchange Trust 1999 to 2003.
[c,d]For calculation of the score, see Haveman-Nies *et al*.[23]

cardiovascular diseases (9%), mortality from cancer (6%) and incidence of Alzheimer's disease (13%). Additionally, two prospective studies suggested that adherence to the Mediterranean diet may not only affect the risk for Alzheimer's disease, but may also slow the disease and reduce the risks of mild cognitive impairment.

In the elderly part of the EPIC study, it was explored how each individual component of the Mediterranean diet contributes to the observed effects. Several of the components appeared to reduce mortality risk, but most clearly a general plant-based diet, correlating well with the Mediterranean diet ($r = 0.62$), was associated with lower all-cause mortality in elderly Europeans in the EPIC study.[25]

Daily meals and other lifestyle factors

The number of meals eaten per day and the consumption of snacks between meals can differ widely between populations. The SENECA study showed large differences in the number of meals eaten per day, with median ranges from six in Denmark to three in the South of France. Meal-based nutrient intake data suggest that the cooked meal in the southern Europe mediates the beneficial effects of the Mediterranean diet. Knoops *et al*.[26] showed that in addition to adherence to daily meals and a Mediterranean diet, other healthy practices are important, such as not smoking, moderate alcohol use and physical activity (Figure 15.3).

Determinants of food choice and vulnerable groups

It is generally recognized that food choice may be affected by biological factors (hunger, appetite and taste), economic elements (cost, income and availability of foods), structural elements (access, education, cooking facilities, skills and time), social characteristics (culture, family, peers and meal patterns) and further attitudes, beliefs and knowledge about food. Clearly, changes in these factors may change food habits and in the aged population it often may lead to a less favourable diet. Age-related energy reduction can be explained by physiological factors such as a lower metabolic rate and less mobility. When these factors coexist with both a decrease in the need to eat and a decrease in the pleasure in eating it, it may predispose to malnutrition.

Fjellström[27] reported that within older populations, there are some subgroups such as socially isolated, lonely, institutionalized and economically deprived people who are more likely to be consuming an unbalanced diet. Early studies have shown that among older persons aged 60–94 years, loneliness and social isolation were related to dietary inadequacies. Food consumption data for elderly people living alone, however, did not show an adverse impact either in the United States or in Europe.

Locher *et al*.[28] found that ethnicity and gender were risk factors for older people's food consumption. Older black women were most at risk followed by older black men and older white women. They concluded that what contribute most to nutritional risk are social isolation, low income level, limited support and social capital, including transportation to food shops and congregated meal sites, and also limited independent life span.

Institutionalized elderly people tend to have a lower energy intake – mainly due to a lower fat intake – and a lower protein intake. Furthermore, nutrient inadequacy is more prevalent in the institutionalized elderly than in community-dwelling groups. At the same time, no clear differences in food patterns were observed. Therefore, the main cause of the higher prevalence of nutrient inadequacy in dependent elderly people is most likely the low level of total food intake. An exception might be the group with a poor state of dentition. In both the NHANES III and SENECA studies, a lower quality of the diet was observed due to avoidance of food groups such as meat, fruit and vegetables. Comparative observations come from a sample of low-income households in the UK.[29]

Table 15.2 Mean (SD) food group intake of 70–77-years elderly of the Framingham Heart Study and SENECA's baseline study, by dietary pattern cluster.

Institutionalized people are often frail and suffer from both functional and cognitive impairment. In addition to an overall inadequate food intake, several studies have pointed to more specific nutrients and functional decline. Below we discuss some specific high-risk nutrients not directly related to a low energy intake.

High-risk nutrients

An inadequate supply of vitamin B_2, vitamin B_6, folate and/or vitamin B_{12} causes hyperhomocysteinaemia. Homocysteine is considered an independent risk indicator of cardiovascular diseases. Prospective studies also suggest a correlation between elevated homocysteine and dementia and osteoporotic fractures Supplementation with folate and less so with cobalamin or pyridoxine demonstrated a reduction in serum homocysteine. So far, trials have not been conducted or are inconclusive in demonstrating a reducing effect on the incidence of cardiovascular disease, dementia or osteoporotic fractures.

Vitamin B_2 contributes to hyperhomocysteinaemia, but is generally not considered as a high-risk nutrient in elderly people consuming sufficient dairy products.

Vitamin B_6 comprises various derivatives of pyridine, including pyridoxine, pyridoxal and pyridoxamine. There are many dietary sources and therefore dietary deficiency is rare. Vitamin B_6 deficiency usually occurs in association with other water-soluble vitamins. Deficiency may result from alcoholism, malabsorption and other factors such as dialysis. Medication may act as pyridoxine antagonist.

Folate represents a group of related pterin compounds; more than 35 forms of the vitamin are found naturally. The various dietary sources include, in addition to plant sources, also liver and other organ meats. Folate in foods is destroyed by excessive cooking; as much as 95% may be lost.[30] Studies have revealed that folate deficiency may range from 2.5 to 34% in the elderly. Causal factors in addition to poor intake and absorption are atrophic gastritis, excessive alcohol intake, smoking and use of some drugs.

Vitamin B_{12} is a group of cobalamin compounds with a corrin ring and a cobalt atom in the centre. Vitamin B_{12} is available only from animal foods. In the SENECA study, ~25% of the participants had a low vitamin B_{12} status: in some, 25% plasma cobalamin levels were $<260\ \text{pmol}\,\text{l}^{-1}$ and plasma methylmalonic acid (MMA) $>0.32\ \mu\text{mol}\,\text{l}^{-1}$.[7] These levels could be only partly explained by insufficient dietary intake or atrophic gastritis. Pernicious anaemia, terminal ileal resection, bacterial overgrowth and use of specific drugs are other possible causes of a deficiency state.

Vitamin C (ascorbic acid) is a water-soluble vitamin widely found in fruits and vegetables. Unfortunately, this vitamin is readily lost from foods during storage and preparation. Such losses may account for about 50% of the potential vitamin content in the total diet. For Dutch and Danish diets, such vitamin C losses amounted to ~45% of the vitamin C content of the diet and, consequently, ~30% of the subjects had too low intakes. Results from the NHANES III study showed that average intake serum levels were normal in Americans, but smokers, those not taking supplements and non-Hispanic black males had higher risks. Low serum levels for the last group were mainly due to low intakes of fruits and vegetables.[31] Older people who make use of catering or restaurant facilities on a daily basis are at particular risk for insufficient vitamin C intake, the reason often being the long distance of carrying prepared dishes from the kitchen to the place of consumption. The absorption of the vitamin seems not to be affected by age. Low vitamin C levels have been associated with, in addition to classical deficiency signs, increased risk of coronary artery disease and senile cataract. The mechanism behind it is most likely the antioxidant properties of vitamin C.

The term vitamin A refers to a family of molecules containing different functional groups on a cyclohexenyl group and include retinol, retinal, retinoic acid and retinyl ester. Dietary sources are mainly retinyl esters provided by animal-derived foods. Plant foods supply vitamin A as carotenoids such as β-carotene, α-carotene and β-cryptoxanthin. Vitamin A is of worldwide concern as a risk nutrient, but has not been observed as a specific problem for elderly people, probably due to lower requirements in old age.[32] An exception might be the observations of very low intakes in some ethnic groups in Asia.[8]

Vitamin D (calciferol) refers to a group of lipid-soluble compounds with a four-ringed cholesterol backbone. Vitamin D is not considered a true vitamin, because the human body can synthesize it with adequate sunlight exposure. In most cultures, about one-third of the vitamin D requirements can be obtained from a diet of fish, meat and milk fat; the remainder has to be synthesized. As a result of limited sunlight exposure and a fourfold reduced capacity of the skin to produce vitamin D, deficiencies occur especially in homebound elderly people. Nevertheless, in the relatively healthy older European participants of the SENECA study, 40% had serum hydroxyvitamin D levels below $30\ \text{nmol}\,\text{l}^{-1}$,[7] and this latter standard is below the currently proposed level of at least $50\ \text{nmol}\,\text{l}^{-1}$.[33] Vitamin D supplementation results in decreased bone loss and fracture rate in both older men and women. More recent trials also indicate improvement of sarcopenia and a decrease in falls.

Calcium is related to bone health and is a risk nutrient in elderly people with no or little dairy products in their diet. This might happen within many cultures and was particularly observed in some Asian centres.[8] It is not, however, specifically an age-related problem.

Zinc deficiency is not rare in older persons, particularly among diabetics. Zinc is available widely in foods but

the bioavailability is better from animal than plant foods. In whole grain products, phytates may inhibit absorption. Red meat, seafood, fresh fruit, vegetables and dairy products are the main sources. Zinc is involved in protein synthesis, nucleic acid synthesis and gene regulation. Further, it is part of several enzymes. Biochemical abnormalities of zinc deficiency include a reduction in plasma zinc concentrations, protein synthesis, activity of metalloproteins, resistance to infection, collagen synthesis and platelet aggregation. Other manifestations of zinc deficiency are anorexia due to impaired taste and smell, impaired vision, confusion and restlessness and sometimes diarrhoea. Zinc measurements are often problematic. Cytokines dramatically reduce serum zinc. Leukocyte zinc levels or zinc hair levels when determined properly may be useful.

Iron has special nutritional interest because of the high incidence of iron deficiency worldwide in younger age groups. Iron is available in many foods in small amounts, but between foods the bioavailability differs considerably. Two broad categories of iron are present in food: haem iron derived mainly from animal foods and non-haem iron in plant foods. Haem iron is much better absorbed. Because of this difference in biological availability, dietary recommendations vary according to the nature of the diet. These recommendations are difficult to meet in diets with a low bioavailability. However, the requirement is sharply reduced in postmenopausal women and their iron status is correspondingly improved. Adult men generally have no problem in meeting their iron requirement. When anaemia is diagnosed, chronic blood loss or deficiency of folate or vitamin B_{12} should be considered. In the elderly using multi-supplements, concern about the iron status should rather be with the avoidance of overexposure than with the prevention of deficiency. To determine iron status, serum iron together with ferritin should be determined. In some cases, measuring soluble transferring receptors may be useful.

Effect of nutritional supplements on health indices in frail elderly people

There are many ways to improve the nutritional situation in old age, mostly aimed at improving nutrient intake in terms of either quantity and or quality. In order to assess the efficacy of nutrition-related interventions in the frail elderly, a number of studies, reviews and meta-analyses have been conducted.[34] The supplements studied varied in composition and also outcome measures. Nevertheless, the results of the studies are more or less in the same direction. Improvement of body weight has been reported, which could be fat, muscle or water. However, a gain in fat mass or water will not improve muscle strength. Most likely a combination with exercise is necessary to improve muscle strength and function. Further, most studies show improvement of biochemical parameters of the nutritional status, such as serum vitamin levels and functional biochemical parameters, for example, serum homocysteine. Beneficial effects were more convincing when the intervention was conducted during a longer period and when the patients had more serious functional impairments.

A literature search indicated that in frail elderly people, a combination of macronutrients and micronutrient (enriched or fortified foods) might be preferred. Such an intervention affects several aspects of the nutritional and health status of this group. The doses should not exceed the recommended daily intakes, because adverse affects of such doses on organ systems have been reported.[35] As stated before, older people are very heterogeneous, with different diagnoses, as reflected in the trials. Some patient groups may be more likely to benefit than others. For instance, patients with hip fractures and who are often undernourished when admitted to hospital may profit more from supplementation than those admitted after stroke and who are less undernourished. More work is required to understand better the mechanisms by which extra nutrient supply can affect patients with different chronic and acute conditions.

Milne *et al*. reported that collected data were limited by the poor quality of most included trials.[35] Trials should have sufficient statistical power and length of follow-up to detect any beneficial effects, have properly concealed allocation and, where possible, blinding. Including outcomes of relevance to patients, such as improvement of functionality and/or quality of life, may help sure better compliance. Owing to the effects of gastrointestinal disturbances, for instance nausea, vomiting or diarrhoea, poor appetite or poor taste of the supplement, compliance might be very low.[36]

For improvement of dietary intake not only supplements may help. Nijs *et al*. showed that simple measures such as providing family-style mealtimes in a comfortable dining room with nicely set tables and choice of cooked food and friendly attentive staff prevented a decline in quality of life, physical performance and body weight decline in nursing home residents.[37] In a cross-sectional descriptive study, preferences for improvement of intake by the elderly were analysed. Out of 15 forced-choice comparisons, food quality improvements, feeding assistance and the provision of multiple small meals and snacks throughout the day were the strongly preferred approaches, as opposed to nutritional supplementation.[38]

Dietary guidelines

In this chapter, we started with the WHO dietary guidelines for the prevention of chronic diseases.[4] Epidemiological studies on nutrition and ageing show that the guidelines for elderly people are very similar to those formulated for

younger adults. However, the priorities should be different. First, it is recommended to aim for stable body weight and maintenance of fat-free mass by sufficient physical activity. When the energy requirement decreases, the need for nutrient-dense foods, as comprised in the healthy diet index or MDS score, should be included. Further sufficient fluid (although the recommended 1.5 l is a maximum rather than an average) is important and, as indicated earlier, attention should be paid to some supplements. For vitamin D, there is sufficient evidence that a supplement is required for groups of elderly people. Homebound elderly people are most at risk. In addition, for elderly people with insufficient intake of dairy products, extra calcium is required and elderly people suffering from atrophic gastritis may benefit from a vitamin B_{12} supplement.

Frail elderly people with a very low energy intake may need enriched or fortified foods with vitamins and minerals added according to the dietary recommendations.

In conclusion, although there are still many questions regarding the relationship between dietary patterns and health and in the effectiveness of supplement use, the epidemiology of nutrition and ageing supplies us with sufficient evidence about the importance of adequate nutritional care and a healthy diet in old age.

Key points

- The relative risks of a high BMI become less pronounced with ageing. If weight loss therapy is indicated in obese elderly, it should result in a minimum loss of lean body mass, especially in sarcopenic obese elderly people.
- A low energy intake (<6.3 MJ/1500 kcal) goes together with an insufficient supply of micronutrients. Therefore, in frail elderly people the focus with meals should be on tasty, nutrient-dense foods.
- Also in an elderly population, healthy dietary patterns are related to decreased total mortality and disease-specific mortality.

CHAPTER 16

The anorexia of ageing

Ian M. Chapman
University of Adelaide, Royal Adelaide Hospital, Adelaide, Australia

The 'paradox' of undernutrition in older people

Overnutrition is the major form of malnutrition in the developed world. A substantial proportion of older people in western countries are overweight or obese according to generally accepted body mass index (BMI) [weight (kg)/height (m^2)] criteria. For example, in a 2000 study, 58% of Americans aged ≥65 years had a BMI of 25 kg m^{-2} or more,[1] the World Health Organization cutoff for overweight. Weight loss is usually recommended for overweight and obese older adults in the same manner as in younger adults. and at any given time a substantial proportion of older people wish to lose weight. Furthermore, there is evidence from studies in species as varied as yeast, spiders, mice and possibly primates that long-term restriction of energy (food) intake by 30–60% compared with *ad libitum* intake prolongs life.[2] It might seem, therefore, that reduced food intake leading to weight loss would be good for the majority of older people. This is not necessarily the case, however. The effects of long-term voluntary energy restriction have not been tested in humans and the benefits observed in other species may not apply to ours. Even if such a restriction is beneficial, it may have to be started in childhood,[3] with consequent inhibition of normal growth. Marked energy restriction in older adults is likely to lead to a substantial loss of beneficial lean body tissue and also fat mass and increase the risk of vitamin, mineral and other dietary deficiencies. Calorie restriction in older adults should be considered 'experimental and potentially dangerous'.[3]

As indicated in the following text, (1) ideal weight ranges are almost certainly higher in older than young adults; (2) weight loss is often associated with adverse effects in the elderly, particularly if unintentional; and (3) undernutrition manifesting as low body weight and weight loss is common in older people and has significant adverse effects. For these reasons, caution should be exercised in recommending weight loss to people aged over 70 years and a high level of awareness needs to be maintained to detect unintentional weight loss and undernutrition in this age-group.

'Ideal' body weight in older people

There is increasing evidence that the adverse effects of being overweight or obese, as defined by standard BMI criteria, are not as great in the elderly as in younger adults. Ideal weight ranges based on life expectancy are higher for older than young adults. For example, in a 12 year study of 324 000 people in the American Cancer Society Cohort, for people under the age of 75 years there was a significant and progressive increase in subsequent mortality as baseline BMI increased above 21.9 kg m^{-2}. These adverse effects of increasing body weight diminished, however, with increasing age above 45 years and were absent altogether over 75 years.[4] Among 4736 people aged 60 or more followed for an average of 4.5 years in the Systolic Hypertension in the Elderly Program (SHEP),[5] those whose baseline BMI was in the lowest quintile (<23.6 kg m^{-2}) had the highest subsequent mortality and those within the highest BMI quintile (≥31 kg m^{-2}), corresponding to the conventional criteria of obesity, had the lowest mortality.

Recommendations for ideal weight ranges in older people vary, but there is good evidence that BMI values below about 22 kg m^{-2} in people over 70 years of age are associated with worse outcomes than higher weights, and BMIs below 18.5 kg m^{-2} are a particular concern. The optimum BMI for survival in people over age 70 years is probably in the range 25–30 kg m^{-2} and there is some recent evidence that BMIs above (so-called) normal may be somewhat more protective in women than men.[6]

Although optimum body weight for older people is probably higher than that for young adults, they in fact tend to weigh less. The decline in body weight with age, as measured by BMI, has been well documented in population-based, cross-sectional and longitudinal

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

studies.[7,8]. For example, in the 1997–1998 US National Health Interview Survey of 68 556 adults, more people aged 75 years and older than those aged 45–64 years were 'underweight' (BMI <18.5; 5 vs 1.2%) and substantially less were 'overweight' (BMI >25; 47.2 vs 63.5%).[7]

Weight loss in older people

The lower average body weight of older than younger adults is not just because overweight people die earlier from obesity-related diseases, leaving the healthy, thin people behind. On average, people over 75 years of age are more likely to lose than gain weight,[9,10] in part explaining why they weigh less than younger adults. For example, in a study that followed 247 community-dwelling American men aged over 65 years for 2 years, on average these men lost 0.5% of their body weight per year and 13.1% of the group had involuntary weight loss of 4% per annum or more.[9] Numerous studies have shown that weight loss in the elderly is associated with poor outcomes, certainly if involuntary, but possibly even when deliberate. The prospective Cardiovascular Health Study[10] for example, studied 4714 home-dwelling subjects aged over 65 years without known cancer. In the 3 years after study entry, 17% of the subjects lost 5% or more of their initial body weight, compared with 13% who gained 5% weight or more. The weight-loss group had significant increases in total [2.09 × ↑ (95% confidence interval (CI) 1.67–2.62)] and risk-adjusted mortality [1.67 × ↑ (95% CI 1.29–2.15)] over the following 4 years compared with the stable weight group. The increased mortality occurred irrespective of starting weight and whether or not the weight loss was intentional. The weight gain group had no increase in mortality. In the SHEP study mentioned above,[5] those subjects who had a weight loss of 1.6 kg per year or more experienced a 4.9 times greater death rate (95% CI 3.5–6.8) than those without significant weight change. Although mortality was also increased if weight increased more than 0.5 kg per year, the increase was less than that with weight loss (2.4-fold vs 4.9-fold increase). Of particular note, the adverse effects on mortality of weight loss were present even in the subjects who were heaviest at baseline (BMI ≥31) and were independent of baseline weight. The combination of initially low body weight and weight loss is especially bad news for older people. In the SHEP study,[5] subjects with a low baseline weight (BMI<23.6 kg m^{-2} who lost more than 1.6 kg per year had a mortality rate of 22.6%, almost 20 times greater than the mortality rate of those with a baseline BMI of 23.6–28 kg m^{-2} whose weight remained stable. This interaction is a particular concern as the tendency for older people to lose weight is variable, with lean individuals probably most at risk.[11] In an older person, unintentional weight loss of 5% or more over 6–12 months is associated with an increased risk of adverse effects, and a loss of 10% or more very likely means protein-energy malnutrition. There are many reasons why weight loss in older people has adverse effects. It some cases, weight loss is due to an illness, such as a malignancy, which is mainly responsible for the poor outcome and the weight loss is partly an 'innocent bystander'. Nevertheless, the weight loss and associated undernutrition are themselves often a significant problem. This is because loss of body weight after the age of 60 years is disproportionately of lean body tissue, that is, sarcopenia,[12] and individuals lose up to 3 kg of lean body mass per decade after the age of 50 years. Unlike loss of fat tissue, such a loss of lean tissue has adverse effects. Sarcopenia is associated with metabolic, physiological and functional impairments and disability, including increased falls and increased risk of protein-energy malnutrition.

Cachexia in older people

Weight loss and resulting adverse outcomes in older people may be due to cachexia, malnutrition, the physiological anorexia of ageing or some combination of these factors. Although there is often considerable overlap between them, cachexia and malnutrition are not the same. Whereas all cachectic patients are malnourished, not all malnourished patients are cachectic.[13] Cachexia is a complex metabolic syndrome associated with underlying illness and characterized by loss of muscle with or without loss of fat mass. The prominent clinical feature of cachexia in adults is weight loss, but inflammation is a key component. Anorexia, insulin resistance and increased muscle protein breakdown are also frequently associated with cachexia. Cachexia is distinct from starvation, age-related loss of muscle mass, primary depression, malabsorption and hyperthyroidism.[14] Inflammation plays a major role in the pathogenesis of cachexia, with an absolute or relative increase in levels of inflammatory cytokines such as tumour necrosis factor alpha (TNF-α), interleukin-1 and interleukin-6.[13] Conditions which often afflict older people which are frequently associated with cachexia include cancer, cardiac failure, chronic obstructive pulmonary disease and chronic renal failure. Recently, the European Society for Clinical Nutrition and Metabolism subclassified cachexia on the basis of severity into cachexia and pre-cachexia, the latter being present when there is (1) an underlying chronic disease, (2) a systemic inflammatory response, (3) anorexia and (4) unintentional weight loss over the previous 6 months of less than 5% of usual body weight.[13]

Undernutrition in older people

Prevalence

Protein-energy malnutrition is common in the elderly. Reported rates vary, in part because of differing methods

used to diagnose this condition, but studies in developed countries have found that up to 15% of community-dwelling and home-bound elderly, between 23 and 62% of hospitalized patients and up to 85% of nursing home residents suffer from the condition.[15]

Adverse effects

Protein-energy malnutrition is associated with impaired muscle function, decreased bone mass, immune dysfunction, anaemia, reduced cognitive function, poor wound healing, delayed recovery from surgery and ultimately increased morbidity and mortality (see Table 16.1). Epidemiological studies have demonstrated that protein-energy malnutrition is a strong independent predictor of mortality in elderly people, regardless of whether they live in the community or in a nursing home, are patients in a hospital or have been discharged from hospital in the previous 1–2 years.[16] The increased mortality rate in elderly people with protein-energy malnutrition is further increased in the presence of other medical diseases, such as renal failure, cardiac failure and cerebrovascular disease. For example, the 9 month mortality rate of 205 patients aged >70 years without cancer, admitted to a medical ward in Sweden, was 18% in 164 well-nourished patients without cardiac failure, 44% in 41 malnourished patients without cardiac failure, but 80% in 10 malnourished patients with congestive heart failure.[16]

Table 16.1 Effects of weight loss and protein-energy malnutrition on function in the elderly.

↓ Muscle function
↓ Muscle relaxation
↓ Muscle mass
↓ Muscle strength
↑ Risk of fracture
↓ Bone mass
↑ Incidence of falls
↓ Functional status
Immune dysfunction
↑ Increased risk of infection
↓ Delayed skin hypersensitivity
T-cell lymphocytopenia
↓ Synthesis of interleukin-2
↓ Cytolytic cell activity
↓ Response to influenza vaccination
Anaemia
Poor wound healing
Fatigue
Pneumonia
Delayed recovery from surgery
↓ Cognitive function
↓ Cardiac output
↓ Intravascular fluid (dehydration)
↑ Incidence of pressure sores
↓ Maximal breathing capacity
↑ Hospital admission and length of stay
↑ Mortality

Causes of undernutrition in older people

Reduced food intake

Ageing is associated with a decline in energy (food) intake. Energy intake decreases by ~30% between age 20 and 80 years.[17] Elderly people on average consume smaller meals more slowly, and fewer snacks between meals,[15] and consistently report that they are less hungry than young adults.[18] For example, the 1989 cross-sectional American National Health and Nutrition Examination Survey (NHANES III) study reported a decline in energy intake, between the ages of 20 and 80 years, of 1321 cal per day in men and 629 cal per day in women,[19] a 7 year New Mexico longitudinal study of 156 persons aged 64–91 years reported a decrease of 19.3 kcal per day per year in women and 25.1 kcal per day per year in men[20] and a Swedish 6 year longitudinal study of 98 people found that between the ages of 70 and 76 years there was a decrease in energy intake of 610 cal per in men and 440 cal per day in women.[21]

The physiological 'anorexia of ageing'

The age-related decline in food intake is not just due to the effects of illnesses that become more frequent with increasing age. Numerous studies have documented an age-related decline in appetite and energy intake in healthy, ambulant non-institutionalized people.[17] Healthy older persons are less hungry and are more full before and become more rapidly satiated after eating a standard meal than younger persons. Much of this decrease in energy is probably a response to the decline in energy expenditure that also occurs during normal ageing. In many individuals, however, the decrease in energy intake is greater than the decrease in energy expenditure, so body weight is lost (see the preceding text). This physiological, age-related reduction in energy intake has been termed *anorexia of ageing*.[15]

Loss of homeostasis

Old age is associated with diminished homeostatic regulation of many physiological functions, including the regulation of energy intake. For example, Roberts *et al*.[22] underfed 17 young and old men by 3.17 MJ per day (~750 kcal per day) for 21 days, during which time both the young and old men lost weight. After the underfeeding period, the men were allowed to again eat *ad libitum*. The

young men ate more than at baseline (pre-underfeeding) and quickly returned to normal weight, whereas the old men did not compensate, returned only to their baseline intake and did not regain the weight that they had lost. Older people also have a reduced ability to detect and respond to dehydration. The combination of age-related physiological anorexia and impaired homeostasis means that both older people and young adults do not respond to acute undernutrition. Consequently, after an anorectic insult (for example, major surgery), older people are likely to take longer than young adults to regain the weight lost, remain undernourished longer and be more susceptible to subsequent superimposed illnesses, such as infections.

Pathological anorexia and undernutrition in older people

Protein-energy malnutrition is particularly likely to develop in the presence of other 'pathological' factors, many of which become more common with increased age (Table 16.2). The majority are at least partly responsive to treatment, so recognition is important.

Poverty

One of the social factors that contributes to decreased food intake in the elderly is poverty, which is associated with an increased rate of hunger and food insecurity.[23] Many older individuals have limited financial means, which makes it difficult to afford food of good nutritional quality.

Social isolation

Older people are more likely to live alone than young adults. Social isolation and loneliness have been associated with decreased appetite and energy intake in the elderly.[24] Elderly people tend to consume substantially more food (up to 50%) during a meal when eating in the company of friends than when eating alone. The simple measure of having older people eat in company rather than alone may be effective in increasing their energy intake.

Depression

Depression, often associated with bereavement and the deterioration of social networks, is a common psychological problem in older people, present in 2–10% of community-dwelling older people and a much greater proportion of those in institutions.[25] Depression is more likely to manifest as reduced appetite and weight loss in the elderly than in younger adults and is an important cause of weight loss and undernutrition in this group. Undernutrition *per se*, particularly if it produces folate deficiency, may further worsen depression, thus setting up a vicious cycle. Treatment of depression is effective in producing weight gain and improving other nutritional indices.[26]

Table 16.2 Non-physiological causes of anorexia in older persons.

Social factors
Poverty
Inability to shop
Inability to prepare and cook meals
Inability to feed oneself
Living alone/social isolation/lack of social support network
Failure to cater to ethnic food preferences in institutionalized individuals
Psychological factors
Depression
Dementia/Alzheimer's disease
Alcoholism
Bereavement
Cholesterol phobia
Medical factors
Cardiac failure
Chronic obstructive pulmonary disease
Infection
Cancer
Alcoholism
Dysphagia
Rheumatoid arthritis
Malabsorption syndromes
Gastrointestinal symptoms
Dyspepsia
Helicobacter pylori infection/atrophic gastritis
Vomiting/diarrhoea/constipation
Parkinson's disease
Hypermetabolism (e.g. hyperthyroidism)
Medications
Anti-infectives
Antineoplastics
Antirheumatics
Nutritional supplements
Pulmonary agents
Cardiovascular agents
Central nervous system agents
Gastrointestinal agents

Dementia

Dementia may also contribute to reduced food intake in the elderly, because individuals simply forget to eat. Up to 50% of institutionalized dementia patients have been reported to suffer from protein-energy malnutrition.[27]

Physical factors

Many older people no longer have their own teeth. Poor dentition and ill-fitting dentures may limit the type and quantity of food eaten in older persons. For example, in one study, half of 260 nursing home patients, aged 60–101 years, in Boston, USA, complained of problems with chewing, biting and swallowing. The patients with dentures were more likely to have poor protein intake than those with their own teeth.[28] Immobility (e.g. stroke), tremor

(e.g. Parkinson's disease) and impaired vision may also affect the capacity of an older person to shop for, prepare and consume food. Common medical conditions in the elderly, such as gastrointestinal disease, malabsorption syndromes, acute and chronic infection and hypermetabolism (i.e. hyperthyroidism), often cause anorexia, micronutrient deficiencies and increased energy requirements.[15] Cancer and rheumatoid arthritis, which produce anorectic effects by releasing cytokines (see the following text), are also common in older persons.

Iatrogenic/medications

The elderly are major users of prescription medications, a number of which can cause malabsorption of nutrients, gastrointestinal symptoms and loss of appetite. For example, digoxin and some forms of chemotherapy can cause nausea, vomiting and loss of appetite. Other medications can deplete the body's mineral stores; high doses of aluminium or magnesium hydroxide antacids deplete phosphate and potassium stores that can lead to muscle weakness and anorexia, and penicillamine induces zinc depletion that can lead to the loss of taste acuity and decreased food intake. The elderly often take multiple medications that increase the risk of drug interactions that can cause anorexia.

Causes of the physiological anorexia of ageing

Declining senses of taste and smell

Taste and smell are important in making eating pleasurable. The sense of taste probably deteriorates with age, although not all studies confirm this. Age-associated changes in taste may influence food choice in the elderly. There is strong evidence that the sense of smell declines with age, particularly after age 50 years. In one study, over 60% of subjects aged 65–80 years and over 80% aged 80 years or more exhibited major reductions in their sense of smell, compared with less than 10% of those aged under 50 years.[29] The decline in the sense of smell is a cause of decreased food intake in the elderly because it makes eating food less enjoyable. It may also influence the type of food eaten; several studies have shown a strong correlation between impaired sense of smell and reduced interest in and intake of food. Consistent with this effect of ageing on the types of food eaten is the observation that ageing is associated with a less varied, more monotonous diet.

Sensory-specific satiety

Sensory-specific satiety is the normal decline in pleasantness of the taste of a particular food after it has been consumed. Sensory-specific satiety leads to a decrease in the consumption of a previously eaten food and a tendency to shift consumption to other food choices during a meal. This acts to promote the intake of a more varied, nutritionally balanced diet. Older people have a reduced capacity to develop sensory-specific satiety,[30] perhaps because of reduced senses of smell and taste. Reduced sensory-specific satiety may in turn favour the consumption of a less varied diet and the development of micronutrient deficiencies.

Hormones and neurotransmitters: a selective review (Table 16.3)

The remainder of this chapter reviews, selectively, some of the emerging information about the control of food intake and why it declines with normal ageing, with particular emphasis on endocrine factors. Recently discovered hormones with effects on feeding include leptin, ghrelin and the orexins. At the time of writing, these discoveries had not yet led to evidence-based therapies, which still largely consist of nutritional supplements. The hope is that endocrine appetite stimulants or antagonists of anorexigenic hormones may have a future therapeutic role.

Table 16.3 Some endocrine factors influencing feeding and their possible contribution to the anorexia of ageing.

	Effect of ageing
Factors that stimulate feeding	
Opioids	↓ activity; not proven in humans
Neuropeptide Y	No good evidence for role
Galanin	Circulating levels unchanged, sensitivity unknown
Orexins	No good evidence for role
Ghrelin	Circulating levels possibly ↓, sensitivity unknown
Testosterone	Stimulatory role unconfirmed (?indirect), ↓ activity with age, possible effects via leptin, ghrelin and others
Factors that inhibit feeding[a]	
CART	Possible ↑ central levels (rodents)
Cholecystokinin (CCK)	↑ circulating levels, ↑ CSF levels, ↑ sensitivity to satiating effects
GLP-1	Few data, possibly ↑ activity
Peptide YY	Few data, no evidence for role
Insulin	Effect on feeding unconfirmed, no evidence for role
Leptin	Situation complex: circulating levels increase in men (↓ testosterone) *but*? leptin resistance
Cytokines	↑ activity likely

[a]CART, cocaine–amphetamine-related transcript; GLP-1, glucagon-like peptide I.

Overview of Appetite Regulation (Figure 16.1)

Central

The central feeding system is dependent on the stimulatory effect of neurotransmitters, including the opioids, noradrenaline, neuropeptide Y (NPY), the orexins, galanin and ghrelin, and the inhibitory effect of corticotrophin-releasing factor, serotonin, cholecystokinin (CCK) and possibly insulin.

Peripheral (gastrointestinal)

The short-term peripheral satiety system is largely driven by gastrointestinal mechanisms. In the longer term, factors such as leptin and cytokines (see the following text) become more important. Gastrointestinal sensory and motor functions are important in the regulation of satiation. Sensory signals induced by the distension by food contribute to initial sensations of fullness during a meal. These sensations are mediated via vagal mechanisms from mechanoreceptors situated within the stomach wall. In young adult humans, gastric distension, using a barostat, reduces food intake by up to 30%. Distension of the distal stomach (antrum) is related to increased sensations of fullness and is likely to be more important than distension of the proximal stomach (fundus). After eating, the stomach relaxes by a process of receptive relaxation, resulting in decreased intragastric pressure and increased gastric volume. This relaxation is particularly marked in the proximal stomach and results in a proximal fundic reservoir where food is retained. Not long before it is emptied into the small intestine, food is propelled distally from the fundus into the antrum. The extent of antral filling and distension relates more closely to feelings of fullness and satiety than does proximal gastric distension. Studies in animals and humans have demonstrated a relationship between postprandial satiety and the rate of gastric emptying. Slowing of gastric emptying may reduce appetite and food intake by increasing and prolonging antral distension and by prolonging the effect of small intestinal satiety signals. People with gastroparesis often exhibit symptoms of early satiety, loss of appetite, nausea and vomiting, and studies in both animals and humans have shown that there is a relationship between postprandial satiation and the rate of gastric emptying.

Once food has entered the small intestine, mechano- and chemoreceptors relay signals to the hypothalamus, resulting in the cessation of food intake. These signals are mediated by the release of gastrointestinal peptide hormones, including CCK, peptide YY (PYY) and glucagon-like peptide-1 (GLP-1). A number of gastrointestinal and pancreatic hormones, including CCK, GLP-1 and amylin, have feedback effects on the stomach to slow gastric emptying, an effect associated with increased fullness and reduced food intake, by increasing and prolonging gastric distension and prolonging the effect of small intestinal satiety signals. Feedback signals from peripheral fat cells via leptin and, possibly, TNF-α and also absorption of nutrients from the gut also contribute to satiation.

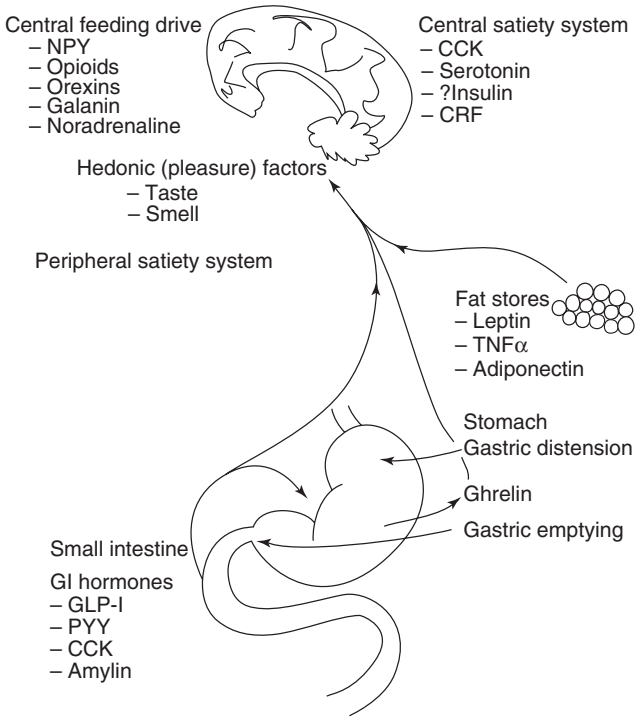

Figure 16.1 Overview of the mechanisms involved in appetite regulation.

The ageing gut

Aging is associated with cell loss in the myenteric plexus of the human oesophagus and a decline in conduction velocity within visceral neurones. The consequent reduction in sensory perception may contribute to reduced food intake by inhibiting the positive stimuli for feeding. The elderly frequently complain of increased fullness and early satiation during a meal. This may also be related to changes in gastrointestinal sensory function; ageing is associated with reduced sensitivity to gastrointestinal tract distension. If anything, reduced sensitivity to the satiating effects of distension might be expected to increase, not decrease, the food intake in older people. Nevertheless, proximal gastric distension has been found to have similar effects on food intake in healthy older and young adults and the role, if any, of impairment of gastric sensory function in causing anorexia of ageing is unknown. Ageing is probably associated with impaired receptive relaxation of the gastric fundus. As a result, for any given gastric volume, there is more rapid antral filling and distension and earlier satiety. This impaired gastric accommodation response in the elderly may be because of altered fundic nitric oxide

(NO) concentrations. Peripheral NO causes receptive and adaptive relaxation of the stomach, leading to dilation of the fundus and, ultimately, slower gastric emptying. The increase in NO with ageing may therefore contribute to the slower gastric emptying observed in the elderly. Most, but not all, studies indicate that gastric emptying slows slightly, but significantly, with increasing age. Clarkston *et al*.[18] found that healthy older subjects were less hungry and more satiated after a meal than young subjects and that postprandial hunger was inversely related to the rate of gastric emptying. The effects of ageing on gastric emptying rate may require ingestion of a relatively large energy content, as small meals have not been shown to have different emptying rates in old compared with young individuals. Delayed gastric emptying in older people may result, in part, from enhanced release of small intestinal hormones such as CCK (see the following text). In contrast, it seems that age has little, if any, effect on small intestinal or colonic motor function and orocaecal and whole gut transit time are not affected in the healthy elderly. Healthy older people do have slower phase III migration velocities and more frequent 'propagated contractions' in the small intestine, but no differences in duration of postprandial motility or amplitude or frequency of either fasting or postprandial pressure waves.

Central neurotransmitters and hormones

Monoamines

The central aminergic system has effects on feeding, with noradrenaline having stimulating, serotonin having inhibiting and dopamine having region-specific stimulatory or inhibitory effects. Ageing may be associated with increased satiating effects of serotonin, without apparent effects on dopamine or noradrenaline.

Opioids

Endogenous opioids play a role in mediating the short-term sensory reward response to food. Exogenous administration of opioid agonists increases food intake in animals and opioid antagonists decrease food intake in animals and adult humans.[31] There is evidence that ageing is associated with a reduced opioid feeding drive (reviewed by Horwitz *et al*.[32]). Elderly patients with idiopathic, senile anorexia have lower plasma and CSF β-endorphin concentrations than normal-weight, age-matched controls.[33] Intraperitoneal (i.p.) morphine injection increases food intake in young but not old mice, whereas i.p. naloxone decreases food intake in young but not older rats. Healthy older men are less sensitive to the inhibitory effects of subcutaneous naloxone on fluid intake than young men[34] and, in one small study of feeding in humans, the suppression of food intake by naloxone was non-significantly greater in the older than young adults: 16 versus 8%.[31] Overall, these results suggest that the stimulatory effect of endogenous opioids does decline somewhat with advancing age and may contribute to the anorexia of ageing. Further work is required to clarify these changes.

Neuropeptide Y

NPY is synthesized in the peripheral nervous system and brain and strongly stimulates food intake. There is preliminary evidence from animal studies that ageing may be associated with reduced NPY activity, perhaps more in males than females. Old rats have lower levels of arcuate nucleus prepro-NPY mRNA than young rats and hypothalamic NPY levels decrease with ageing in male but not female rats. Studies in humans, however, suggest, if anything, *increased* NPY activity with increasing age. CSF NPY levels increase with healthy ageing in women and plasma and CSF levels are increased in elderly people with idiopathic anorexia.[33] In rats, the feeding response to hypothalamic NPY injections diminishes with ageing, whereas the stimulation of feeding by intracerebroventricular NPY administration in mice does not diminish with age. The effects of NPY administration in humans have not been reported. There is currently, therefore, no convincing evidence for an involvement of NPY in the human anorexia of ageing.

Galanin

Galanin is a peptide hormone located in the brain and periphery, which stimulates food intake. Available animal evidence does not suggest a decline in galanin levels with ageing and circulating levels do not differ between young and older women.[35] Declining galanin levels are therefore unlikely to contribute to the anorexia of ageing, but reduced sensitivity to galanin might. The effect of ageing on stimulation of feeding by galanin has not been reported in humans, but older women (not men) display a reduced growth hormone secretory response to galanin compared with young adults.[36]

Orexins (hypocretins)

Orexin A and B (hypocretin-1 and -2) are neuropeptides synthesized in the hypothalamus and involved with feeding and sleep. Orexin deficiency causes narcolepsy in animals and humans and hypophagia and weight loss in animals.[37] Intracerebroventricular orexin injection dose-dependently increases food intake in rodents and orexin antibody reduces food intake (reviewed by Kirchgessner[38]). Orexin A is the subtype mainly responsible for effects on feeding. The majority of evidence does not support declining orexin activity as a cause of the anorexia of ageing. In a cross-sectional study of 82 healthy men and women aged 23–79 years, plasma orexin A concentrations increased with age in both men and women,[37] which should, if anything, favour *increased* appetite and food intake. Studies in mice

have found no changes or increases in total brain orexin levels and hypothalamic orexin A receptor levels with increasing age, while a decrease in hypothalamic orexin gene expression in ageing rats has been described.[39] In humans, the effects of normal ageing on the levels of the orexin receptors and sensitivity to the effects of orexin are unknown.

Cocaine–amphetamine-regulated transcript (CART)

CART is a peptide widely distributed in the brain, including the hypothalamus. In animals, central CART administration reduces feeding and blocks NPY-induced feeding. Sohn *et al*.[40] reported that arcuate nucleus CART mRNA levels were higher and NPY mRNA levels lower in healthy old than young, male rats, whereas testosterone treatment of castrated, older rats significantly lowered CART mRNA levels and increased NPY mRNA levels. This suggests that in males there is ageing-related increased central activity of CART and reduced activity of NPY, both mediated by the normal age-related decline in testosterone. This is an intriguing possibility, but the effects of ageing on CART in female animals have not been reported, nor have those in humans. The evidence that age-related increases in central CART levels may be a cause of the anorexia of ageing is therefore currently derived from one study in male rodents.

'Peripheral' hormones, including gut peptides

Cholecystokinin (CCK)

CCK is present in the hypothalamus, cortex and midbrain and is released from the lumen of the intestine in response to nutrients, particularly fat and protein, in the gut. CCK causes contraction of the gallbladder and relaxation of the sphincter of Oddi. Exogenous CCK administration decreases food intake in animals and humans. CCK is probably a physiological satiety hormone as its suppressive effect on food intake occurs with the administration of doses producing plasma CCK concentrations within the physiological range and administration of CCK antagonists increases food intake in animals and young adult humans.[41] CCK also slows gastric emptying. The satiating effects of CCK appear to increase with age. Most studies in humans have shown plasma CCK concentrations to be higher in healthy older than young adults.[42] Elderly people with idiopathic anorexia have significantly higher plasma levels and non-significantly higher CSF levels of CCK than healthy age-matched controls.[33] Intraperitoneal CCK suppresses food intake more in old than young rats and mice. Intravenous CCK-8 administration has been found to acutely suppress food intake twice as much (31 vs 15%, $p = 0.02$) in older than young adult healthy, human subjects.[43] The combination of increased circulating CCK concentrations and enhanced sensitivity to CCK suggests that CCK may be a cause of the anorexia of ageing and raises the possibility of using CCK antagonists to increase energy intake in undernourished older people.

Glucagon-like peptide-1 (GLP-1)

GLP-1 is released by the lining of the intestine in response to nutrient ingestion, particularly carbohydrates. It stimulates insulin secretion and, together with gastric inhibitory peptide (GIP), is one of the incretin hormones. It also slows gastric emptying. Administration of GLP-1 to humans increases feelings of fullness and reduces food intake.[44] Studies on the effects of ageing on plasma GLP-1 concentrations have found either no effect or increased levels in older people.[42] Further studies are needed to determine if increased GLP-1 activity is a cause of the anorexia of ageing.

Peptide YY (PYY)

PYY is a peptide hormone present in the brain and released from the bowels in response to the presence of fat and carbohydrate in the small intestine. PYY is involved in physiological processes such as memory, pain, blood pressure regulation, appetite and anxiety.[45] In rodents, feeding is increased by central PYY administration, but decreased by peripheral administration. Intravenous infusion of PYY to normal-weight and obese humans aged less than 50 years, in doses that produce postprandial blood levels, reduces short-term food intake by ~30%.[46] This suppression may be mediated by the associated suppression of ghrelin levels, whereas leptin, insulin and GLP-1 are unaltered. There is currently no evidence favouring alterations in PYY activity as a cause of the anorexia of ageing and no difference in plasma PYY concentrations, fasting and in response to intraduodenal nutrient infusions between young and older subjects. Because there is a strong negative correlation between fasting plasma PYY levels and BMI in healthy, non-elderly subjects, studies involving accurate body composition analysis are needed to determine the true effect of healthy ageing on PYY. The effects of ageing on sensitivity to the appetite-suppressant effects of PYY have not been reported.

Leptin

Leptin is produced predominantly in adipose tissue and circulates in amounts directly related to the size of fat stores. It suppresses appetite and food intake. Congenital leptin deficiency in humans is a very rare cause of morbid obesity associated with hyperphagia and leptin treatment produces substantial weight loss in these people. Most obese people, however, have elevated circulating leptin concentrations consistent with their increased fat mass. Leptin resistance is probably a feature of most human obesity and leptin administration to obese people has resulted in only minor weight loss. Although adipose tissue leptin mRNA expression increases with age in mice and rats,

studies in rats and pigs have not found an increase in serum leptin with ageing. Plasma leptin concentrations in humans often increase with ageing, to a large extent because of the increased fat mass that also accompanies ageing. Most studies show that adjustment for fat mass removes this effect.[47] This is certainly so in women, but in men some but not all studies have shown ageing to be associated with an increase in circulating leptin levels, even allowing for fat mass. This appears to be because of age-related decreases in circulating testosterone concentrations. After adjusting for fat mass, plasma leptin levels in men are inversely related to plasma testosterone, while testosterone therapy reduces and inhibition of testosterone production increases circulating leptin levels.[48]

Little is known about the effects of ageing on sensitivity to the effects of leptin. Circulating levels of the soluble leptin receptor do not change with age in humans. Resting energy expenditure and carbohydrate oxidation are predicted by fat-free mass and serum leptin concentration in middle-aged, premenopausal women, but the relationship between fat store size and plasma leptin is much weaker in older adults.[49] Fasting normally dramatically suppresses plasma leptin concentrations, thus stimulating hunger. Reduced suppression of leptin levels by fasting has been reported in ageing rats. Conversely, food intake, fat mass and insulin action are suppressed less by leptin administration in older than young rats. This suggests that ageing may be accompanied by leptin resistance, which would tend to *increase* food intake. The impact of human ageing on the effects of fasting on leptin levels and of leptin administration has not been reported.

Ghrelin

Ghrelin stimulates feeding and growth hormone release. It is present in the hypothalamus but the main site of production is the gastric mucosa. Circulating ghrelin concentrations increase with fasting and with diet-induced weight loss in obese subjects and are elevated in underweight, undernourished young and older subjects. In contrast, circulating concentrations decrease after ingestion of food, particularly fat and carbohydrate, and are reduced in obese people. These changes are consistent with compensatory responses to, rather than causes of, these altered nutritional states. It therefore seems unlikely that reduced ghrelin activity contributes significantly to the anorexia and weight loss in markedly undernourished older subjects. Nevertheless, the effects of ageing and undernutrition on sensitivity to ghrelin have not been reported and ghrelin resistance may occur in these states. In support of this, older subjects are less sensitive to the growth hormone (GH)-releasing effects of intravenous ghrelin (i.v. ghrelin) than young adults.[50] The effect of healthy ageing on circulating ghrelin concentrations has not yet been clarified. A possible rationale for a decline in ghrelin levels with age, particularly in men, is the positive association between circulating testosterone and ghrelin concentrations and the increase in plasma ghrelin concentrations that occurs in hypogonadal men in response to testosterone therapy.[51] As normal ageing is accompanied by reductions in circulating androgen levels (see the following text), this might have the effect of reducing ghrelin concentrations and thus food intake. One study found a rise in plasma ghrelin concentrations with increasing age, but there was no relationship with age *per se* when a multivariate analysis was performed[52] and the study did not include subjects older than 64 years. Two small studies have reported circulating ghrelin concentrations 20%[53] and 35%[54] lower in healthy older (69–87 and 67–91 years, respectively) than young adults, the latter reduction being statistically significant. However, increasing body fat, as indicated by BMI, is associated with decreasing ghrelin concentrations and the older subjects had higher BMIs than the young subjects in both studies. Neither study included detailed body composition analysis, so the lower ghrelin levels in older subjects may have been because of differences in body composition. Another study found no difference in fasting and postprandial serum ghrelin concentrations between healthy older (mean age 78 years) and young adults.[55] On balance, the effect of healthy ageing on circulating ghrelin concentrations has not yet been clarified, but is probably minimal.

Insulin

Human ageing tends to be associated with increased fasting and postprandial circulating insulin concentrations.[56] Increased insulin activity could, therefore, be a cause of reduced food intake in older people. The evidence for a satiating role of insulin is, however, limited. Suppression of food intake by insulin has only been demonstrated in animals and has required central insulin administration at high doses or high-dose, prolonged peripheral administration. Short-term, peripheral, euglycaemic insulin infusions have been shown not to affect appetite or food intake in humans.[57] Moreover, age-associated increases in insulin concentrations are due mainly to insulin resistance resulting from increased adiposity and only to a small extent to ageing itself. It seems unlikely that insulin contributes substantially, if at all, to the anorexia of ageing.

Testosterone and other androgens

Circulating androgen concentrations decline with ageing. This may contribute to the development of sarcopenia and the decrease in functional status that occurs with ageing (reviewed by Bhasin[58]). Whereas androgen replacement therapy (ART) is advocated for men with marked androgen deficiency, there is no consensus for the use of ART in elderly men with less severe ageing-related declines in androgen concentrations or in elderly women.

Studies of androgen replacement have been performed in healthy, older men with androgen deficiency, but although benefits have been seen in muscle mass and, in some cases, strength, there is, as yet, no agreement that this leads to improvements in functional status (reviewed by Morley[59]). Several recent studies have suggested that there may be benefits from treating older men, particularly if frail, with testosterone therapy. Amory *et al*.[60] gave older men with a mean total testosterone within the normal range 600 mg i.m. testosterone weekly for 4 weeks before elective knee replacement surgery and found significant increases in the ability to stand postoperatively and trends to improvements in walking and stair climbing, compared with placebo-treated men. Bakhshi *et al*.[61] gave older men in a rehabilitation programme with low-normal testosterone levels 100 mg i.m. testosterone or placebo weekly and found significant increases in grip strength and the Function Independence Measure after testosterone but not placebo. Chapman *et al*.[62] showed a reduced rate of hospitalization over 1 year in older men and women either undernourished or at risk of undernutrition given a combination of oral testosterone and a nutritional supplement compared with an untreated group. Srinivas-Shankar *et al*.[63] treated older, frail men with low circulating testosterone concentrations with transdermal testosterone or placebo for 6 months and found improvements in muscle strength and also physical function, the latter effects confined to older (≥75 years) and more frail men. These results are not conclusive but justify further studies of testosterone treatment in frail, older people.

In women, serum concentrations of testosterone and the adrenal androgens gradually and progressively decline from the decade preceding menopause. Even if testosterone therapy does not increase food intake in older, undernourished people, it may provide functional benefits by treating the associated sarcopenia and studies to examine this are under way.

Cytokines

Age-associated increases in the production and/or effect of satiating cytokines may contribute to the anorexia of ageing.[64] Cytokines are secreted in response to significant stress, often because of malignancy or infection. Circulating concentrations of the cytokines interleukin 1 (IL-1), interleukin 6 (IL-6) and TNF-α are increased in cachectic patients with cancer or AIDS. They act to decrease food intake and reduce body weight via a number of central and peripheral pathways. Blockade of these cytokines, for example, of TNF-α in mice with TNF-producing sarcomas, significantly attenuates weight loss in high-stress conditions associated with cachexia. Ageing itself may be a form of stress. It is associated with stress-like changes in circulating hormonal patterns; increased cortisol and catecholamines and decreased sex hormones and growth hormone. Increased cortisol and catecholamine levels, in turn, stimulate the release of IL-6 and TNF-α, whereas sex hormones inhibit IL-6. Interleukin 1 and IL-6 levels are elevated in older people with cachexia, whereas plasma IL-6 concentrations apparently increase as a function of normal ageing and correlate inversely with levels of functional ability in elderly people. Higher circulating levels of CRP and cytokine receptors appear also to be associated independently with physical dysfunction and disability.[65] Increased cytokine levels, due to the 'stress' of ageing *per se* or the amplified stressful effects of other pathologies, may thus provide an explanation for some of the decline in appetite and body weight that occurs in many older people.

Diagnoses and treatment of undernutrition in older people

These are covered in Chapter 15, Epidemiology of nutrition and ageing, and Chapter 17, Weight loss.

Key points

- On average, food intake is about 30% lower in the elderly than young adults, because of a physiological decrease in appetite, the anorexia of ageing. This predisposes to the development of protein-energy malnutrition, which is surprisingly common in the elderly.
- The physiological anorexia of ageing predisposes to the development of pathological anorexia and undernutrition when factors that become more common with ageing, such as depression, dementia, poor dentition, social isolation, medications and various illnesses, are superimposed.
- A number of hormones involved in the control of feeding have been discovered recently and knowledge of the hormonal control of feeding is expanding rapidly. Understanding of the anorexia of ageing is in its infancy.
- Current evidence supports the following as causes of the anorexia of ageing:
  ↑ activity CCK
  ↑ activity cytokines
  ↓ activity androgens (particularly in men)
  weaker evidence for ↓ activity ghrelin, ↑ leptin.

CHAPTER 17

Weight loss

David R. Thomas
Saint Louis University Health Sciences Center, St Louis, MO, USA

Introduction

Weight loss is common in older adults and is a harbinger of poor outcome. A loss of 10% or more of body weight between age 50 years and old age is associated with a 60% increase in mortality compared with persons with stable weight.[1] Involuntary weight loss greater than 4% of body weight is an independent predictor of increased mortality in older community-dwelling male veterans. Over a two-year follow-up period, mortality rates were substantially higher in the 13% of the population with involuntary weight loss (28%) than in those who did not lose weight (11%), even after adjusting for baseline age, body mass index, tobacco use and other health status and laboratory measures.[2]

Weight loss is strongly associated with a 76% increase in mortality risk among home-bound older adults, along with male gender and age. This effect of weight loss persists after adjusting for initial body mass index (BMI) (the weight in kilograms divided by the height in metres squared), smoking, health status and functional status.[3]

In nursing home residents, a 10% loss of body weight over a six-month interval strongly predicted mortality in the ensuing six months.[4] When compared with controls, the 16% of subjects who lost at least 5% of their body weight were 4.6 times more likely to die within 1 year.[5] In another study of long-term care residents, a 10-fold increased risk for death was seen for persons who lost 5% of their body weight in any month compared with those who gained weight.[6] For this reason, the United States Long-Term Care Minimum Data Set defines a loss of greater than 10% of body weight within 180 days or 5% within 30 days as an important clinical threshold for triggering resident assessment protocols.[7]

Weight loss is also associated with a decline in functional status. Weight loss of more than 5% in community-dwelling women 60–74 years old was associated with a twofold increase in risk of disability over time, compared with women who did not lose weight, after adjustments for age, smoking, education, study duration and health conditions.[8] Weight loss and undernutrition are also related to functional decline in nursing home residents.[9]

Body weight and weight adjusted for height (BMI) are easily obtained clinical measurements that can predict adverse outcomes in older persons.

The relationship of weight loss to mortality

A body mass index of less than 22 $kg\,m^{-2}$ has been associated with a higher one-year mortality rate and with poorer functional status among older community-dwelling persons.[10] The risk for higher mortality in men older than 65 years begins at a BMI of less than 22 $kg\,m^{-2}$ and increases to a 20% higher risk in men older than 75 years with a BMI of less than 20.5 $kg\,m^{-2}$. Similarly, a higher mortality risk in women begins at a BMI of less than 22 $kg\,m^{-2}$ in women older than 65 years and increases to a 40% higher risk in women older than 75 years with a BMI of less than 18.5 $kg\,m^{-2}$.[11] BMI less than the 15th percentile is an independent predictor of 180 day mortality following hospitalization.[12]

Although there is a strong association between BMI and mortality, the key factor in mortality risk appears to be recent weight loss. Recent weight loss, rather than current BMI, is the strongest predictor for mortality. After excluding subjects with weight loss of 10% or more of their body weight, there is little relationship between BMI and mortality.[13] In persons over 50 years of age who reported an unintended loss of 10 lb (~3.7 kg) or more in the year before evaluation, the age-adjusted death rate was much higher compared with persons who voluntarily lost weight through diet or exercise or who maintained or gained weight.[14] Nearly all of the observational studies on body weight have found that any weight loss is associated with increased, rather than decreased, risk for death.

The data suggest that obesity in older adults may not be an important clinical target for reducing mortality and

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

that a preferred public health emphasis for this age group would be to increase awareness that substantial weight loss after age 50 years is a potential indicator for poor prognosis.

Body weight in the general population is not stable. Some 29% of men and 44% of women in the USA report that they are attempting to lose weight, and 35% of men and 34% of women report that they are attempting to maintain weight. The most common strategy among those attempting to lose weight was to consume less fat, but not fewer calories (35% of men and 40% of women). Only 22% of men and 19% of women reported using a combination of eating fewer calories and engaging in at least 150 min of leisure-time physical activity per week.[15]

In an observational study, overweight and obese persons who were at least 35 years of age and who had a BMI greater than 25 kg m^{-2}, self-reported their intention to lose weight and then reported actual weight change during the past year. Those persons reporting an intentional weight loss had a 24% lower mortality rate compared with persons not trying to lose weight and reporting no weight change. However, mortality rates were independent of actual weight change. The persons who reported trying to lose weight but who had no weight change also experienced a 20% reduction in mortality risk. An unexpected finding was that a decreased mortality rate was also found among those who reported gaining weight but who were not trying to lose weight. In this study, an attempt at weight loss was associated with lower all-cause mortality, but was independent of weight change. A higher mortality rate (31%) occurred only in those persons reporting unintentional weight loss.

Paradoxically, a higher two-year mortality was found in community-living subjects who lost weight by dieting (36%) compared with those who had involuntary weight loss (28%). These data suggest that even voluntary weight loss by dieting may place older persons at risk. The recommendation that older adults voluntarily reduce body weight cannot be supported by the literature and may be hazardous.

Effect of weight loss on comorbid conditions

Only limited data support the notion that intentional weight loss reduces total mortality. However, mortality is only a small part of the substantial burden of disease caused by obesity-related conditions such as hypertension, diabetes mellitus, coronary artery disease, degenerative arthritis and cancers of the breast, uterus and colon. Short-term reductions in caloric intake (dieting) have favourable effects on blood pressure, cholesterol and metabolic rate. These benefits require at least a 20% reduction in caloric intake.

Weight loss has been shown to reduce disease-specific risks such as hypertension and type 2 diabetes. However, it should be noted that overweight/obesity-related comorbidities, particularly those associated with the insulin resistance syndrome (e.g. hypertension, dyslipidaemias and hyperinsulinaemia) can be improved independently of weight loss.[16,17] Blood pressure can be lowered in the absence of weight loss by dietary changes.[18] The effect on blood pressure by non-pharmacological interventions can be maintained for 3–5 years despite significant increases in body weight.[19] Other trials of coronary artery disease have shown prevention effects to be independent of weight loss. The data suggest that improvements in comorbid conditions can be enhanced with lifestyle changes, but that the effect is independent of whether weight loss occurs.

Causes of weight loss

The regulation of body composition is dynamic over time. Minute-to-minute composition is regulated by a person's metabolic state. Day-to-day regulation depends of insulin and glucagon. Month-to-month, hormones such as estrogens and androgens, growth hormone, prolactin, thyroid hormones, catecholamines and corticosteroids regulate body composition. Immune mediators, such as interleukin-1, tumour necrosis factor and interleukin-2, also can affect body composition through modulation of appetite and food intake and direct effects on skeletal muscle.[20]

Weight loss can be either voluntary (a conscious decision to reduce body weight by either restricting calories or increasing energy expenditure) or involuntary (absence of any intention to reduce weight). Involuntary weight loss can occur from a variety of causes, including ingestion of inadequate calories (starvation), disuse atrophy or hormonal deficiencies (sarcopenia), a decrease in appetite (anorexia) or the effects of disease (cachexia), and a combination of these factors[21] (Table 17.1).

Starvation

Simple starvation is caused by pure protein–energy deficiency. Starvation can be short-term (fasting) or long-term (chronic protein–energy undernutrition). Worldwide, starvation is most often caused by lack of food. In developed countries, starvation is usually associated with disease. Starvation occurring in the presence of adequate food results from inability to swallow, a non-functioning gastrointestinal tract or failure of appetite (anorexia).

Older persons ingest fewer calories than younger adults. On average, persons over the age of 70 years consume one-third less calories compared with younger persons.[22] About 16–18% of community-dwelling elderly persons consume less than 1000 kcal daily.[23] This reduction in intake places older adults at risk for protein–energy, vitamin and mineral undernutrition.

Table 17.1 Causes of weight loss.

Type	Mechanism	Cause
Intentional	Decreased caloric intake	Voluntary restriction
	Increased energy expenditure	Exercise
Unintended	Anorexia	Impaired appetite
	Starvation	Inadequate access to food
		Inability to swallow food
		Inability to absorb food
	Cachexia	Cytokine-mediated disease
	Sarcopenia	Age-related loss of muscle mass

The decline in energy intakes that accompanies ageing has been the subject of intensive investigation. Total energy expenditure (TEE) declines with ageing, chiefly due to changes in resting energy expenditure (REE). REE decreases by 10–20% with age, primarily due to a decrease in muscle mass.[24,25] REE is higher in active older adults than sedentary older adults,[26] but a decline in muscle mass occurs in both sedentary and active ageing adults.[27] A decrease in physical activity largely explains the decline in TEE with age.[28] Surprisingly, there is little correlation between physical activity and fat mass in older persons. Higher physical activity is not associated with a lower body fat mass in subjects older than 60 years.

Sarcopenia

Unintended weight loss in older persons may result from a decrease in fat-free mass. Sarcopenia is operationally defined as an appendicular skeletal muscle mass divided by height in metres of more than two standard deviations below the young normal mean. Using this definition, Baumgartner *et al*. found that 14, 20, 27 and 53% of men aged less than 70, 70–74, 75–80 and over 80 years, respectively, met this definition. In women, 25, 33, 36 and 43% in the same age groups had sarcopenia.[29] Although a decrease in muscle mass is the hallmark of sarcopenia, not all sarcopenic persons have a low body mass. At a BMI cut point of $\sim 27\ kg\ m^{-2}$, 14% of men less than 70 years old and 29% of men more than 80 years old were sarcopenic and obese and 5% of women less than 70 years old and 8% of women more than 80 years old were sarcopenic and obese. Although the decline in muscle mass should be reflected in body weight, an increase in fat mass may obscure the body weight loss. Therefore, a relatively small proportion of sarcopenic persons do not exhibit a decrease in body weight.

The fact that muscle mass decreases with age has been known for some time. Earlier work demonstrated that the excretion of urinary creatinine, a measure of muscle creatine content and total muscle mass, decreases by nearly 50% between the ages of 20 and 90 years. This age-related loss of muscle mass appears to be fairly consistent, at a rate of ~1–2% per year after the age of 50 years, and occurs in both sedentary and active ageing adults. In contrast, in healthy young adults, no net change occurs in skeletal muscle mass under equilibrium conditions due to the balance in skeletal muscle protein synthesis and degradation. This age-related reduction in muscle mass and strength is also accompanied by a reduction in motor unit number[30] and by atrophy of muscle fibres, especially the type IIa fibres.[31] An associated decline in protein synthesis, particularly in the synthesis of myosin heavy chains, has been observed.[32]

The loss of muscle mass with ageing is clinically important because it leads to diminished strength and exercise capacity.[33] Dynamic, static and isokinetic muscle strength decreases with age.[34] Maximum oxygen consumption declines with age[35] at a rate of 3–8% per decade beginning at age 30 years. However, after correction for muscle mass, there is no important decline in $VO_{2\,max}$ with ageing, indicating that a change in muscle mass is the significant factor.[36] Up to 65% of older men and women report that they cannot lift 10 lb (~3.7 kg) using their arms.[37] Although sarcopenia is due to a reduction in skeletal muscle mass, not all subjects demonstrate a loss in body weight. An increase in fat mass accompanying ageing may mask the loss of non-fat mass, resulting in normal or even an obese body weight in sarcopenic persons.

Cachexia

Cachexia is the cytokine-associated wasting of protein and energy stores due to the effects of disease. Systemic inflammation mediated through cell injury or activation of the immune system triggers an acute inflammatory response. Persons with cachexia lose roughly equal amounts of fat and fat-free mass while maintaining extracellular water and intracellular potassium. The loss of fat-free mass is mainly from the skeletal muscle.

Table 17.2 Conditions associated with cachexia.

Infections, e.g. tuberculosis, AIDS
Cancer
Rheumatoid arthritis
Congestive cardiomyopathy
End-stage renal disease
Chronic obstructive pulmonary disease
Cystic fibrosis
Crohn's disease
Alcoholic liver disease
Elderly persons without obvious cause

Cytokines are related to a number of disease conditions, including cancer, end-stage renal disease, chronic pulmonary disease, congestive heart failure, rheumatoid arthritis and AIDS[38] (Table 17.2). In subjects with pneumonia, the admission concentrations of α_1-antitrypsin and α_1-acid glycoprotein are better predictors of hospital morbidity than albumin and C-reactive protein levels.[39] In subjects with end-stage renal disease on haemodialysis followed for 3 years, increased IL-1, TNF-α, IL-6 and IL-13 levels were significantly associated with increased relative mortality risk, whereas higher levels of IL-2, IL-4, IL-5, IL-12, T-cell number and function and CH50 were associated with improved survival.[40] Although the cancer anorexia–cachexia syndrome is present in 50% of advanced cancer patients and in 80% of terminally ill cancer patients, serum levels of cytokines are not always directly associated with the onset of cancer anorexia–cachexia syndrome.[41]

Cytokines have a direct negative effect on muscle mass and increased concentrations of inflammatory markers have been associated with a reduced lean mass.[42–44] This direct effect also has been associated with a decline in muscle strength in older adults.

Increasingly, a consensus on the differential effects of starvation and cachexia is developing.[45] Starvation can frequently be distinguished from cachexia (Table 17.3). However, in later stages this distinction is more difficult. The hallmark of starvation is a rapid response to refeeding.

Anorexia

A direct effect of systemic inflammation is appetite suppression. Cytokines directly result in feeding suppression and a lower intake of nutrients and cachexia is nearly always accompanied by anorexia. IL−1β and TNF-α act on the glucose-sensitive neurons in the ventromedial hypothalamic nucleus (a 'satiety' site) and the lateral hypothalamic area (a 'hunger' site).[46]

Acute illness is characterized by a spontaneous decrease in food intake despite an increased need for energy and nutrients.[47] Although seemingly paradoxical, the voluntary suppression of food intake during illness is common to most species. The relationship between hedonic qualities of food, gastrointestinal and central satiation drives and hormonal relationships may explain this observed difference.[48] This response is the most common cause of anorexia observed in the acute care setting.[49] The data suggest that cytokine levels are commonly associated with disease conditions characterized by cachexia and may play a role in mortality, weight loss and appetite suppression. In contrast to starvation, cachexia is remarkably resistant to hypercaloric feeding.

Anorexia may also result from changes in the physiological regulation of appetite and satiety, as a physiological response to ageing.[50] The importance of understanding this relationship lies in addressing pharmacological[51] or dietary interventions[52] that may reverse this anorexia of ageing.

Evaluation of weight loss

Involuntary weight loss is often attributed to occult disease, but rarely is this found to be the cause. A physical cause of weight loss was clinically evident on the initial evaluation in 93% of patients. In another study, the primary cause of undernutrition was found to be identifiable in nearly 90% of medical outpatients.

The evaluation of unintended weight loss begins with identification of persons at risk. Several assessment instruments have proven validity in the assessment of weight loss or subsequent mortality. The Simplified Nutritional Appetite Questionnaire (SNAQ), a four-question assessment instrument, reliably predicts anorexia and the risk of weight loss in the next six months (Figure 17.1).

The Mini Nutritional Assessment (MNA) was developed to assess malnutrition in elderly populations (Figure 17.2).

Table 17.3 Distinguishing starvation from cachexia.

	Starvation	Cachexia
Appetite	Suppressed in late phase	Suppressed in early phase
Body mass index	Not predictive of mortality	Predictive of mortality
Serum albumin	Low in late phase	Low in early phase
Transthyretin	Low in late phase	Low in early phase
Transferrin	Low	Low
Retinol-binding protein	Low	Low
Cholesterol	May remain normal	Low
Total lymphocyte count	Low, responds to refeeding	Low, unresponsive to refeeding
C-reactive protein	Few data	Elevated
Inflammatory disease	Usually not present	Present
Response to refeeding	Reversible	Resistant

Reproduced from Thomas.[38]

Name: _____ Sex (circle): Male/Female
Age: _____Weight: _____ Height: _____
Date: _____

Administration Instructions: Ask the subject to complete the questionnaire by circling the correct answers and then tally the results based upon the following numerical scale: a = 1, b = 2, c = 3, d = 4, e = 5. The sum of the scores for the individual items constitutes the SNAQ score. SNAQ score >14 indicates significant risk of at least 5% weight loss within six months.

1. My appetite is

a. very poor
b. poor
c. average
d. good
e. very good

2. When I eat

a. I feel full after eating only a few mouthfuls
b. I feel full after eating about a third of a meal
c. I feel full after eating over half a meal
d. I feel full after eating most of the meal
e. I hardly ever feel full

3. Food tastes

a. very bad
b. bad
c. average
d. good
e. very good

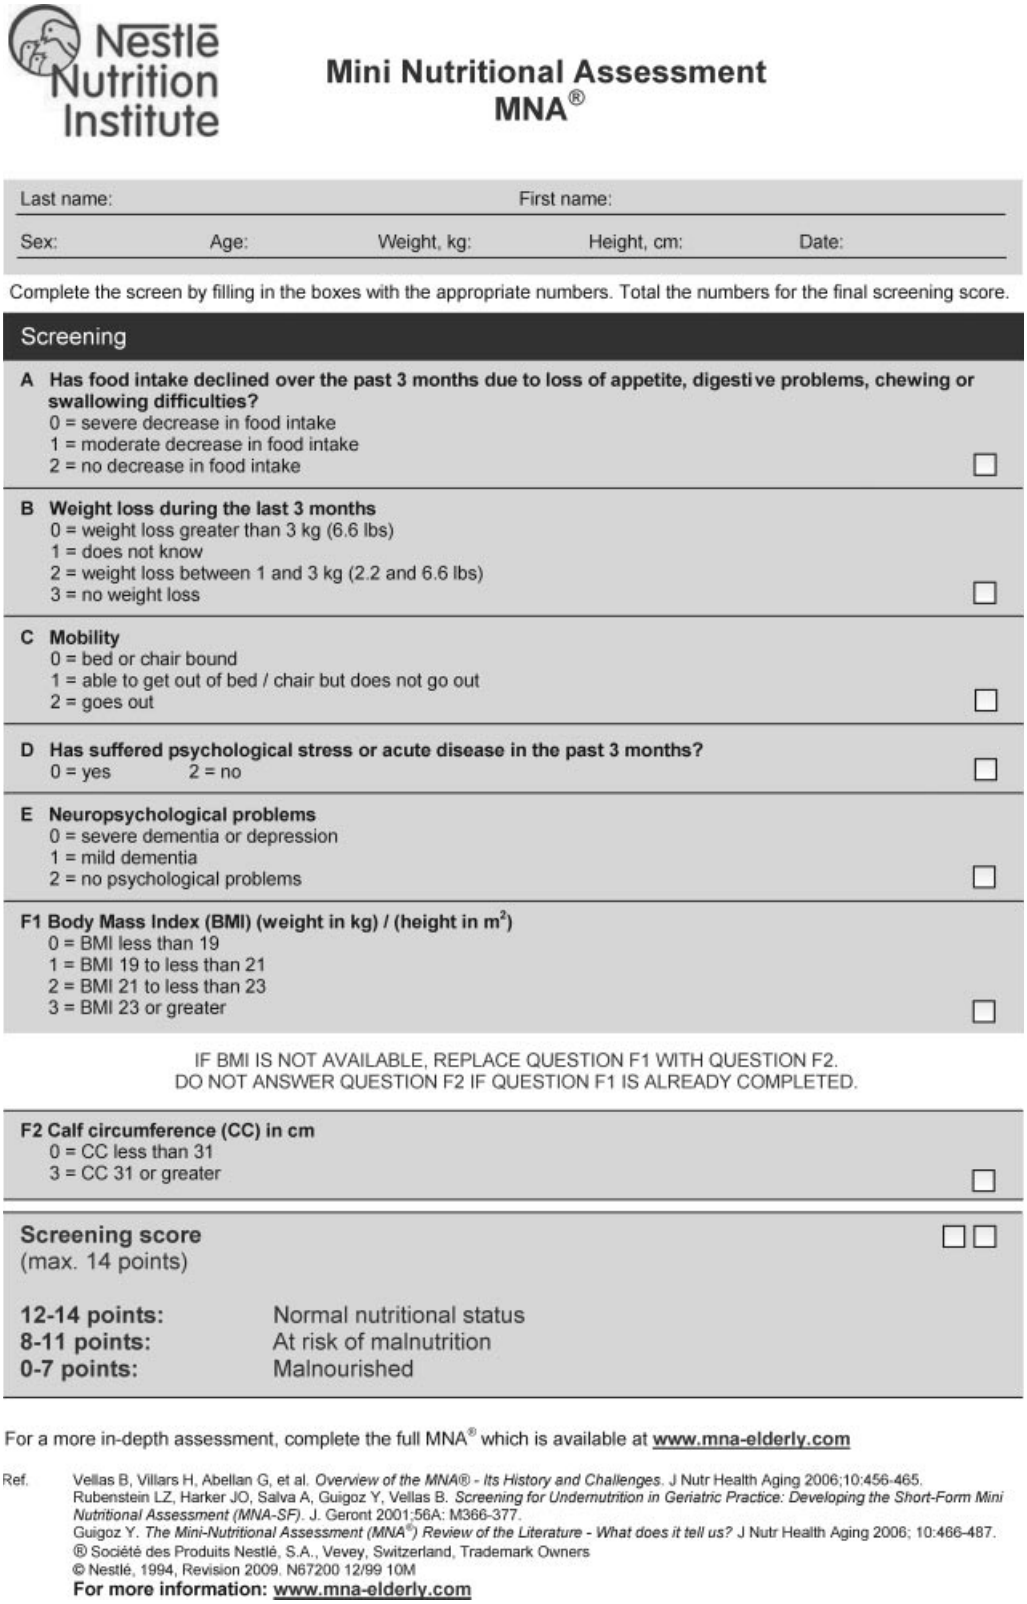
4. Normally I eat

a. less than one meal a day
b. one meal a day
c. two meals a day
d. three meals a day
e. more than three meals a day

Figure 17.1 Simplified Nutritional Appetite Questionnaire (SNAQ). Reproduced with permission from Wilson MM *et al*. Appetite assessment: simple appetite questionnaire predicts weight loss in community-dwelling adults and nursing home residents. *American Journal of Clinical Nutrition* 2005;**82**(5):1074–81. Copyright © 2005, The American Journal of Clinical Nutrition.

Subjects with a normal baseline score had a lower mortality risk [0.35; 95% CI, 0.18–0.66] than subjects with an abnormal MNA score. The subjects judged to be at risk for undernutrition by the MNA had more frequent acute illness, need for more assistance and more weight loss. The MNA was found to be 96% sensitive and 60% specific for body weight loss. A subsequent analysis found that a six-item version of the MNA has equivalent predictive value.

The treatment of undernutrition in the elderly begins with a careful differential diagnostic approach aimed at finding reversible medical causes. Medical conditions that may be associated with anorexia, decreased food intake or increased metabolic requirements should be assessed. Anorexia may be associated with illness, drugs, dementia or mood disorders. Decreased food intake may result from dysphagia, chewing problems, nausea, vomiting, diarrhoea, pain or faecal impaction. Increased metabolic requirements may be precipitated by fever, infection or the presence of chronic skin wounds. Treatment of these conditions may restore appetite and body weight. An algorithm for the approach to the differential diagnosis and management of involuntary weight loss has been published by the Council for Nutrition in Long-term Care.[53]



Nestlé Nutrition Institute

Mini Nutritional Assessment MNA®

Last name: First name:

Sex: Age: Weight, kg: Height, cm: Date:

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake ☐

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C Mobility
0 = bed or chair bound
1 = able to get out of bed / chair but does not go out
2 = goes out ☐

D Has suffered psychological stress or acute disease in the past 3 months?
0 = yes 2 = no ☐

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F1 Body Mass Index (BMI) (weight in kg) / (height in m^2)
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

IF BMI IS NOT AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2.
DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

F2 Calf circumference (CC) in cm
0 = CC less than 31
3 = CC 31 or greater ☐

Screening score (max. 14 points) ☐☐

12-14 points: Normal nutritional status
8-11 points: At risk of malnutrition
0-7 points: Malnourished

Table 17.4 Nutritional interventions.

Voluntarily increase intake
Oral hypercaloric supplements
Pharmacological orexigenic drugs
Anabolic steroids
Enteral feeding tube
Peripheral parenteral supplementation
Total parenteral nutrition

Interventions

For starvation

The first response of caregivers to weight loss, whether due to starvation or to cachexia, is to increase nutrient intake (Table 17.4). In a meta-analysis of 42 trials, nutritional supplementation produced a mean difference in weight gain of 2.3%. A reduced mortality was observed in the supplemented compared with control groups [relative risk (RR) = 0.74; 95% CI, 0.59–0.92] in 32 trials. The subgroup analyses suggested that the effects on mortality were consistently significant when limited to trials in which participants were defined as undernourished (RR = 0.72; 95% CI, 0.55–0.94), when 400 kcal or more was offered per day in the supplement (RR = 0.71; 95% CI, 0.56–0.90), when participants were at least 75 years old (RR = 0.69; 95% CI, 0.54–0.87), when supplementation was continued for 35 days or more (RR = 0.75; 95% CI, 0.56–1.00), when participants were unwell (RR = 0.73; 95% CI, 0.59–0.92) and when participants were in hospital or in a nursing home (RR = 0.67; 95% CI, 0.52–0.86). However, there was no evidence of improvement in functional status or reduction in length of hospital stay with supplements.[54]

A failure to consume adequate nutrients or supplements often leads to enteral feeding. Enteral feeding can frequently be life-saving, but improving nutritional parameters is difficult to verify.[55] There is little evidence for benefit in survival or comfort for enterally fed patients with weight loss due to cancer cachexia, and there are substantial associated risks, discomforts and costs.[56] Enteral feeding in nursing home residents older than 65 years with severe cognitive impairment did not affect survival at 24 months in residents fed by feeding tube compared with residents who were not enterally fed.[57] Survival in other medical conditions does not appear to be affected by enteral feeding. A downward trend in the use of parenteral nutrition in critical care patients has occurred over the last few years, chiefly due to studies showing a higher morbidity with parenteral nutrition compared with enteral nutrition.[58]

Undernourished or high-risk surgical patients did not have postoperative complications reduced to that of well-nourished patients undergoing similar procedures by enteral or parenteral support.[59] The results of percutaneous parenteral feeding in subacute patients was not optimal.[60] These data suggest that factors other than pure starvation are operational, since a response to refeeding is the hallmark of starvation.

For sarcopenia

For persons with sarcopenia, the primary intervention should include resistance exercise interventions.[46] The increase in muscle protein mass is attributable to an acute and chronic increase in muscle protein turnover, resulting in the rate of muscle protein synthesis exceeding that of muscle proteolysis. Coincident with the increase in amount of muscle protein are increases in maximum voluntary muscle strength and muscle fibre hypertrophy.[61] Progressive resistance training 2–3 times per week improves physical function and reduces physical disability and muscle weakness in older adults. Functional limitations such as balance, gait speed, timed walk, timed get up and go, chair rise and climbing stairs also improve.[62] The improvement in muscle mass and strength with resistance exercise extends even to the very old. However, little is known about the duration of these effects once training has stopped.

Bed rest reduces muscle protein synthesis and induces a loss of lean body mass, a model that simulates sarcopenia due to inactivity. Essential amino acid supplementation has been shown to stimulate muscle protein synthesis in healthy volunteers to a greater extent than meals, intact proteins or similar energy intake. Continued stimulation of muscle anabolism positively affects the preservation of lean body mass and the amelioration of functional decrement throughout inactivity. However, in the setting of critical illness, the loss of lean body mass is exacerbated by a persistent hypercortisolaemia. Although essential amino acids promote muscle anabolism during hypercortisolaemia, it is unlikely that a nutritional intervention alone would be effective in maintaining lean body mass during severe stress or prolonged hypercortisolaemia.[63]

For anorexia/cachexia

Various orexigenic stimulants to improve body weight have been studied. Corticosteroids have improved appetite, but have not demonstrated a gain in body weight in clinical trials. Cyproheptadine has been shown to increase appetite in cancer patients without weight gain. Cannabinoids (dronabinol, marinol and nabilone) have shown promise in improving mood and appetite in cancer patients and in AIDS cachexia. Thalidomide, a tumour necrosis factor inhibitor, has produced body weight gain in a small number of patients with HIV-associated wasting syndrome.

Of the pharmacological agents demonstrated to produce weight gain in patients with anorexia and cachexia,

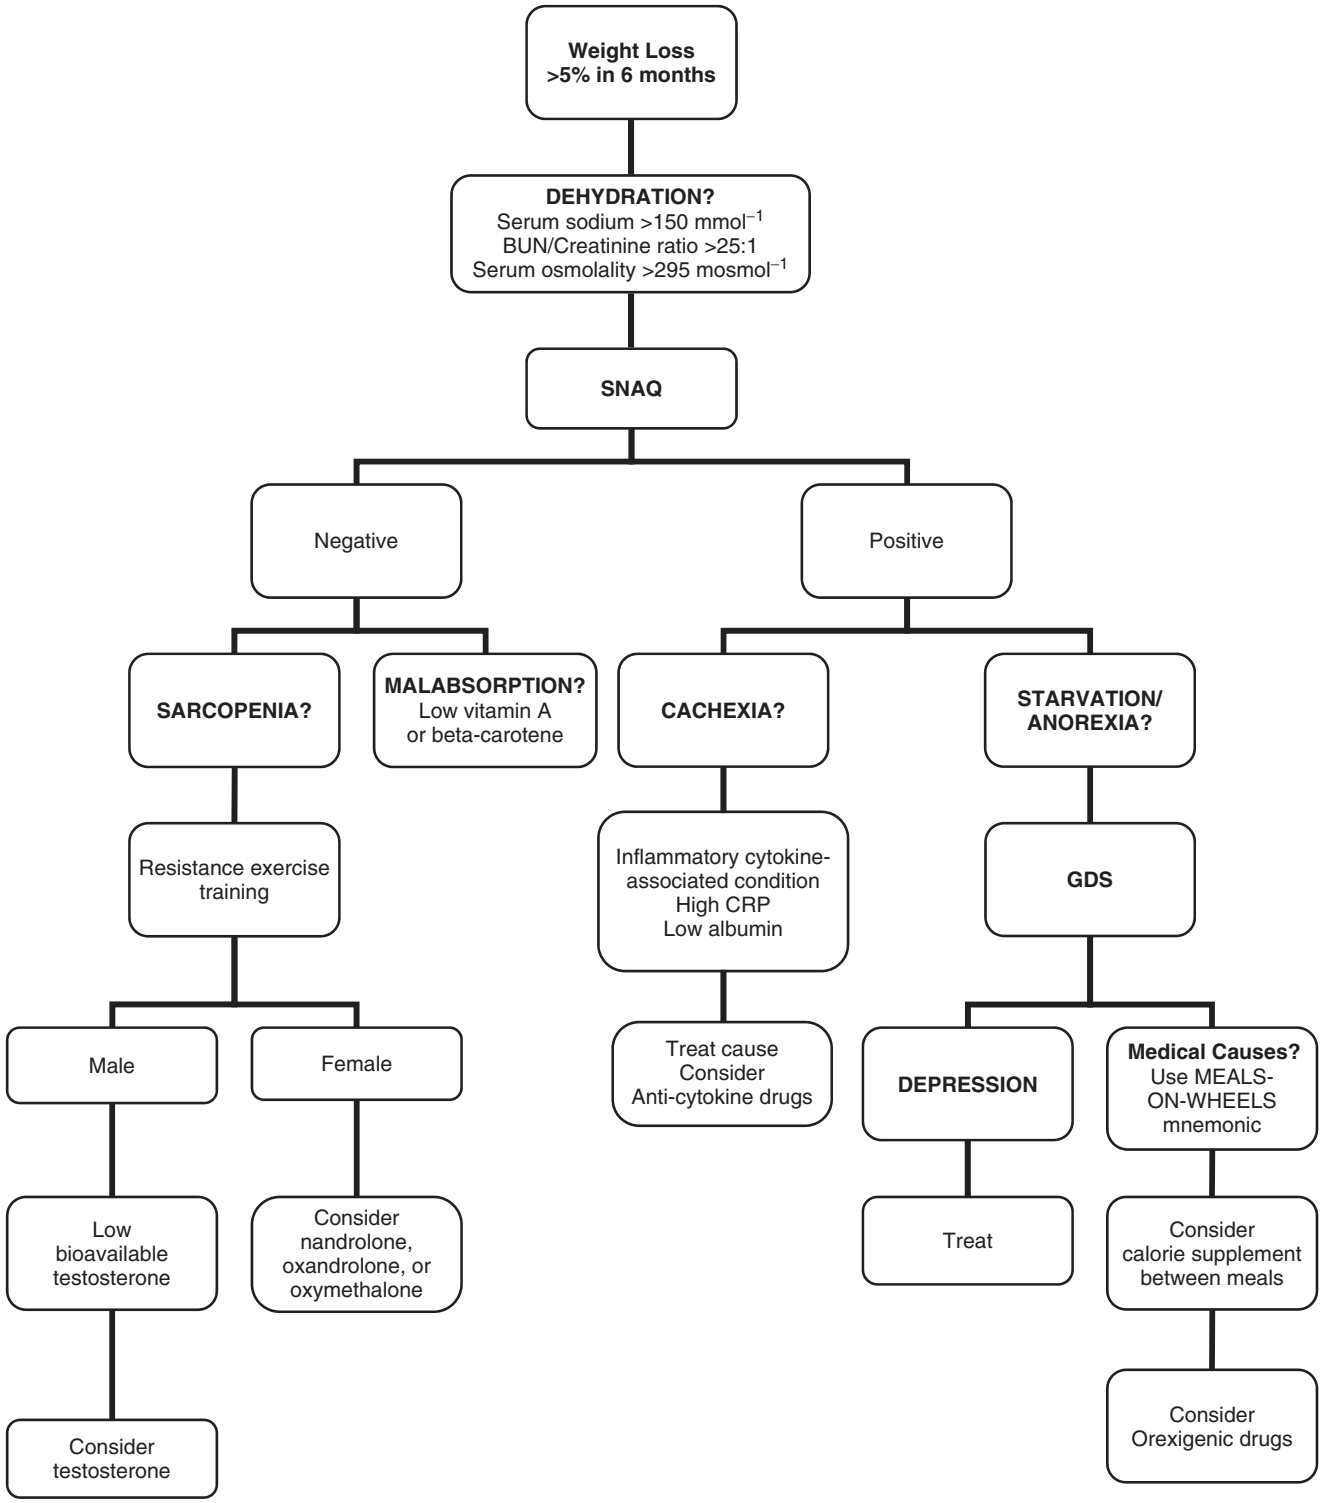

Figure 17.3 Approach to the management of weight loss. CRP, C-reactive protein; GDS, Geriatric Depression Scale; SNAQ, Simplified Nutritional Appetite Questiommaire. Reproduced from Thomas.[21] Copyright © 2007, with permission from Elsevier.

megestrol acetate has been the most widely studied agent. In a meta-analysis of 26 trials, megestrol acetate was found to increase appetite, produce weight gain and improve health-related quality of life in oncology patients, compared with placebo. In AIDS patients, increased weight was demonstrated. Only oedema was significant as an adverse event.[64]

Steroids and hormonal agents such as megesterol acetate are currently widely used in the treatment of cachexia and anorexia. They act through multiple pathways, such as increasing neuropeptide-Y levels to increase appetite and downregulating proinflammatory cytokines. Pharmacological treatment of anorexia with agents that modulate cytokine production may produce weight gain in cachexia states. The action of thalidomide has been linked to inhibition and degradation of TNF-α.[65] The results of these pharmacological trials raise the interesting hypothesis that the improvement in appetite and weight gain may be related to their effect on cytokines. Comparisons of eicosapentaenoic acid combined with a protein energy supplementation versus a protein energy supplementation without eicosapentaenoic acid in the presence of an appetite stimulant provided no evidence that eicosapentaenoic acid improves symptoms associated with the cachexia syndrome.[66]

In contrast to starvation, cachexia is remarkably resistant to hypercaloric feeding. Trials of both enteral and parenteral feeding in cancer cachexia have consistently failed to show any benefit in terms of weight gain, nutritional status, quality of life or survival.[67]

Anabolic steroids

Serum levels of both testosterone and the adrenal androgens decline with age and there are epidemiological data supporting the relationship between the fall in testosterone and the decline in muscle mass, strength and functional status.[68] Clinical trials have demonstrated that the administration of testosterone in older individuals modestly increased both muscle mass and strength, and also bone density.[69] However, while demonstrating an improvement in leg muscle strength, testosterone replacement in older hypogonadal men demonstrated a higher risk for cardiovascular events, effectively terminating the study.[70] Studies of higher doses have been limited by concern for accelerating prostate cancer.[71]

Dehydroepiandrosterone administration has shown conflicting data regarding improvement in muscle mass and strength. The results are more promising in males than in females. An anabolic–androgenic steroid, oxymetholone, produced body weight gain in advanced HIV-1 infection,[72] but not in cachectic cancer patients.[73] The weight gain usually occurred only in patients who were hypogonadal.

Administration of growth hormone in pharmacological doses increases muscle mass but not muscle strength.[74] Recombinant human growth factors have produced weight gain (mean 1.6 kg versus 0.1 kg in the placebo group) in patients with AIDS, but at substantially higher than physiological doses.[75]

Several studies suggest a potential benefit of creatine, especially when combined with exercise to increase stores of phosphocreatine in the muscle and replenish phosphocreatine and adenosine triphosphate, but more studies are needed to confirm these findings.

Conclusion

In older persons, a low BMI is associated with a higher mortality risk. When the observational studies are adjusted for weight loss, nearly all of the higher mortality risk is due to weight loss. Involuntary weight loss has an intensified effect of mortality risk and is usually associated with clinical illness. There are some data to suggest that even voluntary weight loss in older persons may carry a higher mortality risk. Body weight is an easily obtained clinical measurement and weight loss is a profound marker for adverse outcome.

A therapeutic approach to the loss of skeletal muscle mass and strength in older persons depends on correct classification. The term sarcopenia should be reserved for age-related decline in muscle mass not attributable to the presence of proinflammatory cytokines. Cachexia may be a better term for a decline in muscle mass associated with known inflammatory disease states. Although starvation due to protein energy undernutrition is widely regarded as the primary cause of loss of fat and fat-free mass in older persons, a failure to improve with nutritional replacement should trigger a consideration of other causes.

Distinguishing starvation, sarcopenia and cachexia can be difficult, since there can be an overlap between nutrient intake, hormonal deficiency and disease activation. The importance of defining the distinction lies in developing a therapeutic approach to skeletal muscle loss and muscle strength in older persons (Figure 17.3).

Key points

- Unplanned weight loss is common in older adults and is often a sign of a poor outcome.
- Weight loss may be closely associated with functional decline and the additional disability may have important consequences for dependency and place of residence.
- Effective management of weight loss requires a targeting approach to identify high risk individuals, nutritional evaluation, treatment remedial causes and use of selected nutritional supplements.

CHAPTER 18

Dehydration

David R. Thomas
Saint Louis University Health Sciences Center, St Louis, MO, USA

Introduction

Water accounts for about 60% of body weight in an average human, varying mainly with degree of adiposity. As the percentage of body fat increases, the amount of body water decreases. Water is distributed in virtual compartments in the body, moving between compartments by osmosis or by pumps. Total body water (TBW) is about 42 l in a 70 kg person, or 600 ml kg^{-1}. TBW is divided into intracellular fluids (two-thirds TBW, 400 ml kg^{-1}) and extracellular fluids (one-third TBW, 200 ml kg^{-1}). About 75% of the extracellular fluid is distributed interstitially between cells (150 ml kg^{-1}) and about 25% of extracellular fluid is found in the intravascular space (50 ml kg^{-1}).[1]

The spaces define the clinical syndromes of fluid loss. The principal regulator of extracellular water is sodium, because of active transport of sodium into this space. The principal regulator of the larger intracellular compartment is the effective osmolarity of the extracellular fluid. By osmosis, essentially equal tonicity is maintained across both compartments. Intravascular volume depletion leads to hypotension, compensatory tachycardia, decreased tissue perfusion and shock. The intravascular volume is highly protected to prevent these complications, primarily regulated by a sodium pump. Water is transferred to the intravascular volume from the extracellular compartment and the intracellular compartment.

Loss from the extracellular compartment is termed intravascular volume depletion and loss from the intracellular compartment is termed dehydration. Loss from both compartments is termed hypovolaemia.

Water loss

Water can be lost from the body via renal, cutaneous, respiratory and gastrointestinal routes. The kidney is the main controller of body water. The kidneys filter about 150 l of fluid per day, but only about 1% (1.5 l) is excreted as urine. Cutaneous water loss, through sweating, is a major thermoregulatory mechanism. Large amounts of heat are dissipated by sweat. The volume of water loss is usually around 500 ml per day, but can increase substantially in the presence of fever, high environmental temperatures, increased physical activity, increased metabolism or burns. A relatively small amount of water (around 200 ml per day) can be lost through respiration. This loss is affected by ventilatory volume and the environmental relative humidity. A large amount of water passes through the intestines each day and is recovered by the colon. Because of this, a relatively small amount of water (about 100 ml per day) is lost through faeces. However, gastrointestinal loss can increase significantly in the presence of diarrhoea, vomiting or other gastrointestinal pathology and cause severe dehydration.

Regulation of water balance

The balance between water loss and water repletion is regulated by arginine vasopressin (AVP). AVP works as an antidiuretic hormone, thereby regulating water excretion, and also by stimulating thirst, which regulates water ingestion. This balance is so carefully maintained that the osmolarity varies only between 282 and 298 milliosmoles (mOsm) per kilogram. Disorders of this careful balance can lead to severe illness and death.

AVP, the main water-regulating hormone, is controlled by osmotic sensors in the hypothalamus, and to a lesser extent by baroreceptor (pressure) signals. AVP levels increase rapidly with small increases in osmolality and produce sensations of thirst. The osmotic level for stimulation of AVP appears to be 284 mOsm kg^{-1}, with sensations of thirst appearing at a threshold of 294 mOsm kg^{-1}.[2] However, the data suggest that other non-osmotic triggers for thirst occur when the osmolarity is in the normal range. Moreover, there appears to be an individual set point that varies from person to person.[3]

Increased water loss due to exposure to heat, fever, insufficient fluid consumption and physical activity results in an increase in osmolality and a decrease in plasma

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

volume (hyperosmotic hypovolaemia), the main cause of dehydration. In such situations, dehydration stimulates both thirst and increases in AVP levels. This results in thirst, which increases fluid ingestion (when access is available), and a decrease in urinary output due to increased tubular water reabsorption in the nephron. Because of urine concentration, the urine becomes a darker yellowish colour. Changes in urine colour, urine osmolality and urine specific gravity have been used estimate levels of hydration.

The act of drinking rapidly suppresses the release of AVP, through a reflex mechanism in the oropharynx. Water balance is also affected by changes in intravascular volume. A loss of about 10% of circulating intravascular volume also stimulates the osmoreceptors. Loss of intravascular volume directly stimulates thirst and water intake through baroreceptors located in the vascular system. The renin–angiotensin–aldosterone system is also activated by stimulation of the baroreceptors, with the effect of increasing salt intake.

Negative feedback loops operate in conjunction with these systems. Osmotic dilution shuts off the thirst stimulus and AVP secretion. Continued osmotic dilution also stimulates the renin–angiotensin–aldosterone system to retain sodium and restore osmolarity. The renin–angiotensin system controls salt intake and thereby controls intravascular volume. Other hormones include atrial natriuretic peptide, which has a negative feedback to decrease AVP secretion and the renin–angiotensin–aldosterone system. Urodilatin and the oropharyngeal swallowing reflex also appear to play a role. A simplified diagram of volume regulation is shown in Figure 18.1.

Water regulation in older adults

In older persons, the regulation of water balance appears to be impaired. There is a diminished thirst response to in older persons to water deprivation[4] or infusion of hypertonic saline.[5] When older and younger men were restricted in water intake over a 24 h period that produced equal

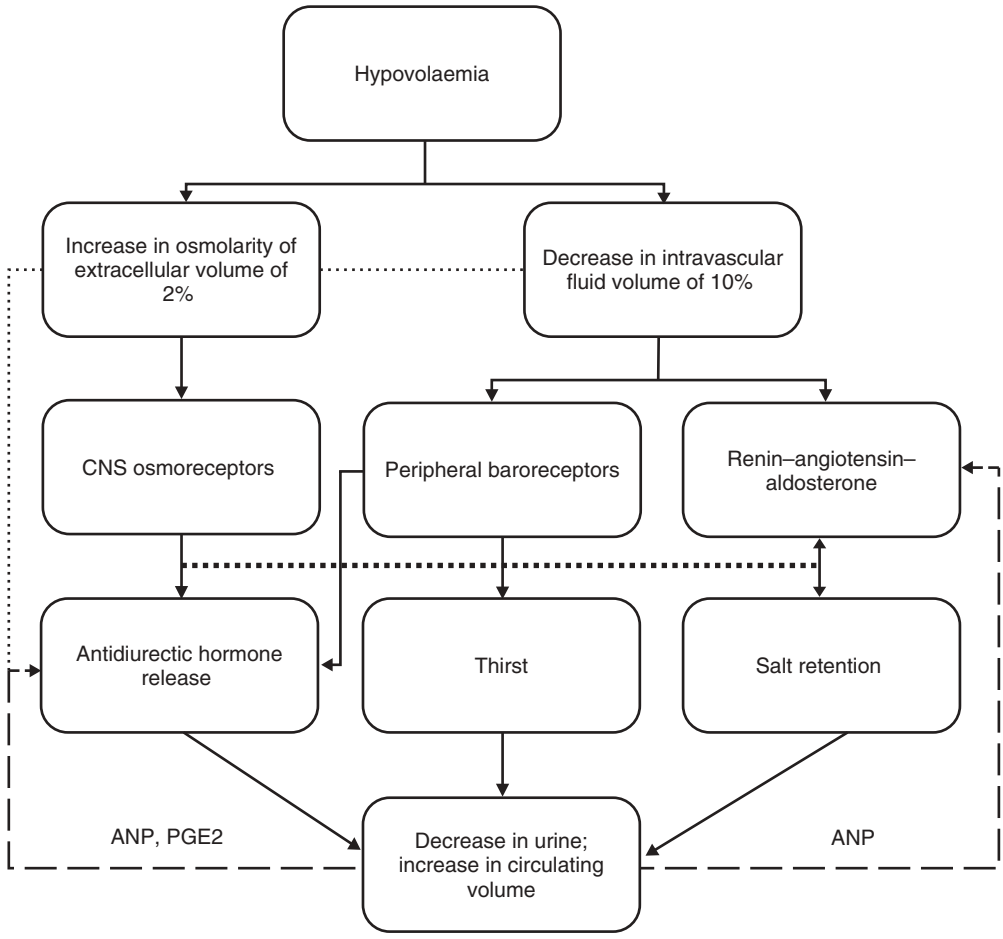

Figure 18.1 Simplified regulation of water balance. CNS = central nervous system; ANP = atrial natriuretic peptide; PGE2 = prostaglandin E2.

weight loss, healthy men aged 67–75 years were less thirsty and drank less water over 2 h compared with younger men.[6] In studies using heat stress and exercise to induce hyperosmolarity and a volume deficit, older individuals tended to operate at a higher plasma osmolality, indicating a shift in the set point of the regulatory system.[7] Again, the perception of thirst was not different in older men. Other studies have found that older men perceived a greater thirst, but drank the same amount of water as younger men in response to passive heat stress.[8]

In the face of water loss producing either an osmoreceptor or a baroreceptor stimulus, older persons exhibit a decreased thirst sensation and reduced fluid intake. Fluid replacement is effective but slower in older persons. Chronic fluid maintenance in response to repetitive dehydration also appears to be reduced, contributing to a decrease in the ability to expand plasma volume. The age differences in the physiological control systems associated with dehydration are more closely associated with a decrease in thirst perception. The data suggest that there is a higher osmotic operating point for thirst sensation under normal daily conditions and a diminished sensitivity to thirst triggered by the vascular baroreceptors.[9]

Dehydration, intravascular fluid loss and hypovolaemia

Physiologically, the term dehydration refers specifically to a decrease in intracellular water. A loss in the intravascular compartment results in intravascular volume depletion. Loss of both intracellular water and intravascular water is more appropriately termed hypovolaemia. Dehydration is always hypernatraemic, whereas intravascular volume depletion can be either hypernatraemic, hyponatraemic or isotonic.

Hypertonic intravascular volume depletion results when water losses are greater than sodium losses. Fever results in loss of water through the lungs and skin and, when combined with limited ability to increase oral fluid intake, is perhaps the most common cause of hypernatraemic intravascular volume depletion. As water is transferred from the intracellular compartment to maintain intravascular volume, total body water decreases, causing dehydration. Characteristic laboratory parameters include hypernatraemia (serum sodium levels $>145\,\text{mmol}\,\text{l}^{-1}$) and hyperosmolality (serum osmolality $>300\,\text{mmol}\,\text{kg}^{-1}$).

Isotonic intravascular volume depletion results from a balanced loss of water and sodium, which can occur during a complete fast. Vomiting and diarrhoea, because of large amounts of both water and electrolytes in gastric contents, will result in isotonic dehydration.

Hypotonic intravascular volume depletion occurs when sodium loss exceeds water loss. This type of dehydration occurs primarily with overuse of diuretics causing excess loss of sodium. The serum sodium is decreased ($<135\,\text{mmol}\,\text{l}^{-1}$) and the serum osmolality is low ($<280\,\text{mmol}\,\text{kg}^{-1}$).

Diagnosis of dehydration

There is no accepted definition of dehydration. A number of parameters have been used to suspect or define dehydration, but all have limitations.[10]

Body composition

The components of body water can be accurately measured by research techniques such as radiological dilution. Bioelectrical impedance[11–13] can determine total body water and extracellular water, estimating the intracellular water by subtraction. Bioelectrical impedance is based on the fact that fat-free mass has a much greater electrical conductivity than fat mass. However, the standard error of the fluid compartment estimates may be as high as ±2 l. Moreover, these modalities may not be readily available in clinical settings.

Body weight

A useful definition of dehydration is a loss of ≥3% of body weight. However, this presumes knowing the stable body weight prior to dehydration. This is useful in athletes and younger persons, but is not practical in older individuals. Weight fluctuations due to disease or drugs may be misleading, and at the lower body weights in older persons may be a total of 3–4 lb (~1.3–1.8 kg), which is in the standard error of measurement of most scales.

Physical examination

The physical signs of dehydration are often confusing, particularly in older adults. Clinical signs of extravascular volume deficit are often misleading. The most helpful physical findings are either severe postural dizziness such that the patient cannot assume an upright position or a postural pulse increment of $30\,\text{beats}\,\text{min}^{-1}$ or more. The presence of either finding has a poor sensitivity for moderate intravascular volume depletion due to blood loss (22%) but a much greater sensitivity for large blood loss (97%). Supine hypotension and tachycardia are frequently absent in extravascular fluid loss, and the finding of mild postural dizziness has no proven value. The presence of a dry axilla supports the diagnosis of dehydration [positive likelihood ratio, 2.8; 95% confidence interval (CI), 1.4–5.4], and a moist mucous membrane and a tongue without furrows argue against the presence of dehydration (negative likelihood

ratio, 0.3; 95% CI, 0.1–0.6 for both findings). In adults, the capillary refill time and poor skin turgor have no proven diagnostic value.[14]

Laboratory parameters

Given the paucity of sensitive clinical signs, laboratory evaluation provides the clinical gold standard. The diagnosis of extracellular volume depletion can be suspected from history and careful physical examination, but requires support of adjunctive data from laboratory studies. The diagnosis of intracellular volume depletion cannot be established without laboratory analysis of serum sodium or calculation of serum tonicity.[15]

Serum osmolarity is very sensitive, rising in dehydration with as little as a 1% change in body weight.[16] During dehydration due to insufficient fluid intake, both plasma sodium and osmolarity are significantly elevated. Serum osmolarity can be measured directly or estimated by the following formula:

$$2 \times (\text{serum sodium} + \text{serum potassium}) + [\text{blood urea nitrogen(BUN)} \div 2.8] + (\text{serum glucose} \div 18)$$

The ratio of BUN to serum creatinine has been used to estimate intravascular volume depletion. A ratio of >20–25 is variably used to define intravascular volume depletion. This ratio may be useful in children or in healthy adults, but is less useful in older adults due to the high incidence of renal disease. For example, a ratio of BUN to creatinine >5 when the increased ratio is due to an elevation in BUN with a normal serum creatinine indicates intravascular volume depletion. However, the same ratio when both the BUN and creatinine are elevated is more likely due to renal disease. Furthermore, the BUN may be low due to low protein intake or liver disease, and the serum creatinine may be low due to muscle wasting, thus limiting the usefulness in determining hydration status.

Urine colour

An eight-level urine colour scale is a reasonable index of hydration in athletic and industrial settings or in research studies using healthy individuals.[17] However, in sick individuals, only a weak relationship between urine colour and urine output has been demonstrated. No correlation between urine colour and body weight change, plasma osmolality or urine specific gravity has been observed.[18]

Problems with the diagnosis of dehydration

Some of the difficulty in the diagnosis of dehydration is in confusion over terminology. Dehydration is often inappropriately used as a non-specific generic term referring to any derangement in any fluid compartments. Clinicians often use the term dehydration when they mean intravascular volume depletion.[15] Furthermore, a diagnosis of dehydration is often inappropriately applied as a medical reason for hospitalization primarily resulting from social considerations.[19]

The diagnosis of dehydration is often made in the face of laboratory data which do not support the diagnosis. At best, this results in a mislabelling of the patient's condition. At worst, the diagnosis results in the inappropriate use of intravenous rehydration therapy.

In a study of the dehydration among hospitalized subjects,[20] a clinical diagnosis of dehydration was made on admission to the hospital in 21% of subjects. Of the patients who had a clinical diagnosis of dehydration on admission, only 19% had a serum osmolarity $>295\,\text{mOsm}\,\text{kg}^{-1}$, only 53% had a BUN/creatinine ratio >20 and only 17% had a serum sodium level $>145\,\text{mg}\,\text{l}^{-1}$. At least half of the diagnoses of either dehydration or intravascular volume depletion were incorrect based on laboratory data. This suggests that very few subjects had criteria for intracellular volume depletion (dehydration) and that clinicians are using the term synonymously with intravascular volume depletion.

During hospitalization, a diagnosis of dehydration was made in 79% of subjects. In these subjects, only 11% had a serum osmolarity $>295\,\text{mOsm}\,\text{kg}^{-1}$, only 50% of subjects had a BUN/creatinine ratio >20 and only 7% had a serum sodium level $>145\,\text{mg}\,\text{l}^{-1}$. Neither a serum osmolarity $>29\,\text{mOsm}\,\text{kg}^{-1}$ or serum sodium level $>145\,\text{mg}\,\text{l}^{-1}$ was present in 47% of subjects. Hence more than half of the subjects given a diagnosis of dehydration during hospitalization did not have confirmatory laboratory data for the diagnosis.

In subjects older than 65 years in this study, dehydration was the primary diagnosis in 26%. In these patients, 80% did not have a serum osmolarity $>295\,\text{mOsm}\,\text{kg}^{-1}$, 39% did not have a BUN/creatinine ratio >20, 77% did not have a serum sodium level $>145\,\text{mg}\,\text{l}^{-1}$ and 31% did not have either a BUN/creatinine ratio >20 or a serum sodium level $>145\,\text{mg}\,\text{l}^{-1}$. This suggests that the admission diagnosis of dehydration was not confirmed by laboratory data in almost one-third of subjects, using any combination of parameters for the diagnosis.

It is difficult to assess the frequency of dehydration due to variations in the definition in published studies. In community-dwelling older adults, the prevalence of dehydration ranged from 0.5% for hypotonic hypovolaemia (defined as a plasma tonicity $<285\,\text{mOsm}\,\text{l}^{-1}$ with orthostatic hypotension) to 60% with hypertonic hypovolaemia (defined as either a plasma sodium level $>145\,\text{mg}\,\text{l}^{-1}$, BUN/creatinine ratio >20 or tonicity $>295\,\text{mOsm}\,\text{l}^{-1}$), or hypotonic hypovolaemia. The elevated

osmolarity and BUN/creatinine ratio in this observational study were associated with chronic disease and functional impairment.[21]

Using only a BUN/creatinine ratio >20 produces extremely high prevalence rates of dehydration. In an emergency department study, 48% of persons over the age of 75 years were diagnosed as dehydrated on admission. However, less than 3% of subjects had a serum sodium level >145 meq l^{-1}, a percentage much closer to other published reports.[22] When unadjusted for other contributing causes, a BUN/creatinine ratio should probably not be used as the sole criterion for a diagnosis of dehydration.

Older persons appear to have a higher set point for osmolarity than younger persons. In a small sample of institutionalized older men followed for 6 months, 40% of the men had at least one serum osmolarity >295 mOsm kg^{-1}. About 20% of men had a serum osmolarity >300 mOsm kg^{-1}, but none had a concurrent serum sodium level >146 mg l^{-1} or a BUN/creatinine ratio >25. The BUN/creatinine ratios ranged from 12 to 34 over the 6 months, with 20% demonstrating elevated ratios consistently throughout the study without clinical evidence of dehydration. Only two patients had both an elevated serum osmolarity and serum sodium level, although both had a normal BUN/creatinine ratio. A normal serum sodium level was maintained in only 60% of the men throughout the 6 months. None of the men had clinical signs of dehydration at any time. These data suggest that in clinically stable long-term care residents, frequent elevations of serum osmolarity occur without overt clinical evidence of dehydration or an accompanying elevated sodium level or BUN/creatinine ratio.[23]

Consequences of dehydration

The diagnosis of dehydration has severe consequences. First, the diagnosis of dehydration is associated with an increase in hospital morbidity and mortality. Among patients with a diagnosis of dehydration admitted to an acute care hospital, the mortality rate was 30%. Hypernatraemic dehydration, defined as a serum sodium levels >145 meq l^{-1} and BUN >25 mg dl^{-1} with serum creatinine <3 mg dl^{-1}, was 2.9%. Subjects older than 85 years had a higher prevalence (5.3%) compared with subjects younger than 65 years (1.6%). A higher mortality (33%) was observed in subjects with a sodium level of 151–153 meq l^{-1}, and an even higher mortality rate in subjects with serum sodium levels >154 meq l^{-1} (71%).[24] Dehydration has been shown to increase by twofold the hospital mortality in patients admitted with stroke,[25] to produce a twofold increase in risk of pressure ulcers[26] and to increase the length of hospital stay in patients with community-acquired pneumonia.[27]

The mortality from dehydration may reflect the underlying disease state rather than a primary disorder in water regulation. In an acute care geriatric unit, 11% of subjects developed a plasma osmolarity of ≥320 mOsm l^{-1} in the 6 months following admission. In-hospital mortality was 35% in the hyperosmolar patients compared with 17% in non-hyperosmolar subjects. Diabetic hyperosmolarity accounted for most of these subjects, whereas hyperosmolar states developed in other subjects in association with infection, cognitive impairment and renal or cardiovascular disease. Impaired functional mobility was a risk factor for in-hospital mortality but not the degree of hyperosmolarity.[28]

Hyperosmolality is either a marker for, or a cause of, increased mortality in frail elderly patients. In a geriatric continuing care unit, the short-term survival of those patients with an osmolality >308 mOsm kg^{-1} was reduced and an increased mortality at 2 years was observed. However, there was no correlation between age and plasma osmolality.[29]

Second, the diagnosis drives the clinical approach to fluid therapy. The choice between resuscitation of the extravascular or intravascular fluid compartments may lead to inadequate fluid management or overhydration. In haemodynamically compromised individuals with orthostatic hypotension and oliguria, replacement with isotonic saline until haemodynamic stabilization is crucial.[30] Overzealous rehydration and improper monitoring may result in congestive heart failure and death in older persons.[31]

Finally, dehydration has been proposed as one of five quality of care indicators in long-term care. The diagnosis of dehydration in a patient admitted from a nursing home or from a home care setting may imply a failure in the quality of health care delivery.[32] However, the difficulty in diagnosing dehydration in older populations results in dehydration performing poorly as a quality of care indicator.[33]

Treatment of dehydration

The correction of dehydration lies in replacing water deficits. Water can be replaced orally, intravenously or by hypodermoclysis.[34] The total amount of estimated daily fluid requirements at baseline for adults older than 65 years is 30 ml kg^{-1} body weight. This requirement represents total dietary water, including that found in consumed foods. Water can be provided in any form, including free water, flavoured drinks or high water content foods. The amount of free water required to meet the 30 ml kg^{-1} per day requirement will be subtracted from the estimated amount of water contained in foods. For most enteral feeding products, about 75% of standard product serving is free water.

The type of oral replacement fluid should be selected based on the source of the water loss. For example, water loss due to extreme physical exertion, which includes loss of sodium and potassium, may require

solutions containing supplemental sugars, salt and potassium. Balanced solutions of water and electrolytes (e.g. sports drinks) may be more effective in fluid replacement under these circumstances. Water loss due to diarrhoea or vomiting likewise may require replacement of sodium and potassium. Oral rehydration formulae, which have been widely used in children, are effective for fluid replacement in older adults.[35]

The use of intravenous fluid replacement depends on the clinical diagnosis, the urgency of the situation or whether the patient is able to take oral fluids. For older persons presenting with dehydration due to free water deficits (e.g. febrile illness) and who are haemodynamically stable, replacement can be made with 5% dextrose in water (D5W). Replacement can be made at a rate of 25–30% of the estimated total free water deficit per day, although the exact rate of replacement depends on the acuity of the loss. Free water deficit (FWD) may be calculated by the following equation:[36]

$$\text{FWD (l)} = \text{weight (kg)} \times 0.45 - [(140/\text{measured serum sodium}) \times \text{weight (kg)} \times 0.45]$$

This equation is useful, but limited by the fact that the patient's baseline weight prior to becoming dehydrated must be known and used in the calculation.

Hypodermoclysis can be use as an alternative method of delivering fluids for patients who are stable and for whom intravenous access is not desired or difficult to establish. Isotonic or hypotonic solutions can be administered at a rate of 1 ml min^{-1} through needles inserted into the subcutaneous tissue of the abdomen or anterior or lateral thighs. Up to 1500 ml can be delivered through a single site and 3000 ml through two sites in 24 h.[37] Hypodermoclysis can produce tissue slough or abscess formation at the site and can result in over-hydration, just as with intravenous fluids.[38]

In persons with intravascular volume depletion who are haemodynamically unstable with significant volume loss (e.g. severe vomiting or diarrhoea), isotonic saline should be used until the patient is haemodynamically stable. Overzealous rehydration and improper monitoring can and do result in congestive heart failure and death in older persons. For this reason, careful monitoring of intravenous fluids and correct differential diagnosis is mandatory.

Prevention of dehydration

The requirement for water in older adults is controversial. Amounts range from 1 ml $kcal^{-1}$,[39] 30 ml kg^{-1} body weight[40] or the sum of 100 ml of fluid per kg for the first 10 kg actual body weight, 50 ml of fluid per kg for the next 10 kg actual body weight, and 15 ml of fluid per kg for the remaining kilograms actual body weight.[41] The first recommendation assumes normal caloric intake, the second recommendation depends on the person's body weight, which may not be normal, and the third recommendation attempts to adjust for current body weight. Direct observations of institutionalized adults indicate a total fluid intake, including fluids derived from meals, of 1783 ± 545 ml.[42]

All of the recommendations include water derived from all sources, including water from food sources. When the amount of water derived from food is subtracted, the most general recommendation for fluid intake (including free water) is 1500–2000 ml per day.[14]

Most older persons do not consume this amount of extra fluids/water. Most community-dwelling adults consume only about 1000 ml per day of fluids.[43,44] Institutionalized older persons may consume less.

Despite almost universal agreement that fluids need to be aggressively offered to older person, there are remarkably few data on prevention in the published literature. A meta-analysis found only two published intervention trials.[45] In a randomized, controlled trial of hydration intervention, the fluid intake of the experimental group exceeded that of the control group by a small amount. Bioelectrical impedance demonstrated a higher extracellular fluid volume (2.1 l), but no difference in total body water or intracellular water. No differences were detected in clinical outcome or confusional episodes between groups.[46]

Verbal prompting and specific beverage preference can increase fluid intake in most, but not all, incontinent long-term care residents. More cognitively impaired residents responded to verbal prompting, whereas less cognitively impaired residents responded to offering a beverage preference. The intensity of staff time was considerable over a 3 day intervention period.[47]

In summary, few data exist to support the assertion that dehydration can be prevented in older adults by close observation or interventional trials.

Conclusion

Water metabolism is carefully regulated and the consequences of dysfunction or disease are serious. Compared with normal physiological regulation, older adults appear to have alterations in thirst perception which are unrelated to arginine vasopressin secretion. Water replenishment after stimulation of the osmoreceptors or baroreceptors appears to be slower and not as complete as in younger persons. The calculated daily water requirement is 30 ml kg^{-1}, of which about 1500–2000 ml should be free water or fluids. Rehydration after water loss depends on the urgency of the need for replacement. Dehydration is common with concurrent disease in older persons and may appear quickly. Because of disordered thirst perception in older persons, encouragement to drink fluids may be necessary. However, older persons may not drink enough fluids to replenish

loss completely owing to a higher set point for their osmoreceptors.

Key points

- Dehydration lacks an accepted definition.
- Clinical signs lack sensitivity in the diagnosis of dehydration.
- Older persons have disordered thirst perception creating a propensity to become dehydrated.
- When oral or intravenous hydration presents problems, hypodermoclysis (subcutaneous fluid administration) has been used successfully.

Introduction

The use of dietary supplements in general and nutrient supplements in particular is prevalent and growing in the United States. In 2007, dietary supplement sales grew to $23.7 billion. Sales of multivitamins, the most commonly purchased of supplements, grew by 3.9% in 2007 to $4.5 billion in sales for the year.[1,2] The ageing of the population and consumer desire to maintain good health and prevent disease have contributed to the increased growth of this industry. However, the current evidence on the use of dietary supplements rests on epidemiological association only.

The specific requirements for micronutrients in the elderly have not been studied until fairly recently. Vitamin and mineral requirements do not remain static over the adult life span. There are several micronutrients for which there is strong evidence that requirements are in fact increased in the elderly compared with younger people, such as vitamins D, B_6 and B_{12}.[3,4] It is clear that individuals change physiologically during ageing and that ageing is often associated with the development of chronic degenerative diseases. The roles that various supplements play in these changes appear to be less defined. There is an overall lack of evidence on the nutritional needs of the elderly, with a particular lack of data from clinical trials. Additionally, there is a critical need for the development of valid and reliable methods to detect undernutrition and for the generation of data to determine the dietary reference intakes (DRIs) of individuals 51–70 and >70 years old.[5]

Nutrition is an important determinant of health. As people age, activity levels and energy requirements tend to decrease. Concomitant decreases in food consumption may cause protein and micronutrient intake to fall below desirable levels. It is well documented that many older persons develop physiological anorexia associated with ageing. Additional factors that increase the risk of undernutrition include physiological changes that affect digestion, absorption and metabolism of nutrients, social isolation, chronic diseases, oral problems, sensory impairment, cognitive impairment, depression, multiple and chronic medication use, poverty and inappropriate food intake.[6–9]

Vitamin disorders in the elderly usually present atypically or are masked by coexisting diseases or a general failure to thrive.[10] Vitamin preparations are consumed on a daily basis by 20–60% of elderly people. These supplements are consumed for various reasons, including the following: to increase energy, improve health, improve appetite and prevent and treat diseases. Older persons may consume potentially toxic amounts of vitamins and minerals by supplementation.[11,12] Drug–nutrient interactions are common in the elderly because of the high incidence of polypharmacy, many of which may occur unrecognized.[13] Table 19.1 summarizes drugs with potential for interaction with various vitamins and minerals.

Prevalence/scope of the problem

There continues to be a lack of evidence on prevalence of vitamin and mineral deficiencies, most studies have concentrated on protein energy malnutrition.[15] The prevalence of vitamin deficiency in usual western diets is higher than generally believed, especially in the elderly.[16] Various studies have revealed that up to 20% of community-dwelling ambulatory adults, 37% of home-bound elderly, 30–60% of hospitalized patients and 17–85% of institutionalized patients are malnourished.[17–22]

According to the National Health and Nutrition Examination Survey (NHANES), up to 16% of Americans over the age of 65 years consume less than 1000 calories per day. The reduced caloric intake is incompatible with maintaining adequate vitamin and mineral intakes. Studies on vitamin deficiencies in older individuals have revealed that vitamin deficiencies vary from 2.6 to 6.8% for vitamin D in the general population to 35% in the institutionalized

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 19.1 Potential micronutrient–drug interactions.[10,14]

Micronutrient	Drug
Calcium	Vitamin D, lysine
Chromium	Vitamin C
Copper	Zinc, iron
Folic acid	Methotrexate, cotrimazole, phenytoin, sulfasalazine, triamterene, zinc, alcohol
Magnesium	Vitamin B_6, calcium
Manganese	Calcium, iron, zinc, copper
Selenium	Vitamin E
Vitamin A	Iron, vitamin E, tetracycline, cholestyramine
Vitamin B_1 (thiamine)	Vitamin B_2, vitamin B_3
Vitamin B_2 (riboflavin)	Ouabain, theophylline, penicillin, boric acid, probenecid, chlorpromazine, phenothiazines, barbiturates, streptomycin, oral contraceptives, antidepressants, probenecid, tobacco, alcohol
Vitamin B_3 (niacin)	Vitamin B_1, vitamin B_2, anticonvulsants, aspirin, clonidine, hydroxymethylglutaryl (HMG)-coenzyme A reductase inhibitors
Vitamin B_6 (pyridoxine)	Magnesium, anticonvulsants
Vitamin C	Copper, iron
Vitamin D	Aluminium hydroxide, corticosteroids, diuretics, rifampin, phenytoin
Vitamin E	Antacids, cholestyramine, colestipol, mineral oil, sucralfate, iron, vitamin A, tobacco, alcohol, coumarins, anticoagulants, indandiones
Vitamin K	Calcium, anticoagulants
Zinc	Diuretics, copper, *N*-acetylcysteine, iron, calcium, magnesium

Table 19.2 Prevalence of vitamin deficiencies in the elderly.

Vitamin	Independent (%)	Hospitalized (%)	Nursing home (%)
Vitamin A	1	Unknown	Unknown
Vitamin B_1 (thiamine)	13–43	40	2–5
Vitamin B_2 (riboflavin)	3–42	12	1–34
Vitamin B_6 (pyridoxine)	5–56	19	21–93
Folate	2.5–34	24	4–24
Vitamin B_{12} (cobalamin)	4–43	Unknown	4–29
Vitamin C (ascorbic acid)	Unknown	Unknown	0–5
Vitamin D	2–5	22	35

patients, while vitamin A deficiency is seen in 1% or less of the older adults. The prevalence for vitamin B deficiency shows marked heterogeneity. The prevalence for vitamin B_1 varies from <5% in the nursing home patients to as high as 43% in independent older persons; vitamin B_{12} deficiency is seen in up to 43% of independent older adults and in up to 29% of nursing home patients.[15,23–26] Table 19.2 gives the prevalence of vitamin deficiencies. Information on prevalence of trace mineral deficiencies comes from the developing world; zinc deficiency is widely recognized to be a common association with malnutrition. Geographic surveys show trends for selenium deficiency in individuals living in areas with low soil content of selenium.[27,28]

Dietary reference intakes

The goal of the Recommended Dietary Allowances (RDAs) was to estimate nutritional requirements for preventing basic deficiency diseases. The recommendations were also meant to be applied as general guidelines for groups, not as a gold standard for individuals. Research, led by the American Heart Association in the 1960s, demonstrated the links between diet and disease. It was already known that deficiency in certain nutrients results in disease. Studies went on to show clearly that increased intake of certain nutrients actually helps to prevent some chronic illnesses. Because of this research and because the RDAs were being used for purposes other than those for which they were created, new recommendations were in order.

The new guidelines are called *Dietary Reference Intakes* or *DRIs*. They were developed by the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, and published in 1998. These were designed to reflect the latest understanding of nutrient requirements based on optimizing health in individuals. For the first time, the group included data for individuals 70 years and older. They are being developed with individuals in mind. They are also concerned about the prevention of chronic degenerative diseases, such as macular degeneration, heart disease and osteoporosis. The DRIs are based on several factors. These include the level of a nutrient needed to meet the needs of a healthy individual and the level at which a nutrient will produce harmful side effects. The DRIs also consider the source of the nutrient, for example, the body is often better able to use nutrients supplied in food than by supplements. The new DRIs also take age and gender into consideration.[15,29–31]

The Board described four categories of reference values:
1 Estimated average requirement (EAR): represents the amount of nutrient intake that meets the requirements of 50% of the individuals in that group. The EAR serves as the basis for developing the recommended dietary allowance.

Table 19.3 Dietary reference intake for micronutrients (Food and Nutrition Board, Institute of Medicine, National Academy of Sciences, 2010)[a].

Micronutrient	RDA/AI[b]				TUL			
	Age 51–70 years		Age >70 years		Age 51–70 years		Age >70 years	
	Male	Female	Male	Female	Male	Female	Male	Female
Vitamin A (μg)	900	700	900	700	3000	3000	3000	3000
Vitamin C (mg)	90	75	90	75	2000	2000	2000	2000
Vitamin D (μg)	15	15	20	20	100	100	100	100

Zinc (mg)	11	8	11	8	40	40	40	40

[a]RDA, recommended dietary allowance; AI, adequate intake; TUL, tolerable upper intake level; ND, not determined.
[b]AI values are in italic type.

2 Recommended dietary allowance (RDA): the daily nutrient intake that meets the nutrient needs of 97–98% of healthy individuals in that group. It is set at two standard deviations above the EAR.

3 Adequate intakes (AI): the average observed or experimentally derived intake by a defined population or subgroup that appears to sustain a defined nutritional state, such as normal circulating nutrient values, growth or other functional indicators of health.

4 Tolerable upper intake level (TUL): represents the maximum nutrient intake by an individual that is unlikely to pose risks of adverse health effects in 97–98% of individuals. It is not intended to be a recommended level of intake.

Table 19.3 gives the DRIs for vitamins and minerals for individuals aged 51–70 and over 70 years.

Factors affecting nutrient intake in the elderly

Total energy intake decreases substantially with age; this results in concomitant declines in most nutrient intakes, including vitamins and minerals. Despite the common occurrence of protein-energy undernutrition in older persons, its presence is rarely recognized. Factors implicated in the decreased nutrient intake in the elderly can be divided into the following categories:[32,33]

- social
- psychological
- medical
- age-related.

Factors affecting the nutrient intake are summarized in Table 19.4.

The antioxidants

One of the leading theories proposed for cellular and organism ageing is that damage to cellular mechanisms and tissues occurs because of chronic damage resulting from oxidative stress caused by oxygen free radicals. Endogenous oxidative damage to proteins, lipids and DNA is thought to be an important aetiological factor in ageing and development of chronic diseases such as cancer, atherosclerosis and cataract formation. The developing recognition that many disease states are caused by oxidative damage and that certain antioxidant compounds may scavenge these damaging oxygen free radicals has resulted in increased interest in vitamins and minerals as antioxidants. Vitamins A, C and E and β-carotene, referred to as *antioxidant vitamins*, have been suggested to limit oxidative damage in humans. Riboflavin (vitamin B_2) and selenium, a trace metal, are also suggested to have antioxidant capabilities.[10,32,34–36]

Table 19.4 Factors affecting nutrient intake in the elderly.

Social

1 Poverty
2 Social isolation
3 Ignorance
4 Problems with meal preparation
5 Inability to shop
6 Lack of recognition of ethnic or other food preferences in institutional settings
7 Monotony of institutionalized food

Psychological

1 Depression
2 Bereavement
3 Alcoholism
4 Dementia
5 Late-life paranoia
6 Late-life mania
7 Anorexia Tardive
8 Sociopathy
9 Overwhelming burden of life

Medical

1 Increased metabolism
   - Movement disorders: Parkinsonism and Tardive dyskinesia
   - COPD
   - Severe cardiac disease
2 Anorexia
   - Drugs: digoxin, psychotrophic drugs, theophylline, cimetidine, ranitidine, L-thyroxine
   - Gallstones, chronic and recurrent infections
   - Malignancy
   - Physiological anorexia of ageing
3 Swallowing problems
   - Oesophageal candidiasis
   - Teeth and denture problems
   - Severe tremors and strokes
4 Malabsorption
   - Late-onset gluten enteropathy
   - Lactose deficiency
5 Feeding problems
   - Severe tremor
   - Strokes
   - Dementia

Age related

1 Anorexia of ageing
2 Decreased olfaction
3 Decreased taste

A large body of epidemiological evidence suggests that eating a diet rich in sources of vitamins has a protective effect on development of disease. The strong association of dietary intake of vitamins and disease in epidemiological studies has not been borne out in clinical trials).[10] Caution must be exercised in interpreting the results of observational studies, as the association of diets rich in fruits and vegetables with reduced risk of cancer and cardiovascular disease may be due to the vitamins themselves, other compounds in fruits and vegetables or the substitution of dietary meat and fat with fruits and vegetables.[37]

Vitamin A and β-carotene

Vitamin A consists of preformed vitamin A (retinol) and the carotenoids such as β-carotene. The carotenoids are a diverse group of more than 600 naturally occurring pigments. Natural sources include yellow, orange and red plant compounds, such as carrots and green leafy vegetables. Humans cannot synthesize carotenoids and depend on dietary intake exclusively for these micronutrients. β-Carotene can act as an antioxidant by quenching the unpaired electrons of free radicals and divert free-radical damage towards itself. Vitamin A refers to preformed retinol and the carotenoids that are converted to retinol. Preformed vitamin A is found only in animal products, including organ meats, fish, egg yolks and fortified milk. More than 1500 synthetic retinoids, analogues of vitamin A, have been developed. Vitamin A intake decreases with age; however, hypovitaminosis A is uncommon even in the very old. The current RDI for vitamin A is 1500 $\mu g\,l^{-1}$(5000 IU). Except at the extreme ranges, retinol levels correlate poorly with vitamin A status and are affected by many non-nutritional diseases. Hepatic levels of vitamin A appear unchanged in adults. About 50–85% of the total body retinol is stored in the liver. It is also found in many other tissues in much lower concentrations.[10,32,38,39]

Dietary proteins undergo proteolysis to release retinyl esters in the stomach. They then join lipids and bile salts to form micelles for absorption through the intestinal mucosa. Preformed vitamin A is absorbed by the intestinal cell by a carrier-mediated mechanism, however; carotenoids are passively absorbed by the intestinal epithelium. Vitamin A is then transported to the liver via the lymphatics. By means of a receptor-mediated endocytosis on the surface of the hepatocytes, the retinol esters are released and stored as retinyl ester. These are further metabolized to combine eventually with retinol binding proteins (RBP) before storage in vitamin A-containing lipid globules within the hepatic stellate cells. In order for vitamin A to reach its target organs, it binds to RBP molecules for release into plasma as a retinol–RBP complex.[10,38–40]

Vitamin A has a number of biological actions. In the eye, it is required for prevention of xerophthalmia and phototransduction. Vitamin A is crucial to cellular differentiation and integrity.[40,41]

Vitamin A deficiency is rarely seen in the United States and other industrialized countries. However, it is still the third most common nutritional deficiency in the world. In the elderly, diminished physical activity reduces intake

and concentrations may drop, but there is little evidence to support the need for supplementation and, indeed, toxicity is manifested more readily with age.[38,40,42–44] Deficiency can result in the following:

- night blindness, complete blindness and xerophthalmia;
- Bitot's spots (areas of abnormal squamous cell proliferation and keratinization of the conjunctiva), which can be seen in young children;
- corneal perforation, keratomalacia and punctate keratopathy, which have been observed in early childhood development;
- non-specific dermatological problems, such as hyperkeratosis, phrynoderma (follicular hyperkeratosis) and the destruction of hair follicles and their replacement with mucous-secreting glands;
- impairment of the humoral and cell-mediated immune system via direct and indirect effects on the phagocytes and T cells.

In a majority of cases, vitamin A toxicity occurs because of the ingestion of large amounts of synthetic vitamin A, about 10 times higher than the RDI, or about 50 000 IU. In the elderly, diminished physical activity reduces intake and concentrations may drop, but there is little evidence to support the need for supplementation and, indeed, toxicity is manifested more readily with age. Hypervitaminosis can occur both acutely and after chronic ingestion. Symptoms of toxicity include dry skin, nausea, headache, fatigue, irritability, ataxia, alopecia, hyperlipidaemia, hepatotoxicity, bone and muscle pain and visual impairments.[10,40,41,45]

Epidemiological studies of dietary vitamin A on possible cancer chemoprevention appear to represent primarily the effect of α-carotene. Studies of relationships between cancer and vitamin A and carotenoids have provided mixed results. Observational data and clinical trial data have not been consistent.

Two large, randomized, placebo-controlled trials assessed the risk of lung cancer among male smokers or asbestos workers receiving α-carotene supplements. The risk of lung cancer was significantly increased among men receiving supplements. In the α-Tocopherol, α-Carotene (ATBC) Cancer Prevention Study, there was an increase in both prostate cancer incidence and mortality among subjects randomized to α-carotene. The excess risk appears to resolve over time once supplements are stopped.[46–48]

There have been no clinical trials of vitamin A intake and breast cancer. However, observational studies of vitamin A intake and breast cancer have yielded varying results. In a study by Kushi *et al.*, no association between dietary vitamin A and breast cancer was observed.[49] In contrast, recent data from the Nurses' Health Study suggest that premenopausal women, particularly those with a positive family history, have significant reductions in breast cancer risk with increasing dietary α-carotene and β-carotene, lutein/zeaxanthin and total vitamin A.[50,51] Data from the Polyp Prevention Study Group did not show a reduction in adenoma risk in patients randomized to receive either α-carotene, vitamin C and E or both α-carotene and vitamins C and E.[52]

Vitamin A and α-carotene supplements have shown no benefit for primary or secondary prevention of coronary heart disease (CHD) in randomized trials and have been associated with potential harm.[53] There is consistent evidence from observational studies that vitamin A intake within the range taken by many people in western societies, is a risk factor for osteopenia and fractures. The Physicians Health Study found that 12 years of α-carotene supplements had no effect overall on the risk of cataract formation, but appeared to decrease the risk significantly among current smokers.[54–57]

On the basis of current clinical data and the lack of clinical efficacy with respect to cancer prevention, along with its possible adverse effects, vitamin A and α-carotene supplement use should be discouraged.

Vitamin E

Vitamin E occurs in eight natural forms as tocopherols (α, β, γ and δ) and tocotrienols (α, β, γ and δ), all of which possess potent antioxidant properties. Vitamin E was originally found to affect reproduction in rats and was given the name tocopherol, derived from the Greek words *toc* (child) and *phero* (to bring forth) to describe its role as an essential dietary substance in normal fetal and childhood development.[58,59]

Vitamin E absorption depends on the breakdown of fatty acids and their uptake via enterocytes to the enterohepatic circulation. The synthesis of chylomicrons is required for transport of vitamin E via the lymphatic system to the liver. Within hepatocytes, chylomicron remnants are broken down by lysosomes and *R*,*R*,*R*-α-tocopherol is preferentially secreted into the bloodstream, packaged within very low density lipoprotein (VLDL) molecules. The transport protein for α-tocopherol is named α-*tocopherol transfer protein* (α-TTP).[60–62]

Vitamin E works as a free-radical scavenger and antioxidant. α-Tocopherol is the biologically active form of vitamin E. It protects polyunsaturated fatty acids (PUFAs), a major structural component of the cell membranes, from peroxidation. Primary sources of vitamin E are vegetable oil, wheat germ, leafy vegetables, egg yolk, margarine and legumes.[63,64] Vitamin E deficiency can be measured by examining serum or tissue α-tocopherol levels.[65]

Deficiency of vitamin E is uncommon in humans except in unusual circumstances. In the elderly, conditions resulting in fat malabsorption can cause vitamin E deficiency. The effects of deficiency are widespread throughout the body and include the following:[40,66,67]

- Neuronal degeneration resulting in spinocerebellar ataxia, decreased deep tendon reflexes or areflexia, peripheral neuropathy and posterior column destruction with impairment of proprioception and vibratory sense. This can result in gait disturbance, which is a basic manifestation of vitamin E deficiency.
- Degenerative myopathy.
- Ocular impairment such as retinopathy and extraocular muscle paresis.
- Brown bowel syndrome, a result of lipofuscin deposition and oxidative damage.
- Red blood cell life span reduction.

The effects of long-term supplementation of vitamin E are unclear. Some studies caution against the use of vitamin E in patients with an increased propensity to bleeding or those taking oral anticoagulants. Impaired absorption of fat-soluble vitamins A and K with large vitamin E supplements have been seen in animal models. Necrotizing enterocolitis is seen in infants supplemented with high doses of vitamin E. It may impair the haematological response to iron in children with iron-deficiency anaemia.[40,68,69]

The protective role of vitamin E against cancers seen in observational studies[49,51,70,71] has not been supported by randomized trials. The ATBC Cancer Prevention Study observed a 32% decrease in prostate cancer incidence and a 41% decrease in prostate cancer mortality among men receiving α-tocopherol compared with placebo.[72] A second report from the ATBC study showed a significant 19% reduction in lung cancer risk associated with higher serum vitamin E levels. The reduction in risk was greatest among men younger than 60 years and among patients with fewer years of cumulative smoking exposure.[73] The SELECT trial followed 35 533 relatively healthy men for a median of 5.5 years. Vitamin E supplementation did not prevent prostate cancer in this population.[74] The Physicians' Health Study II did not reveal any benefit of vitamin E supplementation on the incidence of prostate cancer.[75] The HOPE-TOO trial and the Women's Antioxidant Cardiovascular Study found no effect of vitamin E supplementation on cancer incidence or cancer deaths.[76a,77]

Vitamin E supplementation has shown no benefit in both primary and secondary prevention of CHD.[53] In the ATBC study, daily supplementation with vitamin E had no overall effect on stroke risk. However, a subgroup analysis suggested that vitamin E may increase the risk for subarachnoid haemorrhage and decrease the risk for ischemic stroke, particularly in men with hypertension.[78] In the Heart Outcomes Prevention Evaluation (HOPE) trial, daily supplementation with vitamin E had no effect on progression of carotid intimal medial thickness.[76b] The HOPE-TOO trial (ongoing outcomes) showed that vitamin E at 400 IU was associated with an increase in heart failure.[76a] The Health Professionals Follow-up Study showed no association between supplemental vitamin E and stroke risk.[79]

Data from observational studies have suggested that increased dietary intake of vitamin E may have a protective effect against the development of Alzheimer's disease. A longitudinal cohort study found that both vitamin E and C supplementation protected against the development of vascular dementia and improved cognitive function late in life.[80-82] A randomized trial of selegiline, vitamin E, both or placebo among patients with Alzheimer's disease showed that both selegiline and vitamin E were independently associated with significant reductions in several outcomes, including functional decline.[83] A randomized trial of vitamin E supplementation in healthy older women did not reveal any cognitive benefit.[84]

There have been several studies reporting that vitamin E supplementation improves the immune response. However, randomized, placebo-controlled studies have found no reduction in the incidence of respiratory infections in institutionalized or non-institutionalized elderly patients receiving daily vitamin E supplements.[85-89]

A meta-analysis of vitamin E supplementation that did not stratify trials by dose of vitamin E found no significant effect of supplementation on all-cause mortality.[53] However, a recent meta-analysis that examined the dose–response relationship between vitamin E and overall mortality in a total of 19 randomized clinical trials found that vitamin E supplementation with a dose of ≥400 IU per day was associated with a significantly increased risk of all-cause mortality.[90]

Current evidence for vitamin E supplementation is inconclusive. Data at present suggest that high-dose vitamin E (≥400 IU per day) increases all-cause mortality. Also, individuals taking anticoagulants should be particularly advised against high doses of vitamin E because of the synergistic action of vitamin E with these drugs.

Selenium

Selenium, a trace element, is a component of several enzymes, including glutathione peroxidase and superoxide dismutase. Both of these enzymes are important in the prevention of oxidative and free-radical damage to various cell structures. Evidence suggests that the antioxidant protection conveyed by Se operates in conjunction with vitamin E because deficiency of one seems to enhance damage induced by a deficiency of the other.[91] Se is incorporated as selenocysteine at the active sites of multiple selenoproteins. Selenoproteins are also important for thyroid function, muscle metabolism and sperm function, and also immune function.[92]

Dietary sources include vegetables, grains, Brazil nuts, seafoods and organ meats. The amount of Se in plant food is determined by the amount present in the soil. The mechanism of absorption of Se from the gut is unknown.

Dietary Se has a high bioavailability and its absorption from the gut is unregulated.[93,94]

The risk of Se deficiency seems to increase in proportion to age. Also, low levels have been documented in type II diabetes.[92,95] In China, Keshan disease is seen in areas where the soil is poor in Se. It is an endemic cardiomyopathy which improves with Se supplementation. Se deficiency has been reported in individuals on chronic total parenteral nutrition (TPN).[96] Severe deficiency of Se manifests as cardiomyopathy and myopathy.

Toxicity can result from excessive intake. The most common manifestations are hair and nail loss. Other manifestations include nausea, emesis, tooth lesions, mental status changes and peripheral neuropathy.[97,98]

The potential protective effect of Se status on the risk of developing cancer has been examined in animal and epidemiological studies. Low levels of dietary Se are associated with a greater risk of prostate, oesophageal, colon and antral gastric cancers.[93,99–101] There have been studies evaluating the effect of Se on cancer-related chemotherapy. A study assessing the *in vitro* effects of Se on chemotherapy revealed that the addition of Se enhanced drug-mediated cancer cell death. In another study, the addition of dietary Se at the beginning of chemotherapy prevented the development of resistance to cisplatin.[102,103]

The antioxidant properties of Se have been linked to a lower incidence of cardiovascular disease in humans. However, the therapeutic benefit of Se administration in the prevention and treatment of cardiovascular diseases still remains controversial.[104,105]

Se deficiency has been associated with impaired cell-mediated immunity and enhanced activity of natural killer cells.[106,107] Studies on the coxsackievirus and influenza virus by Beck and co-workers[108,109] have shown that Se prevented the genomic conversion of a non-virulent strain into a virulent strain that occurred in the presence of Se deficiency in mice. These effects of Se may have considerable implications on the elderly population, especially in the institutional setting.

Vitamin C

Vitamin C (ascorbic acid) is a water-soluble vitamin widely found in citrus fruits, raw leafy vegetables, strawberries, melons, tomatoes, broccoli and peppers. Humans cannot synthesize vitamin C and a deficiency results in scurvy. The amount present in food consumed, however, depends on the season of the year, the transportation time to the store, the shelf time before purchase, the form of storage and the method of cooking. Boiling can cause a 50–80% loss of vitamin C. Cooking with minimal water or microwaving food reduces losses.[32,67]

Vitamin C is absorbed in the distal small intestine through an energy-dependent process. Blood concentrations of ascorbic acid are regulated by renal excretion. The greatest concentrations of ascorbic acid are found in the pituitary, adrenal, brain, leukocytes and the eye. Its absorption does not seem to be affected by age. The bioavailability of vitamin C is inversely related to the amount ingested and also the form. Sustained release tablets allow higher absorption than standard pills. It is a reversible biological reductant and provides reducing equivalents for a number of biochemical reactions involving iron and copper. It therefore functions as a cofactor, enzyme complement, cosubstrate or a strong antioxidant in a variety of reactions and metabolic processes.[10,110–113]

Vitamin C has multiple functions. It is an antioxidant and reduces harmful free radicals. It is purported to be an immune enhancer and is known to be crucial to collagen synthesis and to norepinephrine synthesis. The conversion of iron from the ferric (+3) to the ferrous (+2) form requires vitamin C. Without this conversion, methaemoglobin could not be converted to haemoglobin and iron could not be absorbed in the duodenum. Vitamin C is also involved in the reduction of nitrates, a function that possibly is involved in stomach cancer. Vitamin C has a role in prostaglandin and prostacyclin metabolism. It may be capable of attenuating the inflammatory response or even sepsis syndrome.[67,114–116]

Vitamin C deficiency is common in many frail elderly populations. Because vitamin C is supplied only by diet, deficiency is caused by insufficient dietary intake.[10,117–119] Deficiency primarily affects the musculoskeletal and haematopoietic systems. Deficiency results in the following:[67]

- Reduced collagen cross-linking and therefore decreased collagen tensile strength, leading to impaired wound healing and to weakened blood vessels.
- Haemostasis abnormalities occur, producing painful subperiosteal haemorrhages, haemarthrosis, haemorrhagic perifolliculitis, gingival bleeding, ecchymoses, petechiae and nail bed splinter haemorrhages. Some of these manifestations are common in elderly persons and are usually attributed to age-related physiological changes and not to vitamin deficiency.
- Structurally abnormal collagen that produces structurally abnormal osteoid, which produces structurally abnormal bone.
- Scurvy, which is the clinical syndrome produced by deficiency and develops after intake of less than 10 mg per day for 3–6 months. Scurvy includes the previously mentioned physical findings plus the development of corkscrew hairs, glossitis, gingival hyperplasia and bleeding and poor dentition caused by periodontitis and loss of teeth. Iron-deficiency anaemia can also occur. Terminal features include icteris, oedema, hypotension and convulsions.

There have been some reports of excessive use of vitamin C as a risk factor for calcium oxalate nephrolithiasis.

However, a prospective epidemiological study demonstrated that consumption of high doses of vitamin C lowered the relative risk of calcium oxalate stones compared with 250 mg or less of vitamin C per day. Ingestion of large quantities of vitamin C has been rarely associated with fatal cardiac arrhythmias in patients with iron overload, presumably due to oxidative injury. Vitamin C toxicity has been associated with diarrhoea and abdominal bloating. High doses are also associated with false negative guaiac tests and they also alter the results of glucose measurements.[116,120–122]

A large, randomized trial of vitamin C for secondary prevention of CHD found no benefit of supplementation with vitamin C. The Health Professionals Follow-up Study showed no association between supplemental vitamin C and stroke risk. Prospective data from the Nurses' Health Study showed a 45% reduction in the risk of cataract requiring extraction in women using vitamin C supplements for at least 10 years. In contrast, a randomized, placebo-controlled study of high-dose supplementation with vitamins C and E and β-carotene found no reduction in the 7 year risk of development or progression of age-related lens opacities with vitamin C supplementation.[53,79,123,124]

Riboflavin

Riboflavin or vitamin B_2 is an important component of the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). It is involved in an array of biochemical reactions. It is important for oxidative phosphorylation, ATP production and the production of reduced glutathione, which is an antioxidant. Vitamin B_2 has been implicated in a signal transduction role for programmed cell death and regulation of a number of other important intracellular pathways. Dietary sources include dairy products, green leafy vegetables, whole and enriched grains, meats, liver, poultry and fish. It is not destroyed by heat, oxidation or acid but is susceptible to ultraviolet light and alkalis.[67,125]

Riboflavin is released by proteolysis from the ingested food and undergoes passive absorption from the intestinal lumen. It then enters the hepatic cells and undergoes conversion to FAD and FMN. Like other B vitamins in this class, stores are minimal and regulated replacement is necessary through food or supplements.

Vitamin B_2 deficiency is regarded as the most common vitamin deficiency in the United States; it is usually seen in conjunction with other B vitamin deficiencies. There is some evidence that the requirements for riboflavin may increase with ageing and that the glutathione reductase activity declines with ageing. Plasma riboflavin concentrations tend to reflect recent dietary intake. Erythrocyte glutathione reductase assay is a better test for riboflavin deficiency; it is not valid, however, in individuals with glucose 6-phosphate dehydrogenase deficiency.[15,91,125]

Deficiency may be secondary to inadequate dietary intake or a result of chronic diarrhoea, alcoholism or liver disease. Deficiency may manifest as the following:[67,91,125]

- cheilosis
- magenta-coloured glossitis
- inflammation of the oral mucosa
- seborrheic dermatitis
- normocytic normochromic anaemia
- corneal revascularization.

Vitamin B_2 supplementation helps only in the prevention of deficiency. A small randomized controlled trial has shown some benefit of supplementation with a very large dose in the prevention of migraine.[67,126]

Vitamin D

Vitamin D, or calciferol, is a generic term and refers to a group of lipid-soluble compounds with a four-ringed cholesterol backbone. Vitamin D is not a true vitamin, because humans are able to synthesize it with adequate sunlight exposure. By photoconversion, 7-dehydrocholesterol becomes previtamin D_3, which is metabolized in the liver to 25-hydroxyvitamin D3, the major circulating form of vitamin D. In the kidneys, this is converted to two metabolites, the more active one being 1,25-dihydroxyvitamin D_3. It is derived primarily via synthesis in the skin. Dietary sources include fortified milk, milk products, oily fish, egg yolks and fortified foods.[32,40,67]

Vitamin D is absorbed in the form of micelles by the intestinal epithelium to form chylomicrons. Chylomicrons enter the liver via the portal circulation where vitamin D undergoes a hydroxylation process by 25-vitamin D hydroxylase to form 25-hydroxyvitamin D (calcidiol). Further hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D [1,25$(OH)_2$-vitamin D or calcitriol] occurs in the mitochondria of the proximal tubules of the kidney. Vitamin D from any source and in either form is absorbed into the circulation and bound to vitamin D-binding protein. Calcitriol, the biologically active form, has a short half-life of 4–6 h and therefore does not accurately reflect body stores, whereas calcidiol has a longer half-life of 3 weeks. Hence calcidiol is more widely used to measure vitamin D status. Laboratory measurements reflect both vitamin D_2 and vitamin D_3 status. Deficiency is defined as a calcidiol level below 15 mg dl^{-1}.[40,67,127–129]

Increased age is a risk factor for vitamin D deficiency. Several studies have shown that the levels of calcitriol are lower in older people.[3,130] Calcidiol was shown to decline with age in a longitudinal study by Perry *et al*.[131] Factors resulting in low circulating levels in the elderly include the following:

- inadequate intake of vitamin D due to decreased intake of dairy products in their diets;
- decreased ability to form previtamin D_3 in the skin upon ultraviolet light exposure secondary to decreased amounts of 7-dehydrocholesterol levels in the skin with advancing age;
- decreased synthesis of 1,25-dihydroxyvitamin D by the kidney;
- medications interfering with vitamin D metabolism.

Deficiency of vitamin D can result in the following biochemical and physical manifestations:[67]

- low calcium and phosphorus levels and elevated alkaline phosphatase levels;
- secondary hyperparathyroidism;
- osteomalacia;
- fractures;
- neuromuscular irritability;
- proximal myopathy, deep proximal musculoskeletal pain, neuropathy and hyperaesthesia.

Vitamin D excess is associated with hypercalcaemia, hypercalciuria, confusion, polyuria, polydipsia, anorexia, vomiting, muscle weakness and bone demineralization with pain.[40]

A prospective, population-based study showed that lower calcidiol and higher PTH levels increased the risk of sarcopenia in older men and women.[132a] In a case–control study of community-dwelling women, low serum calcidiol concentrations were associated with a higher risk for hip fracture.[132b] Several studies have shown decreased risk of falls in both ambulatory and institutionalized elderly people receiving vitamin D supplementation. However, these studies revealed that the reduction in fall risk is dose dependent and doses lower than 600 IU per day do not reduce the risk for falls.[133,134] A systematic review and meta-analysis of vitamin D supplementation in older adults found that the relative risk of fall was 0.86 (95% CI 0.79–0.93) for those assigned to vitamin D therapy (200–1000 units) compared with placebo. This study included 10 trials in both community and institutional settings in which the fall outcome was explicitly defined.[135] A recent randomized controlled trial using high-dose oral vitamin D supplementation in community-dwelling older women showed an increased incidence of falls in the first 3 months following supplementation.[136] A number of trials have reported a beneficial effect of calcium or calcium plus vitamin D on bone density in postmenopausal women and older men. The data on vitamin D supplementation and fracture rates are more variable.[137–142] A subgroup analysis of the Women's Health Initiative Study revealed that calcium and vitamin D supplementation was associated with reduced fracture incidence in those subjects who were most compliant.

Current evidence, mainly from observational studies, reveals a link between vitamin D supplements and other disease states. Observational studies in humans suggest a link between poor vitamin D status and the risk of nearly all cancers.[143,144] However, the association of vitamin D status with cancer appears to be greatest with colon cancer.[145,146] Also, data from case–control studies indicate a reduced risk of type 1 diabetes with vitamin D supplementation.[147] The Women's Health Initiative Study, revealed an association between higher total vitamin D intake and lower risk for type 2 diabetes.[148] The association of vitamin D status with cardiovascular outcomes has revealed an inverse relation between calcidiol and cardiovascular disease.[149] Low levels of calcidiol have frequently been noted in patients with Alzheimer's disease. In one study, low levels of vitamin D were associated with an increased risk of cognitive decline.[150] At the present time, there is insufficient evidence supporting vitamin D supplementation for prevention or treatment of cancer, diabetes, cardiovascular diseases or cognitive decline.

The daily intake of vitamin D in older adults should be at least 800 IU with at least 1200 mg of elemental calcium in the diet or as a supplement.[40] This is particularly important in the elderly individuals who are unable to expose themselves to sunlight, since a large part of the daily requirements are met by skin synthesis.

Vitamin K

Vitamin K occurs in two naturally occurring forms, phylloquinone found in plants and menaquinones synthesized by the gastrointestinal flora. Vitamin K produced by the gut flora is thought to provide up to 50% of the requirement in humans. Vitamin K is found in various food sources, including green leafy vegetables, vegetable oils and liver[67,151]

Vitamin K is a fat-soluble vitamin absorbed by the intestinal epithelium in the form of micelles. It is then incorporated in chylomicrons and enters the liver via the portal circulation. Within the body, the stores are relatively small. They are mostly hepatic; however, the trabecular and cortical bone also contain substantial concentrations.[40,151]

Vitamin K is an important cofactor for the endoplasmic enzyme γ-glutamylcarboxylase. This enzyme acts as a catalyst for the carboxylation of glutamate to γ-carboxyglutamate. This is an important step for the activation of several coagulation factors within the hepatic cells. It thus plays a central role in blood coagulation, by activating factors II, VII, IX and X. It is also needed for the activity of the natural anticoagulants proteins C and S.[40,67,151]

Deficiency of vitamin K in healthy adults is uncommon because of the widespread distribution of the vitamin in Nature, its recycling within the cells and its synthesis by the gastrointestinal flora. Deficiency can be seen in the following conditions:[40,67,151,152]

- prolonged antibiotic therapy, which disrupts the gastrointestinal flora;
- parenteral nutrition;
- disorders associated with fat malabsorption;
- medications such as anticonvulsants, high doses of vitamins A and E, warfarin;
- starvation.

Deficiency results in prolongation of the prothrombin time and partial thromboplastin time and signs and symptoms of bleeding such as easy bruisability, splinter haemorrhages, mucosal bleeding, melena and haematuria.[40,63,67,151,152] Studies have shown an increase in the incidence of hip fractures in the elderly. There have been studies showing a decrease in bone mineral density in hemiplegic limbs of vitamin D deficit stroke patients.[153,154]

Toxicity associated with excess doses is rare; it can, however, cause haemolytic anaemia and jaundice in infants. Doses greater than 150 μg per day from food supplements can interfere with anticoagulation in patients on warfarin.

Folate

Folates represent a group of related pterin compounds. More than 35 forms of the vitamin are found naturally. The term folic acid is derived from the Latin word *folium*, which means leaf. The pharmacological form is folic acid; it is more bioavailable and does not exist in Nature in this form. The various dietary sources include green leafy vegetables, fresh fruits, yeast, liver and other organ meats. Folate in foods is destroyed by excessive cooking; as much as 95% may be destroyed.[10,67,155]

Folate is required for the transfer of single carbon groups; it is essential in the *de novo* synthesis of nucleotides and metabolism of several amino acids. It is an important component for the regeneration of the 'universal' methyl donor *S*-adenosylmethionine. In the body, homocysteine is remethylated into methionine. The process of remethylation requires folate and cobalamin (vitamin B_{12}). In the presence of folate deficiency, homocysteine levels are elevated.[67,155]

The luminal enzymes convert the polyglutamate forms of folate present in the dietary sources to the monoglutamate and diglutamate forms. Folate is then absorbed from the lumen of the small intestine by both active and passive absorption. In the plasma, folate is present as 5-methyltetrahydrofolate; it is bound loosely to albumin, from which it is readily taken up by the high-affinity folate receptors present on cells throughout the body. Folates undergo enterohepatic circulation and are thus reabsorbed from the gut; they also undergo urinary excretion.[67,155]

Studies have revealed that folate deficiency may range from 2.5 to 34% among elderly persons. Folate deficiency occurs within a few days of insufficient intake; however, clinical signs of deficiency develop after ~4 months of decreased intake. Folate deficiency can be determined on the basis of decreased serum folate levels; however, red cell folate level may be a better indicator if there has been a recent dietary change. Factors responsible for deficiency in the elderly include the following:[10,15,67,155]

- inflammatory diseases of the gastrointestinal tract;
- atrophic gastritis;
- part of generalized malnutrition;
- poor oral intake;
- excessive alcohol intake;
- smoking;
- medications such as cotrimazole, methotrexate, triamterene, phenobarbital and phenytoin.

Folate deficiency can result in megaloblastic anaemia, leukopenia, thrombocytopenia, anorexia, fatigue, delirium, diarrhoea, glossitis and hyperhomocysteinaemia.

Current evidence suggests that high dietary intake of folate is associated with a decreased risk of developing colorectal cancer in both men and women. Data from the Nurses' Health Study reveal a protective effect of high dietary intake of folate on the development of breast cancer. There was a normalization in the risk of breast cancer associated with concurrent alcohol use.[156–158]

Folate deficiency is associated with hyperhomocysteinaemia. Homocysteine is prothrombotic and atherogenic. It causes vascular injury characterized by thickened vascular intima, disruption of the elastic lamina, smooth muscle hypertrophy, platelet aggregation and the formation of platelet-rich occlusive thrombi.[159,160] In a multicentre case–control study by Robinson *et al.*,[161] lower levels of folate and vitamin B_6 conferred an increased risk of atherosclerosis. The increased risk was explained partly by an elevated homocysteine level. In the Health Professional Follow-up Study, increased folate intake was associated with a decreased risk of ischaemic stroke in men.[162] In another study, an inverse association between a high-folate diet and coronary heart disease was found to be strongest among women who consumed up to one alcoholic beverage per day.[163] Data also suggest that there may be a correlation of high homocysteine levels with osteoporotic fractures and dementia.[164–166]

Vitamin B_{12}

Vitamin B_{12} is a group of cobalamin compounds that have a corrin ring with a cobalt atom at the centre. The corrin ring is connected through an aminopropanol bridge to a ribonucleotide. Dietary sources of vitamin B_{12} include meat and dairy products. It is an important cofactor for the enzymes methionine synthase and methylmalonyl-coenzyme A (CoA) mutase. It is essential for the synthesis of succinyl-CoA from methylmalonyl-CoA. Vitamin B_{12} serves as a cofactor in the conversion of 5-methylenetetrahydrofolate (5-methylene-THF) to THF (the active form of folate); during this reaction, the methyl

group is donated to cobalamin, forming methylcobalamin. Methylcobalamin then donates its methyl group to homocysteine to form methionine. The synthesis of methionine is essential for purine and pyrimidine synthesis, methylation reactions and the intracellular retention of folates. A deficiency of cobalamin leads to an increase in homocysteine and methylmalonic acid.[155,167]

Cobalamin is released from the food by the gastric enzymes and bound to R-binding proteins. Further, enzymatic degradation occurs in the small intestine and it then becomes bound to the intrinsic factor (IF). The vitamin B_{12}–IF complex is then absorbed in the ileum and stored in the liver. It is transported through the body attached to the protein transcobalamin II. Vitamin B_{12} undergoes enterohepatic circulation and most of it is reabsorbed from the bile.[10]

The prevalence of vitamin B_{12} deficiency ranges from 4 to 43%. The levels of vitamin B_{12} have been found to decline at the rate of 3.4 pmol l^{-1} annually. Vitamin B_{12} deficiency may be seen in the elderly population as documented by elevated methylmalonic acid with or without elevated total homocysteine concentrations in combination with low or low-normal vitamin B_{12} concentrations. Owing to the long half-life and hepatic stores of vitamin B_{12}, deficiency secondary to inadequate intakes takes 2–6 years to develop. Deficiency is seen in individuals with atrophic gastritis, total gastrectomy, pernicious anaemia (which may be seen in up to 5% of those aged 80 years and above in some populations), terminal ileal resection, bacterial overgrowth of the bowel, drug use such as prolonged use of H-2 antagonists, colchicines and aminosalicylic acid and practice of strict vegetarianism.[10,15,67]

Deficiency can result in the following:[67,155]

- increased homocysteine levels;
- increased methylmalonic acid levels;
- megaloblastic anaemia;
- neurological syndrome manifested as

  i peripheral neuropathy with paresthesias and decreased vibratory sensation, which may progress to ataxia, weakness and an inability to walk; it affects both the dorsal and lateral spinal cord columns and is termed *subacute combined degeneration*;

  ii impaired mentation, memory loss and depression. This syndrome may occur without evidence of anaemia and may not be associated with macrocytic erythrocytes.

Current evidence suggests an increased risk of cardiovascular disease associated with elevated homocysteine levels. Vitamin B_{12}, folate and vitamin B_6 are needed for homocysteine metabolism and deficiency results in elevated levels of homocysteine. Although studies have shown a decreased risk of cardiovascular disease with high levels of folate and vitamin B_6, this has not been shown with vitamin B_{12} supplementation.[32,168]

In a study by Lindenbaum *et al.*,[169] neuropsychiatric disorders due to cobalamin deficiency were seen in the absence of anaemia or an elevated mean cell volume. They recommended measuring serum methylmalonic acid and total homocysteine, both before and after treatment for diagnosis in these patients.

Vitamin B_{12} supplementation should be considered in the elderly and at-risk individuals.

Vitamin B_6

Vitamin B_6 comprises various derivatives of pyridine, including pyridoxine, pyridoxal and pyridoxamine. As a coenzyme, vitamin B_6 is involved in many transamination reactions. It is required for the synthesis of niacin from tryptophan. Vitamin B_6 is involved in the synthesis of several neurotransmitters [γ-aminobutyric acid (GABA), serotonin and norepinephrine] and δ-aminolevulinic acid (and therefore in haem synthesis). Dietary sources include meats, whole grains, vegetables and nuts.[67,91,170]

Pyridoxine-5′-β-D-glucoside is the major, naturally occurring form of vitamin B_6. It undergoes hydrolysis in the intestine and is absorbed by diffusion from the lumen of the small intestine. Vitamin B_6 is not stored and cannot be synthesized. Dietary intake therefore provides the metabolic requirements.[170]

Dietary deficiency is rare; however, there is evidence that the requirements are increased in the elderly. Deficiency may result from alcoholism, malabsorption and high-energy states such as dialysis. Medications such as isoniazid, hydralazine, cycloserine, penicillamine, ethanol and theophylline act as pyridoxine antagonists.[3,67]

Vitamin B_6 deficiency usually occurs in association with deficiencies of other water-soluble vitamins. Deficiency can be diagnosed by assessing plasma or erythrocyte pyridoxal-5-phosphate (PLP) levels. Manifestations of deficiency include the following:[67,91,170]

- stomatitis, angular cheilosis, glossitis;
- irritability, depression and confusion, occurring in moderate to severe depletion;
- normochromic, normocytic anaemia that has been reported in severe deficiency;
- abnormal electroencephalograms, convulsions and peripheral neuropathy.

Long-term use with doses exceeding 200 mg per day (in adults) may cause peripheral neuropathies and photosensitivity.[91]

Elevated homocysteine levels are associated with an increased risk of cardiovascular disease. Vitamin B_6 deficiency is associated with elevated homocysteine levels; low levels of vitamin B_6 may be independently associated with CHD.[168,171] In a case–control study, lower levels of folate and vitamin B_6 were associated with an increased risk of atherosclerosis.[161] The Nurses' Health Study found an

inverse association between higher dietary intakes of folate and vitamin B_6 and CHD.[163] There is evidence of a lower risk of breast cancer in women with higher plasma levels of vitamin B_6.[172] In another study, vitamin B_6 supplementation in the elderly resulted in improvement of long-term memory by improving storage of information.[173]

Zinc

Zinc is a divalent trace metal that plays a critical role in protein synthesis. It also serves as a cofactor, catalyst or a part of several enzymes. It is involved in the synthesis of nucleic acids and gene regulation. Zinc is required for the maintenance of genetic stability and gene expression and for controlling differentiation, proliferation, maturation and programmed cell death. It is essential for the maintenance of plasma membrane integrity. It may have antioxidant and antiatherogenic properties.[27,174,175]

Dietary sources of zinc are red meat, seafood, fresh fruit, vegetables and dairy products. During the process of digestion, zinc is released from these dietary sources. It is primarily absorbed in the jejunum. Its absorption is inhibited by phytates present in many staple foods. Metallothionein, present in the gut enterocyte, is responsible for the homeostatic control of zinc absorption. About 90% of the total body zinc stores are in bone and skeletal muscle. It undergoes enterohepatic circulation. Excretion is mainly faecal, with small amounts being excreted in the urine.[27,92,94]

Data available at present are insufficient to determine the frequency of zinc deficiency in the elderly. Deficiency may be seen with poor dietary intake, inflammatory processes, malabsorption, chronic diarrhoea, sickle-cell anaemia, diabetes, cirrhosis of the liver, thiazide diuretics, lung cancer, following thermal injury, in drug addiction and renal injury.[175,176] Low zinc levels seen in inflammatory conditions result from redistribution of zinc, an action mediated by cytokines. Serum and plasma levels of zinc do not correlate with tissue levels and are not reliable indicators.[27,92,94,175,176] Manifestations of deficiency in the elderly may be subtle; they include the following:

- Impaired immune response. Ageing is associated with an altered T-cell response. Zinc has been identified as a potent T-lymphocyte mitogen. Studies have revealed a beneficial effect of zinc supplementation of immune function.[177–181]
- Anorexia resulting from impaired taste and smell. Several mechanisms have been hypothesized to result in anorexia; however, the relationship between zinc status and anorexia still remains unclear.[182]
- Confusion, irritability and restlessness. Acrodermatitis enteropathica (AE) is an autosomal recessive inherited disease. The manifestations of AE are thought to occur secondary to zinc deficiency. Confusion and apathy in affected children respond to zinc supplementation. Also, zinc deficiency induced in humans may be associated with irritability or apathy, which is reversed with zinc supplementation. However, data on the role of zinc deficiency on mental status in the elderly are limited.[92,183]
- Impaired wound healing. Studies have shown impaired wound healing of pilonidal sinuses and venous leg ulcers in patients with low serum zinc levels.[184,185] Current data on zinc supplementation for pressure ulcers are controversial.
- Diarrhoea has been reported in patients who develop severe zinc deficiency during total parenteral nutrition therapy. There have been no randomized studies on zinc supplementation in the elderly with diarrhoea.[92,186]
- Impaired vision. In a study by Keeling *et al.*,[187] adaptation to darkness was impaired in cirrhotics with low neutrophil zinc concentrations.
- Epidermal abnormalities characterized by skin lesions around body orifices and the extremities as seen in AE. In a study of institutionalized patients with skin lesions and low zinc levels, there was no improvement in skin lesions following supplementation with zinc.[188]
- Impaired spermatogenesis and testosterone steroidogenesis resulting in impaired testicular function. In one study, individuals on a zinc-deficient diet developed decreased libido, depressed serum testosterone levels and marked reduction in sperm count. Hydrochlorothiazide-induced sexual dysfunction associated with low zinc levels may respond to zinc supplementation in some individuals.[92,189,190]
- Disruption of vascular endothelium with possible implications for atherosclerosis.[175]

The Health Professionals Follow-up Study found that zinc supplementation, if taken in doses greater than 100 mg daily or for 10 or more years, was associated with increased risk of developing prostate cancer.[191] Zinc toxicity is relatively unusual; however, high dietary intake may cause nausea, vomiting, epigastric pain, lethargy and fatigue. Immune response may be impaired. It can cause hypocupraemia, macrocytosis or neutropenia.[27]

Copper

Copper plays a significant role in several enzymatic pathways. Some of these enzymes include monoamine oxidase, dopamine-β-hydroxylase, cytochrome *c* oxidase, ferroxidase II, superoxide dismutase and lysyl oxidase. Copper plays an important role in iron absorption and mobilization to sites of erythropoiesis. Copper is essential for inactivation of catecholamines, synthesis and cross-linking of collagen and the conversion of dopamine to norepinephrine.[92,192,193]

The various dietary sources for humans are legumes, nuts and meats.[94] A study by Ma and Betts[194] revealed less than recommended intakes of copper by the elderly. Individuals at risk for copper deficiency include patients

with chronic diarrhoea, those on chronic TPN and those on chronic peritoneal dialysis.[94] Deficiency can be seen in individuals on high-dose oral zinc supplementation. Serum copper levels are used to assess copper status. These levels, however, are affected by inflammation and hormonal status. Ceruloplasmin, the copper-binding protein, is an acute phase reactant. Serum copper levels therefore increase during stress and inflammation.[92] Serum copper levels increase with ageing; however, there is no change in the leukocyte copper levels. Advancing age is also associated with an increase in ceruloplasmin.[192]

Dietary copper is absorbed from the upper gastrointestinal tract (from the stomach to the distal small bowel). Bioavailability is affected by dietary fibre and protein content and the ingestion of other minerals such as zinc. Copper undergoes enterohepatic circulation and only small amounts are excreted in the urine. Portal flow delivers histidine-bound and albumin-bound copper to hepatocytes. Release into the systemic circulation is primarily via the specific transporter known as *ceruloplasmin*.[92,193]

The classic manifestations of copper deficiency can be seen in the congenital disorder Menkes syndrome. It is characterized by eating difficulties, hypothermia, seizure activity, 'steel wool' hair, cerebellar ataxia, profound arteriopathy and early death. Copper deficiency may present as follows:[195-198]

- anaemia, leukopenia and neutropenia; anaemia is unresponsive to iron supplementation;
- hypopigmentation;
- immune dysfunction;
- skeletal abnormalities;
- increased cholesterol with atherosclerosis;
- neurological problems such as Alzheimer's disease.

Copper metabolism seems to be conserved with ageing. Although older individuals ingest smaller amounts than younger individuals, they are able to maintain a metabolic balance.[193]

Severe copper toxicity can result in hepatic necrosis, coma, oliguria, renal failure, hypotension and even death. Mild gastrointestinal symptoms such as nausea, vomiting and abdominal pain can occur in less acute and less serious toxic conditions.[94]

Chromium

Chromium, an essential trace element, was first identified as the glucose tolerance factor which corrected hyperglycaemia in rats.[199] Glucose tolerance factor is a combination of chromium and nicotinamide. Chromium functions as a coenzyme and is also a component of metalloenzymes.[200] Low chromium levels may be seen in some diabetic patients and it may have a role in glucose homeostasis.[201,202] Data suggest that chromium may augment the production and binding of insulin to the receptors.[203] Other data suggest that chromium may have a role in elevating high-density lipoprotein (HDL) and lowering overall cholesterol levels).[204]

Dietary sources of chromium include brewer's yeast, cereals, fruits, vegetables, grains and processed meats.[94,192] Chromium is absorbed in the small intestine and its absorption is determined by the total body chromium concentration. Its absorption is enhanced in the presence of zinc and iron deficiency.[94,205] Vitamin C also enhances its absorption. Non-steroidal anti-inflammatory drugs (NSAIDs) and antacids decrease its absorption.[206,207]

Chromium deficiency is seen in individuals on total parenteral nutrition. Tissue chromium levels decline with age and urinary excretion increases.[94,192] Chromium deficiency has been associated with the following:[92]

- glucose intolerance with peripheral insulin resistance;
- altered lipid metabolism;
- neuropathy;
- encephalopathy.

Chromium toxicity has been described in a patient on chromium supplements who presented with renal insufficiency, elevated liver enzymes, anaemia and thrombocytopenia. Discontinuation of the supplement and supportive measures resulted in normalization of all laboratory values within 1 year. Attention to the use of over-the-counter (OTC) nutritional supplements is important, especially in the elderly.[208]

Table 19.5 summarizes the functions of various vitamins and trace metals and the effects of ageing on these micronutrients.

Conclusion

It is important to maintain adequate intake of micronutrients to maintain health. Data suggest that vitamin and mineral deficiencies exist in the elderly; these are exacerbated during hospitalization, hypermetabolic states, alcohol use, liver disease, diuretic use and laxative abuse. Observational data suggest a link between dietary micronutrient intake and health outcomes. However, randomized control trials have not supported the use of vitamin and mineral supplements among well-nourished individuals. Food still remains the best vehicle for nutrient consumption. The elderly are at great risk of toxicity, with a greater potential for drug–nutrient interactions. Other concerns in the elderly include cost and convenience of administration. The use of vitamin and mineral supplements as anti-ageing treatments or as treatments for specific diseases in the elderly is not supported by the currently available scientific data. Education and counselling are important in this age group in order to maintain adequate nutrient intake via methods that are both convenient and affordable.[6,209]

Table 19.5 Micronutrient functions and the effects of ageing on these micronutrients.

Micronutrient	Function	Effect of ageing
Vitamin A	Prevention of xeropthalmia, phototransduction, cellular differentiation and integrity	Intake decreases with ageing, retinol levels correlate poorly with vitamin A status. Hepatic levels appear unchanged
Vitamin D	Calcium and phosphorus homeostasis	Decreased levels of 1,25-dihydroxyvitamin D
Vitamin E	Antioxidant and free-radical scavenger, stabilization of cell membranes	Unknown
Vitamin K	Central role in blood coagulation	Unknown
Vitamin B_1 (thiamine)	Oxidative decarboxylation of α-keto acids and *trans*-ketolase degradation	Decreased thiamine levels
Vitamin B_2 (riboflavin)	Acts with its coenzymes flavin mononucleotide and flavin adenine dinucleotide in oxidation–reduction reactions	Erythrocyte glutathione reductase activity declines with ageing
Vitamin B_3 (niacin)	Dehydrogenase reactions as a coenzyme for nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate	Probably decrease with ageing
Vitamin B_6 (pyridoxine)	Cofactor for intermediary metabolism	Pyridoxal phosphate levels decline
Folate	Single carbon atom transfer in intermediary metabolism	Unknown
Vitamin B_{12} (cobalamin)	Metabolism of fatty acids and methyl transfer	Levels decrease with ageing
Vitamin C (ascorbic acid)	Antioxidant and reduces harmful free radicals. Important for collagen and norepinephrine synthesis	Levels decrease with ageing
Arsenic	Urea cycle, myocardial muscle function and triglyceride synthesis	Unknown
Boron	Bone structure, mineral metabolism	Unknown
Chromium	Glucose homeostasis, lipid metabolism	Decrease
Cobalt	Erythropoiesis and triglyceride synthesis	No change
Copper	Cholesterol metabolism, erythropoiesis, collagen cross-linking, conversion of dopamine to norepinephrine, electron transport chain, coagulation factor V	Increase in serum, decrease in saliva, hair and heart
Fluoride	Bone structure and tooth enamel	Increase up to age 60, then decline in skeleton
Iodine	Thyroid hormones	Increase in serum after age 45
Lead	Uncertain	Unknown
Lithium	Endocrine secretory functions	Unknown
Manganese	Protein and energy metabolism, mucopolysaccharides	No change in serum, reduced in kidney and heart
Molybdenum	Uric acid production, oxidation of sulfite to sulfate	Unknown
Nickel	RNA and DNA structure, membrane stabilization, iron absorption and metabolism, pituitary function	Increase in lungs
Selenium	Constituent of glutathione peroxidase, T and B cell function, muscle metabolism	Decrease
Silicon	Bone and connective tissue structure	Decrease in aorta and skin
Tin	Induces haemoxygenase and carbon monoxide production	Increased in Alzheimer's disease
Vanadium	Cholesterol synthesis, catalysis of oxidation–reduction reactions	Unknown

Key points

- The elderly are at increased risk of undernutrition as a result of multiple factors such as physiological anorexia of ageing, physiological changes affecting digestion, absorption and metabolism of nutrients, social isolation, chronic diseases, sensory impairment, cognitive impairment, depression and polypharmacy.
- There is an overall lack of evidence on the nutritional needs of the elderly, with a particular lack of data from clinical trials.
- Vitamin disorders present atypically or are masked by coexisting diseases or a general failure to thrive.
- Vitamin preparations are consumed on a daily basis by 20–60% of the elderly and drug–nutrient interactions are common in this population because of the high incidence of polypharmacy.
- The use of vitamin and mineral supplements as anti-ageing treatments or as treatments for specific diseases in the elderly is not supported by the currently available scientific data.

CHAPTER 20

Obesity

Joan Khoo[1], Richard Y.T. Chen[1] and Gary A. Wittert[2]

[1]Changi General Hospital, Singapore
[2]University of Adelaide, Adelaide, Australia

Age-related changes in body composition

At different ages, the same level of body mass index (BMI), calculated as $kg\,m^{-2}$, corresponds to different amounts of fat and fat-free mass. With age, whole-body fat mass (FM) remains relatively stable but increases as a percentage of body weight due to decreased lean mass, whereas both percentage and absolute abdominal fat mass increase. Fat mass peaks at age 60–75 years, whereas muscle mass and strength start to decrease at age 30 years, with accelerated loss occurring after ~60 years of age.[1] In addition, there tends to be a redistribution of fat viscerally and inter- and intra-myocellular fat increases. A number of factors are associated with the age-related changes in body composition. There is a decrease in overall energy expenditure and a significant component of this change relates to decreased physical activity. The decrease in skeletal muscle mass is a consequence of reduced physical activity, increases in pro-inflammatory cytokines (e.g. interleukin-6 and tumour necrosis factor-α) and decreased production or resistance to the actions of anabolic hormones.[1] Visceral obesity, which results in an increase in inflammatory cytokines and a decrease in anabolic hormone levels, is associated with insulin resistance. Intramuscular fat infiltration is associated with both increased insulin resistance and accelerated loss of skeletal muscle strength.[2] Reduced growth hormone and testosterone levels in obese older people have been associated with decreased muscle mass and strength.

Energy expenditure

Age-related decreases in energy expenditure are primarily due to decreased physical activity and reduction in resting metabolic rate (RMR). The decline in RMR with age is not entirely attributable to the reduction in fat-free mass (FFM), as RMR in people aged 60 years and above is lower than that of younger individuals after adjusting for FFM, fat mass and gender. In an 8 year longitudinal study of men and women >60 years of age in Germany, the reduction in RMR per decade was 5% in men and 3% in women after adjusting for body composition, and physical activity energy expenditure also decreased, resulting in a reduction in total energy expenditure per decade of 7.5% in men and 6% in women.[3] In the Baltimore Longitudinal Study of Aging, RMR decreased with age in both men and women independently of BMI, and the rate of decline was faster at age 70–80 than at age 40–50 years.[4]

The thermic effect of food (TEF), which is the increase in energy expenditure in response to macronutrient intake and accounts for up to 10% of total energy expenditure, declines with ageing. The TEF after a glucose load has been found to be ~50% less in healthy men aged 54–75 years than in men aged 19–36 years.[5] Furthermore, TEF was higher in men who habitually exercised than their sedentary counterparts in both age groups.[5] This suggests an additional mechanism by which regular physical activity may prevent obesity in the elderly. Although obese elderly people have lower basal fat oxidation (adjusted for FFM) than younger individuals, 24 h fat oxidation during exercise is higher in normally sedentary older (65 years) men than younger (25 years) men after adjusting for FFM,[6] suggesting that the reduction in nutrient utilization in the obese elderly is largely due to an increase in visceral and intramuscular fat.

Energy intake

Food intake is regulated by a complex system involving orexigenic (appetite-stimulating) and anorexigenic (appetite-inhibiting) hormones that link hypothalamic satiety centres with gastrointestinal function and energy stores (Figure 20.1). Ghrelin, produced in and secreted from the gastric mucosa, is increased by fasting and low-protein diets and inhibited by somatostatin, growth hormone

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

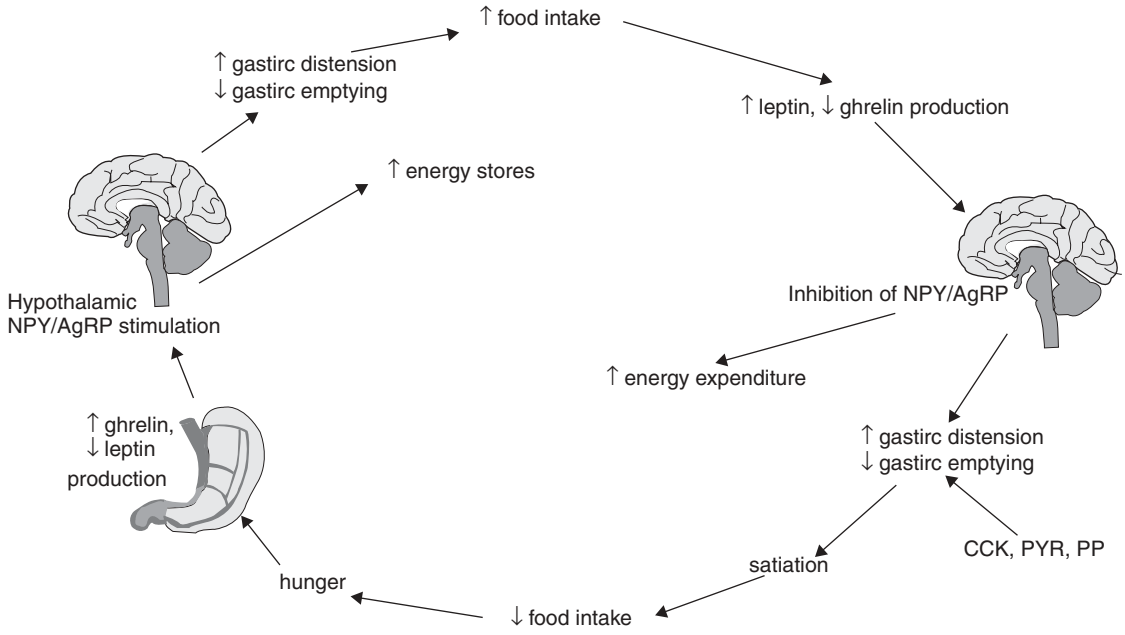

Figure 20.1 Hormonal regulation of energy homeostasis.

and a high-fat diet. Ghrelin is the main orexigenic signal that stimulates neuropeptide Y (NPY) and agouti related peptide (AgRP) in the hypothalamus. NPY and AgRP, which are capable of orexigenic stimuli themselves while simultaneously antagonizing anorexigenic melanocortin pathways, increase appetite, gastric motility and triglyceride stores in adipocytes, but reduce energy expenditure, resulting in net body weight gain. Conversely, the actions of NPY and AgRP are inhibited by the anorexigenic stimulus of leptin, secreted from adipocytes, especially after a meal. Obesity is associated with elevated plasma leptin levels in the elderly, as in younger people.[7] Other gastrointestinal peptides, such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), pancreatic polypeptide (PP) and peptide YY (PYY) 3–36, act in synergy with leptin to reduce gastric emptying, resulting in increased gastric distension, which promotes satiety.

There is evidence of altered synthesis and/or secretion and reduced responsiveness to centrally secreted and gut hormones regulating appetite and metabolism in elderly people as compared with young adults; this may contribute to age-related changes in appetite and energy regulation. Compared with younger people, the plasma level of the hormone CCK, which is secreted from the proximal intestine in response to ingestion of fat and protein and induces satiation, is higher in the elderly,[8] but CCK has a weaker than expected effect in limiting meal size in older people.[8] In elderly subjects (mean age 80.7 years), the effect of a carbohydrate-rich test meal to suppress active and total ghrelin levels is limited as compared with younger subjects.[9] Elderly people tend to be less sensitive to satiety cues, follow eating patterns according to habit or schedule and under-report energy intake.[10]

Assessment of obesity with increasing age

Body mass index is of limited utility in assessing obesity in older people due to the age-related changes in body composition. The relationship between BMI and cardiovascular risk and mortality in the elderly is flattened and a high BMI carries a lower risk than in younger people. In contrast, a low BMI, which reflects a low lean body mass, confers a higher risk in older people in comparison with younger people. The combination of a low lean body mass and increased fat mass, known as sarcopenic obesity, confers the highest risk of frailty and death. Sarcopenic obesity increases in prevalence with age and is associated with functional decline, and also other causes of morbidity and mortality in the elderly. Various definitions of sarcopenic obesity have been proposed, such as relative skeletal muscle index (muscle mass divided by height squared) less than two standard deviations below the gender-specific mean of young adults and percentage body fat greater than median (27% in men and 38% in women); or muscle mass in the lower two and fat mass in the upper two quintiles of the population.[1] Depending on the definition used and populations studied, the prevalence varies from 4.4 to 9.6% in men and from 3.0 to 12.4% in women.[1] Identification of sarcopenic obesity requires precise, simultaneous methods of measuring body fat and muscle mass, such as dual-energy X-ray absorptiometry

(DEXA). Bioelectrical impedance analysis (BIA) tends to underestimate fat mass in obese subjects[11] and the reference ranges for the definition of sarcopenic obesity have not been widely validated. Computed tomography (CT) scanning is of greater precision, but is relatively expensive and may be less accessible.

Waist circumference (WC) correlates with abdominal fat mass as measured by CT and has been proposed as an additional measure for the definition of obesity in the elderly.[7] Adults aged 51–72 years with BMI in the normal range (18.5–25 kg m^{-2}) but WC ≥102 cm (men) or ≥88 cm (women) have a 20% higher risk of all-cause mortality than their counterparts with similar BMI but normal WC.[12] Waist:hip ratio (WHR) is an alternative measure that provides some assessment of lean body mass and subcutaneous fat mass. A WHR exceeding 1.0 is associated with increased risk of obesity-related comorbidities, particularly cardiovascular disease. WHR is a better predictor of obesity-associated morbidity and mortality than BMI in the elderly.[12–14]

Prevalence of obesity in older people

The prevalence of obesity (BMI ≥30 kg m^{-2}) in older people has been increasing in the last decade and ranges from ~15–40%, with a slightly higher prevalence in women (Table 20.1). In the United States, the prevalence of obesity (BMI ≥30 kg m^{-2}) in men aged 60 years and above increased significantly from 31.8% in 1999 to 37.1% in 2008 and remained similar in women in the same age group at ~35%.[15] The 2004 Survey of Health, Ageing and Retirement found that the prevalence of obesity in adults aged above 50 in 10 European countries ranged from 12.8 to 20.2% in men and from 12.3 to 25.6% in women.[16] Obesity will continue to be a major problem in ageing populations worldwide.

Consequences of obesity in the elderly

Overall mortality

In contrast to young and middle-aged populations, in which the mortality risk increases with BMI, the relationship between BMI and mortality in the elderly may be U-shaped or reverse J-shaped, with increased mortality risk at BMI exceeding 35 kg m^{-2}. The range of BMI which is associated with the lowest risk of mortality in older adults in most retrospective studies ranged from 27 to 30 kg m^{-2} [7,16] and is 2–5 kg m^{-2} higher in women than men.[7] Several explanations have been proposed for this apparent paradox of overweight elderly having a lower risk of death: overweight people who are more susceptible to the adverse effects of obesity tend to die younger, leaving their peers of similar weight to be included in studies of older subjects; the effects of confounding conditions such as smoking and weight change due to undiagnosed chronic disease are difficult to separate from the effects of obesity *per se*, and older people may succumb to apparently-unrelated comorbidities. The elderly at greatest risk are those who are simultaneously sarcopenic and abdominally obese.

Body composition, in particular increased abdominal adiposity and reduced muscle mass, as measured by large waist circumference and waist:hip ratio, may be a better predictor of cardiovascular and all-cause mortality than high BMI. In the Rotterdam Study, WC ≥102 cm in men and ≥88 cm in women with normal BMI was associated with 20% higher mortality risk compared with subjects with a combination of normal BMI (18.5–<25 kg m^{-2}) and normal waist circumference[12] In a large study of community-dwelling adults aged 75 years and older, increasing WHR was associated with mortality from cardiovascular disease, with WHR exceeding 0.99 conferring the highest risk of mortality in non-smoking men, and WHR >0.90 in non-smoking women was associated with the greatest risk

Table 20.1 Prevalence (%) of overweight and obesity in older persons.[15,16]

Country	Men		Women	
	Overweight: BMI 25.0–29.9 kg m^{-2}	Obese: BMI ≥30.0 kg m^{-2}	Overweight: BMI 25.0–29.9 kg m^{-2}	Obese: BMI ≥30.0 kg m^{-2}
Austria	51.9	18.0	35.4	19.7

United States	41.3	37.1	35.0	33.6

of death.[13] In the MacArthur Successful Aging Study, a longitudinal study of high-functioning men and women aged 70–79 years, there was a graded relationship between WHR and all-cause mortality in women (relative risk 1.28 per 0.1 increase in WHR) and a threshold relationship in men (relative risk 1.75 for WHR >1.0 compared with WHR ≤1.0.[14]

Mobility-related disability, functioning and quality of life

Aging is associated with reduced muscle strength and mass and increased prevalence of osteoarthritis (OA), which adversely affects mobility, ability to perform activities of daily living and quality of life. Obesity is associated with increased risk of knee OA, possibly due to mechanical strain on weight-bearing joints, although metabolic syndrome is now recognized to be a risk factor for OA. In a community-based study of people aged 65–80 years, up to 96% of obese (BMI $\geq 30\,kg\,m^{-2}$) subjects were frail, as determined by physical performance test scores, peak oxygen consumption and self-reported ability to perform activities of daily living.[17] The same study also found that obesity was associated with a lower health-related quality of life, as assessed by the SF-36 physical function scoring. Sarcopenic obesity in particular is associated with high risk of impaired mobility and reduced functioning. The combination of obesity and low muscle strength was associated with the development of mobility-related disability in 930 people aged 65 years and above in the InCHIANTI study in Italy.[18] Despite the positive association between weight and bone mineral density, a recent study found that high body weight or BMI increased the risk of vertebral fractures in postmenopausal osteoporotic women.[19] Vitamin D deficiency, which is more prevalent in obese sedentary elderly because of reduced exposure to sunlight, impairment of vitamin D synthesis in the skin with ageing and obesity-associated reduction in bioavailability of cutaneous and nutritional vitamin D, is likely to contribute to osteopenia, fractures, muscle weakness and reduced mobility.

Metabolic syndrome and type 2 diabetes mellitus (T2DM)

The prevalence of the metabolic syndrome (defined by the presence of at least three of the following characteristics: WC >102 cm in men and 88 cm in women, high-density lipoprotein cholesterol $<1\,mmol\,l^{-1}$ in men and $1.3\,mmol\,l^{-1}$ in women, blood pressure >130/85 mmHg, serum glucose $>6.1\,mmol\,l^{-1}$) increases with age. Increased body fatness and increased abdominal obesity, rather than ageing *per se*, are thought to be directly linked to the greatly increased incidence of metabolic syndrome and T2DM among the elderly. As in younger people, increased abdominal fat mass is independently associated with the development of metabolic syndrome in older men and women and waist circumference, a surrogate of abdominal adiposity, is positively correlated with dyslipidaemia, fasting glucose and hypertension, independently of BMI and age. Visceral adiposity-mediated inflammation is involved in the pathogenesis of insulin resistance in elderly obese adults. The age-related reduction in insulin sensitivity is likely to be due to increase in adiposity rather than being a consequence of ageing *per se*.

Fatty liver

Infiltration of the liver with fat (hepatosteatosis) is a feature of the metabolic syndrome and insulin resistance. When inflammation is present, the condition is referred to as steatohepatitis. Progression to cirrhosis may occur, particularly in the presence of chronic viral hepatitis. In the elderly, the prevalence of fatty liver has been reported to be 3.3% in male and 3.8% in female non-obese individuals, compared with 21.6% in male and 18.8% in female obese individuals.[20] As in younger individuals, it is independently related to coronary risk factors in the elderly.

Pulmonary function

Lung function, as measured by height-adjusted forced expiratory volume in 1 s and forced vital capacity on spirometry, decreases with age in elderly men and women. Increase in abdominal fat and reduction in lean body mass are significant predictors of lung function decline, which is greatest in people with both of these factors.[21] Abdominal obesity is also associated with obstructive sleep apnoea, hypoventilation due to reduced respiratory compliance and increased work of breathing caused by increased weight on the chest wall. Older obese men are at highest risk of developing sleep apnoea: a 5% increase in BMI is associated with a 27% increase in respiratory disturbance index (number of apnoeas and hypopnoeas divided by estimated hours of sleep) in 60-year-old obese men.[21]

Hypogonadism

According to a consensus statement from the International Society of Andrology, International Society for the Study of Aging Male, European Association of Urology, European Academy of Andrology and American Society of Andrology, hypogonadism is defined by low libido, erectile dysfunction, decreased muscle mass and strength, increased fat mass, osteopenia, reduced vitality and/or low mood, in association with a morning (7–11 a.m.) serum total testosterone level below $8\,nmol\,l^{-1}$ ($230\,ng\,dl^{-1}$). Plasma testosterone levels fall progressively with age, but are significantly lower in men with visceral obesity, independent

of age. In the Massachusetts Male Aging Study,[22] the Florey Adelaide Male Ageing Study[23] and the European Male Ageing Study,[24] obesity was found to be the single most powerful predictor of low testosterone in ageing men. It is likely that, in addition to the effects of increased visceral fat, a range of health (sleep disorders, type 2 diabetes, depression, medication used), lifestyle (poor diet), environmental and psychosocial factors (stress, loss of a partner), account for the age-related decrease in testosterone. Obstructive sleep apnoea, the severity of which is strongly weight related, is associated with low testosterone levels, and also an increased risk of TDM and CVD.[25] Irrespective of cause, a low testosterone level has been shown to be a risk factor for cardio-metabolic and respiratory disease-related mortality.[25] Insulin resistance, increased aromatization of testosterone to estradiol and pro-inflammatory cytokine production in adipose tissue are likely to contribute to secondary hypogonadism in obese men.

Urological problems

Obesity, especially central adiposity, is a risk factor for both storage and voiding type lower urinary tract symptoms (LUTS) in men and women. In the Boston Area Community Health (BACH) Survey of healthy adults aged 30–79 years, waist circumference was significantly higher in men with more severe LUTS, with 43.2% of men with the most severe symptoms having BMI $\geq$30 kg m^{-2}.[26] Women in the BACH survey who reported the most severe urinary symptoms had average BMI 34.5 kg m^{-2} and the highest waist circumference and prevalence of obesity-related metabolic comorbidities.[27] The pathogenesis of obesity-associated urinary tract dysfunction is likely to be multifactorial, due to a combination of mechanical factors such as prostatic hyperplasia in men and the effects of raised intra-abdominal pressure on urethral structures and the pelvic floor in women, alterations in smooth muscle function in the urinary tract secondary to inflammation, and endothelial dysfunction and hyperactivity of the autonomic nervous system.

Psychological problems

Both obesity and ageing are associated with a higher risk of depression. The Health, Aging and Body Composition Study[28] demonstrated a longitudinal relationship between obesity (BMI) and more particularly visceral obesity (as measured by CT), and the development of depressive symptoms in community-dwelling, well-functioning men aged 70–79 years.

Management of obesity in the elderly

Age-related changes in energy expenditure and body composition, the presence of both obesity- and non-obesity-related comorbidities and limited evidence for the benefits of weight loss complicate the formulation of guidelines for the management of obesity in the elderly. Moreover, pharmacological and surgical interventions that are effective in young adults cannot always be safely and successfully translated into an older population. A recent meta-analysis[29] examined nine randomized controlled trials of weight loss in community-dwelling obese (mean baseline BMI $\geq$30 kg m^{-2}) subjects of mean age at least 60 years, for which follow-up data were available for a minimum of 1 year. Overall, intervention subjects lost an average of ~3 kg compared with controls. The meta-analysis concluded that cholesterol levels were not significantly improved and that there was insufficient evidence for benefits of weight reduction on other cardiovascular risk factors, exercise capacity or quality of life. Another meta-analysis of 16 weight loss trials in subjects aged $\geq$60 years or older with baseline BMI $\geq$27 kg m^{-2}, which included interventions of 6–12 months duration,[30] concluded that weight loss produced clinically important benefits in type 2 diabetes, coronary artery disease and osteoarthritis. The authors included only studies which produced more than 3% or 2 kg weight loss, which may account for the significant improvements seen in glycaemic control and cardiovascular risk.

Diet and physical activity

It is important that specific vitamin deficiencies which may be common, for example, vitamins D and B_{12}, are detected and corrected. Optimization of macronutrient intake will have at least the same and perhaps greater benefits in older than younger individuals. In the obese elderly, moderate degrees of caloric restriction with low saturated fat diets to induce weight loss of 5–10%, in combination with regular physical activity, exert beneficial metabolic effects and stabilize age-related loss of muscle mass. Reducing weight *per se* can improve mobility and quality of life by decreasing the mechanical strain on joints and muscle. In men and women aged at least 65 years with BMI $\geq$30 kg m^{-2}, 10% weight loss induced with a low-fat (<30%) diet with moderate caloric restriction (500–750 kcal per day) and supervised group exercise over 6 months has been shown to produce significant improvements in blood pressure, fasting glucose and triglycerides and inflammatory markers.[31] Moderate caloric restriction and exercise were more effective than exercise alone in reducing weight and fat mass and improving insulin sensitivity in adults aged 65 years and above with mean BMI 34.5 kg m^{-2} and metabolic syndrome.[32] Dietary requirements should also be tailored to comorbidities such as diabetes mellitus, hypertension dyslipidaemia, congestive cardiac failure and renal impairment, which are more prevalent in overweight and obese elderly. Greater degrees of caloric restriction with diets providing less than 800 kcal

per day, which are useful in younger subjects to induce weight loss exceeding 10% in a short period, contribute to loss of lean body mass, dehydration and malnutrition (especially protein, vitamins D and B_{12} and fibre) and hence are best avoided in older patients. Weight loss from caloric restriction alone, without adequate physical activity, may reduce muscle and bone mineral mass in sarcopenic obesity, which compromise mobility without a reduction in cardio-metabolic risk.

Regular physical activity in the elderly reduces the risk of obesity, cardiovascular disease, stroke, hypertension, type 2 diabetes, osteoporosis, breast and colon cancer, anxiety and depression and the risk of falls and disability. The American College of Sports Medicine and the American Heart Association recommend a minimum of 30 min of moderate-intensity aerobic physical activity on 5 days per week or vigorous-intensity aerobic activity for at least 20 min on 3 days per week, and also resistance training for muscle strengthening and flexibility exercises on 2 days per week and balance exercises on 3 days per week.

Most weight loss trials in the elderly utilized exercise training in addition to caloric restriction to achieve weight loss of 5–10%.[29–34]. The Positive Action for Today's Health trial found that at least 45 minutes per week of moderate-intensity exercise for 12 months reduced fat mass, insulin and leptin concentrations in overweight or obese women aged 50–75 years.[33] In the Arthritis, Diet and Activity Promotion Trial, supervised exercise for 1 h on at least 3 days per week in combination with caloric restriction to 500 kcal per day for 18 months in elderly (mean age 69 years) people with BMI $\geq 28\,kg\,m^{-2}$ and knee osteoarthritis produced ~5% reduction in body weight and was associated with improved physical function, decreased knee pain and reduced mortality risk.[34] Assessment for ischaemic heart disease, with or without exercise stress testing, may be necessary in the elderly obese before starting an exercise programme. Regular physical activity that includes a resistance component should be used in conjunction with very modest caloric restriction and optimization of macronutrient content (low saturated fat and refined carbohydrate, adequate fruit and vegetables and whole-grain cereals, low-fat dairy products and sufficient protein from unprocessed meat, fish and chicken) to avoid loss of muscle and bone mass and optimize overall health and function, in all lifestyle modification programmes in obese elderly individuals.

Pharmacotherapy and surgery

Pharmacological treatment of hypercholesterolaemia and hypertension in older people is beneficial in the primary and secondary prevention of cardiovascular morbidity and mortality. Metformin has been shown to delay the progression of glucose intolerance and impaired fasting glycaemia to diabetes even in elderly people. Specific pharmacological and surgical therapy to induce weight loss in the elderly should be considered in the event of failure of dietary intervention and exercise to induce weight loss. Sibutramine, (an inhibitor of norepinephrine and serotonin reuptake) and orlistat (inhibitor of lipase in the gastrointestinal tract), the most extensively studied weight loss medications, are FDA approved for the treatment of obesity and have been found to be effective and safe for weight loss and long-term maintenance in studies comprising mostly young to middle-aged adults. In elderly obese patients, orlistat in combination with a hypocaloric diet produces more weight loss than diet alone, with no significant increase in adverse effects,[35] although deficiencies of fat-soluble vitamins may occur and need to be monitored and there are rare reports of severe liver dysfunction. There is a paucity of efficacy and safety data for other weight loss drugs in older patients. Furthermore, comorbidities, impaired cardiovascular and renal function, polypharmacy and age-related changes in drug metabolism are prevalent in the obese elderly, increasing the risk of adverse effects and interactions with other medications. Sibutramine increases blood pressure and is contraindicated in patients with uncontrolled hypertension, coronary artery disease, stroke and arrhythmias. The safety of phentermine has not been established in the elderly, but it seems likely that it may result in complications similar to sibutramine. In 2010, sibutramine was withdrawn from marketing due to increased risk of cardiovascular events in overweight and obese adults aged 55 and above in the Sibutramine Cardiovascular Outcomes Trial.

Bariatric surgery is recommended for patients with BMI $\geq 40\,kg\,m^{-2}$ without or BMI $\geq 35\,kg\,m^{-2}$ with obesity-related comorbidities who have failed non-surgical attempts at weight reduction.[36] Laparoscopic gastric banding, vertical banded gastroplasty and Roux-en-Y gastric bypass are highly effective in producing weight loss and result in improvement or complete resolution of obesity-related comorbidities. Combined restrictive and malabsorptive procedures such as gastric bypass result in greater and more sustained weight loss than purely restrictive procedures (gastric banding and gastroplasty). Long-term (>2 years) remission of type 2 diabetes, hypertriglyceridaemia, hypercholesterolaemia and obstructive sleep apnoea is achieved in 75–90% of patients after successful surgery[36] and most patients enjoy improvements in mobility, osteoarthritis, cardiovascular disease, asthma, respiratory function, fatty liver disease, psychosocial status and quality of life. However, less than 5% of bariatric surgery procedures have been performed in patients aged >60 years, due to concerns about anaesthetic and operative fitness. In a study of 1339 patients from the University Health System Consortium Clinical Data Base, compared with younger people, elderly patients who underwent bariatric surgery had more comorbidity, longer lengths of stay, more postoperative pulmonary, haemorrhagic and

wound complications and higher in-hospital mortality rates.[37] Nevertheless, this study concluded that bariatric surgery in the elderly was safe because the observed mortality was better than the expected (risk-adjusted) mortality.

Multidisciplinary management of the obese elderly

Obese elderly persons are ideally managed by a multidisciplinary team, consisting of physicians, dieticians, therapists and exercise trainers, psychologists, caregivers and a bariatric surgeon if necessary. Primary care physicians are best placed to initiate weight loss interventions as part of individualized management of obesity and related comorbidities in each patient, involve other members of the multidisciplinary team as appropriate and coordinate the roles of team members (Table 20.2), follow up on weight maintenance and encourage therapeutic lifestyle modification.

Table 20.2 Multidisciplinary management of obesity in older persons.

Physician

- Assess the need for weight loss and readiness of patients to lose weight
- Identify barriers to weight loss, e.g. excessive caloric intake, insufficient physical activity, psychosocial factors
- Counselling on behaviour change, referral to dietician, therapists/trainers and psychologist
- Individualize weight loss targets and monitor efficacy and tolerance of interventions
- Pharmacological treatment if necessary: metformin, orlistat, analgesics for joint and muscle pain, vitamin D supplementation
- Referral for bariatric surgery if lifestyle modification and pharmacological treatment fails and/or severe obesity is unlikely to respond to non-surgical treatment alone
- Continue follow-up and medical management after successful weight loss

Dietician

- Detailed advice on diet modification
- Reinforcement of compliance with diet, e.g. by food diaries, educational media, regular weigh-ins

Physiotherapists, occupational therapists, exercise trainers

- Develop individualized exercise programme to focus on specific areas as required, e.g. mobility, endurance, strength, flexibility
- Advise on home modification and specific equipment to facilitate mobility and safety
- Caregiver training

Psychologist

- Identify and assist in overcoming psychological barriers to behaviour change, e.g. anxiety, depression, poor self-image
- Motivate continuing attempts at weight loss
- Counselling pre- and post-bariatric surgery

Bariatric surgeon

Caregivers in the home, hospital, and long-term care facilities should be involved as much as possible in all aspects of weight management in the obese elderly

Conclusion

Obesity in the elderly is multifactorial, due to age-related changes in activity, caloric intake and energy regulation (Table 20.3). As a result of the increase in fat mass, especially visceral fat and the reduction in lean mass, sarcopenic obesity is more prevalent in the elderly and is associated with increased risk of morbidity and mortality (Table 20.4). The management of obesity is multidisciplinary, focusing on regular and appropriate physical activity with moderation of emphasis on optimization of nutrition rather than simply caloric restriction. and the role of pharmacotherapy remains to be defined, but bariatric surgery has proven utility and may be indicated under extreme circumstances (Table 20.5).

Table 20.3 Mechanisms of obesity in older persons.

1 Reduced energy expenditure
   - Decreased physical activity
   - Decreased resting metabolic rate
   - Changes in nutrient utilization
   - Decreased fat oxidation
2 Lesser degree of decrease in energy intake compared to expenditure
   - Reduced response to satiety cues
   - Fixed timing of meals
3 Age-related changes in body composition
   - Increased fat mass
   - Decreased muscle mass
4 Dysfunctional gut and energy hormone regulation
   - Leptin resistance
   - Lack of ghrelin suppression after food intake

Table 20.4 Consequences of obesity in older persons.

- ↑ Cardiovascular and all-cause mortality
- Impaired physical functioning and mobility, osteoarthritis
- Metabolic syndrome, type 2 diabetes, hypertension, dyslipidaemia
- Hepatic steatosis
- Obstructive sleep apnoea, ↓ lung function
- Hypogonadism in men
- Sexual and urological problems in men and women
- Psychological problems
- ↓ Quality of life

Table 20.5 Management of obesity in older persons.

1	Lifestyle modification
	• Caloric restriction and low fat diet
	• Physical activity: endurance, strength, flexibility, balance training
2	Pharmacological
	• Treatment of metabolic risk factors
	• Orlistat for weight loss in conjunction with diet and exercise
3	Bariatric surgery

Key points

- Obesity in old age involves decreased energy utilization and alterations in caloric intake.
- Sarcopenic obesity is a major functional problem in older persons.
- Physical activity is a key to the management of old age obesity.

SECTION 2

Gastro Disorders

CHAPTER 21

Changes in gastrointestinal motor and sensory function associated with ageing

Christopher K. Rayner and Michael Horowitz
University of Adelaide, Royal Adelaide Hospital, Adelaide, Australia

Introduction

This chapter reviews changes in gastrointestinal motor and sensory function associated with healthy ageing, together with what is known about the underlying causes and their clinical significance. Illnesses with gastrointestinal complications that are common in the elderly are also discussed, along with medications that potentially affect gastrointestinal motility. The focus is on the oesophagus, stomach and small intestine, since the oropharynx (Chapter 59, Communication disorders and dysphagia), gallbladder (Chapter 23, Liver and gallbladder) and colon and anorectum (Chapter 24, Sphincter function, and Chapter 25, Constipation) are dealt with elsewhere, as are mucosal functions of secretion and absorption.

Control of gastrointestinal motility and sensation

Patterns of motor activity, involving the circular and longitudinal layers of smooth muscle that extend throughout the length of the gut, are coordinated by plexuses of nerves within the gut wall known collectively as the enteric nervous system. Located in the submucosa (submucous plexus) and between the muscle layers (myenteric plexus), this network contains an equivalent number of neurons (about 100 million) to that present in the spinal cord.[1] The intrinsic sensory neurons, interneurons and motor neurons that comprise the enteric nervous system control basic contractile activity such as reflex responses to distension. However, these intrinsic patterns of gut motility are modulated by both extrinsic neural and humoral signals. Central modulation of gut motility occurs via extrinsic sympathetic and parasympathetic nerves, while gut sensation is conveyed to higher centres by both the vagus and spinal afferent nerves, with noxious signals transmitted predominantly via the latter. Descending pathways to the spinal cord modulate the transmission of sensory signals.

Pathophysiology of the ageing gut

In rodent models of ageing, there is a substantial reduction in the number of neurons in the enteric nervous system, which becomes increasingly prominent more distally in the gut (40% loss in the small intestine and 60% in the colon, in the myenteric plexus of rats).[2] Similar neuronal loss is reported in the oesophagus in older humans, while in the human colon the decline in neuron numbers begins as early as the fourth year, but is most marked between young adulthood and old age.[3] Losses are selective for cholinergic neurons and involve both the myenteric plexus (involved with initiation and control of smooth muscle contraction) and the submucous plexus (involved in secretion and absorption and also motor control).[4,5] Nitrergic neurons, which generally mediate inhibitory motor responses, are protected in number but develop axonal swelling and glial cells are also lost in parallel with neurons. Regarding the extrinsic nerve supply to the gut, the number of vagal fibres innervating the upper gastrointestinal tract does not appear to decline in ageing rats, but afferent and efferent fibres undergo morphological changes.[4] In particular, vagal afferents associated with both the muscle wall and the mucosa of the gut degenerate with age, potentially compromising both sensory feedback and gut reflexes.[6] The underlying causes of neuronal loss with ageing remains unclear, although caloric restriction appears to be protective.[7] Recent data also indicate a loss of interstitial cells of Cajal in the ageing human colon;[7] these specialized cells are responsible for the propagation of the electrical rhythm of the gut on which muscle contraction is superimposed. Limitations to our understanding of the pathophysiology of the ageing gut include a relative lack

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

of studies relating to the upper gut and the sphincters and the paucity of human data compared with animal models.

The relatively good preservation of gastrointestinal motility in the healthy elderly may imply that the large number of neurons in the enteric nervous system provides a considerable functional reserve, but even this may be limited; transit of a radiolabelled meal through the upper gut occurs at a comparable rate in the healthy elderly and the young, but is slower through the colon in the elderly, where the loss of enteric neurons is greatest.[8] It may therefore not be surprising that constipation is the one gastrointestinal complaint that clearly stands out in the elderly compared with the middle aged.[7] In the oesophagus, selective loss of intrinsic sensory neurons could explain why contractile activity in response to distension (so-called 'secondary peristalsis') occurs less frequently in the healthy elderly than the young.

In contrast to motor function, gut sensation is more consistently impaired with age, as reflected by decreased perception of balloon distension in the oesophagus,[9] stomach[10] and rectum[11] in comparison with young subjects. A selective loss of intrinsic sensory enteric neurons may be responsible. However, the amplitude of cortical evoked potentials recorded from scalp electrodes during repeated oesophageal distension in older subjects is lower than in the young, raising the possibility that altered central processing of signals might also contribute to diminished sensation.[12] In addition to mechanical stimuli, perception of chemical stimuli such as acid decreases with age, suggesting a generalized impairment of gut sensation.

Oesophagus

Patients with disordered oesophageal function can present with dysphagia or 'heartburn' or less specific symptoms such as chest pain or chronic cough. Age-related changes in oesophageal motility are extensively documented, but probably impact mainly on the very old. Classic oesophageal motility disorders such as achalasia, although uncommon, can present particular challenges in the elderly. Gastro-oesophageal reflux disease (GORD) is as prevalent as in the young, often presents atypically and is more likely to be severe.

Changes in oesophageal motor function related to ageing

The oesophagus incorporates striated muscle in the upper portion and smooth muscle in the lower, with an upper oesophageal sphincter (UOS) and lower oesophageal sphincter (LOS) at either end. The term 'primary peristalsis' refers to the coordinated sequence of contraction associated with swallowing, propagated from proximal to distal oesophagus. The LOS relaxes early in this sequence to allow the swallowed bolus to enter the stomach. 'Secondary peristalsis' is triggered by reflux of gastric contents into the oesophagus or experimentally by balloon distension and serves to clear the oesophagus of acid and bile. 'Tertiary contractions' represent spontaneous, uncoordinated oesophageal motor activity. While both tonic contraction of the LOS and its position within the diaphragmatic hiatus are important barriers against acid reflux, transient sphincter relaxations, particularly after a meal, are the most prevalent mechanism of acid reflux in most GORD patients. Defences against reflux include neutralization of acid by saliva (which contains bicarbonate), together with acid clearance by primary and secondary peristalsis.

Oesophageal motility may be evaluated by manometry. In this procedure, a catheter incorporating multiple lumens within a relatively small external diameter is passed through the nose or mouth and perfused with water. Each lumen terminates in a sidehole at a different level of the oesophagus and, when coupled to pressure transducers and displayed as recordings of pressure over time, the assembly provides information about the amplitude, duration and propagation of pressure waves (Figure 21.1). Incorporation of either a sleeve sensor or multiple closely spaced sideholes into the assembly is ideal for measurement of both the resting pressure and

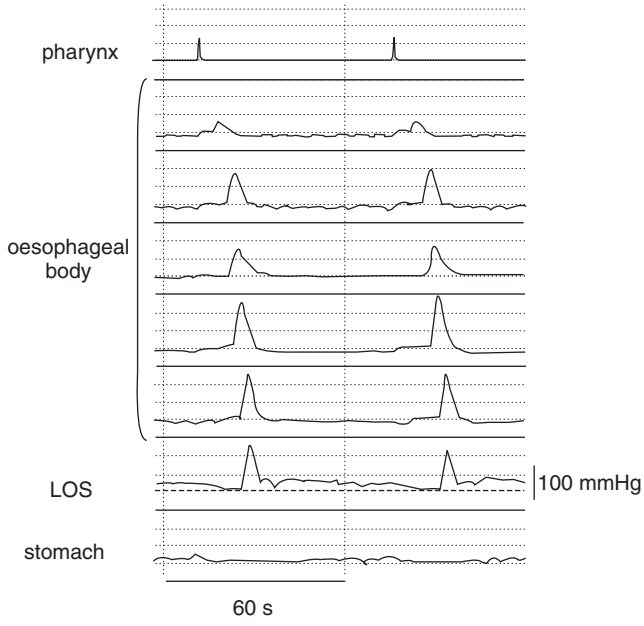

Figure 21.1 Normal oesophageal manometry recording during water swallows, showing primary peristalsis. The pharyngeal pressure wave indicates the onset of swallowing, which is followed by an orderly sequence of waves from one channel to the next. Note the swallow-induced relaxations of the LOS, whose pressure decreases to approximate intragastric pressure (dashed line).

relaxation of the UOS and LOS. Solid-state transducers, mounted at intervals along a catheter, represent an alternative method of manometry to water-perfused catheters. Multi-channel intraluminal impedance, a technique that records electrical impedance between sequential pairs of electrodes, is emerging as a method of evaluating flow of liquid and air in the oesophagus. While offering new insights into oesophageal function, it has yet to be applied specifically to the elderly. Radiographic imaging of swallowed contrast agent can reveal abnormal oesophageal wall movements (especially cineradiography), dilatation or delayed oesophageal transit. Transit can also be evaluated by the passage of a radiolabelled bolus, imaged by a gamma camera – a technique known as scintigraphy. While endoscopy is most useful in demonstrating mucosal lesions or strictures, it may also provide evidence of abnormal motor activity in disorders such as oesophageal spasm or achalasia.

The effects of ageing have been studied more extensively in the oesophagus than any other gastrointestinal region, reflecting both its accessibility and the importance of swallowing disorders in the elderly. Soergel *et al*. coined the term 'prebyoesophagus' in 1964 when reporting radiological and manometric observations in a group of nonagenerians.[13] Only two of 15 subjects had 'normal' oesophageal motility and on barium examination there was a high prevalence of tertiary contractions, delayed clearance and oesophageal dilatation. Manometry showed non-peristaltic, multi-peaked pressure waves. These subjects, however, could scarcely be described as healthy elderly, given the high prevalence of dementia and other chronic illnesses, including diabetes. Not surprisingly, more recent studies indicate that the prevalence and severity of oesophageal motor dysfunction in healthy ageing is less than suggested by early reports.[14] While there are other reports of oesophageal dysmotility in the very old,[15] in subjects aged less than 80 years there appears to be little difference in primary peristalsis when compared with young people, although simultaneous contractions may occur more frequently. The impact of ageing on the amplitude of oesophageal pressure waves may vary by site; distal oesophageal amplitudes increase with age, while a decrease is reported more proximally. Nevertheless, the magnitude of these changes is modest.[16] Secondary peristalsis is elicited less consistently by distending stimuli in the healthy elderly compared with the young[17] and increasing oesophageal stiffness, together with an increased threshold for perceiving distension, may contribute to this phenomenon.[18] In fact, changes in biomechanical properties and primary and secondary peristalsis are observed from as early as 40 years of age.[19]

In the healthy elderly, while both the length of the UOS high pressure zone and its resting pressure are less than in young subjects, relaxation and opening of this sphincter are delayed.[20] The result is a prolongation of the oropharyngeal phase of swallowing and an increase in intra-bolus pressure in the hypopharynx. Although not clinically significant in the healthy elderly, these findings must be taken into account when evaluating swallowing studies in older patients with oropharyngeal dysphagia, where the use of reference ranges derived from the young would be inappropriate. Reflex responses of the UOS to oesophageal stimuli (increased pressure with oesophageal balloon distension and decreased pressure with air distension) appear to remain intact with healthy ageing, but reflex UOS contraction in response to laryngeal stimulation is impaired;[21] the latter could predispose to aspiration. The fact that only the frequency and not the magnitude of the response is diminished suggests that the sensory side of the reflex arc is impaired.

The elderly have an increased prevalence of hiatus hernia (around 60% of those aged over 60 years)[22] and both the resting pressure and intra-abdominal length of the LOS decline with age, while acid exposure increases,[23] implying a predisposition to GORD. Other predisposing factors include reduced flow of saliva and impaired acid clearance. The frequency of transient LOS relaxations, the major mechanism of acid reflux in most individuals, has not been specifically studied in the elderly, nor have mucosal repair mechanisms been compared with the young. The number of reflux episodes appears similar in both age groups, but their duration appears to be more prolonged in the elderly;[24] this may relate to impaired clearance mechanisms. The refluxate may be less acidic due to a higher prevalence of atrophic gastritis in the elderly, but it should be recognized that its bile content may be important in mucosal injury (e.g. Barrett's mucosa) and this has not been studied specifically in relation to age.[14]

Clinical presentation of disordered oesophageal motility

Disordered oesophageal motor function may present with symptoms of difficulty in swallowing (dysphagia) or chest pain. In both nursing homes (50–60%) and general medical wards (10–30%), there is a high prevalence of dysphagia when patients are specifically questioned,[25] although less than half of elderly subjects who reported dysphagia in a population-based survey had consulted a physician about the problem. Potential consequences of dysphagia include aspiration, which contributes substantially to mortality and inadequate intake of nutrition.

Swallowing disorders can be classified into those of oropharyngeal (difficulty initiating a swallow) or oesophageal (impaired transport of swallowed material) origin and these can usually be distinguished with a careful history and examination. The oropharyngeal component of swallowing comprises preparatory (chewing

food, mixing with saliva and bolus formation), oral (propulsion of the bolus by the tongue and palate to the pharynx) and pharyngeal (transport through the UOS while protecting the airway) phases. A comprehensive discussion of dysphagia of oropharyngeal origin is included in Chapter 59, Communication disorders and dysphagia.

Potential causes of oesophageal dysphagia are listed in Table 21.1. Key points in the history include whether dysphagia is for solids or liquids, is intermittent or progressive and whether there are associated reflux symptoms such as heartburn.[26] Progressive difficulty in swallowing solids is suggestive of a structural lesion, while dysphagia for both liquids and solids is associated with motility disorders. Endoscopy provides a means to visualize and biopsy structural lesions and may be therapeutic (e.g., dilatation of a peptic stricture). Endoscopy and biopsy are also likely to be helpful when odynophagia (painful swallowing) is the presenting complaint and in the patient with dysphagia can help exclude eosinophilic oesophagitis, which is increasingly being recognized even in older patients.[27] Barium videofluoroscopy provides complementary information regarding motor function and also structural lesions, and manometry is of greatest use in confirming or excluding a diagnosis of achalasia.

Of the primary oesophageal motility disorders, achalasia, diffuse spasm and nutcracker oesophagus are diagnosed over a wide age range. Although the peak incidence of achalasia is in early to mid-adulthood, a second, smaller peak occurs in the elderly.[16] Oesophageal spasm is more commonly diagnosed in people over 50 years of age, whereas non-specific motility disorders are particularly associated with an older population. However, the range of manometric diagnoses in the very old (age 80–93 years) presenting to a clinical motility unit with dysphagia was reported to be broadly similar to that in younger patients.[28]

Achalasia

Achalasia is an oesophageal motor disorder of unknown aetiology, associated with incomplete or absent swallow-induced LOS relaxation and absence of peristalsis in the oesophageal body. Occasionally, simultaneous oesophageal pressure waves of large amplitude are observed (so-called 'vigorous' achalasia). Inflammation of the myenteric plexus is an early histological finding, followed by ganglion loss and neural fibrosis. The condition typically presents with dysphagia for both liquids and solids, although weight loss, regurgitation and aspiration may also be presenting symptoms, particularly in the elderly. Conversely, chest pain is reported less often than in young patients.

A barium swallow may show impaired peristalsis, delayed emptying and dilatation of the oesophageal body (the latter more characteristic in the elderly than the young), with 'bird's beak' or 'rat's tail' tapering at the LOS (Figure 21.2). At manometry, the resting

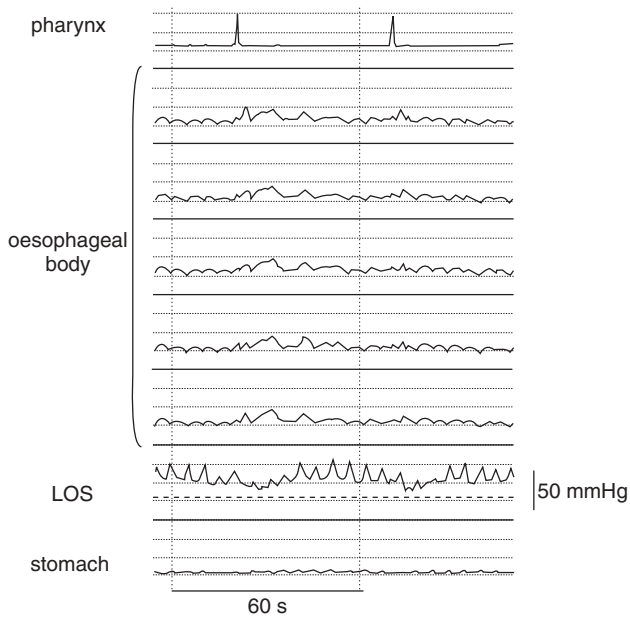

Figure 21.3 Oesophageal manometry in achalasia. Note the simultaneous, small-amplitude pressure waves in the oesophageal body and minimal relaxation of the LOS on swallowing.

LOS pressure may be high or within the normal range, but LOS relaxation on swallowing is either absent or incomplete. In the oesophageal body, pressure waves are simultaneous and of small amplitude or absent altogether (Figure 21.3). Endoscopy (and sometimes endoluminal ultrasound or computed tomography) must be performed to exclude 'pseudo-achalasia', especially in the elderly; this entity presents with features of achalasia, but is due to carcinoma of the distal oesophagus or cardia. A short history of symptoms and disproportionate weight loss are particularly suggestive of the diagnosis.

Pneumatic dilatation and surgical myotomy (now usually performed laparoscopically) represent the most efficacious treatments for achalasia. Relief of dysphagia after surgery appears as good for older as for younger patients (about 80%),[29] while older patients my get better relief from pneumatic dilatation than the young.[30] Oesophageal emptying is improved in a smaller percentage and neither therapy addresses aperistalsis of the oesophageal body. Pneumatic dilatation produces controlled tearing of the LOS and is associated with a risk of oesophageal perforation (about 3%) and induction of reflux symptoms (about 10%). Not infrequently, repeat dilatations are required, although two-thirds had no need for further dilatation in a recent report where an initial series of dilatations was guided by their effect on LOS pressures.[31] While myotomy may be associated with a greater risk of GORD, it can be combined with an anti-reflux procedure. The lower morbidity of dilatation may favour this procedure over surgery in older patients, with the caveat that a thoracotomy is required if perforation occurs. Pneumatic dilatation is more cost-effective than surgical myotomy.

Endoscopic injection of botulinum toxin into the LOS represents an alternative and safe therapy, but adequate symptom relief may be achieved in fewer patients (around 60%)[32] and the benefit lasts around 6 months, so that repeated treatments may be necessary. Therefore, this therapy is best reserved for patients in whom comorbidities represent contraindications to surgery or pneumatic dilatation; this group typically includes the frail elderly. This must be counterbalanced by evidence that the response to both pneumatic dilatation and botulinum toxin is better in older than younger patients. The cost of botulinum toxin injection is slightly greater than that of pneumatic dilatation, but substantially less than that of surgery.

Pharmacological therapy to reduce LOS pressure (nitrates, calcium channel antagonists or sildenafil) is of limited efficacy (possibly even less in the elderly than the young), requires frequent dosing and is associated with side effects.

Patients with achalasia have an increased risk (estimated as 16-fold) of squamous cell carcinoma of the oesophagus, but the absolute risk is small and surveillance endoscopy has not been advocated.[33] Occasional patients have persistent dysphagia despite therapy, together with a tortuous, dilated oesophagus that empties poorly; in these circumstances, oesophagectomy may be required.

Diffuse oesophageal spasm and 'nutcracker oesophagus'

These disorders are diagnosed in a minority of patients with dysphagia or chest pain and in many cases the relationship between symptoms and motor abnormalities is unclear. Criteria for the diagnosis of diffuse oesophageal spasm are inconsistent; the presence of simultaneous oesophageal pressure waves in more than 10%, but fewer than 100% of wet swallows, regardless of amplitude, is a reasonable definition[34] (Figure 21.4). The barium swallow may show segmentation of contrast by contractions or a 'corkscrew' appearance (Figure 21.5). Similar manometric abnormalities may occur in association with diabetes mellitus, alcohol abuse, amyloidosis, progressive systemic sclerosis and GORD. 'Nutcracker oesophagus' is characterized by large-amplitude oesophageal pressure waves, but peristalsis is maintained. The management of both diffuse spasm and nutcracker oesophagus is discussed below, in relation to non-cardiac chest pain.

Non-specific oesophageal motility disorders

Many patients referred for investigation of symptoms such as dysphagia or chest pain have manometric features that

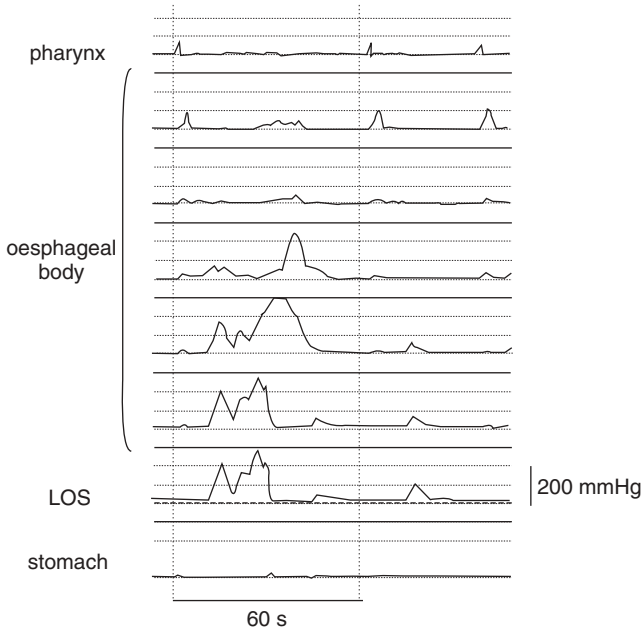

Figure 21.4 Manometry recording in diffuse oesophageal spasm. Note the simultaneous pressure waves after water swallows, including multi-peaked and large-amplitude waveforms.

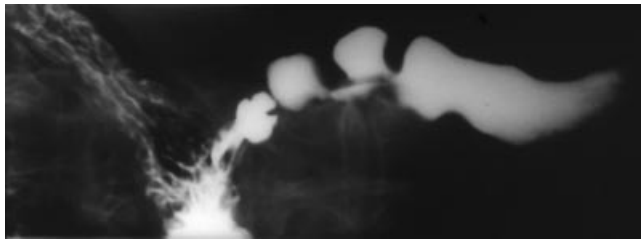

Figure 21.5 Barium swallow in a patient with diffuse oesophageal spasm, demonstrating segmentation of the barium column by contractions, producing a 'corkscrew' appearance.

are outside the normal range, but do not meet formal criteria for the diagnosis of disorders such as achalasia and diffuse spasm. In cases where peristaltic waves are of abnormally small amplitude, absent or fail to traverse the whole oesophagus, often associated with a low LOS pressure, a category of 'ineffective oesophageal motility' has been proposed.[35] Non-specific abnormalities of oesophageal motor function are evident in more than one-third of presentations with dysphagia in patients aged over 65 years, in contrast to the young, where a specific diagnosis can usually be made. It is important to recognize that a causal association cannot be assumed, since the presence of radiographic or manometric abnormalities of oesophageal function correlates poorly with symptoms. Moreover, no specific therapy is available. Symptomatic management includes acid suppression when GORD is a feature and optimizing nutrition.

'Pill oesophagitis'

An important cause of dysphagia or odynophagia in older individuals is mucosal injury caused by impaction of medications in the oesophagus, the incidence of which is likely to be increasing as the number of medications prescribed in this group escalates. Risk factors which are more prevalent in the elderly include less saliva, delayed oesophageal transit and immobility. Capsules may present a greater risk than tablets, due to slower oesophageal transit. The most frequent sites of hold-up are the upper and mid-oesophagus, corresponding to extrinsic compression from left main bronchus, aortic arch or enlarged left atrium and also to a zone of small-amplitude pressure waves between the proximal and distal oesophagus. Numerous medications are associated with oesophageal injury, including potassium chloride, tetracyclines, aspirin, non-steroidal drugs, quinidine, theophylline, ferrous sulfate and alendronate.[36]

Symptoms usually resolve when the offending drug is withdrawn, but may sometimes be persistent and related to stricture formation. Perforation and bleeding are other complications, associated particularly with potassium chloride, quinidine and non-steroidal drugs. The typical endoscopic or barium swallow appearance in pill oesophagitis is of small superficial ulcers. There is anecdotal evidence that sucralfate is beneficial in severe or persistent disease. As a preventive measure, patients should be advised to take oral medications in the upright position, followed immediately by a full glass of water.

Non-cardiac chest pain

Chest pain is a prevalent symptom in the community and not infrequently presents a diagnostic difficulty, especially in older patients who are at greater risk of ischaemic heart disease than the young. The oesophagus is often implicated when cardiac causes have been excluded, but musculoskeletal, pulmonary, pericardial, gastric and biliary pathology should also be considered and an association with panic disorder has been reported.[37]

GORD may be responsible for a proportion of non-cardiac chest pain (NCCP) and about 50% of NCCP patients have excessive oesophageal acid exposure on pH studies. Many patients with excessive acid exposure do not have reflux oesophagitis, which limits the value of endoscopic examination. Rather, a trial of double-dose proton pump inhibitor (PPI) for 2–8 weeks (depending on symptom frequency) is a useful and cost-effective initial test in NCCP, with a sensitivity and specificity as high as 80% each for a diagnosis of GORD. If symptoms are relieved, the dose of medication can subsequently be titrated down to the minimum effective dose. If PPIs are ineffective, then oesophageal manometry and ambulatory pH measurement (while remaining on the PPI) are indicated; the former is

particularly helpful for excluding achalasia. Endoscopy should be performed whenever there are 'alarm symptoms' such as dysphagia, anorexia, weight loss, haematemesis or anaemia. The threshold for endoscopy in older patients should be lower than in the young (age less than 40 years).

The association between NCCP and oesophageal motility disorders, including diffuse oesophageal spasm and 'nutcracker oesophagus', is less strong than previously assumed and even when these disorders are demonstrated, a causal relationship can be difficult to establish, even with 24 h ambulatory manometry.[38] Furthermore, medical therapy for oesophageal motility disorders with smooth muscle relaxants such as nitrates, calcium channel antagonists or sildenafil has limited efficacy and surgical myotomy has had only anecdotal success.

Visceral hypersensitivity is now thought to play a major role in non-GORD-related NCCP and pain-modifying agents, such as tricyclic antidepressants or selective serotonin reuptake inhibitors, have been shown to be superior to placebo in the management of this disorder. Limited data also suggest that theophylline, an adenosine receptor antagonist, may be beneficial. Caution should be exercised in the elderly due to potential side effects of all these agents, particularly when prescribing tricyclics.

Many studies indicate that NCCP, although often persisting over a number of years, has an excellent prognosis in terms of mortality, although the latter point is controversial[39] and may depend on the population from which those with NCCP are drawn.

Gastro-oesophageal reflux disease (GORD)

GORD presents in the elderly with more severe disease (erosive oesophagitis, stricture or Barrett's oesophagus) than in the young,[40] perhaps related to the predisposing factors discussed earlier or to a longer duration of disease.[22] Conversely, symptoms are characteristically milder or may be qualitatively different in the elderly, so that dysphagia, vomiting, respiratory difficulty, weight loss or anaemia are not uncommon presenting features, while 'typical' reflux symptoms such as heartburn occur less often than in the young[41] – the latter perhaps as a result of diminished oesophageal sensitivity. In the general population, symptoms of heartburn or regurgitation have a high sensitivity (about 70%) for a diagnosis of GORD, but a low specificity, when using 24 h pH monitoring as the 'gold standard'; corresponding data are not available for an ageing population. The 'alarm symptoms' mentioned for NCCP are indications for prompt endoscopic investigation.

Atypical or 'extra-oesophageal' manifestations of GORD include chronic cough and asthma and may be mediated either directly by acid–pepsin reflux or by oesophageal acid exposure triggering vagal reflexes. The prevalence of excessive acid reflux in patients complaining of these symptoms is controversial and, as for NCCP, the most useful diagnostic test may be a therapeutic trial of intense acid suppression with double-dose PPI for 2–8 weeks, depending on symptom frequency.

There appear to be no significant differences in the capacity to heal oesophagitis in older patients when compared with the young and PPIs maintain their superiority over histamine receptor antagonists in this age group. No dosage adjustment is needed in the elderly to compensate for age-related changes in renal or hepatic function, but downward titration of the dose according to symptoms may be less appropriate than in the young, especially when the original symptoms were mild or in the setting of complicated GORD. Indeed, continued therapy with a PPI seems markedly to reduce relapse of oesophagitis, compared with stopping therapy after an initial 6 months of treatment.[42] Long-term use of PPIs has generally been regarded as safe; reports of an increased risk of osteoporotic hip fracture[43] have not subsequently been substantiated,[44] although there may be a greater risk (about 1.5-fold) of community-acquired pneumonia,[45] while *Clostridium difficile* infection,[46] malabsorption of vitamin B_{12}[47] and interstitial nephritis also represent potential adverse effects. Concerns about an increased risk of gastric or colon cancer have not been substantiated.[48] Long-term acid suppression in individuals with *Helicobacter pylori* is associated with an increased prevalence of atrophic gastritis, which is thought to be a risk factor for gastric cancer. Therefore, *H. pylori* eradication is generally recommended in patients on long-term PPI therapy, but this is unlikely to be of significance in the very old. Cisapride was commonly used to treat GORD prior to its withdrawal from the market, but there is no good evidence to support the use of currently available prokinetic drugs for GORD in general[49] and there is no information specific to the elderly. Maintenance therapy for GORD has not been specifically compared between elderly and young patients, but long-term medical therapy is likely to be more cost-effective than anti-reflux surgery in older patients, on the basis of the number of years of medical therapy likely to be needed. Nevertheless, the healthy elderly have outcomes from laparoscopic fundoplication that are comparable to the young,[22] with an equivalent safety profile.[50,51] Endoscopic anti-reflux procedures to date have not fulfilled their initial promise and their use should be restricted to clinical trials.

Stomach and duodenum

Although only a modest delay in gastric emptying is observed with healthy ageing, both the perception of gastric distension and humoral responses to duodenal nutrient exposure differ markedly from the young and could contribute to the 'anorexia of ageing'. Moreover, postprandial hypotension, a common cause of falls and syncope in the elderly, can be regarded as a gastrointestinal disorder and

can be related to both the rate of gastric emptying and the small intestinal response to ingested nutrient.

Changes in gastric motor function related to ageing

The stomach is responsible for the accommodation of ingested food and fluids, their mixing with digestive enzymes and grinding of solids into small particles.[52] Gastric emptying reflects the coordinated motor activity of the stomach and duodenum, which is controlled by feedback from neural and humoral signals generated by the interaction of nutrients with the small intestine. As a result of this, the rate of energy delivery to the small intestine is relatively constant and independent of the ingested nutrient load. Small intestinal feedback may be modulated by previous patterns of nutrient intake, so that gastric emptying is retarded in starvation, while emptying of glucose is more rapid after dietary glucose supplementation. The proximal region of the stomach, comprising the fundus and much of the gastric body, relaxes after meal ingestion and acts as a reservoir for the solid component of the meal, while liquids begin to empty. Tonic contraction of the proximal stomach also generates a pressure gradient to assist gastric emptying. The distal stomach, comprising the antrum and pylorus, is responsible for grinding solids and for generating flow across the pylorus – the latter is predominantly pulsatile, rather than continuous. Contractions of the stomach are linked to an underlying electrical rhythm of about three cycles per minute, generated by a gastric pacemaker.

Scintigraphy remains the 'gold standard' for measurement of gastric emptying and the use of dual isotopes allows both the solid and liquid components of a meal to be studied (Figure 21.6).[53] Regional meal distribution can also be evaluated by defining regions of interest within the stomach. Ultrasonography and ^{13}C isotope breath tests are alternative methods of measuring gastric emptying, although the former is restricted to liquid meals. Manometry is used predominantly for research purposes to record the frequency, amplitude and organization of lumen-occlusive contractions in the antrum, pylorus and duodenum. Proximal gastric relaxation in response to a meal can be evaluated in the laboratory using an electronic barostat; the volume of air required to maintain a fixed pressure in an intragastric bag is used as an index of proximal gastric tone. The electrical rhythm of the stomach may be recorded from cutaneous electrodes, although the clinical significance of abnormalities of this electrogastrogram (EGG) is unclear, since they are not specific for particular gastrointestinal disorders.

Healthy ageing appears to be associated with modest slowing of gastric emptying of both solids and nutrient-containing liquids, but the rate of emptying generally remains within the normal range for young subjects.[54,55]

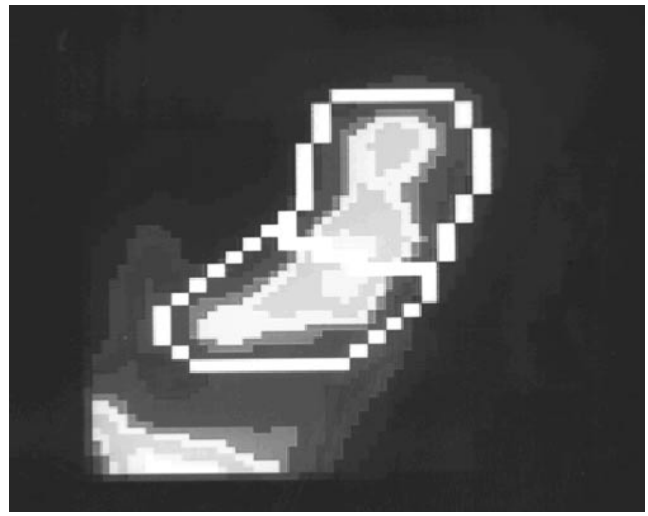

Figure 21.6 Scintigraphic gastric emptying study. Part of the radiolabelled meal is evident in the stomach, while some has emptied into the small intestine (bottom left). Proximal and distal gastric 'regions of interest' are outlined.

The relative slowing of gastric emptying may have implications for appetite regulation, potentially contributing to the 'anorexia of ageing'; prolongation of gastric distension and of exposure of the small intestine to nutrients might lengthen the period of postprandial satiation. Slow gastric emptying, and also alterations in gastric pH (for example, higher pH postprandially than in the young) could also influence the absorption of orally administered medications[56] and a slight reduction in paracetamol absorption has been reported in the healthy elderly compared with the young. However, absorption of benzodiazepines, tetracycline or L-dopa is not significantly altered with age *per se*. A number of systemic disorders, which occur frequently in the elderly, are associated with markedly delayed gastric emptying or gastroparesis (Table 21.2) – acute gastroparesis may also result from the administration of a number of drugs (Table 21.3).

There is little information about the effects of ageing on the mechanics of the stomach, but fasting and postprandial antral motility did not differ between patients aged 18–39 and those aged 40–69 years who were being investigated for unexplained gastrointestinal symptoms.[57] Proximal gastric compliance is unchanged in the fasting state in the healthy elderly compared with the young, but perception of gastric distension is diminished,[10] akin to the reduction in visceral sensitivity evident in the oesophagus and stomach. Moreover, proximal gastric accommodation to a meal is delayed compared with young controls, which might contribute to early satiation. Conversely, the antrum is more distended after a nutrient drink in the healthy elderly and antral width correlates with both satiation and satiety in both young and

Table 21.2 Causes of delayed gastric emptying.

Acute
- Drugs (opiates, anticholinergics, L-dopa)
- Postoperative ileus
- Viral gastroenteritis
- Metabolic (hyperglycaemia, hypokalaemia)
- Critical illness

Chronic
- Idiopathic/functional dyspepsia
- Post-surgical (including fundoplication)
- GORD
- Chronic liver disease
- HIV infection
- Endocrine and metabolic (diabetes mellitus, hypothyroidism, chronic renal failure, anorexia nervosa)
- Muscular and connective tissue diseases (myotonic dystrophy, muscular dystrophy, dermatomyositis, systemic sclerosis, amyloidosis, tumour-associated)
- Neurological (central nervous system disease, spinal cord injury, chronic idiopathic intestinal pseudo-obstruction, idiopathic autonomic degeneration)

Table 21.3 Medications with effects on gastrointestinal motility.

Decreased motility or gut transit
- Opiates
- Anticholinergics
- L-Dopa
- Tricyclic antidepressants
- Calcium channel antagonists
- Nitrates
- Phosphodiesterase type 5 inhibitors (e.g. sildenafil)
- Clonidine (an α-2 agonist)
- Sumatriptan (a 5HT-1P agonist)[a]

Increased motility or gut transit
- Metoclopramide
- Domperidone
- Erythromycin (a motilin analogue)[b]
- Beta-blockers
- Selective serotonin reuptake inhibitors

[a]Relaxes the gastric fundus and delays gastric emptying, but increases oesophageal motility.
[b]Stimulates gastric emptying but slows small intestinal transit.

old subjects.[58] EGG recordings are similar in healthy old and young subjects, with subtle differences in the response to nutrients.

There is some evidence for altered responses to the presence of nutrients in the small intestine in the elderly compared with the young. In particular, intraduodenal nutrients stimulate greater cholecystokinin release in the healthy elderly, even allowing for elevated fasting concentrations of CCK in this group,[59] while intraduodenal glucose is more satiating than in the young. This enhanced small intestinal feedback could contribute to both delayed gastric emptying and impaired appetite. Furthermore, there is some evidence that the higher prevalence of *H. pylori* infection and atrophic gastritis in the elderly compared with the young is associated with a decline in levels of the orexogenic peptide ghrelin.[60]

Postprandial hypotension

Blood pressure can decrease markedly after meals in the elderly and this represents an important but often underrecognized clinical problem, leading to syncope and falls.[61] Older people with type 2 diabetes are at particular risk because of the associated autonomic neuropathy. Postprandial hypotension should, in the broadest sense, be regarded as a gastrointestinal disorder, since the postprandial decline in blood pressure appears to be related to the regulation of splanchnic blood flow and the release of gastrointestinal peptide hormones and can be attenuated by administration of the somatostatin analogue octreotide. Among the macronutrients, both carbohydrate and fat contribute to the fall in blood pressure.[62] After oral or small intestinal administration of glucose, the magnitude of the fall in blood pressure is related to the rate at which glucose enters the small intestine.[63] Dietary and pharmacological approaches to slow gastric emptying and small intestinal carbohydrate absorption (e.g. acarbose or dietary interventions such as smaller but more frequent meals) may prove to be effective in the treatment of postprandial hypotension,[64] while distending the stomach (e.g. by drinking a glass of water) can attenuate the postprandial fall in blood pressure.[65]

Small intestine

Although small intestinal function is critical to good nutrition in the elderly, its motility does not appear to be substantially altered with healthy ageing, but can be affected by a number of systemic illnesses.

Changes in small intestinal motor function related to ageing

The small intestine is more difficult to study than the oesophagus or stomach due to its length and relative inaccessibility. Like the stomach, the frequency of its contractions is linked to an underlying electrical rhythm – in this case 8–12 cycles per minute. During fasting, the small bowel undergoes cyclical activity about every 90 min, known as the migrating motor complex (MMC), consisting of motor quiescence (phase I), irregular contractions of increasing frequency (phase II) and a brief period (5–10 min) of regular contractions that propagate distally and serve to sweep

the lumen of debris (phase III). After a meal, the MMC is interrupted by irregular motor activity propagated over short distances that facilitates digestion and absorption.

Small intestinal manometry is carried out in specialized research laboratories and has limited clinical application. Transport through the small intestine can be measured more readily, either by a breath test (which detects an increase in hydrogen resulting from breakdown of ingested non-absorbable carbohydrate, such as lactulose, by colonic bacteria and therefore reflects oro-caecal transit) or by scintigraphy.

MMC periodicity was not altered in healthy elderly volunteers aged 81–91 years compared with the young, using ambulatory jejunal recording, although the propagation velocity of phase III was slower. The elderly had comparable amplitude and frequency of pressure waves to the young during phase III of the MMC and postprandially, but more propagated clustered contractions during fasting and postprandial recordings.[66] The functional significance of the latter phenomenon is unclear, but similar patterns are seen in patients with irritable bowel syndrome. Nevertheless, small intestinal transit in the healthy elderly seems to be comparable to that in the young, in contrast to the delayed transit characteristic of the colon.[8] This is consistent with the observation that small bowel bacterial overgrowth is uncommon in healthy older individuals.[67]

Ageing is associated with an increased prevalence of conditions, such as diabetes mellitus, that potentially affect small intestinal motility, in addition to small intestinal diverticula. Such conditions may induce stasis of small intestinal contents and, together with the reduction in gastric acid secretion often seen on the elderly, predispose to bacterial overgrowth, a potential cause of malnutrition and diarrhoea.[68] However, it should be noted that bacterial overgrowth is rare in the healthy elderly.[69] Small bowel bacterial overgrowth may be diagnosed by culture of duodenal aspirates or by hydrogen breath tests (with glucose or xylose as a substrate), although reports as to their sensitivity and specificity vary widely. A subsequent negative test following a course of antibiotics increases the diagnostic certainty. Treatment is with antibiotics such as metronidazole, tetracycline or quinolones or the non-absorbed antibiotic rifaximin,[70] given for 1–4 weeks and may need to be repeated on a cyclical basis in the event of recurrence. However, there is a paucity of well-controlled data to guide practice in this area.

Systemic disorders associated with disturbance of gastrointestinal motility

Although the effects of healthy ageing *per se* on gastrointestinal motility are modest, the prevalence of co-morbidities increases with advancing age and these may impact on gut function; Parkinson's disease and diabetes mellitus are typical examples. Progressive systemic sclerosis is less common, but has profound effects on gastrointestinal motility. Furthermore, numerous medications can affect gastrointestinal motility; some of these are listed in Table 21.3.

Parkinson's disease

Gastrointestinal dysfunction represents a common manifestation of Parkinson's disease[71] and may both precede and predominate over the somatic motor symptoms.[72] Involvement of the dorsal motor nucleus of the vagus may influence parasympathetic innervation, while abnormalities of the enteric nervous system itself (such as Lewy bodies and loss of dopaminergic neurons) are also evident. Nevertheless, the pathophysiology of gastrointestinal complications of Parkinson's disease has been insufficiently studied and the relative contribution of loss of dopaminergic neurons in the ENS compared with defects of other aspects of neuronal function is unclear.

Dysphagia affects a majority of patients (50–90%), not necessarily in parallel with the duration or severity of other features of the disease. Disturbance of the oropharyngeal phase of swallowing and impaired oesophageal transit, associated with non-peristaltic or tertiary pressure waves, are prominent. Heartburn is a common symptom and could be related to impaired acid clearance. The effects of either L-dopa or anticholinergic therapy on swallowing disorders are inconsistent; both drugs may be associated with either improvement or deterioration of dysphagia. Limited data indicate benefit from apomorphine, which is administered by subcutaneous infusion.

Gastric emptying may be delayed, even in the absence of L-dopa therapy, which in turn slows gastric emptying further. Delayed gastric emptying may contribute to a high prevalence of symptoms such as nausea and bloating and result in impaired nutrition and absorption of oral medications. In particular, L-dopa may be metabolized to dopamine if retained in the stomach and become unavailable for systemic absorption. In patients suffering from the 'on–off' phenomenon of motor fluctuations, gastric emptying may normalize in the 'on' phase, whereas conversely, variations in the rate of emptying may result in erratic L-dopa absorption and in themselves contribute to the 'on–off' phenomenon. Direct infusion of L-dopa into the duodenum has been advocated as a solution to this problem and it has also been suggested that the ratio of dopa decarboxylase inhibitor to L-dopa be increased to improve availability of dopamine both peripherally and centrally.[72] Metoclopramide is contraindicated in parkinsonian patients due to its effects on striatal dopamine receptors, but other prokinetic agents such as domperidone (which does not cross the blood–brain barrier) can be used. Small intestinal, colonic

and ano-rectal dysmotility are also common in Parkinson's disease and may be associated with bowel dilatation and constipation. Oro-caecal transit time is prolonged compared with age-matched controls.

Diabetes mellitus

Diabetes mellitus, particularly type 2 diabetes, is increasing dramatically in prevalence worldwide and occurs frequently in older individuals. Disordered motor function involving all segments of the gastrointestinal tract is common in diabetes and there is a high prevalence of gut symptoms,[73] although there is little information specific to elderly patients with diabetes.[74] Although both disordered motility and gut sensation have been attributed to irreversible autonomic neuropathy, it is now recognized that acute changes in the blood glucose concentration have a major influence on gut function.[75] Studies in a limited number of patients with gastroparesis refractory to medical treatment have revealed losses of both interstitial cells of Cajal, which are responsible for generating the electrical rhythm of the stomach, and myenteric neurons, while staining for inhibitory neurotransmitters is reduced and a few have evidence of gastric myopathy.[76]

In the oesophagus, manometric abnormalities observed in diabetes include a reduction in amplitude of pressure waves, abnormal waves forms and failure of peristalsis, which are associated with delayed oesophageal transit. LOS pressure may be diminished and the prevalence of GORD is increased.

Up to 50% of patients with longstanding diabetes have delayed gastric emptying for solids, liquids or both. Motor correlates of these abnormalities include diminished antral motility and impaired coordination of antroduodenal pressure wave sequences, together with reduced fundic tone. Both the delay in gastric emptying and the underlying motor mechanisms are more marked during acute hyperglycaemia compared with euglycaemia. Disordered gastric emptying potentially contributes to upper gut symptoms, impairs absorption of nutrients and orally administered medications and may result in, and also arise from, poor glycaemic control. Although a delay in gastric emptying may actually improve the postprandial blood glucose profile in non-insulin-requiring patients due to a slower release of carbohydrate to the small intestine, it is likely to result in a mismatch between the absorption of glucose and the onset of insulin action in patients receiving exogenous insulin. Patients with upper gut symptoms referable to the stomach should be investigated with endoscopy to exclude mucosal lesions or obstruction, and consideration can then be given to evaluating the rate of gastric emptying, ideally with scinitigraphy. Diabetic gastroparesis is usually treated with a prokinetic drug, such as metoclopramide, domperidone and erythromycin (an analogue of motilin). The previous agent of choice, cisapride, was withdrawn from many markets due to a risk of cardiac arrhythmia. The role of pyloric injections of botulinum toxin in refractory patients is unclear; a recent retrospective analysis suggested that older patients (aged 50 years or greater) are less likely to benefit than the young,[77] while two trials involving this therapy have not demonstrated any benefit compared with sham injections.[78,79] Similarly, the benefit of implantable gastric electrical stimulators has not yet been adequately demonstrated in controlled trials and, to date, there has been no subgroup analysis of outcomes that specifically addresses efficacy in older patients.

Small intestinal motility is also frequently abnormal in diabetes mellitus. During fasting, the duration of the phases of the migrating motor complex is reduced, whereas postprandially, bursts of non-propagated pressure waves may occur, together with disordered flow patterns of chyme. Small bowel transit appears widely variable in patients with diabetes and its relationship to gastrointestinal symptoms and glycaemic control remains to be clarified. Both diarrhoea and constipation appear common in diabetes; small bowel bacterial overgrowth, coeliac disease and pancreatic exocrine insufficiency should be specifically excluded when patients with diabetes present with diarrhoea. Loperamide and clonidine (an α-adrenergic agonist) may be of benefit when no specific cause of diarrhoea is uncovered, although older patients may be particularly susceptible to adverse reactions (constipation, urinary retention and glaucoma for loperamide; hypotension, bradycardia, sedation and dry mouth for clonidine).

Progressive systemic sclerosis

The peak incidence of progressive systemic sclerosis is in the fifth and sixth decades and gastrointestinal involvement occurs in a majority, affecting multiple regions of the gut, although the correlation between histological involvement and symptoms may be weak.[80] Oesophageal dysmotility has a prevalence of about 80%, with diminished amplitude of pressure waves and sometimes a lack of peristalsis, in the distal (smooth muscle) oesophagus, leading to impaired acid clearance and severe reflux disease. LOS resting pressure also tends to be extremely low. Furthermore, the stomach, small and large intestines and anorectum may be involved, with clinical manifestations of gastroparesis, pseudo-obstruction, bacterial overgrowth (sometimes associated with small intestinal diverticula), malnutrition and constipation or faecal incontinence. Smooth muscle atrophy and fibrosis underlie some of these disturbances,[81] but inhibition of cholinergic transmission in the enteric nervous system by antibodies to M3 muscarinic receptors may be important in the pathogenesis. Similar effects on gastrointestinal motility may be seen in other connective

tissue disorders and in amyloidosis. PPIs are effective in the treatment of GORD, though high-dose therapy may be needed. The role of surgery in refractory reflux symptoms has been controversial, but good results can be achieved.[82] Prokinetic drugs have a role when gastrointestinal transit is delayed.

Functional disorders

Functional gastrointestinal diseases are often potentially overlooked in the elderly.[83] They are characterized by recurrent or persistent symptoms referable to the gut, occurring in the absence of demonstrable organic disease. This group of disorders includes functional dyspepsia (upper abdominal pain, bloating or nausea) and irritable bowel syndrome (IBS) (abdominal discomfort, which may be relieved by defaecation, associated with abnormal bowel habit), and other syndromes related to the oesophagus, anorectum and biliary tract, defined most recently by the Rome III criteria.[84]

The prevalence of IBS appears to be less in the elderly than the middle aged in the United States and United Kingdom[85] and at all ages the prevalence is greater in women than men. Somewhat surprisingly, the incidence, as opposed to prevalence, of IBS appears to increase with age, in at least one US population.[86] This may potentially reflect an increase in healthcare-seeking behaviour in the elderly, although no information regarding consulting behaviour in IBS is available specifically for this age group. In a study of 70-year-olds in a Danish community, although 6–18% had gastrointestinal symptoms consistent with IBS according to various definitions, symptoms had resolved in at least half within the following 5 years,[87] which is probably similar to the prognosis of IBS in the general community. However, it is common for new symptoms to arise in IBS as others resolve.[88] Similar patterns were observed for upper gut symptoms suggestive of functional dyspepsia, indicating that abdominal symptoms are frequent in the elderly, but fluctuate considerably over time. In the general population, around 10% of functional gut disorders follow a bout of infectious gastroenteritis, but recent evidence suggests that the elderly are less prone to developing chronic postinfective symptoms than the young. In contrast to IBS, there is little information regarding the prevalence of functional dyspepsia in older populations.

Although, as discussed, visceral sensitivity seems to decline in healthy ageing, patients with functional dyspepsia or IBS have, as a group, increased sensitivity to gastric and rectal distension. Nevertheless, chronic gastrointestinal symptoms consistent with IBS are common in the elderly, although not markedly greater than in the young, with the possible exception of constipation. Visceral sensitivity has not been studied in the elderly with gut symptoms, nor has tolerance to visceral pain (the lowest level of stimulation at which a subject withdraws or asks to stop). The latter may be relevant, since pain tolerance for somatic stimuli appears to decrease with ageing. The prevalence of *H. pylori* is greater in the older individuals than the young (about 60% at 60 years) but, in the absence of peptic ulceration, its contribution to dyspepsia is controversial.[22]

It is important to exclude organic diseases such as cancer and mesenteric ischaemia when gut symptoms arise in older patients, particularly as the prevalence of organic disease is greater than in the young.[89] For example, when patients present with altered bowel habit, the threshold for colonoscopic investigation should be low. However, it is interesting to note that mesenteric ischaemia seems to occur more often in patients with IBS than those without.[90] Comorbidities such as Parkinson's disease, medications, thyroid disease, diabetes, depression and small bowel bacterial overgrowth must also be considered.

Chronic gastrointestinal symptoms impair quality of life, but many elderly do not present to their doctors, so their impact may go unrecognized in older populations. Depression associated with chronic pain does not appear to be greater in the elderly than the young, but it should be borne in mind that 'gut' symptoms such as anorexia or bowel habit disturbance can also be features of depression. The effects of anxiety on the perception of persistent, as opposed to acute, pain have not been studied closely.[89]

All potential therapies for functional gut disorders must be evaluated against the high placebo response rate (between 20 and 70%) associated with these syndromes, but no clinical trials have focused specifically on the elderly[85] and the potential for adverse effects (e.g. sedation, urinary retention, postural hypotension, blurred vision or glaucoma with tricyclics or hyoscine) needs to be borne in mind in this group. For the management of abdominal pain, the antispasmodics otilonium, hyoscine and peppermint oil[91] and the antidepressants have a good evidence base. The dose of a tricyclic antidepressant used in functional gut disorders is typically lower than standard doses used to treat depression. Selective serotonin reuptake inhibitors may be better tolerated than tricyclics, but there are fewer data regarding their efficacy in IBS and venlafaxine appears less helpful than tricyclics in functional dyspepsia.[92] Probiotics may be of benefit for bloating. Psychotherapy and hypnotherapy have recently shown promise in the management of functional bowel disorders and their efficacy may be comparable to that of pharmacological therapies such as antidepressants,[93] but no information is available about their applicability to the elderly.

When constipation is a feature of IBS, adequate hydration and fibre supplements should be tried, with the caveat that bloating may be exacerbated by a high fibre intake. Osmotic laxatives or lubiprostone (a locally acting type 2 chloride channel activator, which induces intestinal fluid secretion) are other options.[94]

When diarrhoea and faecal urgency predominate, loperamide can be beneficial; a liquid formulation, if available, makes dose titration easier. Alosetron (a 5HT-3 antagonist) may have a place in diarrhoea-predominant IBS in women, but the association of this drug with ischaemic colitis suggests the need to exercise caution, especially in older patients. Randomized controlled trials have included only a few patients over 65 years old. In theory, supplemental fibre should improve the water-holding capacity of stool, but its benefit in diarrhoea has not been proven.

Acknowledgement

The authors wish to thank Professor Richard Holloway, Department of Gastroenterology and Hepatology, Royal Adelaide Hospital, for providing material for the figures and contributing suggestions for the manuscript.

Key points

- Gastrointestinal motor function is relatively well preserved with healthy ageing, but a general decline in visceral sensation is apparent.
- Systemic illnesses and medication use can often impair gut function in the elderly.
- The consequences of disturbed gut motility and sensation include swallowing disorders, impaired nutrition and absorption of medications and altered bowel habit.
- Functional gastrointestinal disorders are prevalent in the elderly, but organic disease must be rigorously excluded.

CHAPTER 22

Gastrointestinal bleeding

Syed H. Tariq
Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

Gastrointestinal (GI) bleeding is a common, life-threatening condition. The source of GI bleeding could be upper or lower or a combination of both. The type of GI bleeding also varies by amount of bleeding, which could be massive and clinically apparent in the form of haematemesis or haematochezia or it could be hidden or obscure. Upper GI bleeding (UGIB) refers to GI blood loss whose origin is proximal to the ligament of Treitz. Acute UGIB can manifest as haematemesis, coffee ground emesis and the return of bright red blood via nasogastric tube and/or melaena. Haematochezia could occur with UGIB when the bleed is brisk. Lower GI bleeding (LGIB) usually is defined as bleeding distal to the ligament of Treitz.

GI bleeding is a common geriatric problem.[1,2] In the United States, about 350 000 patients are hospitalized for UGIB each year[3] and 35–45% of these are 60 years or older.[4] The incidence of UGIB ranges between 50 and 150 per 100 000 population per year.[5] Women 60 years of age account for 60% of UGIB.[6] The mortality of UGIB has remained at ~6–10% for the last 60 years.[7–9] There is no difference in morbidity and mortality between young and old persons.[10]

The exact incidence of LGIB is not known,[11] but the incidence of hospitalization is about 20–27 episodes per 100 000 persons per year, with a 200-fold increase with advancing age from the second to the eighth decades.[12–14] Most patients with LGIB have favourable outcomes despite advanced age and other comorbid conditions.[15,16]

The mortality for LGIB is 4–10% or greater and is more common with severe bleeding and those undergoing emergency surgery.[17–19] Hospitalized patients admitted for other causes in whom bleeding starts in hospital have significantly higher mortality than those admitted already with LGIB (23 versus 2.4%). The independent predictors of all-cause mortality were increasing age, duration of hospital stay and number of comorbid conditions.[12]

Economic impact

The economic burden of LGIB is not known, but is presumably significantly higher given the prevalence of this disorder in older adults. Thomas *et al*. estimated that diverticular haemorrhage alone cost US$1.3 billion in 2001.[20] The average cost for a patient with LGIB in Canada is approximately US $3000 with an average length of stay of 7.5 days.[21] The estimated direct and indirect cost of peptic ulcer disease exceeds US$9 billion per year.[22]

Clinical presentation

It might be difficult at times to determine the accurate clinical presentation in older people because of poor vision or poor cognition, for example, providing a vague description of haematemesis versus haemoptysis. Haematemesis is defined as vomiting of blood and is caused by UGIB from the oesophagus, stomach or proximal small bowel. The blood may be bright red or it may be old and take the appearance of coffee grounds. Melaena is defined as passage of black, tarry and foul-smelling stools. The black, tarry character of melaena is caused by degradation of blood in the more proximal colon. Haematochezia refers to bright red blood from the rectum that may or may not be mixed with the stool. Occult GI bleeding denotes bleeding that is not apparent to the patient and is caused by small amount of bleeding. However, patients' and physicians' reports of stool colour are often inaccurate and inconsistent.[23] In addition, bright red bleeding, could also be seen be seen from lesions in the right colon.[24]

The manifestation of GI bleeding varies with underlying medical problems; for example, a patient with underlying ischaemic heart disease may present with chest pain after brisk bleeding. Coexisting heart failure, hypertension, renal disease, diabetes, or pulmonary disease may be aggravated by severe GI bleeding, resulting in a shock. Some patients with chronic blood loss may present with signs of

Table 22.1 Clinical predictors of poor outcomes risks of rebleeding without endoscopic intervention.

Clinical factors	
Haemodynamic instability (shock, hypotension)	
Bleeding manifested as haematemesis or haematochezia	
Failure of blood to clear with gastric lavage	
Age >60 years	
Coagulopathy	
Presence of underlying serious medical condition	
Hospitalized patients	
Endoscopic factors	*Risk of rebleeding without endoscopic intervention (%)*
Clean base	<3
Flat spot	<8
Adherent clot	30–35
Non-bleeding vessel	Up to 50
Arterial bleeding	Almost 100

anaemia (weakness, pallor, dizziness, fatigue) or cirrhosis and portal hypotension. GI bleeding can also cause hepatic encephalopathy in patients with existing liver disease or develop hepatorenal syndrome. Orthostatic changes may be seen with moderate to severe bleeding.

Clinical course

The hospital course of GI bleeding is similar in both young and older persons. The need for endoscopic therapy, admission to intensive care, blood transfusion requirements, need for surgery and length of hospital stay are not different.[1,10,25] The length of hospital stay shortened from 1970–80 into the 1990s.[25] In 1992 and 1994, the mean hospital stay for UGIB in older adults (>60 years of age) was 6.0 days compared with 5.6 days in those <60 years of age. Table 22.1 describes factors predicative of ulcer rebleeding and clinical factors leading to increased mortality in older adults. The risk of rebleeding is higher for arterial bleeding, adherent clot and non-bleeding vessels compared with clean base and flat spot. Also, mortality rates are higher for arterial bleeding compared with clean base.[26,27]

Causes of GI bleeding

In the elderly, oesophagitis and gastritis in combination with peptic ulcer disease account for 70–91% of hospital admissions for UGIB. A greater percentage of patients with Mallory–Weiss tears, GI varices and gastropathy are seen in the younger population as a result of the greater degree of alcohol abuse in this age group.

Tables 22.2 and 22.3 summarize the site of different studies, number of patients, age and physician by specialty involved for UGIB and LGIB, respectively. Table 22.4 shows the prevalence of UGIB in different studies. The prevalent UGIB causes are gastric ulcer (5–43%), duodenal ulcer (6–42%), gastritis (6–42%), oesophagitis (2–15%), oesophageal varices (1–20%), Mallory–Weiss tear (1–16%) and others (combination of lesions) (2–17%). The common causes of LGIB are summarized in Table 22.5, the prevalent causes being diventricular bleeding (17–56%), angiodysplasia (3–30%), haemorrhoids (3–28%) and polyps (2–30%).

Evaluation and management of GI bleeding

In this section the general evaluation and management of GI bleeding is discussed. For disease specific treatment refer to gastroenterology texts.

Initial evaluation

The first step in the management of GI patients is stabilization with blood transfusion and other treatment deemed necessary before any diagnostic evaluation. If a patient's initial blood pressure and pulse rate are normal, one can consider performing orthostatics to look for volume loss. Orthostatic changes are usually suggestive of 10–20% loss in circulatory volume; although supine hypotension suggests >20% volume loss. Hypotension with a systolic blood pressure of <100 m Hg or baseline tachycardia suggests significant haemodynamic compromise that requires urgent volume resuscitation. All patients require a complete history and physical examination: blood studies (platelet count, prothrombin time, partial thromboplastin time); liver function tests, renal functions and complete blood counts. Determination of blood group and type and cross-match of 2–4 units of blood should be arranged urgently.

Seven independent predictors of the severity of acute LGIB have been identified: hypotension, tachycardia, syncope, non-tender abdominal examination, bleeding within 4 h of presentation, aspirin use and more than two comorbid diseases.[48] These predictors can be helpful in classifying patients into three risk groups. Patients with more than three risk factors had an 84% risk of severe bleeding, those with one to three risk factors had a 43% risk and those with no risk factors had a 9% risk.[32] In a prospective study of patients admitted with LGIB, three predictors of severity and adverse outcome were identified: initial haematocrit <35%, abnormal vital signs and gross blood on rectal examination.[31]

Volume restoration

Restoration of intravascular volume is established by inserting two large-bore intravenous peripheral lines with an 18 gauge catheter or central venous line. Fluids used for resuscitation include normal saline, lactated Ringer's solution and 5% hetastarch, with blood transfusion as soon as it is available to improve the oxygen-carrying capacity. Those patients who are in shock may need volume administration using infusion devices or vasopressors if clinically indicated.

Correction of coagulopathy is essential, if possible using fresh frozen plasma to correct/prolong coagulation parameters. Parenteral vitamin K may be used for prolonging prothrombin time from warfarin therapy or nutritional deficiency. Platelet transfusion could be indicated if platelets are low or dysfunctional. Protection of the airways may be needed in circumstances where there is a decrease in mental status (shock, encephalopathy), massive haematemesis or active variceal haemorrhage is present. Antisecretory therapy with a proton pump inhibitor (PPI) is warranted and could be done either orally or intravenously. Antibiotics should also be considered if the patient has underlying cirrhosis.

History

A detailed history could point towards a possible diagnosis. Pain in the epigastric region relieved by food or antacid suggests peptic ulcer disease. Weight loss and anorexia

may suggest GI malignancy, but in the geriatric population the most common cause of weight loss is depression and should be ruled out before initiating malignancy work-up in non-anaemic and non-bleeding patients. Dysphagia can be due to stricture or cancer of the oesophagus. Mallory–Weiss tears can be caused by intractable vomiting. Haematemesis usually suggests UGIB, but precautions should be taken as older people may have poor vision and be unable to provide an accurate description. Melaena could be seen in both UGIB and LGIB and usually requires about 100 ml of blood. The stool remains positive for blood for almost 2 weeks. Patients with inflammatory bowel disease or infectious colitis (*Shigella, Salmonella, Campylobacter*) usually present with bloody diarrhoea, fever and abdominal pain. One needs to be very cautious in initiating diagnostic work-up in older patients with bleeding diathesis with skin tears and ecchymosis, since this be seen in older patients with minor trauma. Occult blood or haematochezia could be the first sign of colon cancer or polyps. Painless LGIB can also be seen in diverticulosis, angiodysplasia and ulcerated cancerous lesions. Blood on the surface of stool or blood on toilet paper suggests internal haemorrhoids. It is equally important to determine a patient's cognitive ability by using a Mini-Mental Status Examination or Saint Louis University Mental Status Examination to access cognition.[49,50] If a patient is demented then it is advisable to obtain history from the caregiver accompanying the patient or by obtaining history from the nursing home staff.

One should remember to obtain history of aspirin, non-steroidal anti-inflammatory drug (NSAID) and anticoagulation drug use. Some over-the-counter cough medications are usually combined with aspirin and patients may not be aware of it.

Physical examination

A detailed physical examination starting with inspection of the nose and throat is important to exclude bleeding in this area. One should look for signs of chronic liver failure (spider angiomas, hepatosplenomegaly, ascites and jaundice), and also for arteriovenous malformation, especially of the mucous membranes, which may be associated with hereditary haemorrhagic telangiectasia (Rendu–Osler–Weber syndrome), in which multiple angiomas of the GI tract are associated with recurrent bleeding. Cutaneous nail bed and GI telangiectasia may be associated with connective tissue disease or scleroderma. A digital rectal examination is very important to feel for masses and fissures and obtain a sample of stool, to be tested chemically for blood. It is also mandatory to comment on the colour of stools. Internal haemorrhoids, if thrombosed, could be felt by digital examination. If UGIB is suspected, a nasogastric lavage should be performed. Bloody nasogastric lavage is suggestive of UGIB but is negative in about 10% of cases. Coffee ground aspirates indicate bleeding that is slow or has stopped, but bright red blood indicates active bleeding. Continuous nasogastric aspiration help monitor the status of bleeding.

Excluding UGIB

Excluding UGIB is an important step because 2–15% of patients with presumed LGIB will have UGIB. Nasogastric

lavage is a quick and safe procedure but, to avoid unnecessary patient discomfort, it should be reserved for patients with evidence of brisk bleeding in whom an upper endoscopy is not anticipated and risk stratification is needed. Nasogastric lavage containing gross blood, 25% blood-tinged fluid or strongly guaiac-positive dark fluid was found to have 80% sensitivity for bleeding above the ligament of Treitz and positive and negative predictive values of 93% and 99%, respectively.[30] The presence of bile increases the sensitivity of nasogastric lavage,[29] although the correlation between the presence of a bilious aspirate versus presence of bile acids has been questioned.[28] The blood urea nitrogen to creatinine ratio is a non-invasive test also used to help distinguish upper versus colonic sources of bleeding. In one study, a ratio of 33 or higher had a sensitivity of 96% for UGIB, although overlap was observed with LGIB, especially in patients with UGIB without haematemesis.[51] Oesophagogastroduodenoscopy remains the gold standard for excluding an upper GI source in patients presenting with severe bleeding, especially those with haemodynamic instability.

Oesophagogastroduodenoscopy (EGD) can be performed at the bedside in the intensive care unit or in the GI suite and is the preferred method for the investigation and therapy of UGIB. It has the highest diagnostic accuracy and therapeutic capacity and low morbidity. It can be performed early in the clinical course, after the patient is haemodynamically stabilized.

Colonoscopy is performed if the lower GI tract is suspected as a cause of bleeding; its yield is higher if performed in the first 24 h. Colonoscopy is best performed in patients whose condition has clinically stabilized and who can tolerate adequate bowel purge. In order to achieve good results, the patient should be able to drink an adequate bowel prep. Many patients find polyethylene glycol (PEG)-based preparations difficult to take because of the large volume of fluid they are required to consume.

When colonoscopy is negative and LGIB is suspected, *tagged red blood cell (TRBC) scanning* should be considered. RBCs labelled with technetium-99m remain in the circulation for 48 h and extravasate into the lumen with active bleeding. This extravasation is can be detected as a pooling of the radiotracer on scanning with a gamma camera. Bleeding rates as low as $0.1\,ml\,min^{-1}$ can be detected in research settings. When the test is positive, it is accurate in about 80% of cases. About 20% of the localization is false positive, which precludes the use of this test alone for surgical resection of the bowel. The clinical utility of this test is for screening before arteriography.

Arteriography allows localization and potential therapy for GI bleeding when the bleeding rate exceeds $0.5\,ml\,min^{-1}$. It can provide the aetiology, especially bleeding diverticula or angiodysplasia. Angiography can also be used in brisk UGIB when endoscopy is impossible. Embolization of the bleeding artery is infrequently performed because of the risk of bowel infarction. Small-bowel enteroscopes can be used when radiological evaluation suggests a jejunal bleeding source or in recurrent (obscure) GI bleeding in which conventional endoscopy is unrevealing.

Surgery is considered when the blood transfusion requirement exceeds 4–6 units over a 24 h period or 10 units overall, and also with more than two or three recurrent bleeding episodes from the same site. It is prudent to perform colonoscopy before undergoing emergency total colectomy. The extent of comorbid conditions and the degree of bleeding need to be factored in when considering surgery. Therapies for specific lesions are mentioned here that require a different treatment modality than already mentioned.

Variceal haemorrhage

Management of variceal bleeding usually requires intensive care monitoring and endotracheal intubation for airway protection. Octreotide infusion should be initiated immediately ($50–100\,\mu g\,h^{-1}$ bolus followed by an infusion of $25–50\,\mu g\,h^{-1}$). Octreotide is usually well tolerated and reduces portal pressure. Vasopressin is an alternative pharmacological agent but is used less frequently because of the side effects: myocardial ischaemia and infarction, mesenteric ischaemia and infarction, ventricular arrhythmias, cardiac arrest and cutaneous ischaemic necrosis. Concomitant infusion of nitroglycerin is used at times to reduce the undesirable side effects of vasopressin.

Variceal ligation or banding is the endoscopic therapy of choice. It is very effective and superior to sclerotherapy.[52–54] Complications of banding include superficial ulcerations, dysphagia, transient discomfort, transient chest discomfort and rarely oesophageal stricture. *Sclerotherapy* is also effective but is used less frequently because of its complications (ulceration, stricture, perforation, pleural effusion, adult respiratory distress syndrome and sepsis). Recurrent bleeding may be seen in up to 50% of patients but will respond to repeated treatment. Fever may be seen in up to 40% of patients, but if it persist for more than 2 days a bacteraemia test may be necessary.

Transjugular intrahepatic portosystemic shunts (TIPS) have been used in the treatment of complications of portal hypertension. TIPS are used for the control of acute variceal bleeding and prevention of variceal rebleeding when pharmacological therapy and endoscopic therapy have failed. The major limiting factors for TIPS success are shunt dysfunction and hepatic encephalopathy. Because shunt stenosis is the most important cause of recurrent complications of portal hypertension, a surveillance programme to monitor shunt patency is mandatory.[55]

Shunt surgery (portacaval or distal splenorenal shunt) should be considered in patients with good hepatic reserve

if the patient fails endoscopic or pharmacological therapy, having difficulty in returning for follow-up visits, increased risk of death for recurrent bleeding or lives away from medical care. The morbidity and mortality are high with this procedure, as also is postoperative encephalopathy.

Balloon tamponade has a major role in the therapy of variceal haemorrhage. It is used temporarily to stabilize a patient in situations when more definite therapy is available. The commonly used balloon tamponade are the Sengstaken–Blakemore tube and the Minnesota tube, both having a gastric and oesophageal balloon.

Angiodysplasia can occur anywhere in the GI tract and can be occult or overt GI bleeding. Actively bleeding angiodysplasia is best treated by endoscopic therapy (heater probe, laser or organ plasma coagulation), intra-arterial vasopressin or embolization during angiography or surgical resection. Endoscopic ablation is recommended even when non-bleeding angiodysplasia are found in the presence of iron deficiency anaemia. The associated anaemia should be treated with iron.

Stress ulcer is encountered in patients who are in the intensive care unit and on ventilation for more than 48 h with coagulopathy, sepsis, burns and cerebrovascular events. Prophylactic therapy should be administered in patients who are at increased risk. Histamine-2 receptor antagonist, sucralfate and proton pump inhibitors can be used.

Diverticulosis is usually seen on endoscopy, but bleeding develops in about 5% of the patients with diverticula. Bleeding usually stops in these patients 80% of the time but may reoccur. Persistent bleeding may require intra-arterial vasopressin during angiography or even surgical resection.

Aortoenteric fistula is an uncommon but lethal cause of GI bleeding. These patients usually have a history of aortic graft surgery and present with bleeding after surgery. The fistula site is usually aortoduodenal but can be anywhere in the small and large intestine. The classic presentation is herald bleed hours to weeks before massive GI bleeding. Recognition of this condition is essential, as undiagnosed cases could be fatal. Endoscopy with examination of the fourth portion of the duodenum is essential and should be performed immediately. Angiography or computed tomographic scanning may show a leak at the graft site. A negative study does not exclude an aortoenteric fistula. If suspicion is high, a surgical consultation is essential.

Radiation proctitis/colitis results years after exposure to radiation therapy. Intermittent haematochezia results from aberrant superficial mucosal vasculature in the distal colon. Treatment is usually supportive and laser photocoagulation of the mucosal telangiectasias.

Haemorrhoids is the most common cause of haematochezia in outpatient clinics. Treatment is usually avoidance of constipation by using a fibre-rich diet and supportive care. Surgical and endoscopic banding of the haemorrhoids is also available.

Conclusion

GI bleeding is a common geriatric problem. The incidence of GI bleeding is about 35–45% in people 60 years of age and older. The incidence of LGIB is unknown. The causes of GI bleed vary in different studies. The diagnosis and management of GI bleeding are similar to those in young adults in many ways.

Key points

- 40% of persons with GI bleeding are over 60 years of age.
- *Helicobacter pylori* should be excluded in all persons with UGIB.
- Persons with LGIB require endoscopy.
- Angiodyplasia is not uncommon in older persons.

>
> (Selzer, 1976)

Age-related hepatobiliary changes

Liver

Traditionally, hepatic biochemical parameters such as serum transaminases, hepatic alkaline phosphatase, γ-glutamyltranspeptidase and serum bilirubin are considered indices of liver function. These parameters, which are indeed more reflective of disrupted hepatocyte integrity and liver dysfunction, are not altered with ageing (James, 1997; MacMahon and James, 1994). However, there is an age-related compromise in more objective and sophisticated dynamic liver function indices. Available data show that with ageing hepatic volume and perfusion may decrease by approximately 30%. Other indices of hepatic metabolic function, such as nitrogen synthesis and aminopyrine clearance, also decrease with ageing. Likewise, age-related reduction in hepatic microsomal cytochrome content may compromise efficient drug metabolism in the elderly (Wynne *et al*., 1989; Fabbri *et al*., 1994; James, 1997).

Histological studies have identified decreased smooth endoplasmic reticulum and fewer mitochondria in hepatocytes from older adults (Schmucker, 1990) Age-related reduction in hepatic regeneration is particularly concerning. Several studies suggest that the older liver is more vulnerable to stress, perhaps due to an age-related reduction in mitogen activated protein kinase activity (Liu *et al*., 1996). These cellular changes contribute to the poorer outcomes observed in older adults following hepatic insult.

Few studies have specifically examined the effect of ageing on the gallbladder and biliary tract. With ageing, there is an increase in the diameter of the common bile duct, due to replacement of biliary ductal myocytes with connective tissue cells (Kialian and Aznaurian, 1995).

In addition, the lithogenicity of bile increases, resulting in an increased tendency to form cholesterol and calcium bilirubinate stones (Siegel and Kasmin, 1997). These preceding changes, set against a background of lifetime exposure to potentially hepatotoxic agents, set the stage for hepatobiliary disease as a major contender in geriatric medicine.

Hepatic diseases of the elderly

Viral hepatitis

Classically, viral hepatitis is defined as hepatic inflammation induced by infection with specific hepatotrophic viruses. Histological features include diffuse or patchy necrosis of the liver acini. Severity of clinical presentation is variable. Some patients are asymptomatic, while others may complain of flu-like and fairly non-specific symptoms such as myalgia, athralgia, anorexia, nausea, vomiting and diarrhoea. Physical examination may reveal fever, jaundice, hepatomegaly and, in some cases, cutaneous manifestations such as purpura, urticaria and other skin lesions.

Geographical distribution and prevalence of viral hepatitis vary with the infecting agent (Figure 23.1).

Hepatitis A virus

Hepatitis A virus (HAV) is a 27 nm single-stranded, non-enveloped RNA picornavirus. Although infection typically occurs by faecal-oral transmission, a few cases of HAV have occurred through haematogenous transmission (Centers for Disease Control and Prevention, 1999). Onset of symptoms is usually 2–6 weeks after exposure. In younger adults, hepatitis A infection is usually subclinical with mild symptoms.

[1]This chapter is as in the Fourth Edition.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

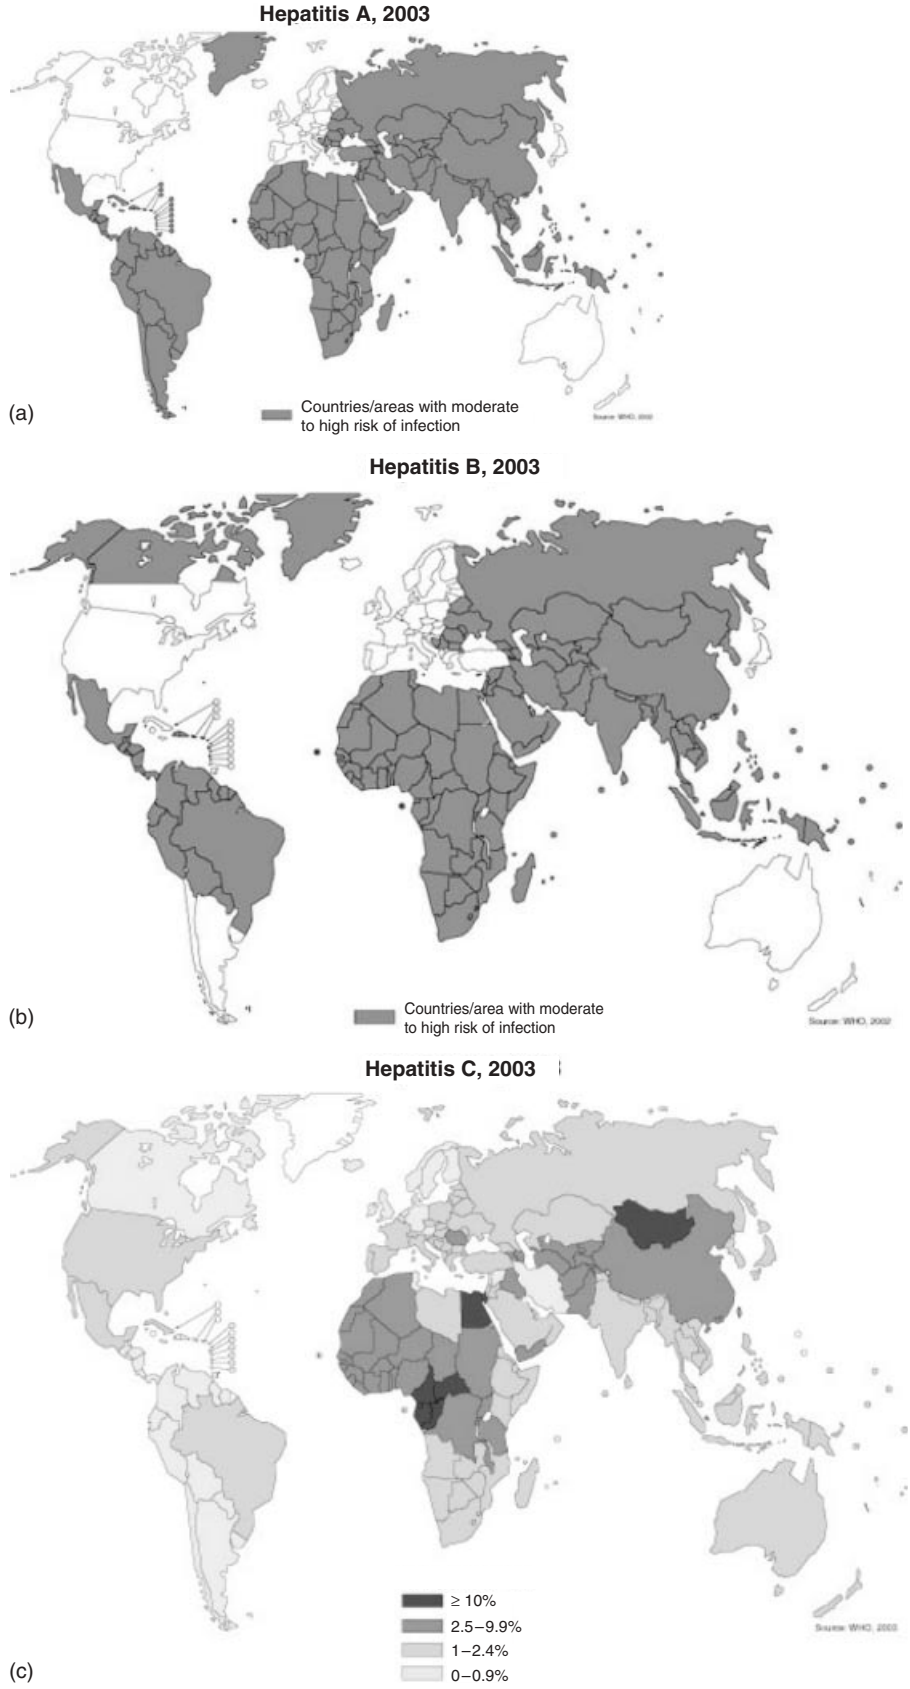

Figure 23.1 Geographical distribution of hepatitis A, B and C.

Jaundice is present in less than 10% of cases. In contrast, although hepatitis A infections are less frequent in older adults, symptoms are likely to be more severe. In addition, the risk of developing and dying from complicating fulminant liver failure is far more common in infected elders. Reported case fatality rate among patients over the age of 65 years is 4% compared with 0.07% in patients aged 15–24 years (Forbes and Williams, 1988). Current recommendations state that older persons travelling to endemic areas should receive HAV vaccination. Additionally elderly food handlers and patients with chronic liver disease are also advised to receive HAV vaccination, although data regarding the efficacy and cost-effectiveness of the vaccine in older adults are lacking (James, 1997).

Hepatitis B virus

Hepatitis B virus (HBV) is a 42 nm double-stranded, enveloped DNA hepadna virus. HBV is a highly infectious virus transmitted through sexual intercourse or contact with infected blood, blood products and saliva. Vertical maternofetal transmission also occurs during childbirth. The incubation period of HBV is approximately 120 days (Lok and McMahon, 2001). Although most infections occur in young adulthood, serological evidence of HBV infection is threefold higher among older adults aged between 64 and 74 years. Rates of HBV infection are also higher among nursing home residents compared to those in community dwelling elders. Sporadic outbreaks of HBV infection in nursing home residents have been linked to inappropriate sharing of razors and bathing appliances. Data indicate that in older adults who contact HBV, the risk of progressing to chronic hepatitis is over 50% compared with 5% following acute infection in younger adults. Nevertheless, acute hepatitis B is rare among older adults, and older adults with acute HBV infection are usually only mildly symptomatic (Marcus and Tur-Kaspa, 1997; Reeder and Halket, 1987). Nevertheless, age remains a risk factor for the development of life-threatening fulminant hepatitis. Perhaps as a result of more prolonged exposure, older adults with HBV infection are more likely to develop hepatocellular carcinoma and liver cirrhosis (Beasley, 1988; MacMahon and James, 1994).

Hepatitis C virus

Hepatitis C virus (HCV) is a 55 nm enveloped RNA flavivirus, with an incubation period ranging from 15 to 90 days. Of the six known genotypes, type 1 is the most common in the United States. Although transmission is primarily haematogenous, a few cases have been transmitted through saliva and human bites (Bukh *et al*., 1995; Chu *et al*., 2002). Data indicate that the prevalence of acute HCV infection among older adults equals, and, in some cases, surpasses that in the general population. Within the United States, reported seroprevalence rate among adults aged over 70 years is 1%, compared with 1.8% among the general population (Alter *et al*., 1999). In an Italian cohort aged over 65 years, the HCV infection prevalence rate was over 4% compared with 3.2% among a comparable cohort of young subjects (Monica *et al*., 1998). Although the incidence of new cases has declined over the past decade, projections indicate that over the next 20–30 years the prevalence of HCV among older adults will increase significantly.

As in younger adults, infection with HCV in elders is only mildly symptomatic during the acute phase. However, the clinical course in older patients is much more aggressive and lethal. Similarly, advanced age at diagnosis of the disease portends more rapid progression to fibrosis and cirrhosis (Seeff, 1997; Watson *et al*., 1996). Other risk factors for the development of cirrhosis include alcohol use and obesity. Studies show that in patients who acquire HCV over the age of 60 years the risk of developing cirrhosis is reported to be as high as 46%, compared to approximately 7% among patients in the fourth decade of life. Reasons for the aggressive clinical course with ageing are not clearly known, although age-related immunocompromise has been proffered as a likely theory (Simmonds *et al*., 1996).

Hepatitis D virus

Hepatitis D virus (HDV) is a single-stranded RNA viroid that is dependent on the HBV envelope protein for replication and pathogenicity. Transmission of HDV occurs haematogenously or through sexual contact and results in either coinfection or superinfection. Coinfection occurs when there is simultaneous transmission of both HDV and HBV, while superinfection refers to HDV infection of a previously HBV positive patient. Patients with coinfections have a better prognosis and progress to chronic disease in less than 5% of cases. In contrast, 70–90% of superinfected patients develop cirrhosis. Although HDV infection causes less than 5% of chronic hepatitis, it accounts for approximately 7500 new infections annually and has a mortality rate of 30% (Alter and Hadler, 1993). Data in older subjects are lacking.

Hepatitis E virus

Hepatitis E virus (HEV) is a single-stranded RNA calicivirus that is transmitted feco-orally. This virus tends to infect younger adults and is rare in developed countries. Characteristically, pregnant women have a 20% mortality rate from this disease compared with 1% in the general population.

Older people travelling to endemic regions such as Asia, Mexico and Africa may be at risk. Prophylaxis is ineffective and the avoidance of consumption of foods and water that may be contaminated is strongly recommended (Gilchrist, 1999).

Hepatitis F virus

Viral particles identified in the stool of post-transfusion, non-A, non-B, non-C, non-E hepatitis cases and injected into Indian rhesus monkeys caused acute hepatitis with elevated transaminases. Consequently, this viral enteric agent was named *hepatitis F virus* (HFV). However, to date there are no convincing corroborating scientific reports. Although sporadic cases in humans may have been identified in Europe, United States, and India, the validity of this virus remains questionable (Deka *et al*., 1994).

GB virus type C (GBV-C)

This virus belongs to the Flaviviridae and was previously referred to as hepatitis G virus (HGV). Currently, the lack of proven association of this virus with either acute or chronic hepatitis has discouraged the use of the name HGV (Dickens and Lemon, 1997). The name GBV-C was derived from a surgeon, whose initials were GB, after marmosets inoculated with his serum developed hepatitis. On the basis of this single observation, the surgeon was erroneously thought to have post-transfusion hepatitis. Later evidence did not support this diagnosis (Almeida *et al*., 1976). Indeed, GB virus type C (GBV-C) infection is common, but is yet to be associated with definite pathogenicity (Dickens and Lemon, 1997). Currently, the major clinical significance of this agent lies in the fact that HIV-positive patients infected with GBV-C may have prolonged survival (Xiang *et al*., 2001). Few data exist regarding the pattern of GBV-C infection in ageing adults.

Transfusion transmitted virus

Transfusion transmitted virus (TTV) is a single-stranded DNA virus. Despite the name, feco-oral transmission of the virus also occurs. Infection is usually acquired in childhood and may persist for years. Its role in causing hepatitis or other diseases has not been proven. Even though one of the genotypes of TTV is suspected to cause hepatitis, the pathogenicity of TTV in humans remains poorly defined (Takacs *et al*., 2003). The prevalence of TTV is also unclear. Available data indicate that the virus has been identified in 1% of blood donors, 18% in post-transfusion subject, 15% of patients with liver cirrhosis and 27% in patients with end-stage liver failure (Naoumov and Petrova, 1998). Notably, high TT virus load has been found to be independently associated with the occurrence of hepatocellular carcinoma among patients with HCV-related chronic liver disease (Nishizawa and Okomoto, 1997).

Autoimmune hepatitis

Autoimmune hepatitis is characterized by severe chronic hepatitis in the presence of circulating autoantibodies. Characteristically, there is frequent progression to liver cirrhosis. Originally described as a disease of young women, autoimmune hepatitis is now known to affect all age groups and both genders. Approximately 20% of all patients diagnosed with autoimmune hepatitis are over the age of 65 years (Newton *et al*., 1997). Diagnostic criteria for autoimmune hepatitis are unchanged with age, and the prognosis for affected older adults is no worse than for younger adults (Table 23.1). Nonetheless, older adults present with less acute symptoms, but are more likely to have severe histological inflammation and necrosis. Unfortunately, data indicate that older adults are less likely to be prescribed immunosuppressive therapy, even though this has been shown to prolong survival in patients with severe disease. There are no data to support the benefits of therapy in older adults with mild disease (Czaja and Freese, 2002).

Drug-induced hepatitis

Several unique factors predispose the elderly to drug-induced hepatotoxicity. These include polypharmacy and, subsequently, an increased risk of drug-induced adverse effects and drug–drug interactions. Age-related physiological changes, such as reduced liver mass, hepatic hypoperfusion and reduced activity of phase 1 hepatic drug-metabolizing enzymes, further increase the likelihood of hepatic injury in response to toxic drugs. Age-related changes in body composition may compromise the volume of distribution, thereby increasing serum drug levels. Hypoalbuminaemia resulting from excess cytokine elaboration, related to ageing or disease, may reduce protein binding and further increase the likelihood of drugs attaining toxic levels. Finally, altered pharmacodynamics with ageing affect the response to drugs at the tissue level (Regev and Schiff, 2001; Varanasi *et al*., 1999).

Not surprisingly, drug-induced liver disease occurs more frequently, and is more severe, in older adults. In addition, older patients with coexisting renal or hepatic disease are more likely to be affected. Documented prevalence of drug-induced hepatitis ranges from 50 to 140 per 1 million person-years in adults aged between 70 and 79 years (Almdal and Sorensen, 1990; Sgro *et al*., 2003). Overall, the incidence of drug-induced liver disease may be higher in older adults simply because these drugs are used more frequently. Non-steroidal anti-inflammatory drugs (NSAIDs) are used extensively by older adults for a variety of arthritic and non-arthritic conditions. All NSAIDs are potentially hepatotoxic. Nevertheless, the reported rate of NSAID-induced hepatotoxicity is less than 1%. Affected patients are usually asymptomatic, with elevated hepatic transaminases. Hepatic alkaline phosphatase may also be mildly elevated. Notably, patients with piroxicam-induced hepatitis may present with severe cholestatic features. NSAID hepatitis

Table 23.1 Diagnostic criteria for autoimmune hepatitis (Alvarez *et al*., 1999; Czaja and Freese, 2002).

Criterion	Definite	Probable
Genetic liver disease	Normal α1-antitrypsin, ceruloplasmin, iron and ferritin levels	Partial α1-antitrypsin deficiency, non-specific serum copper, ceruloplasmin, iron and ferritin abnormalities
Viral infection	No markers of current infection with HAV, HBV, HCV	No markers of current infection with HAV, HBV, HCV
Toxic or alcohol injury	Daily alcohol $<25\,g\,day^{-1}$ and no recent use of hepatotoxic drugs	Daily alcohol $<50\,g\,day^{-1}$ and no recent use of hepatotoxic drugs
Laboratory features	Predominant serum aminotransferase abnormality, globulin, gamma-globulin or immunoglobulin G level >1.5 times normal	Predominant serum aminotransferase abnormality; hypergammaglobulinaemia of any degree
Autoantibodies	ANA, SMA or anti-LKM1 >1:80; no AMA	ANA, SMA or anti-LKM1 >1:40, or other autoantibodies[a]
Histological findings	Interface hepatitis No biliary lesions, granulomas or prominent changes suggestive of another disease	Interface hepatitis No biliary lesions, granulomas or prominent changes suggestive of another disease

[a]Perinuclear antineutrophil cytoplasmic antibodies, antibodies to soluble liver antigen/liver pancreas, actin, liver cytosol type 1 and asialoglycoprotein receptor.
ANA, antinuclear antibody; SMA, smooth muscle antibody; LKM, liver kidney microsomal antibody; AMA, antimitochondrial antibody.

usually responds well to withdrawal of the offending agent. All older adults started on NSAIDs should have their liver function evaluated within two to three months of starting therapy (Hepps *et al*., 1991; Solomon *et al*., 2003).

Following a decline in the use of methyldopa, hepatic disease associated with the use of cardiac medications exhibited a decline. However, with the increased use of amiodarone, hepatocellular disease related to cardiac medications has begun to increase. Affected patients are usually asymptomatic. Approximately half of all patients on amiodarone exhibit a rise in serum transaminase levels. Amiodarone-induced hepatitis may occur with both oral and intravenous administration. These changes resolve if amiodarone is withdrawn early in the course of treatment. Other histological findings of amiodarone-induced hepatitis include steatohepatosis, cholestatic hepatitis and micronodular cirrhosis (Tameda *et al*., 1996; Traverse *et al*., 1994; Gonzalez Galilea *et al*., 2002)

With most medications, the increased prevalence of drug-induced hepatotoxicity in older adults is a consequence of increased exposure. However, certain drugs such as benoxaprofen, halothane and several antituberculous agents – isoniazid (INH), rifampicin and pyrazinamide – are inherently more likely to cause hepatotoxicity in older adults (Varanasi *et al*., 1999; Nagayama *et al*., 2003). Benoxaprofen is a non-steroidal agent, which was withdrawn by the United States Food and Drug Administration (FDA) following several reports of fatal liver failure occurring specifically in adults over the age of 70 years. Similarly, animal studies indicate an age-related increase in sensitivity to the effects of halothane, resulting in an increased risk of hepatic failure and death among older adults exposed to this agent.

INH hepatitis is rare in young patients but occurs in more than 2% of patients aged over 50 years. Increased sensitivity to INH in older adults is related to changes in hepatic physiology and altered pharmacokinetics. INH metabolism produces toxic reactive metabolites presumably from acetylation. Traditionally, persons with the rapid INH acetylator phenotype were considered more prone to toxicity. Most recent studies have failed to confirm this relationship. Indeed, convincing data suggest that slow acetylators may divert larger amounts of INH to an alternative metabolic pathway (cytochrome P450 2E1) that results in production of a toxic reactive metabolite (Huang *et al*., 2003). The precise mechanism underlying INH toxicity is still unknown.

Presenting features of INH toxicity range from asymptomatic elevation of transaminases to fulminant hepatic failure requiring liver transplantation (Vasudeva and Woods, 1997). Thus, patients on INH should receive serial serum transaminase measurements to facilitate early detection of hepatotoxicity.

Diagnosis and management of hepatitis

Clinical presentation of hepatitis varies widely and affected patients may be entirely asymptomatic. Some patients present with flu-like symptoms, such as fever, chills, skin rash, nausea, vomiting, myalgia, arthralgia or malaise. System-specific symptoms such as jaundice, abdominal discomfort, dark urine, easy bruising, and hepatomegaly may also occur. Certain hepatitides, such as hepatitis C, are

characteristically asymptomatic during the acute phase. Diagnosis in such cases is usually delayed until several years after infection. In autoimmune hepatitis, despite the chronic nature of the disease, 40% of patients present acutely with fever, jaundice, polyarthralgias, myalgias, thrombocytopenia and biochemical evidence of severe hepatic dysfunction (Krawitt, 1996).

Serum testing in most cases of hepatitis will reveal elevated transaminases. In mild cases, elevation usually does not exceed three times normal, while in severe cases there may be a 20-fold increase. Clinical detectable jaundice is usually not present until serum bilirubin exceeds 3 mg dl^{-1}. With severe disease, prothrombin time increases, and this is usually indicative of impending liver failure. Additional blood testing should be done in all cases to determine the a etiology of the hepatitis. Thus, viral antigen and antibody studies are conducted to screen for hepatitis A–E. GBV-C RNA may be identified using a reverse transcriptase polymerase chain reaction test. This test is not available for commercial use. There are also no serological assays routinely available for the diagnosis of GBV-C (HGV) or TTV (Stapleton, 2003).

An autoantibody profile for circulating autoantibodies should be conducted to screen for autoimmune hepatitis. Most patients will have elevated levels of circulating autoantibodies. However, only two-thirds will have one of the more specific autoantibodies. Patients are frequently screened for antinuclear and/or antismooth muscle antibodies (Lohse *et al*., 1995; Czaja and Freese, 2002). Tests for other autoantibodies such as soluble liver antigen, liver cytosol antigen and the asialoglycoprotein receptor antibody are also helpful diagnostic tools with high specificity (Manns *et al*., 1987; Martini *et al*., 1988; Treichel *et al*., 1994). Laboratory tests for autoimmune hepatitis should include serum protein electrophoresis. This may reveal hypergammaglobulinaemia with a selective increase in IgG levels. Human leukocyte antigen (HLA) typing may be helpful as most patients are positive for HLA B8, DR3 or DR4 (Donaldson *et al*., 1994).

The diagnosis of drug-induced hepatitis is usually one of exclusion based on the patient's medication history, which should include questions pertaining to the use of prescription, over-the-counter and herbal medications.

Imaging techniques, such as ultrasound, computed tomography (CT) scans, and MRI are helpful in further evaluation of patients with suspected hepatitis for a etiology and severity of disease. Definitive diagnosis, assessment of severity, acuity and activity of disease are based on histological findings and require a liver biopsy.

On the basis of liver biopsy findings, hepatitis may be characterized as acute or chronic. Autoimmune hepatitis and all the viral hepatitides except HAV, HEV and HFV exist in both the acute and chronic phases. Histologically, chronic hepatitis may be further characterized into four stages: (i) chronic persistent to mild chronic active hepatitis; (ii and iii) chronic active hepatitis with scarring; and (iv) cirrhosis (Bach *et al*., 2000). Rapidity of clinical progression through these stages cannot be predicted.

The cornerstone of treatment of any hepatitides is primarily supportive care. Rest, adequate nutrition and avoidance of additional injury from alcohol or other toxic insults should be stressed. Currently no specific medication is recommended for hepatitis A, D, E or G. In 25–50% of patients with chronic HBV infection, treatment with interferon α-β results in disease remission within 6 months. Oral nucleoside analogues, such as lamivudine and famciclovir, have been shown to reduce HBV levels and the risk of fulminant hepatic failure in more than 50% of patients treated with these agents (Hoofnagle and DiBalart, 1997; Lai *et al*., 1998). The decision to treat patients with HCV is usually made on an individual basis, using factors such as compliance, disease severity, and likelihood of favourable response. Standard therapy consists of pegylated interferon alpha and ribavarin. Following 24 weeks of therapy, undetectable levels of HCV RNA are achieved in over 50% of patients, indicating a sustained response. Patients infected with HCV genotype 1 are less likely to respond, with only 42–46% of patients achieving a sustained response with treatment. Forty-eight weeks of therapy is advised to maximize chances of favourable response. Patients infected with HCV genotype 2 or 3 have a sustained response exceeding 75% and generally require only 24 weeks of therapy. If HCV RNA remains detectable following the course of treatment, therapy should be discontinued, as less than 2% of patients will subsequently respond (Manns *et al*., 2001; Fried *et al*., 2002; Hadziyannis *et al*., 2002).

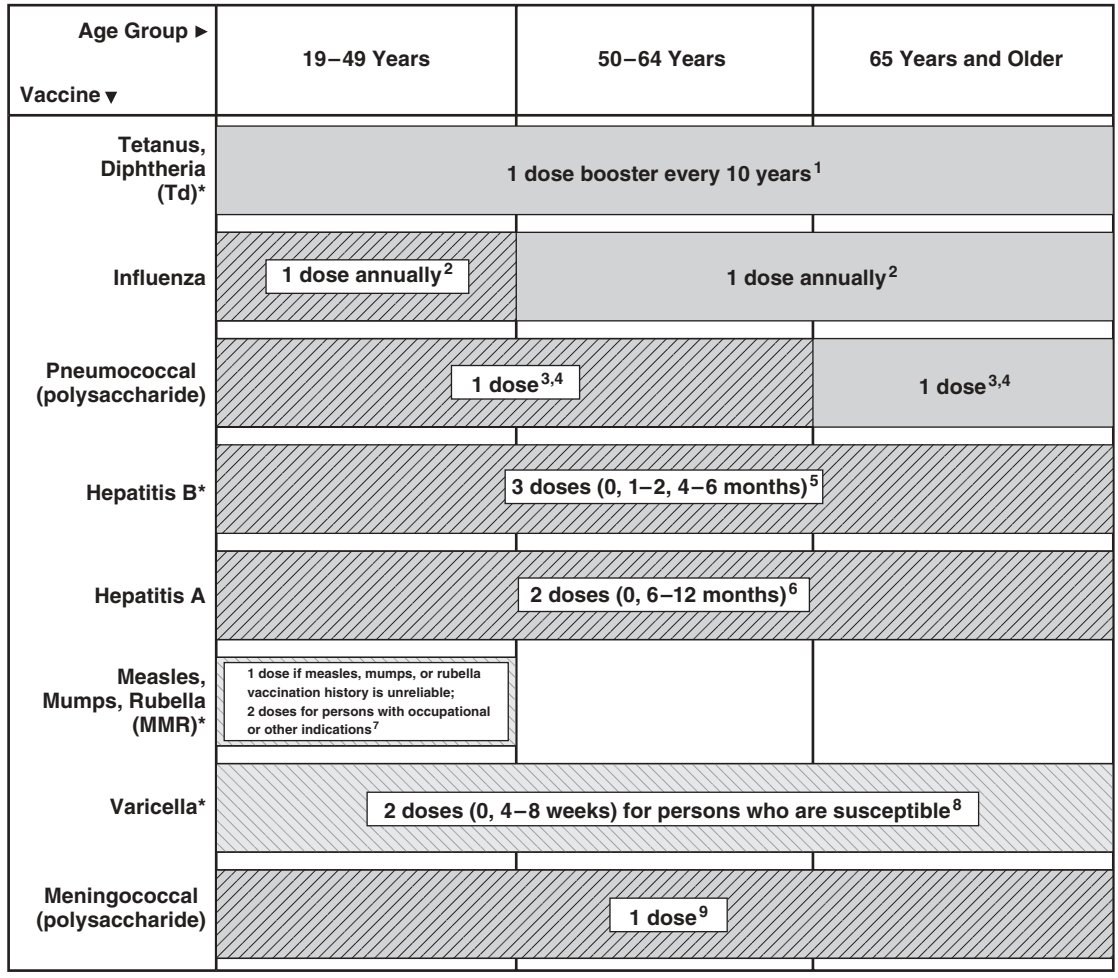
Currently vaccinations are available only for HAV and HBV (Figure 23.2).

Patients with severe autoimmune hepatitis [aspartate transaminase (AST) > 10-fold or AST>fivefold and serum gamma globulin>twofold] are definite candidates for treatment. Combination therapy using azathioprine and corticosteroids has been shown to prolong survival and improve outcomes in affected adults. Patients with mild autoimmune hepatitis do not benefit from treatment (Newton *et al*., 1997).

Alcoholic liver disease

Excessive alcohol use is a major cause of liver disease. Approximately 10% of men and 2% of women over the age of 60 years suffer from an alcohol use disorder. Although age does not alter alcohol dehydrogenase activity, studies suggest a difference in the clinical course and outcomes of alcoholic disease in older adults compared with younger subjects. Older adults who present with alcoholic liver disease are more likely to have severe symptoms and present with complications such as portal hypertension or liver

Recommended Adult Immunization Schedule, United States, 2003–2004 by Age Group



See Footnotes for Recommended Adult Immunization Schedule, by Age Group and Medical Conditions, United States, 2003–2004 on back cover

For all persons in this group | **Catch-up on childhood vaccinations** | **For persons with medical/ exposure indications**

*Covered by the Vaccine Injury Compensation Program. For information on how to file a claim call 800-338-2382. Please also visit www.hrsa.gov/osp/vicp To file a claim for vaccine injury contact: U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington D.C. 20005, 202-219-9657.

This schedule indicates the recommended age groups for routine administration of currently licensed vaccines for persons 19 years of age and older. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

Report all clinically significant post-vaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available by calling 800-822-7967 or from the VAERS website at www.vaers.org.

For additional information about the vaccines listed above and contraindications for immunization, visit the National Immunization Program Website at www.cdc.gov/nip/ or call the National Immunization Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Approved by the Advisory Committee on Immunization Practices (ACIP), and accepted by the American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Family Physicians (AAFP)

Figure 23.2 Summary of recommendations published by The Advisory Committee on Immunization Practices – Centers for Disease Control, Department of Health and Human Services.

cirrhosis. Prognosis in older patients is directly related to age. Patients presenting with alcoholic liver disease over the age of 70 years have a mortality rate at one year of about 75% compared with 5% in patients aged less than 60 years (Varanasi *et al*., 1999; Beresford and Lucey, 1995; Corrao *et al*., 1997; James, 1997)

Laboratory testing reveals elevated serum aspartate aminotransferase, bilirubin and alkaline phosphatase. Liver biopsy reveals a spectrum of histological changes ranging from steatosis, through acute hepatitis to cirrhosis. Animal models indicate that toxic oxidative stress and proinflammatory cytokine elaboration, arising from metabolism of ethanol to acetate, contribute significantly to the onset of alcohol-related steatosis and progressive forms of liver damage. Elevated serum concentration levels of tumour necrosis factor alpha (TNF), interleukin (IL)-6, IL-8, IL-18 and transforming growth factors occur in patients with alcoholic liver disease. Cytokine levels have been shown to correlate with liver dysfunction and clinical outcome. Cessation of alcohol intake results in resolution of steatosis and restoration of normal hepatic architecture within a few weeks. Acute alcoholic hepatitis, which comprises cellular inflammation and fibrosis, also responds to alcohol cessation. Persistent alcohol intake results in progressive fibrosis and subsequent cirrhosis within 5 years in 40% of affected patients (McClain *et al*., 2004; McClain *et al*., 1999).

Treatment of alcoholic liver disease does not vary with age. Abstinence is the cornerstone of effective management and is critical to the success of all other adjunctive therapy. Most patients with alcohol dependence are undernourished, which further increases their mortality risk. Severely undernourished veterans with acute alcoholic hepatitis had a 30-day mortality rate of 52% compared with a 2% mortality rate in their counterparts with only mild undernutrition. Protein energy undernutrition compromises the immune system and may therefore have a permissive effect on the toxicity of alcohol. In addition, hepatic regeneration may be compromised by impaired protein synthesis. Thus, aggressive nutritional support is recommended for patients with alcoholic liver disease.

Corticosteroids have been shown to ameliorate cytokine production, suppress acetaldehyde catabolism and thereby blunt the hepatic inflammatory response. Nevertheless, data from several meta-analyses have failed to demonstrate consistent benefit from corticosteroid therapy in alcohol-related liver disease. Paucity of data in addition to potential side effects of steroid therapy in older adults renders steroid therapy an unwise choice in older adults. Several research studies are aggressively exploring the role of cytokine antagonism in the treatment of alcohol liver disease. Theoretically, TNFα antagonists could prove useful in suppressing alcohol-related hepatic inflammation. Recent studies suggest that anti-TNF therapy may improve histological features and enhance survival (Spahr *et al*., 2002; Tilg *et al*., 2003). However, well-controlled randomized trials are lacking. Pentoxifylline, a phosphodiesterase inhibitor, has proved useful in reducing the risk of hepatorenal syndrome (Akriviadis *et al*., 2000).

Several studies have evaluated the effect of antioxidants, such as *S*-adenosylmethionine and silymarin (milk thistle), in the treatment of alcoholic liver disease. Available evidence fails to confirm benefit from any of these agents (Pares *et al*., 1998; Mato *et al*., 1999). Other potentially antioxidative agents such as propylthiouracil and phosphatidylcholine have also been studied. They had no effect on outcomes or survival (Rambaldi and Gluud, 2001; Lieber *et al*., 2003). Colchicine, an inhibitor of collagen synthesis, produced a paradoxical increase in the risk of adverse events (Rambaldi and Gluud, 2001).

Hepatocellular carcinoma

In North America, hepatocellular carcinoma is predominantly a disease of older adults, with 50% of cases occurring in adults over the age of 60 years. In contrast, the peak incidence of hepatocellular carcinoma (HCC) in Sub-Saharan Africa and China occurs in young to middle adulthood. Older adults are more likely to present with advanced disease and their survival rates are significantly lower than those of younger patients (10.5 weeks compared with 18.5 weeks in younger adults Collier *et al*., 1994; Regev and Schiff, 2001).

Hepatocellular carcinoma in older adults is more likely to be related to HCV than HBV (Hoshida *et al*., 1999). Data from a Korean study identified a serological positivity ratio of 29.7 for hepatitis B surface antigen in patients younger than 50 years compared with 0.9 in patients older than 60 years (Lee *et al*., 1993). Infection with HBV in the earlier years of life as opposed to in adulthood, as is the case with HCV, probably accounts for this difference. Additionally, the latent interval between acquisition of HCV and the development of hepatocellular carcinoma is significantly longer than with HBV.

Available data indicate that treatment outcomes of hepatocellular carcinoma are unaffected by age. There is difference in morbidity, early mortality or long-term survival between older and younger patients treated with either surgical resection or chemo-embolization (Bismuth, 1999; Hanazaki *et al*., 2000). Thus, age should not be used as the sole determining criterion for deciding treatment options.

Diseases of the gallbladder and biliary tract

Gallstone disease

Age-related changes in biliary metabolism result in increased cholesterol saturation of bile and gallbladder

dysmotility. In addition, there is increased activity of HMG-CoA reductase and reduced activity of 7-*alpha*-hydroxylase. These changes enhance the lithogenicity of bile. Consequently, there is an increase in the prevalence and severity of gallstone disease, specifically cholesterol, and calcium bilirubinate stones, in older adults (Bowen *et al*., 1992; Affronti, 1999).

In the United States, the incidence of gallstones in Caucasian women increases from 5% in the third decade of life to 25% in the seventh decade. Complications such as choledocholithiasis, emphysematous cholecystitis, ascending cholangitis and pancreatitis are more apt to occur with ageing. Although the precise reasons are yet to be defined, it has been proffered that atherosclerosis in older adults may cause gallbladder ischaemia, thereby enhancing susceptibility to disease (Kahng and Roselyn, 1994).

Clinical features

Although asymptomatic cholelithiasis is a common occurrence in older patients, most of them never experience complications. However, in older adults the frequent coexistence of multiple illnesses and the atypical presentation of diseases render complications more sinister and possibly life threatening when they do occur. Approximately one-fifth of older adults presenting with cholecystitis are likely to have coexisting choledocholithiasis and biliary colic, compared with about 5% of younger subjects. Ascending cholangitis is also more likely to occur in older patients. Following emergent cholecystectomy, approximately 50% of older subjects will develop choledocholithiasis (Siegel and Kasmin, 1997; Reiss and Deutsch, 1985; Rosenthal and Anderson, 1993).

Older adults are more likely to manifest with atypical features that may confound early diagnosis. Blunted febrile responses and minimal leukocytosis in the face of infection may delay diagnosis of cholecystitis. Abdominal pain in patients with impaired cognitive function may be poorly localized. Data indicate that in patients over the age of 65 years, 56% may be afebrile on presentation, 84% have poorly localized abdominal pain and 5% may be completely pain free. Delirium resulting from infection in cholecystitis may misdirect clinical focus toward the nervous system.

Physical diagnosis is less accurate in older patients. Murphy's sign in older adults is poorly sensitive (48%) compared with a sensitivity of 90% in younger patients. In older patients, Charcot's triad (right upper quadrant pain, jaundice and fever) is more likely to present as Reynold's pentad with the additional features of delirium and hypotension (Hendrickson and Naparst, 2003; Parker, 1997; Adedeji, 1996). The onus rests with health professionals to maintain a keen sense of awareness of the likelihood of this disorder in older patients.

Diagnosis and management

Ultrasound is the imaging modality of choice in suspected cholelithiasis and cholecystitis. However, health professionals should be aware that older adults have a higher incidence of acalculous cholecystitis, which may not be identified on ultrasound. Utilization of hydroxy iminodiacetic acid (HIDA) scans as an adjunct in such cases may be helpful. Increasingly sophisticated endoscopic procedures have considerably enhanced diagnostic and therapeutic options in biliary tract disease (Hendrickson and Naparst, 2003). Ideally, an endoscopic retrograde cholangiopancreatography (ERCP) should always precede a cholecystectomy to facilitate accurate definition of the required surgical procedure. Endoscopic ultrasound is a newer technique that is just as sensitive as, but less risky than, ERCP. This may become the preferred procedure for older frail patients (Canto *et al*., 1998).

ERCP is a safe and effective procedure in older adults. With experienced operators, the success rate is approximately 98%. Evidence suggests that older adults tolerate ERCP better than younger patients. In a cohort of 64 patients over the age of 90 years undergoing therapeutic ERCP, Kasmin *et al*. 1995 identified a complication rate of 3% with no incidents of pancreatitis and no procedure-related deaths. Within the general population the expected overall complication rate ranges from 5 to 10% (Affronti, 1999).

Newer techniques such as endoscopic ultrasound, intraductal ultrasonography, magnetic resonance cholangiopancreatography and three-dimensional computed tomography continue to improve diagnostic accuracy (Domagk *et al*., 2004).

Adoption of a 'wait and see' approach is advocated as a reasonable therapeutic option in the management of cholelithiasis. However, data to support this were derived from studies of younger patients. The increased risk of complications and mortality following emergent surgery make this a less favourable solution for older adults. Reported mortality rates for elective procedures range from 4 to 10%, which are comparable to data obtained from younger adults. In emergent situations the mortality rate in older patients rises as high as 20% (Rosenthal and Anderson, 1993). Accordingly, the risks of expectant therapy in older adults with apparently asymptomatic disease must be carefully weighed against the benefits of elective intervention.

Laparoscopic cholecystectomy is the preferred therapeutic option in symptomatic cholelithiasis. Advantages of this procedure over open cholecystectomy include reduced length of stay and less patient discomfort. Anecdotal reports suggests that this minimally invasive procedure is well tolerated by older adults who are otherwise reasonable candidates for surgery. However, studies have yielded

conflicting results with regard to morbidity and mortality data. The decision to perform laparoscopic cholecystectomy is still operator dependent. Nevertheless, increased proficiency at this procedure is rapidly relegating open cholecystectomy to the position of a salvage procedure following failure of a laparoscopic cholecystectomy (Kahng and Roselyn 1994; Ido *et al*., 1995).

Pharmacological dissolution has rapidly fallen out of favour as a viable primary therapeutic option. Chenodeoxycholic acid was the first agent developed to reduce lithogenicity of bile and dissolve gallstones. Complete dissolution was rarely achieved and occurred in less than 15% of patients. Added disadvantages to the use of this agent were a high recurrence rate (50%), significant adverse effects and high cost. A newer and similar agent, ursodeoxycholic acid, is better tolerated and may be more effective. However, definitive evidence in older adults is lacking (Kahng and Roselyn 1994; Weinstein *et al*., 1990).

Similarly, there is a striking lack of data concerning the safety and efficacy of contact dissolution in older adults. Methyl *tert*-butyl ether (MTBE), a potent cholesterol solvent, is instilled into the gallbladder during percutaneous transhepatic cholangiography to facilitate direct contact dissolution of gallstones. Catheter-related complications, MTBE toxicity, the high recurrence rate and the virtual absence of any data in older adults render this an inadvisable and obsolete option (Thistle and May, 1989).

Finally, biliary electroshock wave lithotripsy is a non-invasive procedure that appeared to be a potentially favourable option for older adults. However, the efficacy of this technique depends on multiple factors, including size, calcium content and number of stones, and adequate gallbladder function and motility. Few patients qualify for this procedure (Magnuson *et al*., 1989). There are no data in elders.

Gallbladder perforation

Gallbladder perforations are more likely to occur in the fundus because, compared with the rest of the gallbladder, the fundal portion is relatively poorly vascularized. Type 1 gallbladder perforations are acute and associated with biliary peritonitis. Type II perforations are subacute and characterized by the presence of a pericholecystic abscess. Type III perforations generally result in a fistulous tract between the gallbladder and the duodenum.

Type III perforations occur most frequently and are more likely to be complicated by gallstone ileus. Although uncommon in the general population, gallstone ileus is the commonest cause of small bowel obstruction in older women, occurring in 25% of such cases. Definitive management is surgical enterotomy and stone extraction (Kahng and Roselyn, 1994)

Emphysematous cholecystitis

This is a life-threatening condition characterized by gangrene of the gallbladder due to an infection with gas-forming organisms. Emphysematous cholecystitis is more likely in older patients with diabetes. Clostridial organisms are implicated in most patients. Cholelithiasis is present in only half of affected patients. Ischaemia has been implicated in this condition although the precise pathogenetic mechanisms remain unclear. Mortality is very high and emergent cholecystectomy is indicated (Affronti, 1999).

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune disease characterized by progressive destruction of intrahepatic biliary ducts and chronic cholestasis. Although predominantly a disease of middle-aged women, over one-third of patients are over the age of 65 years (Metcalf *et al*., 1997). Several large case series indicate that the mean age at presentation is approximately 60 years with the peak incidence occurring between 70 and 79 years (Metcalf *et al*., 1997; Howel *et al*., 1997).

In patients who are symptomatic at presentation, advanced age is an independent adverse prognostic factors (Regev and Schiff, 2001). Treatment is generally reserved for selected older patients who are symptomatic. Outcomes for asymptomatic patients do not differ from that of the general population. Asymptomatic patients often come to attention following investigation of an unexplained elevation of serum alkaline phosphatase. Diagnosis of PBC is usually confirmed by the detection of antimitochondrial antibodies. Extrahepatic manifestations of PBC include hypothyroidism, sicca syndrome, hypothyroidism and cutaneous xanthoma. Fat-soluble micronutrient deficiencies may occur, resulting in an increased risk of osteoporosis and impaired coagulation (James, 1997).

Medical therapy is not very helpful in treating PBC. Colchicine may retard progression of liver fibrosis and improves laboratory values in patients with PBC but it has no effect on signs or symptoms of the disease. Corticosteroids and D-penicillamine are ineffective treatment options. Conflicting results have been obtained regarding other immunosuppressive agents such as azathioprine (Imuran), methotrexate and ciclosporin A. Ursodeoxycholic acid is a promising pharmacological agent. Data demonstrate not only improved symptoms and biochemical parameters but also retarded progression of PBC following ursodeoxycholic acid therapy. Recent evidence also suggests a role for selective estrogen receptor modulators in the treatment of PBC. Tamoxifen therapy has been associated with a decrease in serum alkaline phosphatase level in two women with coexisting PBC. Authors of these case reports suggest that tamoxifen may act on cholangiocyte

estrogen receptors to inhibit cholangiocyte proliferation. Further evidence is needed to support this hypothesis (Bergasa *et al*., 2004; Reddy *et al*., 2004). In contrast, orthotopic liver transplantation has very good outcomes in patients with end-stage liver disease resulting from PBC (Bergasa *et al*., 2004).

Liver transplantation

Liver cirrhosis, portal hypertension and liver failure have a major impact on both hepatic and all-cause mortality in older adults. Indeed, the presence of liver cirrhosis in the setting of concomitant disease is an adverse prognostic factor. Subjects with chronic liver disease and complicating cirrhosis aged over 80 years had a cumulative survival rate of 59 and 19% at 5 and 9 years, respectively, compared with 86 and 69% in their non-cirrhotic counterparts with chronic liver disease (Hoshida *et al*., 1999; del Olmo *et al*., 2000; O'Mahony and Schmucker, 1994). Although management of liver cirrhosis in older adults is similar to that in younger adults, long-term survival rates are much worse in the elderly.

Previously, advanced age was considered a contraindication to liver transplantation and patients older than 55 years were rarely accepted as transplant recipients. More recent evidence indicates a survival rate among older transplant recipients comparable to that of younger subjects. Age, as an isolated criterion, is therefore no longer considered a contraindication to liver transplantation (Tran *et al*., 2004; Fattovich *et al*., 1997).

Currently, approximately 20% of transplant recipients in the United States are over the age of 60 years compared with less than 10% in 1989 (Seaberg *et al*., 1998). Additionally, quality of life, morbidity and one year survival rates in older transplant recipients are comparable to those in their younger counterparts. Five year survival rates in older transplant recipients are worse due to excess cardiac, neurological, infective and neoplastic deaths (Zetterman *et al*., 1998; Varanasi *et al*., 1999). Incidentally, the incidence of organ rejection following transplantation has consistently been shown to be lower in older adults, possibly as a result of age-related immune dysfunction (James, 1997).

Although the scarcity of donor organs has inappropriately fostered the use of age as a prioritizing factor, the absence of significant differences in outcomes does not justify this practice in older patients who would otherwise qualify for liver transplantation.

Similarly, available data indicate that livers harvested from elderly donors (50–70 years) may be transplanted with reasonable success rates. However, eligible older donors must be carefully screened to avoid the risk of early postoperative liver dysfunction and compromised graft survival (Hoofnagle *et al*., 1996).

Key points

- Age-related pathophysiological changes include hepatic hypoperfusion, decreased hepatic mass, reduced activity of phase 1 hepatic drug-metabolizing enzymes, compromised hepatic regeneration, relative dilatation of the common bile duct and increased lithogenicity of bile. These changes result in enhanced vulnerability of the ageing hepatobiliary system to disease.
- Hepatobiliary diseases are a major cause of morbidity and mortality in older adults. The mortality rate from chronic liver disease in adults aged over 65 years is 3–6 times higher than that in middle-aged adults. Biliary disease is the leading indication for acute abdominal surgery in older adults. Older adults with viral hepatitis are more likely to develop complications such as fulminant hepatic failure, liver cirrhosis and hepatocellular carcinoma
- Twenty percent of all patients diagnosed with autoimmune hepatitis are over the age of 65 years. Drug-induced hepatitis is more common in older adults due to multiple factors including increased exposure to drugs, compromised hepatic metabolism and increased risk of hepatotoxicity with the use of certain drugs in older adults.
- Older adults are more likely to present with atypical features of biliary tract disease, and life-threatening complications such as gallbladder perforation and emphysematous cholecystitis. Emergency biliary surgery has worse outcomes in older adults. The risks of expectant therapy in older adults with asymptomatic biliary tract disease must be weighed against the benefits of elective intervention.
- Advanced age is not an absolute contraindication to liver transplantation. Quality of life, morbidity and one-year survival rates in older transplant recipients are comparable to those in their younger counterparts.

CHAPTER 24

Sphincter function

Syed H. Tariq
Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

Faecal incontinence is a common condition which affects up to 21% of community-dwelling elderly individuals over the age of 65 years,[1–3] and prevalence in the institutionalized elderly exceeds 50%.[4,5] An acute diarrhoea can result in an incontinence episode even in healthy people, when the rectal reservoir is overwhelmed by liquid/loose stools. Patients with faecal incontinence experience anxiety, fear of embarrassment, emotionally and socially devastating silent suffering, isolation and depression.[6] Faecal incontinence, along with urinary incontinence, is among the leading reasons for nursing home placement.[7]

Anatomy and physiology of the anal canal and rectum

In order to understand better the clinical presentation, evaluation and treatment options for faecal incontinence, the anatomy and physiology of the anal canal and rectum are briefly reviewed along with changes that occur with ageing.

The *rectum* is a tubular structure, 12–15 cm in length, with the anal canal extending about 4 cm, from the anal verge to the anorectal ring. The anal canal is separated by a dentate line into an upper mucosal lining and lower cutaneous segment. The area above the dentate line is supplied by the sympathetic and parasympathetic systems, whereas below the dentate line the somatic nervous system provides innervation. Just above the dentate line there are 8–12 rectal columns (anal cushions) with their bases connected to each other. The high-pressure zone of the anal sphincter is formed by the combination of muscles (internal anal, external anal and the puborectalis) and anal cushions.[8,9]

The *internal anal sphincter* is a circular muscle layer that starts from the rectum. The internal anal sphincter is tonically contracted at rest, preventing the involuntary loss of stool and gas.

Tone of the anal sphincter

The internal anal sphincter contributes 50–85% of the resting tone of the sphincter with the external anal sphincter contributing 25–30%, the remaining 15% coming from the anal cushions.[10–12] In response to rectal distension, the internal anal sphincter tone increases initially, followed by decreased tone constituting the anorectal inhibitory response.[8]

Changes with ageing

The thickness of the internal anal sphincter increases with age, as confirmed by ultrasound and magnetic resonance imaging.[13–15] The functional significance of this change is unclear. It could be a compensatory change for the maintenance of continence,[12] but this is unlikely, as the age-related changes in anal sphincter pressures are modest in healthy individuals.[16,17] The most likely explanation is increased connective tissue or 'sclerosis' of the internal anal sphincter with ageing.[18]

The *external anal sphincter* is a striated muscle surrounding the inner smooth muscle and terminating distal to the internal anal sphincter. Both the puborectalis and the external anal sphincter provide voluntary control of continence in response to various stimuli such as the increased intra-abdominal pressure that occurs with coughing, rectal distension and anal dilatation.[9,19] Voluntary anal sphincter pressure decreases with age and the pressure is lower in women than in men.[20]

The levator ani muscle is a major component of the pelvic floor and is composed predominantly of three striated muscles: iliococcygeus, pubococcygeous and puborectalis. The puborectalis muscle plays the largest role in continence and is a U-shaped loop of striated muscle slinging around the posterior aspect of the external anal sphincter, pulling the anal canal forwards creating the anorectal angle (Figure 24.1). The puborectalis and resultant anorectal

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

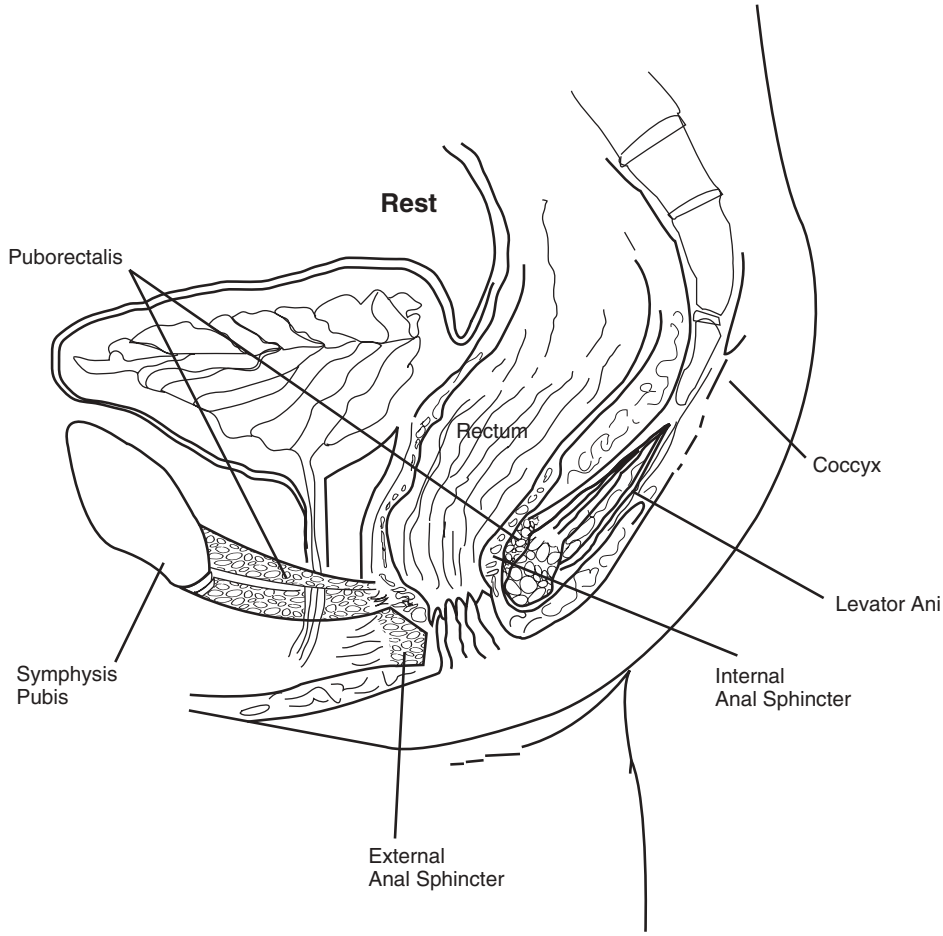

Figure 24.1 Anatomy of the anorectum at rest.

angle aid in the maintenance of continence, as this angle becomes more acute with voluntary sphincter contraction, providing an anatomical obstruction to the distal movement of stool retained above the angle.[21]

Physiology of defecation

Both the sensory and motor neurons of the anorectum interact to maintain continence and control the process of defecation. The desire to defecate is usually preceded by propagation of contractions in the proximal colon, resulting in the movement of faeces into the rectum with relaxation of the distal colon/rectum, relaxation of the internal anal sphincter and contraction of the external anal sphincter until the socially appropriate time for defecation.[22,23] The sensory receptors in the anal canal determine the nature of luminal contents, that is, whether the contents are solid, liquid or gas.[24] When voluntary defecation is desired, the intra-abdominal pressure rises due to abdominal wall contraction. The muscles of the pelvic floor (external anal sphincter, puborectalis and other muscles of the levator ani) relax. Relaxation of the puborectalis results in straightening of the anorectal angle, providing a straightened conduit for stool movement (Figure 24.2). The anal canal relaxes with the increased rectal pressure, resulting in the evacuation of stool.

Mechanism of continence

Continence is maintained through the combined action of the external and internal anal sphincters and the puborectalis muscle. Determinants of continence include resting anal tone, resistance to opening at the anus, rectal compliance, normal anorectal sensation and the consistency of stools.[25] In addition, mobility and intact cognition are required in order to have a controlled bowel movement. Impairment in any of these mechanisms may result in faecal incontinence.

Prevalence and importance

The prevalence of faecal incontinence in the general population is reported to be 2.2%,[26] but the study referred to did

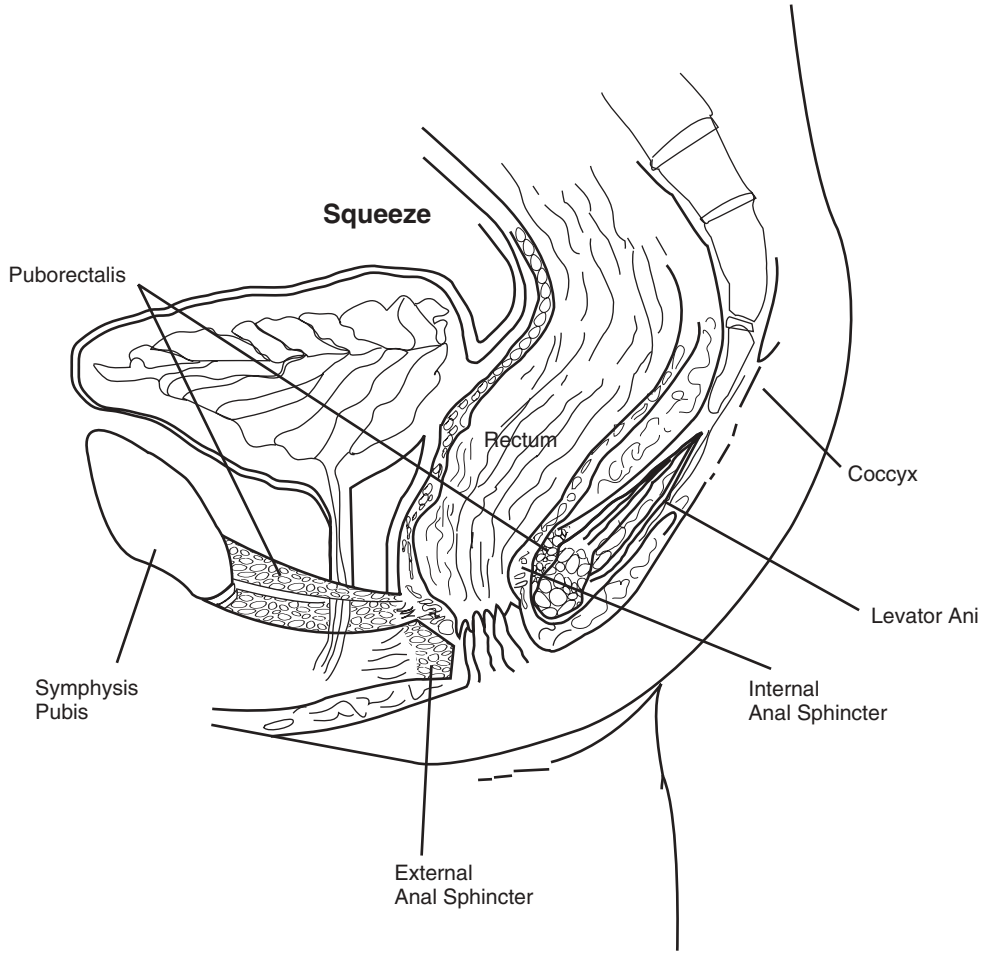

Figure 24.2 Anatomy of the anorectum during squeeze.

not include individuals residing in nursing homes. When individuals over the age of 65 years were studied, the frequency of faecal incontinence increased from 3.7 to 27% (Table 24.1). The greatest prevalence of faecal incontinence is found in nursing homes, with more than 50% of long-term care residents affected by chronic faecal incontinence.[5] A higher prevalence of faecal incontinence is seen in geriatric hospital wards (20–32%) and geriatric psychiatry patients (up to 56%),[28,29] and 80% of patients hospitalized with dementia also experienced faecal incontinence.[10] Double incontinence (i.e. faecal incontinence and urinary incontinence) occurs 12 times more commonly than faecal incontinence alone, with 50–70% of patients with urinary incontinence also suffering from faecal incontinence.[28–30] This is not surprising, as the combination of urinary and faecal incontinence is the second most common cause of institutionalization of elderly persons.[31]

Faecal incontinence is a marker for poorer overall health and is associated with increased mortality.[4,32] Incontinent nursing home residents experience more urinary tract infections and pressure ulcers.[33] The total health care costs attributable to faecal incontinence are difficult to determine as few studies have examined healthcare costs for faecal incontinence alone. Most healthcare cost information comes from nursing homes caring for patients with faecal incontinence, urinary continence or both. The nursing home-related costs for incontinence were $3.26 billion in 1987 and the yearly cost of adult diapers alone is $400 million.[34,35] The additional health expenditure reaches in excess of $9000 per patient-year of incontinence.[33]

Risk factors and causes of faecal incontinence

The risks and causes of faecal incontinence are summarized in Table 24.2. Risk factors for faecal incontinence include a prior history of urinary incontinence, the presence of neurological or psychiatric disease, poor mobility, age greater than 70 years and dementia.[25,36] Possibly the most common predisposing condition to faecal incontinence is faecal impaction, which is reported in up to 42% of elderly patients admitted to geriatric units.[37] These patients are

Table 24.2 Risk factors and causes of faecal incontinence.

Risk factors[23,27]
Prior history of urinary incontinence
Presence of neurological disease
Presence of psychiatric disease
Poor mobility
Age >70 years
Dementia
Causes of faecal incontinence[36]
A Faecal impaction
B Loss of normal continence mechanism
  1 Local neuronal damage (e.g. pudendal nerve)
  2 Impaired neurological control
  3 Anorectal trauma/sphincter disruption
C Problems overwhelming normal continence mechanism
D Psychological and behavioural problems
  1 Severe depression
  2 Dementia
  3 Cerebrovascular disease
E Neoplasm (rare)

often chronically constipated resulting in incontinence from leakage around the large faecal impaction. The problem is further complicated by the presence of decreased rectal sensation, allowing the progressive accumulation of stool in the rectum.[38] Faecal incontinence in diabetes mellitus occurs from autonomic neuropathy and is exacerbated in the presence of diabetic diarrhoea.[39] Pelvic neuropathy may result from prolonged straining and birth trauma. Faecal incontinence results in these patients because of sphincter damage and pudendal neuropathy.[40] Trauma to the anal canal such as anal surgery, including haemorrhoidectomy, anal fissure repair and anal dilatation, may disrupt the anal sphincter muscles, resulting in impaired continence.[41,42] Patients with total internal sphincterotomy have a 40% risk of faecal incontinence, while partial sphincterotomy carries a risk of 8–15%.[43–45]

Clinical subgroups

There are three main types of faecal incontinence: (a) overflow (b) reservoir and (c) rectosphincteric. Overflow incontinence is specially seen in cognitively impaired, bedridden nursing home individuals and the risk factors are outlined in Table 24.3. Reservoir incontinence is seen in individuals with diminished colonic or rectal capacity. This condition is commonly seen with radiation proctopathy, rectal ischaemia, idiopathic inflammatory bowel disease and proctocolectomy with ileoanal anastomosis. Rectosphincteric incontinence is seen in conditions associated with structural damage to one or both anal sphincters, pudendal neuropathy affecting the external anal sphincter and or puborectalis muscle and/or rectal sensation, or degenerative or myogenic disorders affecting the internal or external anal sphincter.

Evaluation of faecal incontinence

The goals in evaluating faecal incontinence include establishing the severity of incontinence, understanding

Table 24.3 Risk factors for overflow incontinence.

Inadequate fibre
Inadequate water intake
Immobility
Inadequate toileting facilities
Mental status changes
Metabolic abnormalities
Hypothyroidism
Hypercalcaemia
Medication
Narcotics

Rectal examination

the pathophysiology present and directing the patient to appropriate therapy for their condition. This is accomplished through history, physical examination and investigations targeted at determining the aetiology of faecal incontinence.

History and physical examination

The physician may find it difficult to recognize faecal incontinence since patients usually will not volunteer information about incontinence unless asked. This information is best elicited through direct questioning regarding bowel habit and continence. It is helpful to identify when the symptoms first occurred, and to determine if the patient has any sensations such as the passage of stool or gas, fullness in the rectum or warning symptoms such as abdominal cramps and urgency. Inquiry about the home environment may reveal barriers to bathroom facilities, especially in nursing homes and particularly in patients with walkers. Table 24.4 summarizes important areas to address during history. Colitis of any cause may result in loose stools that overwhelm the continence mechanisms. In the evaluation of faecal incontinence, several components of the neurological history deserve attention. A cerebrovascular accident may limit the patient's physical ability to use the toileting facility. The new onset of faecal incontinence may also herald the presence of cord compression, especially when associated with other neurological symptoms.

A thorough review of prescription and over-the-counter medicines and supplements may reveal an underlying cause for the altered bowel habit. Medicines causing diarrhoea include magnesium-containing antacids and poorly absorbed sugars such as sorbitol and mannitol (used in dietetic products). Sorbitol is also frequently used as a base in elixirs, for example, theophylline elixir. The intentional or inadvertent use of cathartics may contribute to diarrhoea and incontinence.

The physical examination helps to identify the pathophysiology of faecal incontinence and can guide the ordering of appropriate tests for further evaluation.[46] The usual physical examination may be supplemented by a Mini-Mental Status Examination or Saint Louis University Mental Status Examination, which help identify patients with cognition problems.[47,48] The neurological examination includes assessment of general patient mobility, motor strength and sensory testing. The 'anal wink' is elicited by stroking the skin lateral to the anal canal and observing the contraction. Absence of this reflex suggests significant neural damage. Anal gaping can be seen when the buttocks are parted in patients with paraplegia.[49] The perineum should be inspected for dermatitis, haemorrhoids, fistula, surgical scars, skin tags, rectal prolapse, soiling and ballooning of the perineum (suggesting weakness of the pelvic floor). Following inspection, the next step is digital rectal examination to note the baseline sphincter tone, squeeze pressure, any asymmetry of the sphincter on squeeze and the amount and character of the stool (hard pellets or soft). The positive predictive value of digital examination is 67% for detecting decreased anal tone when compared with anal manometry.[50] Patients with high or normal sphincter tone can also be incontinent, especially in the setting of large rectal volumes or altered rectal sensation. In patients with lesions of the spinal cord or cauda equina, the sphincter tone may be normal, but when pressure is applied to any part of the anorectal ring the phenomena of gaping can be seen. Findings in the normal elderly patient typically reveal lower anal canal pressures.[51]

Diagnostic tests

A number of tests are available to provide data on colonic and anorectal function.[52] Table 24.5 outlines most of the tests necessary for the investigation of faecal incontinence. In the elderly population, the most important thing is to exclude faecal impaction. Even in the absence of stool in the rectal vault, higher impaction may be present. If the patient is at risk, a plain abdominal radiograph is required to exclude high impaction. A flexible sigmoidoscopy or colonoscopy examines the colorectal mucosa for evidence of colitis, neoplasia, inflammatory bowel disease, colonic and rectal ischaemia, laxative abuse and other structural abnormalities. Anorectal manometry provides comprehensive information regarding anorectal function as it quantifies anal sphincter tone and assesses anorectal sensory responses, the anorectal inhibitory reflex and rectal compliance.[53] Anorectal manometry either provides new information or confirms the suspected diagnosis in patients with faecal incontinence.[54] A finding of decreased rectal compliance may point to faecal incontinence from increased stress on the continence mechanism as the stool is received in the rectum (i.e. a stiff rectum does not accommodate the stool bolus, resulting in overflow).[55] Electromyography measures the neuromuscular integrity between the distal portion of the pudendal nerve and the anal sphincter muscle.[56] Electromyography correlates well with anorectal manometry but its use in the routine assessment of faecal incontinence is controversial.[52,57] Anal ultrasound defines the internal and external anal sphincters.[58] Anal ultrasound can be used to identify isolated sphincter defects, present in about two-thirds of incontinent patients.[59,60] Ultrasonographic findings correlate with both surgical and electromyographic findings.[61,62] Magnetic resonance imaging (MRI) has also been used to evaluate the sphincter defects, with definition superior to anal ultrasound as it provides higher spatial resolution and better contrast for lesion characterization.[63] Endoscopic ultrasound (EUS) allows the identification of perianal disease such as fistula and abscess and assessment of sphincter integrity in faecal incontinence.

Treatment

The treatment of faecal incontinence depends on the underlying aetiology and severity of the incontinence.

Redirection in persons with cognitive impairment
Habit training
Adding fibre to the diet except when inflammation is present
Prompt voiding
Kegel exercise
Antidiarrhoeal agents (once infection is excluded)
Biofeedback
Surgical (few or no data on older persons)
Sphincter repair
Neosphincter operation
Alternative therapy
Artificial anal sphincter implantation
Injection of glutaraldehyde
Sacral nerve stimulation
Colostomy

Table 24.6 summarizes the main treatment options for faecal incontinence. Minor degrees of faecal incontinence can be treated conservatively, whereas patients with severe faecal incontinence require more aggressive treatment. Overflow incontinence treatment options include disimpaction, bowel cleansing and habit training. Treatment options for reservoir incontinence include a reduction in dietary fibre, treatment of underlying inflammation, use of loperamide and colostomy in severe cases.

Patients with mental impairment such as dementia may simply need to be directed to the toilet or reminded of its use. Physical limitations and environment obstacles need to be addressed if these are contributing to incontinence, as they can often be overcome by simple measures. Habit training involves a regular schedule of defecation, usually after breakfast, often incorporating the use of supplemental fibre and regularly scheduled enemas when defecation is delayed more than 2 days. Habit training is particularly effective for patients with overflow incontinence.[64] It has been shown that prompted voiding increases the number of continent bowel movements and reduces number of incontinent bowel movements; this study was designed primarily for urine incontinence.[64] Sphincter training exercises ('Kegel' exercises) alone do not increase the number of continent episodes.[65] In diabetic patients where gut dysmotility is suspected, clonidine may be used. Topical application is preferred over the oral preparation. A trial of cholestyramine may be helpful if bile acid malabsorption is suspected. Antidiarrhoeals such as loperamide are helpful when the stool is loose.[66] A double-blind crossover study of 30 patients receiving loperamide, codeine or diphenoxylate with atropine for 4 weeks found

that all reduced the stool frequency but loperamide and codeine were more effective in reducing faecal incontinence compared with diphenoxylate.[67] Diphenoxylate and codeine have more central nervous system side effects than loperamide and are generally best avoided in the elderly in this setting.

Biofeedback is classically described as a learning theory with operant conditioning as its theoretical basis, and was first described by Engel *et al*.[68] Biofeedback is a non-surgical, non-invasive, relatively inexpensive outpatient method of treating faecal incontinence.[69] Biofeedback for faecal incontinence involves improving the strength of the external sphincter and improving anorectal sensation.[65] Biofeedback provides immediate and long-term improvement of faecal incontinence.[70] Biofeedback training teaches the patient to recognize small volumes of rectal distension and to contract the external anal sphincter while simultaneously keeping the intra-abdominal pressure low. This is accomplished by measuring the anal canal pressure, showing this to the patient on a visual display and providing verbal feedback. Table 24.7 shows the success rate, age range and number of sessions involved in different studies. Better results are achieved when treating motivated, mentally capable patients. Patients should also have some degree of rectal sensation and be able to contract the external anal sphincter.[71] Miner *et al*. compared active sensory biofeedback with sham retraining.[72] In the active group, biofeedback training reduced incontinent episodes by 80% per week in this study, whereas the control group showed no change from the baseline. This improvement lasted over 2 years in 73% of patients available for follow-up. Geriatric patients with limited mobility who had faecal incontinence were treated initially for faecal impaction but 13 of them continued to be incontinent. These patients were then treated with biofeedback, which improved sphincter strength and reduced incontinence episodes by more than 75%.[65] A review of biofeedback showed improved continence in 13 of 14 studies.[73] In a review of 46 studies involving the use of biofeedback for faecal incontinence in 1364 patients (76% female), less than 20% of these studies included randomization and most involved relatively small numbers of subjects. Improvement in continence occurred in at least half of the patients. No specific details regarding age-related differences were noted.[74]

Surgical therapy

Surgical intervention is generally considered when more conservative measures have failed in patients with severe incontinence and identifiable anatomical defects. Although surgery is more commonly recommended in younger patients, the appropriately selected elderly patient fairs well with surgical intervention.[75]

Sphincter repair

In the setting of an isolated sphincter defect, especially anterior sphincteroplasty is very successful[76,77] Three basic approaches have been described: direct apposition, overlapping anterior sphincteroplasty and plication procedures (anterior, posterior and total pelvic floor repair). An improvement in anal function was reported, demonstrated by anal manometry before and after anterior sphincter repair.[78] There was a 96% improvement in anal function compared with preoperative symptoms (all women aged 22–75 years, mean age 37.8 years). The outcome of surgical repair is variable as some patients may continue to have incontinence and others develop new bowel problems postoperatively.[79]

Neosphincter operations

Muscle transposition may be considered for severe faecal incontinence where standard therapy has failed. Techniques include graciloplasty, dynamic graciloplasty and gluteus maximus transposition. The results of graciloplasty vary significantly.[80–82] The result of graciloplasty is improved by electrical stimulation after the implantation of electrical electrodes and a pulse generator.[83] Electrical stimulation provides the gracilis muscle with the properties to function as a sphincter.[84] In a prospective multicentre trial, 66% of patients with graciloplasty achieved continence in a follow-up at 2 years.[85] The performance of graciloplasty in the elderly has not been reported.

Alternative therapies

Newer techniques have been developed for the treatment of faecal incontinence, but these procedures are described predominantly in younger age groups. A multicentre prospective trial was carried out in 12 patients who had failed conventional management for severe faecal incontinence and had an artificial anal sphincter implanted.[86] A successful outcome was achieved in 75% of the patients with a mean age of 33 years. This surgical technique has not been specifically applied to the elderly.

Injections of glutaraldehyde cross-linked collagen are simple and well tolerated for patients who do not respond to conservative therapy and have a surgically incorrectable problem (internal sphincter dysfunction). Of 17 patients (mean age 53 years) who participated in a study, 65% had symptomatic improvement, 12% had minimal improvement and 18% had no improvement.[87]

Sacral nerve stimulation for faecal incontinence has been shown to improve faecal continence along with improved quality of life in selected patients.[88] In a non-randomized study, the application of radiofrequency energy to the sphincter improved continence and quality of life.[89] Finally, for severe faecal incontinence when all the other

procedures failed, a diverting colostomy is usually the surgical procedure of choice.

Conclusion

Faecal incontinence is a common problem in the elderly population, particularly affecting individuals in the community and nursing homes. In addition to the inconvenience of the incontinence for the patient and caregiver, it is a marker of poor health and associated increased mortality. Patients and their caregivers must be questioned specifically about the presence of faecal incontinence and its severity. All patients with faecal incontinence warrant an initial medical evaluation, including the exclusion of faecal impaction by rectal examination and X-ray film of the abdomen. Cognitively impaired patients benefit most from habit training. Several surgical procedures are available and may be helpful in selected older persons in selected centres. Future studies are needed to identify which patients will obtain the most benefit from these interventions and to determine the most cost-effective evaluation and treatment regimens in the ageing population.

Key points

- Faecal incontinence is a common problem that is often not reported to the physician.
- In persons with faecal incontinence, faecal impaction should always be excluded.
- In healthy elderly with faecal incontinence, anal manometry and biofeedback should be utilized.
- Anal ultrasound can also be used to identify a defect suitable for treatment with sphincteroplasty.
- Common causes of faecal incontinence include cognitive impairment and faecal impaction.

CHAPTER 25

Constipation

Charlene M. Prather
Saint Louis University, St Louis, MO, USA

Defining constipation

Constipation most classically refers to reduced defecation frequency and hard stools. Physicians typically define constipation as less than three bowel movements per week. Patients more frequently describe constipation as defecatory difficulty with predominant complaints of straining or hard stools. This holds particularly true in older adults. Understanding the patient's view of 'constipation' assists in the evaluation and treatment process.

The normal defecatory process requires sufficient cognition recognizing the need to defecate, normal colon transit and normal pelvic floor function. Normal colon transit ranges from 24 to 72 h. Defecation is most often preceded by high-amplitude propagated colonic contractions. These colonic contractions occur in response to meals, particularly those with higher concentrations of calories and fat. Colonic motility is also more robust during waking hours and quiescent at sleep. Once stool is delivered to the rectum, defecation may be voluntarily initiated through a set of coordinated actions. First the stool bolus must be sensed through local sensory neurons and recognized centrally. Initiation of the defecation may follow with relaxation of the puborectalis muscle, opening of the anorectal angle and relaxation of the anal sphincters and accompanied by a simultaneous rise in intra-abdominal pressure (Figure 25.1). An abnormality affecting any of these areas results in the development of an altered bowel pattern (Table 25.1).

Constipation may be defined in many different ways. Simply stated, primary constipation refers to constipation without an obvious cause and secondary constipation results from external aetiologies. These external causes of altered bowel function may include neuromuscular disorders, metabolic abnormalities, medications, insufficient diet or mechanical factors obstructing the movement of stool. Constipation may be further defined as acute or chronic. Chronic constipation indicates that symptoms have been present for more than 3 months and typically dates back years. Acute constipation requires a more rapid investigation into the aetiology, including evaluation for structural abnormalities or recent medication changes. Patients with chronic constipation may initially be treated symptomatically with fibre and/or simple laxatives. Those not responding to usual treatments require further investigation to evaluate for evidence of slow transit constipation or dyssynergic defecation (also called pelvic outlet dysfunction). Although constipation commonly occurs in the setting of the irritable bowel syndrome (IBS), new-onset IBS occurs less frequently in older than in younger patients. Specific criteria have been defined for identifying constipation by different investigators. The most commonly used are the Rome criteria, now in their third iteration, a classification used primarily for the purpose of clinical trials.[1]

Epidemiology, pathophysiology and impact

Constipation has long been misunderstood as a common problem associated with ageing. The prevalence of self-reported constipation, physician visits and laxative use increases with ageing.[2–4] In contrast, reported stool frequency does not change with age.[2,3] Challenges in defining the prevalence of constipation in elders relates to the variety of criteria used in different studies. Self-reported constipation affects 27% of individuals aged 65 years and older, whereas only 17% of elders meet more stringent (e.g. Rome criteria) diagnostic criteria for constipation.[5] When adjusting for race and laxative use, odds ratios for less than three bowel movements per week in individuals aged 70–79 and $\geq$80 years were 0.61 [95% confidence interval (CI), 0.51–0.72] and 0.85 (95% CI, 0.68–1.03), respectively, compared with individuals <40 years of age.[2] Thus, age alone is not an independent risk factor for reduced stool frequency. Likewise, little evidence exists to support low-fibre diets, lack of fluid or reduced exercise as contributing to constipation in the otherwise healthy older patient.[6,7]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

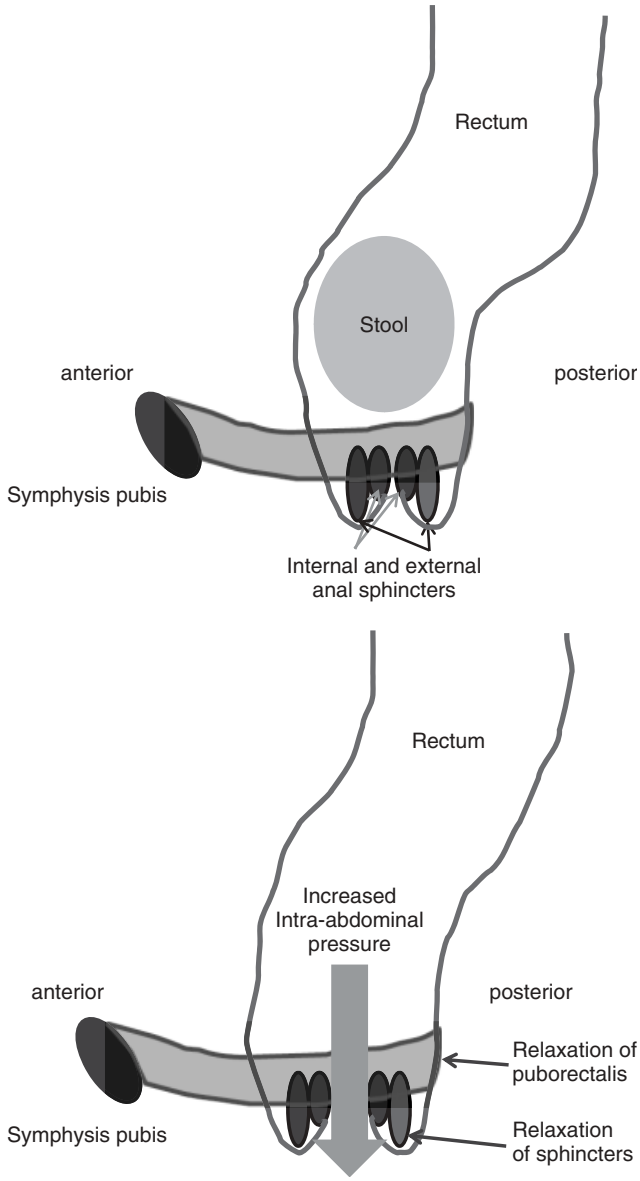

Figure 25.1 Illustration of the defecatory process.

Women report fewer bowel movements per week than do men. Non-whites and individuals of lower socioeconomic status report fewer stools.[8] In frail elders, up to 45% report constipation as a health concern.[9] The prevalence of constipation is higher in nursing home residents, a finding partially explained by the use of constipating medications.[10] Nursing home residents frequently (58%) use laxatives, usually on an as-needed basis.[11] In older persons, the development of constipation typically represents the effects of medications and/or comorbid disease. The traditional perception of constipation as a result of ageing no longer holds; the healthy older person is not predestined to develop constipation.

Table 25.1 Anatomical distribution of changes associated with constipation.

Central nervous system
Awareness of need to defecate
Cerebrovascular accident
Dementia
Peripheral nervous system
Controls myogenic activity of puborectalis
Pudendal nerve injury
Enteric nervous system
Controls rectal sensory function, peristalsis and internal anal sphincter
Parkinson's disease
Desensitization (chronically distended rectum)
Diabetes mellitus
Skeletal muscle
Contraction/relaxation of puborectalis and external sphincter
Direct muscular damage (e.g. prior birth trauma, sphincterotomy)
Rheumatological disorders (e.g. scleroderma, reduced muscular strength)
Incoordination
Idiopathic
Parkinson's disease
Cerebrovascular accident

Elders reporting constipation more often describe straining and hard bowel movements than reduced stool frequency.[2,12,13] Population-based prevalence of constipation includes 40% of community-dwelling adults over the age of 64 years.[14] The risk factor most commonly reported for constipation is medication use, including non-steroidal anti-inflammatory drugs (NSAIDs).[14]

Despite the lack of difference in risk factor-adjusted constipation rates between elders and younger individuals, elders more frequently use laxatives. Up to 50% of elderly women reporting use laxatives. Overall, 20–30% of community-dwelling elders use laxatives on at least a weekly basis. In nursing homes, 58% of residents receive laxatives on at least an intermittent basis.[11] Few economic studies in the USA have outlined the costs of laxative use by elders. Annual estimated healthcare costs using an administrative claims database (excluding out-of-pocket costs) were $7522 per person (average age 52 years) at one health maintenance organization.[15] Most elders self-treat with over-the-counter products; hence the economic impact of laxative use is probably considerably higher than this estimate.

The findings of similar stool frequency but increased defecatory difficulty parallel the reported physiological changes that occur in the digestive tract with ageing. Colon transit overall is generally well preserved with ageing in humans.[16] Changes in pelvic floor function may contribute to defecatory difficulty, with older women demonstrating reduced opening of the anorectal angle and a greater degree

of perineal descent compared with younger women.[17] Pudendal neuropathy also occurs more commonly with ageing and may negatively affect pelvic floor function.[18] Other factors correlated with constipation in ageing include reduced caloric intake, use of multiple medications, haemorrhoids and pain in the abdomen.[19,20] Many diseases that occur more commonly in elders also contribute to the development of constipation, such as diabetes mellitus, Parkinson's disease and stroke.[21–23] Prior surgery may also affect bowel function in elders. In women over 50 years of age, hysterectomy results in prolonged colon transit time and greater complaints of constipation and straining than in controls.[24] Since ageing alone has little influence on the development of constipation, when complaints of constipation occur in elders, it commonly relates to medical comorbidities and increased defecatory difficulty.

The consequences of constipation in elders make it a significant health problem. The presence of chronic constipation impacts functioning in daily living, and elders with these complaints rate their health lower than people without gastrointestinal symptoms.[25] These findings were not confounded by the presence of other chronic illnesses or medication use. Health-related quality of life is reduced in patients with chronic constipation.[26] The presence of constipation has also been hypothesized to increase urinary tract symptoms with treatment of constipation resulting in reduced urinary frequency, urgency and dysuria.[27] Constipation is also associated with bowel incontinence and treatment of constipation reduces incontinence episodes.[28,29] Immobile or cognitively impaired individuals with constipation face an increased risk of faecal impaction and stercoral ulceration.[28,30] Constipation reduces quality of life and diminishes self-perceived health in community-dwelling elders.[25] More effective strategies are needed for reducing the burden of illness and costs associated with constipation.

Aetiology of constipation

Of the multiple causes of constipation in older persons, most relate to medication use or coexisting medical illness (Tables 25.2 and 25.3). The most commonly implicated medications are opiates, NSAIDs and medications with anticholinergic effects. Although immobility and reduced fluid and fibre intake are often implicated in the development of constipation, there is little evidence to support this folklore. Increased physical activity does not reliably improve constipation.[31] Reduced caloric intake correlates more closely with constipation in elders than do differences in fibre intake.[19] Likewise, reduced liquid intake does not appear to cause constipation in most elders.[13] Increased psychological distress correlates with reports of constipation by elders, although the mechanism for this association remains unknown.[13,19]

Table 25.2 Medications commonly associated with constipation.

Anticonvulsants
Antidepressants (SSRIs and TCAs)[a1]
Antihistamines
Antipsychotics
Bromocriptine
Calcium channel blockers
Calcium supplements
Diuretics
Ferrous gluconate and ferrous sulfate
Levodopa
Non-steroidal anti-inflammatory drugs
Opiates

[a] SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Mechanical obstruction
Colonic neoplasia
Colonic stricture (intrinsic or extrinsic)
Anal stenosis
Metabolic
Amyloidosis
Chronic kidney disease
Diabetes mellitus
Electrolyte disturbance (hypercalcaemia, hypomagnesaemia)
Hyperparathyroidism
Hypothyroidism
Neurological
Autonomic neuropathy
Cerebrovascular accident
Dementia
Multiple sclerosis
Parkinson's disease
Rheumatological
Polymyositis
Scleroderma
Psychiatric
Depression

Clinical approach

History

The evaluation of constipation begins first with understanding the patient's perspective on their altered bowel function and the time course of constipation development. The acute or subacute onset of constipation requires a more aggressive diagnostic approach to exclude structural lesions, including colon neoplasia, stricture and volvulus. Likewise, the presence of weight loss, rectal bleeding,

history of inflammatory bowel disease, family history of colorectal neoplasia or presence of iron deficiency anaemia require a structural examination to exclude cancer or other aetiology. Additional helpful details in the patient history include onset of constipation, frequency of bowel movements, sensation of incomplete evacuation, straining to defecate, consistency of the stool, associated abdominal pain, the need for digitation, perineal splinting or unusual postures for defecation to occur, episodes of bowel incontinence, prior abdominal or pelvic surgery, prior abdominal or pelvic radiation therapy and prior pregnancies. It is also necessary to review current medications and supplements, current and previously used laxatives with their degree of effectiveness, use of enemas and use of complementary therapies to treat constipation (e.g. high colonics, herbs, teas). Dietary history includes a general survey of calories ingested, fibre intake and restricted foods. Given the consistent association of constipation with depression and anxiety, a brief psychological assessment is also warranted. In general, the ideal, evidence based approach to the diagnostic evaluation of constipation remains to be identified.

Physical examination

The physical examination is directed to identifying underlying medical causes for constipation, excluding faecal impaction, and providing a preliminary assessment of anorectal function. A faecal mass may be palpable on abdominal palpation. Rectal examination includes inspection of the perineum at rest and with strain. Normal perineal descent during strain is 1–4 cm. No perineal descent suggests failure of the pelvic floor to relax and allow the passage of stool. Excessive perineal descent, sometimes characterized as a ballooning of the perineum, indicates excess laxity to the pelvic floor musculature and dyssynergic defecation. This finding is most common in multiparous women. The strength of the anal sphincter muscle at rest and with squeeze is assessed. Puborectalis and anal sphincter relaxation during strain provide a measure of proper of the appropriateness of pelvic floor function. Failure of relaxation or very high anal sphincter resting pressure suggests dyssynergic defecation. The presence of weak anal sphincter pressures may place the patient at risk for incontinence during treatment of the constipation. Rectal prolapse can be associated with difficult evacuation due to blockage of the anal canal with rectum. These patients usually also described episodes of bowel incontinence. A more severe rectal prolapse can be identified during strain in the left lateral decubitus position. A better way to assess for rectal prolapse is to have the patient strain over a commode. The examiner places a gloved hand below the anus and can feel the rectal prolapse descend and touch the glove. The degree of rectal prolapse can be assessed by visual inspection. The physical examination, including rectal examination. is a necessary part of the evaluation of any constipated patient.

Diagnostic tests

Laboratory tests often recommended in the evaluation of constipation include a complete blood count, metabolic panel that includes electrolytes, creatinine, magnesium and calcium and sTSH (sensitive thyroid-stimulating hormone). Stool examination for occult blood should be assessed. The need for a colonic structural examination is dictated by the need for routine colorectal screening, presence of worrisome signs such as bleeding or anaemia or recent change in bowel habit. The yield of colonoscopy in identifying neoplasia is no different in the individual with constipation compared to what would be identified in an asymptomatic population undergoing screening. Many patients with long-standing constipation and no warning symptoms can undergo a therapeutic trial with fibre or an osmotic laxative, preserving further evaluation for those who fail to respond to simple interventions.

Patients with more severe or medication-unresponsive constipation may benefit from further evaluation, including physiological testing. It is difficult to predict the underlying pathophysiology of chronic constipation by symptoms alone.[32] The presence of slow transit constipation or dyssynergic defecation may be suspected by a poor response to a trial of supplemental fibre.[33] Additional tests include colon transit measurement, colonic manometry, anorectal manometry, balloon expulsion testing and defecography. Colonic transit measurements may be performed scintigraphically or using radiopaque markers and plain abdominal radiographs. In practice, few centres have scintigraphy readily available. A variety of techniques have been described for measuring colonic transit using radiopaque markers, some providing data on regional colon transit. Since treatments have not yet been identified for treating regional colonic abnormalities, total colon transit measurements suffice. The 5-day colon transit measurement involves ingestion of a commercially available capsule containing 24 radiopaque markers (Sitzmark) and performing a plain abdominal radiograph 5 days later).[34] Transit is considered prolonged when five or more markers remain (Figure 25.2). Although markers remaining predominantly in the rectum suggest dyssynergic defecation or outlet dysfunction, the distribution pattern of the markers throughout the colon does not reliably differentiate between primary slow transit versus colon transit delayed as a result of outlet dysfunction (i.e. dyssynergic defecation).

Dyssynergic defecation refers to physiological difficulty with the rectal evacuation process. Synonyms include pelvic outlet dysfunction, pelvic floor dysfunction, anismus and paradoxical puborectalis contraction. Uncommonly, difficult rectal evacuation may be due to an anal stricture,

Figure 25.2 An abdominal radiograph obtained 5 days after ingestion of a capsule containing 24 radiopaque (small circles) markers. The presence of 16/24 markers on day 5 indicates the presence of slow colonic transit. The majority of the markers reside in the rectum with a few markers scattered in the sigmoid and descending colon.

obstructing rectocele or internal intussusception. The last two findings are most often the result of abnormal straining, rather than a primary problem themselves. The presence of dyssynergic defecation can be evaluated by anorectal manometry, electromyography of the anal sphincter, balloon defecation and defecography. Anorectal manometry involves measuring the pressures of the anal sphincter with a manometric probe in response to different manoeuvres, including straining. During strain, a rise in intra-rectal pressure should occur and the anal sphincter should relax. The presence of a paradoxical increase in sphincter pressure suggests the possibility of dyssynergic defecation. False positives occur at least 10% of the time with all tests of pelvic floor function. Therefore, two tests that independently confirm the same findings are required to make a secure diagnosis of dyssynergic defecation. Balloon expulsion testing is performed by placing a small balloon in the rectum and filling the balloon with 50–60 ml of warm water. The patient is asked to sit on a commode and expel the balloon. Normal expulsion occurs in 60 s or less. A prolonged time or failure to expel the balloon suggests dyssynergic defecation.[35] Anorectal manometry and balloon expulsion testing are the most commonly performed tests to identify dyssynergic defecation. Electromyography will also assess for proper anal sphincter muscle relaxation and contraction. The need to place needles in the anal sphincter has made this technique less attractive for most patients. Defecography involves placing a paste in the rectum. The patient sites on a commode and radiographs are obtained during defecation. Defecography assesses the opening of the anorectal angle and provides an assessment of sphincter opening, perineal descent and rectal emptying. Defecography typically is reserved for cases where an underlying structural abnormality is suspected or when other tests for dyssynergic defecation are equivocal. Additional physiological tests of colon transit and pelvic floor function are required in only the subset of patients refractory to medical management. Even in this highly selected group of patients, an abnormality is identified only 50% of the time.[36] Patients with refractory symptoms and normal physiological studies are defined as having 'normal transit constipation'. Many of these patients meet criteria for irritable bowel syndrome, particularly if their symptoms have been long-standing.

Treatment

The initial treatment strategy for constipation nearly always includes the ingestion of more dietary or supplemental fibre. Increased fibre intake improves stool consistency and accelerates colon transit in many individuals.[37] However, constipated elders actually consume more fibre at baseline than non-constipated controls.[38] Nonetheless, fibre generally provides a safe, inexpensive first-line approach. Increased fluid intake is also frequently recommended. Although this may have value in the dehydrated patient, increasing fluid intake in chronic constipation rarely improves constipation symptoms.[7] Likewise, increased physical activity is also recommended without clear evidence of efficacy.[7,39] General non-pharmacological advice given first line includes information about a normal bowel habit, ingestion of a healthy, fibre-rich diet and taking advantage of the meal-related increase in colonic motor activity. Given the strong association of constipation in older persons with medication use, elimination or adjustments should be made in medications, substituting less constipating alternatives where possible. Medications used in the treatment of constipation are listed in Table 25.4.

Pharmacological management

Bulking agents

Bulking agents commonly used include wheat or oat bran, psyllium, calcium polycarbophil, carboxymethylcellulose and partially hydrolyzed guar gum. There have been few high-quality randomized controlled studies assessing the

Table 25.4 Medications used in the treatment of constipation.

Agent	Daily dose
Bulking agents	
Bran (wheat or oat)	4–10 g (generally $\frac{1}{4}$ –$\frac{1}{2}$ cup)
Calcium polycarbophil	2–4 g
Hydrolyzed guar gum	3–6 g
Methylcellulose	2–4 g
Psyllium	3–6 g
Osmotic	
Lactulose	10–40 g
Magnesium salts	Generally avoided in elders
Sorbitol 70% solution	15–60 ml
Polyethylene glycol (PEG)	17–34 g
Stimulant	
Aloe	Safety/efficacy not established
Senna	15–30 mg
Bisacodyl	5–10 mg
Other	
Lubiprostone	8–24μ g b.i.d.
Probiotics	*Bifidobacterium infantis* 1 capsule daily
	Yogurt 8–16 oz daily
Methylnaltrexone	Weight-based dosing

efficacy of these agents. Studies with psyllium generally show improved stool form and frequency.[40,41] Studies assessing the efficacy of wheat bran, oat bran, calcium polycarbophil, carboxymethylcellulose and partially hydrolyzed guar gum are inadequate for assessing the efficacy of these agents. Fibre supplements may result in increased gas or bloating. This effect may be minimized by gradually increasing the dose of fibre. The effect of the fibre supplement may take 2–4 days before the patient sees results.

Stool softeners

Stool softeners such as dioctyl sodium sulfosuccinate (Colace) or dioctyl calcium sulfosuccinate (Surfak) are reported to soften the stool, easing defecation. Despite the widespread use of these agents, there are no randomized controlled trials showing efficacy. One study comparing dioctyl sodium sulfosuccinate with placebo showed no improvement in stool frequency or consistency.[42] Another study comparing dioctyl sodium sulfosuccinate with psyllium found psyllium to be superior.[43] The therapeutic use of stool softeners appears limited for the treatment of chronic constipation.

Osmotic laxatives

Osmotic laxatives improve stool form and bowel movement frequency by increasing the amount of water retained in the lumen of the gut. Polyethylene glycol (PEG) and lactulose have therapeutic value in the treatment of constipation. Other osmotic laxatives include sorbitol, magnesium salts and saline salts. PEG, lactulose and sorbitol have the greatest safety margins. Use of saline or magnesium salts comes with a risk for significant electrolyte disturbance, especially in older persons. Elders with normal renal function may become hypermagnesaemic with chronic use, especially at higher doses.[44] Magnesium salts should not be used in renal disease and saline salts should be avoided in chronic renal failure, end-stage liver disease and heart failure. PEG appears to be the best tolerated overall in elders. Lactulose and sorbitol undergo bacterial metabolism in the gut, leading to increased symptoms of bloating, abdominal cramping and flatulence in some patients, limiting their tolerability.

Several randomized, placebo-controlled trials of PEG showed efficacy in the treatment of chronic constipation. Compared with placebo, PEG improves stool consistency and stool frequency.[45] One study compared PEG with lactulose, showing improved efficacy with PEG and fewer side effects.[46] No studies using PEG directly assessed efficacy in older adults. One study in adults with a mean age of 45 years showed efficacy, safety and few side effects over a 6 month period with an isosmotic PEG electrolyte solution.[47]

Lactulose improves stool frequency and consistency with a success rate of 80% compared with a placebo response of 60%.[48] A study of nursing home residents with constipation compared lactulose with a glucose solution. Lactulose improved stool frequency, reduced the need for enemas and reduced faecal impaction over a 12 week period.[49] The difference in number of faecal impactions between the two groups was an astounding difference of six for lactulose versus 66 for glucose. A literature review revealed no placebo-controlled randomized trials assessing the primary efficacy of sorbitol in the treatment of constipation. One randomized comparative trial of lactulose and sorbitol in elders found no difference in laxative effect and no strong preference for one laxative over the other by the study subjects.[50] Abdominal symptoms were similar between the two groups except for greater complaints of nausea in the lactulose group. The cost of sorbitol is generally less than that of lactulose, making it the preferred agent for many patients.

Magnesium hydroxide is the most commonly used magnesium-containing osmotic laxative. Despite the fairly widespread use of this laxative, there are no high-quality studies demonstrating efficacy and safety in treating constipation. Nonetheless, magnesium intake is well known to cause diarrhoea, supporting its use in the treatment of constipation. Magnesium salt intake in normal subjects results in a linear increase in stool weight with a 7.3 g increase in faecal weight for every millimole increase in stool magnesium.[51] A cross-over

study comparing magnesium hydroxide and 8.7 g of a bulk laxative in geriatric long-stay patients showed increased stool frequency in the magnesium hydroxide group.[52] Magnesium salts must be used with caution in older patients with consideration given for periodic monitoring of serum magnesium levels in those taking magnesium-containing laxatives chronically. The use of sodium-containing laxatives has not been well studied in the treatment of constipation. Sodium-containing laxatives are better absorbed systemically than magnesium-containing laxatives. When oral Phospho-soda was used as a colonic preparation for diagnostic examination, significant changes in electrolytes occurred.[53] Even in the setting of a normal creatinine, an age-related increase in phosphate occurred.[53] Sodium-containing laxatives cannot currently be recommended for the routine treatment of constipation in older persons.

Stimulant laxatives

The adverse effects that stimulant laxatives have in the treatment of constipation remain one of the most steadfast medical myths.[7] Stimulant laxatives have been reported to damage the colon and cause laxative dependence. This perception may relate to the occurrence of melanosis coli, a dark brownish discoloration of the colon that occurs with long-term use. The presence of melanosis coli has no functional significance. Prior studies reporting damage to the colonic enteric nerves and smooth muscle were anecdotal and uncontrolled. It is likely that many of these patients had pre-existing abnormalities of the colon. When used at recommended doses, stimulant laxatives are unlikely to harm the colon. Stimulant laxatives result in abdominal discomfort and electrolyte imbalance in some patients.[54]

No high-quality, placebo-controlled studies have assessed the efficacy of stimulant laxatives in the treatment of chronic constipation. Most commonly available stimulant laxatives include the anthraquinones, diphenylmethane derivatives and ricinoleic acid. Anthraquinone laxatives include senna-containing products and aloe. An observational (uncontrolled and not blinded) study using a senna-containing concentrate as part of a programme that included a stool softener and increased fibre and fluid intake resulted in improved bowel evacuation in 86% and prevented faecal impaction in nursing home patients with constipation.[55] Compared with placebo, bisacodyl 10 mg daily for 3 days increased stool frequency, improved stool form and reduced straining in adults with constipation.[56] A comparison of bisacodyl with sodium picosulfate (uncontrolled) showed improvement with both in about three-quarters of subjects.[57] Stimulant laxatives are typically reserved for patients who do not respond to other laxatives. They are widely available without a prescription and are frequently used.

Prokinetic agents

There are no currently available FDA-approved prokinetic agents for use in chronic constipation. Tegaserod, a $5HT_4$ agonist, improves the symptoms of constipation in adults.[58] Data regarding efficacy in individuals over the age of 65 years have not been reported. Tegaserod was removed from the market due to a *post hoc* analysis showing an increased occurrence of ischaemic events with tegaserod compared with placebo. Neostigmine, an acetylcholinesterase inhibitor, produces prompt colonic decompression. The use of neostigmine is reserved for hospitalized patients with acute colonic pseudo-obstruction.[59]

Chloride channel agonist

Lubiprostone selectively activates chloride C-2 channels to increase intestinal fluid secretion. Lubiprostone does not affect colonic motility or sensation in humans. Patients reported more spontaneous bowel movements with lubiprostone compared with placebo (six versus four per week, $p = 0.001$) with the majority of patients experiencing a bowel movement within the first 24 h.[60] The main side effect seen with lubiprostone was nausea. This effect is mitigated when the medication is taken with a meal and appears to be less problematic in elders.

Opioid antagonists

Opiate pain medications are well known to cause constipation. A peripheral mu opioid antagonist reverses opiate-induced constipation without affecting the analgesic effects or causing withdrawal symptoms.[61,62] This medication is administered subcutaneously every other day using a weight-based dosing. The response can be rapid with a median time to first bowel movement of 30 min. Alvimopan, also a mu opioid antagonist, has been studied in postoperative ileus with good results. It has not been approved for use in chronic constipation and currently is only used in the hospital setting. For elderly patients with chronic constipation due to opiates, future development of peripheral opiate antagonists shows promise. Methylnaltrexone use is appropriate for opiate-induced constipation that has not responded to other measures.

Miscellaneous agents

Misoprostol, a prostaglandin agonist, stimulates intestinal secretion and intestinal transit. Its use is limited by the common occurrence of side effects, including abdominal pain and cramping.[63] Its use is reserved for patients with refractory constipation. Colchicine, well known for causing diarrhoea in the acute treatment of gout, may be used in patients refractory to other medications.[64] Colchicine frequently causes increased symptoms of abdominal pain, limiting its use. Glycerine suppositories have long been used as an over-the-counter agent for stimulating

bowel movements. The medical literature is lacking in assessments of their effectiveness. Linaclotide increased cyclic guanosine monophosphate, stimulating chloride and bicarbonate secretion. Published phase 2 trials showed a dose-dependent improvement in stool frequency.[65] Phase 3 trials have been completed but this agent has not yet undergone FDA approval.

Enemas

The use of enemas in the treatment of constipation is typically limited to the acute situation. There is no medical evidence to support the routine use of phosphate enemas in the treatment of constipation.[66] The use of phosphate enemas is well described to cause serious hyperphosphataemia, especially in patients with renal insufficiency.[67] Any enema must be used with caution owing to the risk of colonic perforation.[68] Soap suds enemas should not be used. Small-volume tap water enemas may be helpful in emptying the rectum. Larger volume tap water enemas may be used on occasion, but even these can result in hyponatraemia.[69] In patients with very refractory constipation, the use of antegrade enemas has been described.[70,71] Antegrade enemas involve creating a caecostomy placed surgically or endoscopically. Water or PEG is flushed through the tube periodically to facilitate colonic emptying. No high-quality, controlled trials have assessed any of these enema therapies.

Special categories of constipation

Medication use is strongly correlated with the development of constipation in older persons. Where possible, unnecessary medications should be discontinued and necessary medications switched to a less constipating alternative when one is available. For example, verapamil causes more constipation than other calcium channel blockers. Chronic opiate use results in constipation in up to 50% of individuals.[72] Methadone and fentanyl may be less constipating than other morphine derivatives.[73,74] Methylnaltrexone, a peripheral mu opioid receptor antagonist, improves oral caecal transit and induces laxation without inducing opiate withdrawal symptoms.[75] Opiates potently slow gastrointestinal transit and allow enhanced intestinal absorption of fluid. A rational approach involves outlining a strategy to prevent constipation at the initiation of opiate use. There have been no high-quality studies to indicate the best strategy. As noted previously, methylnaltrexone improved stool frequency in opiate-induced constipation. It is typically reserved for patients with more refractory symptoms as it is administered by injection every other day. PEG improved stool form in methadone-induced constipation.[76] Stimulant laxatives are also commonly used for opiate-induced constipation.

Constipation commonly occurs in Parkinson's disease related to dyssynergic defecation from incoordination of the pelvic floor musculature during defecation and the constipating effect of medication used to treat Parkinson's disease. Psyllium has been used successfully to treat constipation in these patients.[77] Individuals with dementia frequently develop constipation. Sorbitol and lactulose have been reported to be successful in an observational study.[78]

The use of combinations of laxatives has rarely been addressed in the literature but is commonly encountered in practice when a single agent is ineffective. The most common combination is an osmotic laxative with a stimulant laxative. In patients with continued complaints of constipation despite the use of a single laxative, obtaining a plain abdominal radiograph to assess the degree of stool retention may be helpful. Patients with a large amount of stool (and no evidence of faecal impaction) may be treated with a colon preparation such as balanced electrolytes plus PEG (e.g. NuLYTELY) to cleanse the colon. The patient may be then started on an osmotic laxative with a stimulant laxative available on an as-needed basis every 2–3 days if a satisfactory bowel movement does not occur. Patients without significant stool loading should be assessed for the presence of irritable bowel syndrome. About 11% of elders have symptoms consistent with irritable bowel syndrome.[25] Patients with irritable bowel syndrome may benefit from medications directed at neuromodulation, although caution must be used due to the anticholinergic effects of many of these agents.[79]

Patients with refractory constipation and slow transit constipation benefit from subtotal colectomy and ileorectostomy.[80] Fortunately, this is rarely required as nearly 90% of patients with slow transit constipation respond to laxatives.[81] When dyssynergic defecation is present, biofeedback improves defecatory function in ~70% of patients.[82] Patients with both slow transit constipation and dyssynergic defecation should first be treated with biofeedback. When slow transit constipation persists after successful treatment of dyssynergic defecation, subtotal colectomy may be considered. Surgical therapy is most successful in patients without upper gut motility disorders or significant psychological symptoms.[83]

The optimal treatment for faecal impaction is not clear. Patients able to tolerate oral therapy may benefit from PEG or other osmotic laxatives with or without the use of enemas.[84] Patients with a hard or very large faecal bolus in the rectum may require manual removal of the faeces. Hyperosmotic, water-soluble contrast enemas have also been used with success in relieving faecal impaction.[85]

Conclusion

Complaints of constipation and use of laxatives remain common in older persons. When controlling for comorbidities, constipation is no more common in elderly than in younger persons. Stool frequency remains unchanged with

ageing. Elders more commonly complain of straining and hard stools. Risk factors for constipation include medication use, chronic medical illness and psychological distress. Healthy elders are no more likely to develop constipation that younger persons. Constipation adversely affects elders' sense of well-being and quality of life. The economic impact is also significant due to the cost of laxatives alone. In patients with up-to-date colorectal cancer screening who lack worrisome symptoms such as bleeding or weight loss, empirical treatment is appropriate with bulking agents or simple laxatives. Patients who fail to respond require a more detailed evaluation. Identifying the most effective treatment strategy for constipation in elders, whether in the community or long-term care setting, remains unclear due to the lack of high-quality therapeutic trials for most laxatives. Data support the use of psyllium, lactulose, sorbitol, PEG and lubiprostone in elders with constipation. The safest, best tolerated and least expensive laxatives (including the use of bulking agents) should be implemented first before prescribing the more expensive laxatives. Improved research in this area is needed to identify the most effective, economically viable therapeutic agents. New agents are just around the corner, providing more options for the treatment of constipation.

Key points

- Reports of constipation and use of laxatives are very common in older persons.
- Stool frequency is no different in elders compared with younger persons, with elders complaining most of straining and hard stools.
- The use of medications and chronic medical illnesses correlate more closely with the development of constipation in elders.
- Patients lacking worrisome symptoms may undergo an empirical therapeutic trial, reserving diagnostic testing for those who fail to respond.
- The best available evidence supports the use of psyllium, lubiprostone and osmotic laxatives (especially PEG) in the treatment of constipation in elders.
- Methylnaltrexone, available as an injection, is an important advance in the treatment of opiate-induced constipation.

CHAPTER 26

Management of diarrhoea

Lenise A. Cummings-Vaughn
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Overview of diarrhoeal illness

Although the definition of diarrhoea appears clear, there are specific parameters that need to be met prior to making a diagnosis. According to Gerding *et al.*,[1] there are three separate parameters which include new onset of >3 partially formed or watery stools over a 24 hour (h) period, ≥6 watery stools over 36 h or ≥8 unformed stools over 48 h. Once the diagnosis has been made, diarrhoea can be further classified as acute or chronic. Acute diarrhoea is diarrhoea lasting for 14 days or less. Persistent diarrhoea lasts for longer than 14 days. Chronic diarrhoea is diarrhoea lasting for longer than 1 month. The consequences of fluid and electrolyte loss are especially concerning for elderly adults. Furthermore, the management of diarrhoea can differ from the general adult population due to various comorbidities, living arrangements and inherent immune susceptibility that exist among elderly adults.

Diarrhoea is a common cause of death worldwide and one of the most common infectious illnesses in elderly nursing home patients.[2] This is particularly important in the treatment of the elderly as there is an inherent decline in immune defences which are often compounded by many close contacts derived from living in long-term care facilities. Once diarrhoea has been distinguished from incontinence and faecal impaction, one can further classify the type of diarrhoea. In addition, diarrhoea presenting with incontinence can represent a decompensation of existing poor gastrointestinal (GI) function in the elderly.[3] The subdivisions of acute and chronic diarrhoea can be further broken down into more categories according to the cause and presentation. Acute diarrhoea is usually infectious in nature, but can also be caused by medications, nutrition, diverticular disease and ischaemia.[3] Chronic diarrhoea can be further subclassified as secretory or watery, osmotic, fatty or bloody (inflammatory or exudative).[3]

Some elements of the GI tract, for example, immune function, change with age; a healthy ageing GI tract's absorptive capacity, mucosal anatomy and motility should be unchanged. Therefore, even in the elderly, the main goal in diarrhoeal management remains the identification of the aetiology of diarrhoea and preventing dehydration.

Acute diarrhoea

Infectious

Infectious diarrhoea is the most common cause of diarrhoea. The infectious causes of diarrhoea include viruses, bacteria and parasites.[2] The most common viruses include Norwalk virus, rotavirus and calicivirus. The bacteria include *Clostridium difficile, Clostridium perfringens, Campylobacter, Escherichia coli, Salmonella, Shigella, Staphylococcus* and *Vibrio*. Lastly, the parasites include *Giardia lamblia, Entamoeba histolytica, Cryptosporidium* and *Cyclospora*.[2,3]

C. difficile is the most common healthcare infection causing diarrhoea.[4] The organism is a spore-forming Gram-positive anaerobic bacillus with two exotoxins. Toxin A is an enterotoxin and toxin B is a cytotoxin. There are currently hypervirulent strains that are identified as B1, NAP1 and ribotype 027/toxinotype III. These hypervirulent strains produce 23 times more toxins A and B, which causes increased resistance to treatment.[5] Similarly to less virulent strains, they are associated with fluoroquinolone and cephalosporin use. The rate of *C. difficile* colonization in LTCF is 4–20% and outbreaks are severe.[6] In 1986, Bender *et al*. found 19 deaths from the 49 cases of infection in an outbreak in a Baltimore nursing home.[7] The outbreak lasted for 7 months despite precautions, antimicrobial use restrictions and treatment. *C. difficile*-associated disease (CDAD) is defined as diarrhoea, per previously defined criteria, pseudomembranes or stool toxin A or B or stool culture positive for toxin-producing *C. difficile* and no other recognized aetiology for diarrhoea.[1] Although the predominant presentation is with diarrhoea, ileus or absence of diarrhoea can occur in less than 1% of presentations. Therefore, with increased clinical suspicion, a toxin assay or culture must be performed on non-diarrhoeal stool. Some sources

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

estimate that >10% of hospitalized patients are colonized with *C. difficile*.[1] A history of treatment with antimicrobial or antineoplastic agents within the previous 8 weeks is present in virtually all patients, but is not included in the case definition to avoid bias and to allow comparison of antimicrobial use as a factor. In clinical practice, antimicrobial use is considered to be part of the operative CDAD definition. A response to specific therapy for CDAD is suggestive of the diagnosis and can be confirmatory.[1] Direct visualization using endoscopy detects pseudomembranes only 51–55% of the time.

CDAD is associated with proton pump inhibitor therapy (PPI). Akhtar and Shahee[8] studied the incidence and association of *C. difficile*-associated diarrhoea and PPI. The study found a significant association of *C. difficile* associated with antibiotics or chemotherapy [odds ratio (OR) = 2.3, 95% confidence interval (CI) = 1.5–3.7] and with PPI use (OR = 2.0, 95% CI = 1.6–2.6).

Brandt *et al*.[9] noted in 1999 that the response to treatment of CDAD was similar in groups less than and older than 60 years of age. In addition, the associated mortality between the groups was also the same. However, owing to the modest sample size of 89 CDAD patients in the study, there may have been insufficient statistical power to detect small yet meaningful differences. The older group was significantly more likely to have an elevated white blood cell count (>10 400 cells mm^{-3}) and nosocomial infection after >2 weeks of hospitalization. Both exposures from increased hospital stay or healthcare-associated contacts and also susceptibility may account for the increased rate of CDAD in the elderly.

The other bacterial and parasitic causes of diarrhoea and treatments are listed in Table 26.1. These infections can usually be distinguished by the type of diarrhoea, watery or bloody, or the time to diarrhoea onset. The invasive or inflammatory causes of diarrhoea include enteroinvasive *E. coli, Shigella* and *E. histolytica*. The Shiga-like toxin and Shiga toxin-producing organisms include *E. coli* and *Shigella*, respectively. While *E. coli* usually produces diseases at between 10 h and 6 days, *E. coli* O157:H7 can take up to 4 days to produce disease. *Shigella dysenteriae* can take up to 1 week to produce disease. *Salmonella, Yersinia enterocolitica* and *Campylobacter* produce disease 12–48 h after ingestion. Akhtar[2] reported a Maryland nursing home resident outbreak of *Salmonella* with a 24% rate of death in those affected.

Other infectious causes of diarrhoea are viruses, including Norwalk, Norwalk-like virus and rotavirus. These viruses are common causes of diarrhoea in the paediatric population. However, they have been noted to cause epidemic diarrhoea in the nursing home in The Netherlands[10] and Spain.[11] The viruses differ by the predominant time of year for presentation, with rotavirus causing disease during the cooler months. They are both acquired by the faecal–oral route; therefore, direct contact or contact with contaminated food and water is the most likely means of spread. A retrospective cohort study of nursing home residents and staff between December 1998 and January 1999 in the Rotterdam region found 107 attacks of acute onset diarrhoea or vomiting in the 120 residents and 102 staff members studied.[10] The resident gastroenteritis attack rate was 62% without any significant difference among number of room-mates or eating place. The study found that the nursing home staff contributed to the spread of illness. Those residents who were infected were older (77 versus 72 years, $p = 0.04$). In addition, the rate of attack increased with age, which was postulated to be related to mobility, intensity of nursing care and immune health.

Table 26.1 Infectious diarrhoea.

Pathogen	Medication/therapy
Bacteria	
Clostridium difficile	Metronidazole or vancomycin p.o.
Campylobacter jejuni	Erythromycin or azithromycin p.o.
Salmonella typhi	Ofloxacin or norfloxacin p.o.
Shigella	Trimethoprim–sulfamethoxazole or ofloxacin
Vibrio cholerae	Tetracycline
Parasitic protozoa	
Cryptosporidium parvum	Nitazoxanide p.o.
Entamoeba histolytica	Metronidazole then iodoquinol (diiodohydroxyquinoline) p.o.
Giardia lamblia	Metronidazole, furazolidone or nitazoxanide p.o.

Adapted from Refs 2 and 19.

Diagnosis of infectious diarrhoea should be guided by the initial presentation and history. Without fever, signs of dehydration, bleeding, abdominal pain or coexisting disease, supportive care without further testing can be appropriate.[2] However, the presence of the aforementioned symptoms and disease states or lack of resolution after supportive therapy for 48 h warrants further investigation. Depending on the clinical suspicion for *C. difficile*, stool toxin assays should be performed. In addition, in order to control disease dissemination, hand hygiene, barrier protection and environmental precautions (cleansing, disinfecting and disposables) are imperative. Specific antibiotic and antiparasitic treatment options for infectious causes of diarrhoea are included in Table 26.1.

Bloody

A common cause of lower GI bleed is diverticula. Diverticular colitis can be the cause of both chronic and acute diarrhoeal disease. It is believed the 60% of 80-year-olds have diverticulosis. Estimates indicate that 10–30% of GI

bleeds are from diverticula.[12] Bleeding is caused by non-circumferential rupture of the underlying vasa rectum.[12] In addition, the most common life-threatening bleeds are lower GI diverticular bleeds. Risk factors of diverticular bleeds include hypertension, anticoagulation, diabetes mellitus and ischaemic heart disease.[12] Bloody diarrhoea also occurs with ischaemic colitis, which will be considered in the next section.

Specific treatment for bleeding diverticula includes vasopressin infusion, embolization and surgery. According to Lewis,[12] vasopressin infusion via angiogram is 36–90% effective in the initial treatment of diverticular bleeds and 22–71% in recurrent bleeding. In addition, the success rate for selective embolization was noted to be 71–90%, with a relatively lower rebleeding rate than vasopressin infusion at 15–20%.

Ischaemic

Ischaemic colitis usually presents with colicky lower abdominal pain, diarrhoea, vomiting or rectal bleeding.[13] The acute presentation is often abrupt onset of pain and bloody diarrhoea; however, the problem can also be chronic in nature. Lactic acidosis is the most common metabolic disorder. Mesenteric ischaemia includes various presentations, such as acute mesenteric ischaemia, chronic mesenteric ischaemia, non-occlusive mesenteric ischaemia, mesenteric venous thrombosis and colonic ischaemia. Ischaemic vulnerability occurs in the splenic flexure and the rectosigmoid. Both areas are often referred to as 'watershed areas' because they represent incomplete anastomosis of the marginal artery between the inferior mesenteric and superior mesenteric or hypogastric, respectively.[14] Causes are varied, from embolism and atherosclerotic changes to mesenteric vessels, hypovolaemia, vasculitis, trauma, radiation or disseminated intravascular coagulation,[15] and medications as noted in Table 26.2. Six factors that are significantly related to ischaemic colitis include age over 60 years, haemodialysis, hypertension, hypoalbuminaemia, diabetes mellitus and constipation-inducing medication.[16]

Cangemi and Picco[14] described high mortality associated with ischaemia because of delayed diagnosis in the elderly and noted the appropriate studies for accurate diagnosis. Angiography is the gold standard in the diagnosis of acute mesenteric ischaemia. Multidetector computed tomographic (CT) angiography is also an option, but does not provide a therapeutic option.

Treatment of ischaemic colitis includes supportive care, which encompasses intravenous fluid resuscitation, bowel rest, antibiotics and avoiding vasoconstrictive medication. Mesenteric angiography can be used for direct visualization and treatment with vasodilators such as papaverine or thrombolytics.[14] The treatment of choice for both acute and chronic mesenteric ischaemia is surgery, with independent predictors for surgical mortality including age over 70 years, diagnosis after 24 h and metabolic acidosis in acute ischaemia.[14] With treatment symptoms resolved in about 2 days, but without treatment the ischaemia can progress to necrosis and result in perforation and shock.[16]

Table 26.2 Causes of mesenteric ischaemia: medications.

Vasoconstrictors (digitalis)
Norepinephrine
Cocaine
Pseudoephedrine
Argot alkaloids
Oral contraceptives
Estrogens
Diuretics
Antihypertensives
Non-steroidal anti-inflammatory drugs
Meloxicam
Chemotherapeutic agents
Paclitaxel
Alosetron

Tube feeding/medications

Diarrhoea is commonly reported when a patient receives tube feeding, but there is not necessarily a causal relationship.[17] Since enteral feeding contains the nutrient-rich environment appropriate for bacterial growth, contamination of the feed can be causative. Therefore, any reusable components of the enteral feeding, including bags and tubing, need proper cleaning between uses. In addition, the opened packages should be refrigerated.[17] Another cause of diarrhoea with feeding is the flow rate. The initiation of feeding alone can result in diarrhoea, so it is recommended that enteral feeding be started at a low rate and titrated to the nutritional supplemental goal. The type of feed also has implications in causing diarrhoea. Gavi *et al*.[17] noted that isotonic formulations appear to be better tolerated when started at full strength, but hypertonic or elemental formulae should be started at half strength and then titrated to full strength 24 h later.

Treatment of enteral feeding diarrhoea includes decreasing the flow rate, supplementing fibre or changing to a lactose-free formulation as an initial measure.[3] However, these measures often do not identify the true cause of the diarrhoea. It is important to remember that medications are often switched to liquid formulations once tube feeds are started. These formulations often contain sorbitol, which can be a cause of diarrhoea.[18] This should always be considered and investigated.

Common medications implicated in causing diarrhoea include sorbitol-containing medications, magnesium,

non-steroidal anti-inflammatory drugs (NSAIDs), H2 blockers, proton pump inhibitors, antineoplastics, antiretrovirals and antibiotics.[13] Selective discontinuation of medications can elucidate the offending medications when multiple causes are possible.

Supportive treatment

Supportive treatment to prevent dehydration is the first-line therapy in all acute diarrhoeas. The Centers for Disease Control (CDC) recommendations[14] for treatment of diarrhoea with dehydration include the use of fluid and electrolyte replacement with oral rehydration solutions (ORS). If oral replacement is possible, the use of Pedialyte, Gastrolyte or other commercially available solutions with electrolyte and glucose is recommended. This hydration is to be taken in small, frequent amounts. Treatment should be based on degree of dehydration determined from physical findings, vitals and urine output. Although opiate antimotility agents such as loperamide and diphenoxylate with atropine may decrease the volume, use can compound illness when diarrhoea is caused by a bacterium or bacterial toxin. Therefore, the use of these medications should be restricted to individuals without bloody or mucoid diarrhoea.[19] Other non-specific medications include clonidine and octreotide.[3] For mild to moderate fluid loss, ORS administration is calculated as 50–100 ml kg^{-1} body weight over 3–4 h and 120–240 ml ORS for each diarrhoeal episode. For severe fluid loss, lactated Ringer's solution or normal saline should be administered intravenously in boluses of 20 ml kg^{-1} body weight until perfusion and mental status improve, and then 100 ml kg^{-1} body weight ORS administered over 4 h or 5% dextrose–½ normal saline intravenously at twice maintenance fluid rates.[19] In addition, the CDC states that ongoing fluid loss has the same parameters as mild to moderate fluid loss. If oral therapy is not possible, alternative routes include nasogastric tube or intravenous administration of 5% dextrose–¼ normal saline with 20 mequiv. l^{-1} potassium chloride. Hydration in the elderly can be complicated by common medical problems such as heart failure and renal failure.

Chronic diarrhoea

Watery

A watery diarrhoea occurs from either secretory or osmotic mechanisms. Ingestion of solutes and sugars that are poorly absorbable can cause osmotic diarrhoea. Many of the solutes are used in laxative or antacid preparations, such as magnesium sulfate/hydroxide and citrate. In addition, sugars such as sorbitol and fructose, often found in sweets and food, can also cause osmotic-type diarrhoea. Lactase phlorizin hydrolase or lactase activity is noted to be lost by most people by the age of 20 years.[3] There is a mutation that allows persistent function of the hydrolase, but this also can declines with age. This mutation is found commonly in northern European genetic pools,[3] but the hydrolase decline and deficiency also predominate in certain racial and ethnic groups. Lactose is unable to be metabolized into an absorbable form. Surgical causes of osmotic diarrhoea often involve disruption of absorption that occurs with small bowel partial or complete resections, ischaemia or vagotomy. Short bowel or gut syndrome develops when only 2 m of small bowel is present for absorption.

The most common cause of chronic diarrhoea is secretory and the long differential of causes includes, but is not limited to, endocrinopathies, medications, microscopic colitis, bile acid malabsorption, motility disorder, diverticulitis, laxatives, idiopathic, vasculitis and neoplasia.[3] Endocrine causes of diarrhoea include diabetes, Addison disease, hyperthyroidism and tumours secreting gastrin, vasoactive intestinal peptide, catecholamines and adrenaline. Medications can be a direct cause of diarrhoea because of either drug interactions or decreased clearance.[3] Although neurological disruption or disorders can cause dysmotility, irritable bowel syndrome should still be considered in the elderly although it usually presents earlier in life.

One of the epidemic causes of idiopathic secretory diarrhoeas is Brainerd diarrhoea. Brainerd diarrhoea was named after a town in Minnesota where the first outbreak occurred in 1983. It is characterized by acute onset watery diarrhoea that lasts for 4 weeks or longer and in some reports up to years. It can occur sporadically or in outbreaks and often affects adults aged 41–65 years.[20] According to Vugia *et al*. in 2006, there have been nine outbreaks since 1985. The last published report was of an outbreak that occurred in late 1998 in Humboldt County, California.[20] There were 23 patients identified and the median age of the population was 64 years. The maximum duration median was 16.5 in 24 h and often included faecal urgency and incontinence. Of the 21 patients contacted after 6 months, 18 still had loose stools three or more times per day or were taking antidiarrhoeal medications. All of the patients received antidiarrhoeal medications and 13 received antibiotics. Further investigations have been made on the pathology of chronic watery diarrhoea. Bryant *et al*. described the histological changes in biopsy specimens of Brainerd diarrhoea specimens from an outbreak on a cruise ship to the Galapagos Islands.[21] The 12 small bowel biopsies were negative and the 20 patient colonic biopsies showed epithelial lymphocytosis, surface degenerative changes or thickened subepithelial collagen plates. The lymphocytosis was greater than in control samples of normal colon and with varied comparisons to various colitis (acute, ulcerative and collagenous) presentations. The exact aetiology and treatment of this chronic watery diarrhoea remain unknown.

Distinguishing secretory from osmotic diarrhoea is the first step with watery diarrhoea. While calculating an osmotic gap is usually considered useful in corroborating evidence for secretory or osmotic diarrhoea, some believe that it does not solely differentiate secretory from osmotic diarrhoea because of bacterial metabolism and possible elevated electrolytes in secretory diarrhoea.[22] An osmotic gap >125 with a pH <5.3 characterizes osmotic diarrhoea, while an osmotic gap <50 is usually found in secretory diarrhoea. Other tests can be effective in detecting carbohydrates such as a hydrogen breath test in lactose intolerance and testing for faecal reducing substances. Diagnosis of secretory diarrhoea includes exclusion of infection and structural disease, selective testing for endocrinopathies and secretory tumours and a cholestyramine trial to exclude bile acid diarrhoea.[3] Osmotic diarrhoea testing involves stool analysis for pH to detect carbohydrate malabsorption and magnesium levels to detect ingestion or laxative use.[3]

Inflammatory

Inflammatory bowel disease (IBD) mainly comprises Crohn's disease (CD) and ulcerative colitis (UC), but also includes microscopic colitis. Individuals 60 years of age and older comprise 10% of individuals with IBD.[23] In CD, the Montreal and Vienna classifications use age as a factor. In the Vienna classification, the age is stratified as either above or below 40 years of age. In the Montreal classification, there are three classifications: A1 below 16 years old, A2 between 17 and 40 years old and A3 above 40 years old.[24] Therefore, the population over 65 year of age is not specifically addressed in either classification. According to Picco and Cangemi, the disease presentation is similar in the age stratifications of before and after the age of 40 years.[23] However, the older age group appears to have a higher colonic only involvement than in the younger age group. Hospitalization and azothioprine use were lower after age 40 years, but overall surgical treatment appeared to be similar. In addition, after age 40 years, UC symptoms are believed to be less severe, with some atypical symptoms such as constipation and predominant proctocolitis versus colitis in younger patients. In addition, initial presentations are more severe.

According to Picco and Cangemi,[23] CD has shown survival differences in studies in which patients were followed for an extended period of time. Examples include a 21 year follow-up in Olmsted County, Minnesota, and a 54 year follow-up in Copenhagen, Denmark.[23] Although there may be a slightly increased mortality with CD among older individuals and with prolonged disease, the significance of age at the time of diagnosis has not been established.[23]

Microscopic colitis, including both lymphocytic colitis and collagenous colitis, is not uncommon in the elderly and the median age of onset is 68 years.[3] Unlike UC and CD, microscopic colitis does not usually present with haematochezia. According to Schiller,[3] the illness is secondary to luminal antigen causing an increase in lamina propria inflammatory cells and intraepithelial lymphocytes. Collagenous colitis is more common in women and accounts for up to 20% of chronic diarrhoeas in those older than 70 years.[23]

Inflammatory diarrhoea is established by the presence of faecal leucocytes. Faecal occult blood may also be present. Establishing the cause of inflammatory diarrhoea includes exclusion of structural disease with imaging or direct visualization and biopsy with sigmoidoscopy and colonoscopy for the colon or endoscopy for the small bowel.[3]

Acute treatment for both CD and UC includes reducing inflammation and treating infection with antibiotics. Chronic treatment includes immunomodulators, anti-inflammatory medications and surgery. The immunomodulators used include ciclosporin, infliximab, certolizumab, adalimumab, azathioprine, methotrexate and 6-mercaptopurine. The anti-inflammatory medications used include corticosteroids, mesalamine, sulfasalazine and 5-aminosalicylic acid. Specific difficulties with the treatment of older adults with IBD include side effects and the method of administration. The elderly often have pre-existing problems with continence, so retention of enemas or suppositories presents a unique challenge. Picco and Cangemi[23] noted that foam preparations have better retention qualities. In addition, the side effects of antibiotics such as metronidazole used in colonic CD can cause peripheral neuropathy and results in subsequent discontinuation. Corticosteroids used in both UC and CD can cause significant side effects such as osteoporosis, bone fractures, mental status change, diabetes and hypertension.[23] In addition, bone marrow suppression can occur with allopurinol when combined with azathioprine or 6-mercaptopurine. Whereas surgery can be curative for UC, remission or reduction or symptoms is the result with CD. In addition, surgery presents challenges such as possible ileostomy and malabsorption.

The treatment for microscopic colitis is different to that for UC and CD. UC and CD treatments have been used without significant data. However, in a systematic review, Chande *et al*.[25] reviewed the relevant data for induction of response, histological response and maintenance of response. For collagenous colitis, 10 randomized trials were studied which showed that budesonide resulted in significant induction and maintenance of clinical and histological response and was well tolerated. Although bismuth subsalicylate, prednisolone and mesalamine (with or without cholestyramine) showed possible evidence of effectiveness, *Boswellia serrata* extract and probiotics were not effective in the treatment of collagenous colitis according to the systematic review. Only three randomized controlled trials were reviewed

for lymphocytic colitis treatment. Budesonide also showed some evidence of induction of clinical and histological response and was well tolerated.

Steatorrhoea

Steatorrhoea is fatty diarrhoea resulting from malabsorption of dietary fat. This diarrhoea is characterized by bulky, foul-smelling stools that float. Some causes of malabsorption include pancreatic insufficiency, coeliac disease, bacterial overgrowth, cholestasis, CD, parasitic disease and Whipple disease. The most common causes are pancreatic insufficiency 30%, celiac disease 30% and bacterial overgrowth 20%.[25] Weight loss medications such as orlistat and fat substitutes such as olestra can also be causative. The signs of malabsorption can be subtle. Common symptoms include anorexia, bloating and excessive flatus. Fat malabsorption results in secondary nutrient deficiencies and systemic disease such as anaemia, hypoalbuminaemia, osteoporosis, cramps and paraesthesias.[25] In addition, these deficiencies can be an added burden in those with existing nutritional challenges.[3] Although the establishment of steatorrhoea is usually established by the gross characteristic faeces, a Sudan stain can be used to detect the presence of fat. In order to find the cause, structural disease must first be excluded with small bowel radiographs, CT scan or small bowel biopsy.[3] Once structural disease has been excluded, pancreatic insufficiency is ruled out with a secretin or cholecystokinin test, empirical trials of enzyme replacement therapy and stool chymotrypsin activity. The antigliadin immunoglobulins IgA and IgG and antiendomomysial IgA are particularly specific for coeliac sprue.

Conclusion

Diagnosis of acute and chronic diarrhoea should be guided by the initial presentation and history. Alarm symptoms including fever, bleeding, abdominal pain and haemodynamic instability are important in guiding both diagnosis and treatment. Although distinguishing diarrhoea by its most common acute and chronic presentations is helpful, it is always important to remember that the disease process can evolve over time. For example, the initial presentation of inflammatory bowel disease may cause a watery diarrhoea that may develop into a malabsorptive diarrhoea.

Key points

- Diagnosis of chronic and acute diarrhoea should be guided by the initial presentation and history.
- Alarm symptoms including fever, bleeding, abdominal pain and haemodynamic instability are important in guiding both diagnosis and treatment.
- Acute diarrhoea includes infectious, bloody and ischaemic types.
- Chronic diarrhoea includes watery, inflammatory and steatorrhoea types.

CHAPTER 27

Diseases of the pancreas

John S. Morris[1] and John E. Morley[2]

[1]Princess of Wales Hospital, Bridgend, UK

[2]Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

The ageing pancreas

The pancreas has considerable functional reserve so that any anatomical changes associated with age have little, if any, effect on pancreatic function. Morphological changes, however, do occur as part of the ageing process. Ectasia of the main pancreatic duct occurs, which can cause confusion in the interpretation of the appearances on endoscopic pancreatography. Additionally, ductal epithelial hyperplasia and intralobular fibrosis, which rarely lead to pancreatic atrophy, can occur. In an autopsy study of the elderly in the UK, ductal narrowing not due to strictures, space-occupying lesions due to the superior mesenteric artery, splenic artery, aorta, vertebral osteophytes, sympathetic ganglia and lymph nodes were noted. The study also showed metastases in the pancreas, which could be mistaken for primary pancreatic tumours. Finally, ageing can be associated with impaired pancreatic blood supply due to atherosclerosis.

Functional studies have been carried out on elderly patients and compared with those on younger patients. The volume of pancreatic secretion falls in the elderly, as do the outputs of lipase, trypsin and phospholipase.[1] There does not appear to be a corresponding fall in fat absorption. Changes are very variable in older persons, suggesting that disease processes such as arteriosclerosis and not ageing, *per se*, may be responsible for the small changes seen.

Inflammatory diseases of the pancreas

Acute pancreatitis

Although alcohol abuse is the major cause of acute pancreatitis in the middle aged, it is less common as a cause in the elderly. Acute pancreatitis, however, occurs with increasing frequency in the elderly because of an increased prevalence of gallstones. A recent English study showed that hospital admission rates for acute pancreatitis had doubled over a 30 year period in all age groups but the case fatality rates had not altered.[2] Hospital admissions for acute pancreatitis per 100 000 were 13 or more for both men and women over 65 years of age and the case fatality rates were 8 per 100 patients at 29 days after presentation and 7.4 at 30–364 days after presentation. Corresponding rates in the over-75 years old age group were even higher. In addition to alcohol and gallstones, other predisposing factors for acute pancreatitis in the elderly include hypercalcaemia (usually due to hyperparathyroidism), hypertriglyceridaemia and obstruction to pancreatic flow such as that caused by tumours, endoscopic pancreatography and uraemia. Acute pancreatitis occurs in up to 30% of patients following cardiac bypass surgery, perhaps because of the administration of large doses of intravenous calcium chloride. Acute pancreatitis is also associated with biliary sludge and cholecystectomy or endoscopic papillotomy may prevent recurrence. Elderly patients are more likely to be taking prescribed medication, but whether drugs are a major cause of acute pancreatitis is debatable. Most reports of drug-related pancreatitis are anecdotal and the potential severity of the disease precludes drug challenges. A large retrospective German study of acute pancreatitis implicated drugs as a possible cause in only 1.4% of the patients. The disease was mild and ran a benign course.[3] It is now recognized that autoimmune pancreatitis is not rare in older persons.[4] On imaging, it is characterized by pancreatic enlargement with an irregular narrow pancreatic duct. Histologically there is lymphoplasmacytic infiltrate with swirling fibrosis and obliterative phlebitis. The tissue stains positive for IgG4-positive cells. Serum levels of IgG4 are also elevated. It can be associated with biliary structures, retroperitoneal fibrosis, parotid infiltration and mediastinal lymphadenopathy. The condition is highly sensitive to steroid therapy.

Pathophysiology of acute pancreatitis

The basic underlying pathophysiological mechanism in acute pancreatitis is pancreatic duct obstruction. This allows autodigestion of the gland by its own enzymes. Reflux

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

of bile and duodenal juices into the pancreatic duct are also important. In the majority of patients, the process is self-limiting but in some the disease becomes fulminating. This leads to pancreatic necrosis and activation of inflammatory cytokines, which can result in generalized organ failure (systemic inflammatory response syndrome). If the necrosed pancreas becomes infected by gut bacteria, the disease is often fatal.

Presentation of acute pancreatitis

The illness characteristically presents with severe abdominal pain, often leading to acute hospital admission. The pain usually occurs in the epigastrium and radiates through to the back and is often relieved by sitting forward. This presentation, however, may differ in the elderly when the illness may be confused with myocardial infarction or a perforated abdominal viscus.

The physical signs are those of an acute abdomen. Jaundice, vomiting, fever, tachycardia and hypotension may occur. If severe, haemorrhagic pancreatitis supervenes with retroperitoneal haemorrhage, which leads to bruising in the flanks (Grey Turner's sign), around the umbilicus (Cullen's sign) or even below the inguinal ligament (Fox's sign).

Diagnosis of acute pancreatitis

The diagnosis is supported by the finding of high levels of amylase in the serum. Elevated levels of serum lipase are more specific than elevated amylase levels. The serum lipase rises within 4–8 h, peaks at 24 h and returns to normal in 8–14 days.

Radiological examinations are increasingly important and sophisticated. Straight abdominal X-rays may show a sentinel loop – an area of small bowel ileus adjacent to the inflamed pancreas. In severe pancreatitis, the chest X-ray can reveal a pleural effusion, areas of atelectasis and pulmonary oedema. These appearances occur in patients of all ages.

Ultrasonography is important. Gallstones and dilated bile ducts suggest pancreatitis of biliary origin. Overlying gas shadows often impair visualization of the pancreas, but when seen, the gland appears swollen. Ultrasonography is important in detecting pancreatic pseudocyst and fluid collections within the abdomen. Enhanced computed tomography (CT scanning) is useful in showing evidence of pancreatic necrosis and localized fluid collections both in and outside the pancreas (Figure 27.1). CT scanning may also reveal gallstones and bile duct or pancreatic duct dilatation not obvious in ultrasound scanning. In selected patients, endoscopic retrograde cholangiopancreatography (ERCP) is useful in showing dilated bile ducts and gallbladder stones (Figure 27.2) and has the added advantage that bile duct stones can be cleared. When acute pancreatitis is diagnosed by these imaging methods, biochemical tests (serum levels of amylase and lipase) are elevated in over 90% of patients.

Assessment of the severity of acute pancreatitis

In an individual patient, the severity of disease is judged by clinical observation. In an attempt to compare disease

severity between centres, assess the results of therapeutic intervention and perhaps decide referral to specialized centres, various scoring systems have been introduced. One of the earlier scoring systems was introduced by Ranson *et al*.[5] The index takes account of age, white blood cell counts, glucose levels, LDH and AST levels at admission and the decrease in haematocrit, elevation of the blood urea, decrease in serum calcium, pO_2, base deficit and fluid balance at 48 h. Using similar measurements, modified 'Glasgow criteria' were later introduced.[6] These prognostic indices are of proven value in predicting severe disease but suffer from the disadvantage that measurements are made over a period of 48 h. A score of >3 by either system indicates severe disease. The 'APACHE II' can be calculated on admission and is more sensitive and specific at 48 h after admission. The APACHE II grading system has the advantage that it can be measured from admission and throughout the hospital stay.[7] Assessment of disease activity using CT scanning has also been studied and shown good correlation with local complications and mortality.[8]

Management of acute pancreatitis

Mild disease requires only observation and symptom control. Antibiotics are not routinely given. The 20–30% more ill patients need admission to an intensive care unit and careful monitoring. Nutrition is important and there is a debate as to whether the patient should be nourished by enteral routes or by parenteral routes. A meta-analysis suggested that enteral feeding was more appropriate. Compared with parenteral feeding, enteral feeding reduced the number of surgical interventions and the number of infections. Additionally, parenteral feeding is immunosuppressive and favours inflammation.[9] The feeding tube should be placed in the jejunum to prevent pancreatic stimulation.

Routine antibiotic therapy in severe acute pancreatitis is controversial. Although the evidence is slight, a Cochrane review suggested that patients with proven pancreatic necrosis should be given broad-spectrum antibiotics active against gut organisms for up to 2 weeks.[10] In patients with bile duct stones, endoscopic duct clearance, particularly if there are signs of concomitant biliary disease, should be carried out as soon as possible. Patients with gallstones who develop mild acute pancreatitis should undergo cholecystectomy during their index admission. Steroids are the treatment of choice for autoimmune pancreatitis.

Indications for surgery in acute pancreatitis include pancreatic pseudocyst and pancreatic abscess. Removal of necrosed pancreas should be considered in patients with continuing fever after antibiotics who have clear signs on CT scanning. The surgery is hazardous and best done by surgeons skilled in pancreatic surgery. Surgical intervention can be life saving and age alone does not preclude it.

Chronic pancreatitis

Whereas the pancreas is normal before and after an attack of acute pancreatitis, the gland is always histologically abnormal in chronic disease. The histological changes include an increase in the intralobular fibrous tissue, atrophy of the acini and a chronic inflammatory infiltrate. Macroscopically, ductal changes, mainly duct dilatation, occur when there is an obstructive cause of the disease. Pancreatic tissue is difficult to obtain and histological changes are patchy so that the diagnosis of chronic pancreatitis is seldom made histologically.

Incidence and prevalence rates for chronic pancreatitis, particularly in the elderly, are uncertain. Chronic pancreatitis is rarely diagnosed for the first time in patients over 65 years of age. The most common cause of the disease is alcohol, so most cases of chronic pancreatitis present in the fourth and fifth decade of life. Estimated prevalence rates for all ages range from 0.04 to 5%.[11] In an English study of hospital admissions, age-standardized admission rates for chronic pancreatitis rose by 100% in the decade ending in 2000.[12] In the USA, the National Discharge Survey indicated that only 12% of patients were 65 years of age or older.[13]

Causes of chronic pancreatitis

Alcohol is the commonest cause of chronic pancreatitis overall but is less common as a cause in the elderly. In the elderly, autoimmune pancreatitis must be considered; pancreatic insufficiency of unknown origin (possibly vascular insufficiency) occurs most commonly in older persons without other symptoms of pancreatitis. Chronic pancreatitis occurs in chronic ductal obstruction such as that caused by a periampullary tumour, in pancreas divisum in which the head and body of the pancreas develop separately and each has its own duct, in hyperlipoproteinaemia and in hyperparathyroidism. Pancreatic insufficiency is a cause of 'geriatric cachexia'.

Postmortem examinations reveal that pancreatic stones occur in ~15% of patients over the age of 90 years and that changes of chronic pancreatitis are seen. The significance of these findings is uncertain as there is no correlation with clinical disease.[14]

Clinical presentation of chronic pancreatitis

Severe abdominal pain, a characteristic of chronic pancreatitis in younger patients, is less severe or even absent in the elderly. Weight loss, diabetes and fat malabsorption occur.

Occasionally, chronic pancreatitis is recognized when pancreatic calcification is noted on a straight X-ray of the abdomen (Figure 27.3).

Clinical examination is usually normal, although there may be localized tenderness in the epigastrium. Signs of malnutrition occur late in the disease.

Figure 27.3 Plain abdominal X-ray showing pancreatic calcification in chronic pancreatitis. Courtesy of Dr N. Al-Mohktar

Diagnosis of chronic pancreatitis

Establishing a diagnosis is difficult. Serum amylase and lipase levels are usually normal or only slightly elevated. If there is associated obstruction of the intrapancreatic bile duct, bilirubin and alkaline phosphatase levels are elevated. Steatorrhoea results from exocrine insufficiency and can be recognized by Sudan staining of the stool and quantified when the patient eats a daily diet containing 100 g of fat. Faecal fat excretion resulting from chronic pancreatic disease is usually higher than that seen in other causes of fat malabsorption. Faecal elastase levels fall with ageing and are a sensitive diagnostic test for malabsorption. Measurement of serum vitamin A and β-carotene can be used to screen for fat malabsorption.[15]

Tubeless pancreatic function tests are increasingly valuable in suggesting the diagnosis. The *p*-aminobenzoic acid (PABA) excretion index is based on the ability of pancreatic chymotrypsin to split orally administered *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid. The released PABA is then measured in the urine. The pancrealauryl test is similar. Pancreatic esterases release fluorescein, which is again measured in the urine. Provided that hepatic, renal and intestinal functions are normal, low levels of PABA or fluorescein in the urine suggest pancreatic insufficiency. Analysis of intestinal volume, concentrations of pancreatic enzymes and bicarbonate following a standard test meal or the intravenous administration of cholecystokinin can indicate exocrine insufficiency. The conditions under which the test is performed need to be carefully controlled so its use is confined to those with special experience.

Imaging procedures

Imaging procedures have superseded function studies in the diagnosis of chronic pancreatitis. Plain abdominal radiography may show calcification. Calcification appears more rapidly in patients with alcoholic rather than idiopathic pancreatitis and consequently is less common in the elderly. In about two-thirds of patients, ultrasonography shows swelling of the gland or duct dilatation. CT scanning provides similar information but may be more sensitive.

Endoscopic retrograde pancreatography has become essential in the diagnosis and assessment of chronic pancreatitis. It demonstrates duct abnormalities, which are classified as mild, moderate or severe. Endoscopic pancreatography shows minor abnormalities of the smaller pancreatic ducts, allowing a diagnosis of chronic pancreatitis to be made in patients in whom other imaging procedures have been normal.

Pancreatography is of particular value therapeutically. Duct strictures amenable to dilatation, stenting or partial gland resection may be apparent only endoscopically. Finally, endoscopy is a valuable aid in the diagnosis of pancreatic cancer.

Complications of chronic pancreatitis

Diabetes is more difficult to control in chronic pancreatitis and episodes of hypoglycaemia are likely because of poor diet or malabsorption. Hyperglycaemia is an inevitable consequence of major pancreatic resections (see Chapter 101, Diabetes mellitus). Pancreatic pseudocysts in chronic pancreatitis are less likely to resolve spontaneously than those in acute pancreatitis and often have to be drained. Rupture of a pseudocyst into the peritoneum leads to pancreatic ascites. High amylase levels in the ascitic fluid confirm the diagnosis. Octreotide may help control the ascites by reducing pancreatic secretion. Occasionally, the cyst ruptures into the pleural space, usually on the left side, leading to a pleural effusion. Rarely, a chronic pancreatic pseudocyst may be the source of haemorrhage which can be life threatening. Haemorrhage may also result from oesophageal varices arising from obstruction to the splenic or portal vein by the inflammatory process in the pancreas.[16]

Management of chronic pancreatitis

Pain is less common in the elderly, but when it occurs, it impairs the quality of life. Opiate drugs should be avoided because of the danger of addiction. Non-steroidal anti-inflammatory drugs (NSAIDs) and tricyclic

antidepressants may be useful. The pain is often related to high intraductal pressures and pharmacological attempts to lower the pressures have been made. Cholecystokinin stimulates the release of pancreatic enzymes. Theoretically, increasing intraluminal levels of pancreatic enzymes by orally administered pancreatic enzymes should decrease native cholecystokinin production and lower intraductal pressure, hence relieving pain. The evidence in favour of this approach is slight because of the difficulty in conducting double-blind trials and high placebo response.

Octreotide is a powerful inhibitor of pancreatic secretion and has been used to reduce pancreatic secretion. Its disadvantage is that it has to be given subcutaneously on a daily basis, although long-acting preparations are now available. Its value remains uncertain.

If drug therapy fails to control pain, coeliac axis block is often successful. If endoscopic pancreatography shows duct strictures, stent placement often relieves pain. Surgical pancreatic resection or total pancreatectomy should seldom be considered as a method of pain relief in the elderly.

Attempts to control steatorrhoea by orally administered pancreatic enzymes are useful and the dose should be titrated to achieve maximum effect. Malabsorption of fat-soluble vitamins occurs and should be treated with appropriate supplements.

Pancreatic tumours

Endocrine tumours of the pancreas

Endocrine tumours of the pancreas are rare. Some of the tumours also occur in extrapancreatic sites. The tumours are classified according to the hormone they excrete. The most common tumour is insulinoma, which secretes insulin and gives rise to episodes of hypoglycaemia or even coma. Glucagonoma is associated with weight loss, diabetes and a rash and somatostatinoma gives rise to diabetes, gallstones, weight loss and steatorrhoea. Gastrinoma gives rise to peptic ulcer and weight loss, tumours secreting growth hormone release hormones that give rise to acromegaly, tumours producing ACTH give rise to Cushing's syndrome and tumours producing pancreatic polypeptide result in abdominal pain, gastrointestinal (GI) bleeding and diarrhoea. Most of the tumours have a malignant potential and may be part of the multiple endocrine neoplasia syndrome. Table 27.1 describes the common pancreatic endocrine tumours.[17]

Cystic tumours of the pancreas

These tumours are rare. Serous cystadenomas are small, rarely over 2 cm in size and are of little clinical import. Mucinous cystic neoplasms range from benign to dysplastic to frankly malignant types. Intraductal papillary mucinous tumour was described about 10 years ago and is yet to be studied in detail.[18]

Cancer of the pancreas

Pancreatic cancer is diagnosed in over 7000 people in the UK each year. The diagnosis is difficult to make and only ~15–20% of patients have tumours amenable to surgery at presentation. The 1 year survival rate is around 20% and only 5% of patients are alive 5 years after diagnosis.

The predominant risk factor is old age (Figure 27.4), although there is a relationship to cigarette smoking. Genetic and general medical conditions such as familial breast cancer, hereditary chronic pancreatitis, chronic pancreatitis and diabetes are also risk factors. In many patients, there is a preceding history of depression, often requiring psychiatric help.

Clinical features

Cancer of the head of the pancreas presents with jaundice, often with epigastric or back discomfort. Later in the clinical course, other symptoms of cholestatic jaundice such as itching, pale stools and dark urine occur. Anorexia and weight loss are common. Tumours of the body and tail of the pancreas present more insidiously and are often recognized only when distal spread of the disease has occurred.

Diagnosis of pancreatic cancer

Following initial assessment, ultrasonography is usually the first imaging procedure. The tumour is seldom seen because of overlying gas shadows. If the tumour is in the head of the pancreas, however, bile duct obstruction may occur and the level of the obstruction visualized.

Table 27.1 Pancreatic endocrine tumours

Type	Age at diagnosis (years)	Five year survival rate (%)	Clinical characteristics
Insulinoma	50–60	90	Fatigue, hypoglycaemia
Gastrinoma	60–70	55	Gastric pain, weight loss
Glucagonoma	50–60	90	Weight loss, diabetes, rash
Somatostatinoma	60–70	30	Diabetes, gallstones, weight loss, steatorrhoea
VIPoma	40–60	45	Flushing
Pancreatic peptideomas	40–60	40	None

CT scanning provides similar information and may help in identifying tumour expansion outside the confines of the gland such as metastatic tumour in the liver or adjacent lymph nodes (Figure 27.5). Endoscopic cholangiopancreatography allows more precise delineation of ductal anatomy and, taken in conjunction with other investigations, helps to decide whether the tumour is resectable. Stent insertion to relieve ductal obstruction at this stage is controversial, should surgery become a management option. A meta-analysis suggested that preoperative biliary drainage was associated with a greater complication rate compared to those patients who underwent surgery alone.[19]

Pancreatic cancer can be confused with chronic pancreatitis. Attempts should be made to verify histologically the diagnosis of a tumour. Tissue or cytological preparations can be obtained by ultrasound or CT-guided fine needle aspiration, although there may be a risk of cancer seeding.

Management of pancreatic cancer

Surgery alone offers the hope of cure and even if performed only offers a 5 year survival rate of 20%. Adjuvant therapy with fluorouracil-based chemoradiation is an option, although others recommend chemotherapy alone.

In patients with unresectable disease, chemoradiation can be used. Gemcitabine is currently under investigation as a radiosensitizer and the agent may also be used as part of a combined chemotherapy protocol.

Palliation is often the only management option. The relief of bile duct obstruction and pain control remain the only treatment modalities that can be offered.

Key points

- Pancreatic cancer is the main pancreatic disease associated with ageing.
- Acute pancreatitis associated with gallstone disease is the commonest cause of acute pancreatitis in the elderly.
- Autoimmune pancreatitis with elevated IgG4 is becoming more commonly recognized.
- There is no good evidence that relates drugs to the development of pancreatitis.
- Although morphological change occurs in the elderly, pancreatic function appears to be maintained.

SECTION 3

Haematological Disorders

CHAPTER 28

Anaemia

Anjali S. Kamat and David R. Thomas
Saint Louis University Health Sciences Center, St Louis, MO, USA

Introduction

Anaemia has been associated with both frailty[1] and mobility impairment in older persons,[2] and is an independent risk factor for increased mortality over 5 years.[3] Anaemia has been shown to lead to functional impairment,[1,2] and is a risk factor for falls in older persons.[4–6] Anaemia is associated in older adults with decreased muscle density and muscle strength, as measured by ankle extension.[7] Women with a haemoglobin concentration between 130 and 140 g l^{-1} have better mobility and lower mortality compared with those with a haemoglobin concentration of less than 120 g l^{-1}.[2]

Anaemia is strongly associated with an increase in subsequent myocardial infarction and poor outcomes following a myocardial infarction.[8] Among a population-based cohort of older patients with congestive heart failure, anaemia was present in 17% of subjects. Mortality risk was 34% higher in anaemic patients.[9] In a Medicare cohort of patients with congestive heart failure, mortality rate increased by 1.6% for every 1% decrease in haematocrit.[10] Prolonged anaemia also results in left ventricular hypertrophy.[11]

Anaemia is often a comorbid condition complicating other conditions. Subjects who have anaemia tend to be older, have a higher prevalence of a stroke and gastric ulcer, use more medications and have higher creatinine levels. These factors suggest that anaemia may result from underlying disease; however, the association held even when these diseases were excluded.[3]

Quality of life is impaired in persons with anaemia and anaemia produces a high level of fatigue.[12] Vascular dementia, but not Alzheimer's dementia, has been associated with anaemia.[13]

Treatment of anaemia increases haemoglobin concentration, improves quality of life and may decrease mortality.[12,14,15] Patients with congestive heart failure and an ejection fraction of less than 40% who received treatment for anaemia had a 42% improvement in New York Heart Association class score compared with the control patients who had a decrease of 11.4%.[16] Correction of anaemia also produces a decrease in the left ventricular hypertrophy.[11]

Despite the growing evidence of these poor outcomes associated with anaemia in older persons, the diagnosis is often overlooked and, more important, undertreated.[17]

Definition and prevalence

Haemoglobin and haematocrit values differ little between the healthy elderly population and the younger population. Thus, anaemia is not a normal finding in older persons and haemoglobin concentration should not be adjusted downwards in older persons.[18,19] The World Health Organization defines anaemia as a haemoglobin concentration of less than 130 g l^{-1} in men and less than 120 g l^{-1} in women.

The prevalence of anaemia increases with each decade of life over the age of 70 years. In the Established Population data for adults aged 71 years or older, haemoglobin concentration was inversely associated with age. In men and women aged 71–74 years, 9% were anaemic. The proportion of anaemic persons increased differentially with age, reaching 41% for men and 21% for women aged 90 years or older, respectively.[20] A similar trend was reported in the third National Health and Nutrition Examination Survey, where the prevalence jumped from 11% in males aged 70–79 years to 22% in males aged 80–89 years.[21]

There is a marked gender difference in the frequency of anaemia. In a population-based study, the corrected annual incidence of anaemia was higher in men older than 65 years (90.3 per 1000 subjects) compared with women older than 65 years (69.1 per 1000 subjects).[22] This Olmstead County Study showed that before the age of 55 years, the prevalence of anaemia was lower in men (~3%) than women (~6%), but this reversed after age 65 years (prevalence 21% in men and 16% in women). These gender differences in haemoglobin concentration result chiefly from differences in testosterone concentration, and hypogonadism in older males (andropause) is commonly associated with an ~1 g l^{-1} fall in haemoglobin concentration.[23,24] Androgen

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

deficiency may also occur in older women. Furthermore, men who have functional hypogonadism from pituitary adenomas are anaemic,[25] and men with prostate cancer who are undergoing therapy with total androgen blockade are anaemic.[26]

Owing to the increase in prevalence of anaemia with age, the development of anaemia has been often attributed to age alone, called ' idiopathic anaemia of ageing', although ageing in itself cannot directly cause anaemia since studies have shown that in healthy older individuals aged between 60 and 98 years, haemoglobin levels do not change significantly.[19] However, ageing has been shown to be associated with a progressive reduction in haematopoietic reserve, which makes older individuals more susceptible to develop anaemia during haematopoietic stress.[27,28] In addition, reduced bone marrow functional reserve, lower oxygen requirement secondary to lean body mass and reduced erythropoietin production all contribute to causing anaemia in the older population.

A very high prevalence of anaemia occurs in long-term care settings. In 481 long-term care patients with an average age of 81.4 years, the prevalence of anaemia was 31.4%.[2] In another study, the prevalence of anaemia was 40%.[8] In a small study of nursing home residents, of 60 anaemic patients 23% had iron deficiency anaemia, 13% had anaemia of chronic disease, 10% had anaemia of chronic kidney disease, 5% had myledysplastic syndrome and 3% had another form of anaemia. Thus, unexplained anaemia accounted for 45% of all cases and had no diagnostic classification after investigation.[29]

Iron deficiency anaemia occurs in 3% of children aged 1–2 years, 2% of adolescent girls, 1% of adolescent boys and men and 5% of women of childbearing age. In persons older than 50 years, 7% have iron deficiency anaemia.[30] Few data exist on the population prevalence of pernicious anaemia. Data are largely based on surveys of subjects with florid manifestations or from retrospective analyses of previously diagnosed disease. In one population-based survey, the estimated prevalence was 2.7% in women and 1.4% in men. The frequency of pernicious anaemia was higher in both black women (4.3%) and white women (4.0%).[31]

Anaemia associated with chronic renal insufficiency is common. Approximately 13.5 million adults in the USA have a creatinine clearance of 50 ml min^{-1} or less and about 800 000 adults have chronic renal insufficiency-associated anaemia, defined as a haemoglobin concentration of less than 110 g l^{-1}, according to a study of the National Health and Nutrition Examination Survey (NHANES) III data.[22] In that study, a statistically significant decrease in haemoglobin concentration was seen among men starting at a creatinine clearance of 70 ml min^{-1} or less and among women starting at 50 ml min^{-1} or less. At any given level of creatinine clearance, men had a larger decrease in haemoglobin concentration than women. For example, compared to subjects with a creatinine clearance more than 80 ml min^{-1}, the decrease in haemoglobin concentration for subjects with a creatinine clearance of 20 to 30 ml min^{-1} was 10 g l^{-1} in women and 14 g l^{-1} in men.

A substantial number of subjects with chronic renal insufficiency may not have sufficient iron stores to support erythropoiesis. In the National Health and Nutrition Epidemiological Study III, among those persons with a creatinine clearance of 20–30 ml min^{-1}, 46% of women and 19% of men had a transferrin saturation of less than 20% and 47% of women and 44% of men had a serum ferritin of less than 100 ng ml^{-1}.[21]

The most common cause of anaemia in a prevalence study of older persons was anaemia of chronic disease, accounting for 35–40% of cases. Iron deficiency anaemia was responsible for 8–15% of cases. Chronic kidney disease was responsible for 6–8% of cases. Blood loss accounted for 7% and myelodysplasia for about 5%. Vitamin B_{12} deficiency was responsible for another 5%. As in most studies of older persons, a large number of anaemias were undiagnosed despite evaluation.[32]

In the older population, anaemia of chronic disease and anaemia associated with chronic renal disease are the most common causes of anaemia. Renal insufficiency accounts for the greatest percentage of anaemic individuals with the diagnosis of anaemia of chronic disease (27%). Most of these patients have an erythropoietin deficiency. However, other causes of anaemia of chronic disease account for about 73% of cases. These conditions include cancer (non-chemotherapy patients), congestive heart failure, hepatitis C, inflammation, diabetes and rheumatoid arthritis, osteoarthritis, hypertension, stroke, asthma and recent surgery. Often, patients can have more than one cause of anaemia of chronic disease (e.g. iron deficiency, chronic kidney disease and rheumatoid arthritis). For this reason, nutritional anaemias including deficiency in iron, vitamin B_{12} or folate and anaemia due to blood loss and drug side effects should be excluded in persons with chronic disease.

Anaemia of chronic disease is associated with an increase in inflammatory markers such as C-reactive protein (CRP), and due to the common feature of inflammation among the causes of anaemia it has been suggested that anaemia of chronic disease should be referred as anaemia of chronic inflammation (ACI). It is important to differentiate ACI from iron deficiency anaemia as features of both can coexist and overlap. A low serum ferritin is diagnostic of iron deficiency, but in the presence of inflammation ferritin can be normal and therefore iron deficiency cannot be ruled out.[33–35]

Hepcidin, a polypeptide synthesized in the liver and which increases in the presence of chronic inflammation, has been shown to reduce the intestinal absorption of iron

and block the effective use of iron stores from the reticuloendothelial system,[36] suggesting that hepcidin plays a significant role in iron absorption, probably through hormonal action.[37] Anaemia of chronic inflammation may cause a decreased response to erythropoietin.[38] Whether these effects are independent of the inflammatory process or a result of low iron availability is not yet known. Some patients respond to erythropoietin treatment but treatment of anaemia of chronic inflammation is based on treating the underlying inflammatory process.

Differential diagnosis

Manufacture of blood proceeds in the bone marrow in a complex, regulated manner. Anaemia can be due to failure of the bone marrow to manufacture adequate blood components, gradual or rapid blood loss from haemorrhage or a rapid breakdown of blood components (haemolysis) in the marrow or peripherally. Causes of failure of the bone marrow to produce adequate blood components includes primary impairment of haemoglobin synthesis (haemoglobinopathy) or an altered maturation of blood cells (myelodysplastic syndromes) or inadequate nutrients (vitamin B_{12}, folate, pyridoxine or iron) necessary for blood production (see Table 28.1).

A careful differential diagnosis is the cornerstone of management. Several schemes for a differential diagnostic approach have been proposed – none of which is perfect. A corrected reticulocyte count is useful to determine bone marrow function. Anaemia associated with an increased reticulocyte count occurs when the bone marrow responds to red cell destruction (haemolysis) or haemorrhage. The presence of elevated concentrations of unconjugated bilirubin and lactic acid dehydrogenase usually accompanies haemolysis. If these concentrations are normal, haemorrhage from an occult source of blood loss should be sought. A stool occult blood should be obtained, as gastrointestinal bleeding is the most common cause of occult blood loss.

A low or normal corrected reticulocyte count in the presence of anaemia indicates an inadequate bone marrow response. In the presence of a low corrected reticulocyte count, determination of red cell morphology indices is useful (see Figure 28.1).

Table 28.1 Causes of anaemia.

Bone marrow failure:
Genetic (haemoglobinopathy)
Inadequate nutrients (vitamin B_{12}, folate, pyridoxine or iron, trace minerals)
Inadequate erythropoiesis (myelodysplastic syndromes)
Haemorrhage
Haemolysis

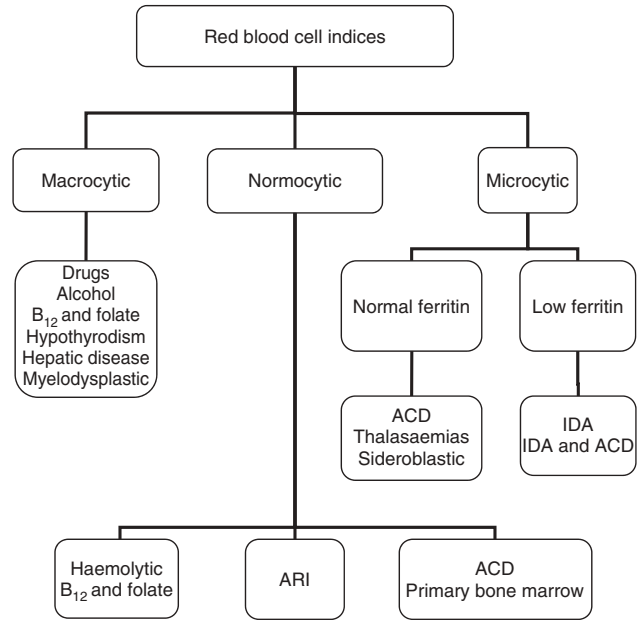

Figure 28.1 Algorithm for diagnosis of anaemia using red blood cell morphology. ACD, anaemia of chronic disease; ARI, anaemia of renal insufficiency; IDA, iron deficiency anaemia. Categories overlap when the morphology of the anaemia may present in one of several ways.

An elevated mean corpuscular volume (macrocytosis) suggests vitamin B_{12} or folate deficiency, hepatic disease, myelodysplasia, hypothyroidism, certain drugs or alcoholism. Measurement of vitamin B_{12} and folate concentrations will determine anaemia due to these causes in the majority of cases. Confirmation of vitamin B_{12} deficiency in those patients who have values in the lower normal range should be obtained, since about 50% of patients with subclinical disease may have normal vitamin B_{12} levels. A more sensitive method of screening for vitamin B_{12} deficiency is the measurement of serum methylmalonic acid and homocysteine levels, which are increased early in vitamin B_{12} deficiency. A homocysteine level will be elevated in both vitamin B_{12} and folate deficiencies, but a methylmalonic acid level will be elevated only in vitamin B_{12} deficiency. Renal failure is the only other confounding cause of an elevated methylmalonic acid concentration.

Myelodysplasia syndrome (MDS) can be associated with a normal serum lactic acid dehydrogenase, normal bilirubin and low reticulocyte count. An elevated mean corpuscular volume with abnormalities in red cell corpuscular shape suggests myelodysplastic anaemia when nutritional deficiency, drugs and chemotherapy have been excluded. MDS anaemia is a bone marrow failure state associated with

varying degrees of pancytopenia where at any given time 90% of stem cells are quiescent and 10% are cycling. About half of these patients will have a neutropenia. In MDS, the bone marrow is hypercellular and up to 90% of these cells are undergoing apoptosis at the same time. Cytokines are released which activate caspases, which are cysteine proteases, and these destroy DNA-repairing enzymes. There is an increase in tumour necrosis factor-alpha (TNF-α) in the bone marrow of the majority of MDS patients. Interleukin (IL)−1β may also contribute in the pathogenesis of MDS.[39]

The World Health Organization classification for MDS is shown in Table 28.2.

In subjects with a low or normal mean corpuscular volume, the likely diagnoses include anaemia of chronic disease, anaemia of renal disease and iron deficiency anaemia. Persons with microcytosis, a low serum iron and low ferritin concentrations have iron deficiency anaemia. If the iron is low and the ferritin is high, it is suggestive of anaemia of chronic disease.[40] Thalassaemia syndromes and sideroblastic anaemias (either primary or secondary) may be associated with a microcytic morphology.

Unfortunately, iron deficiency anaemia and anaemia of chronic disease commonly coexist in older persons. In these cases, soluble transferrin receptor may be useful in determining the diagnosis. Circulating soluble transferrin receptors is a relatively new tool in the diagnosis of anaemia. The receptor assay is elevated in iron deficiency anaemia even in the presence of chronic disease, but normal or only slightly raised in anaemia of chronic disease. As ferritin concentrations are elevated in inflammation, liver disease, renal disease, cancer and in some elderly women, soluble transferrin receptors can be of use in making the diagnosis of iron deficiency. Soluble transferrin receptor divided by the logarithm of ferritin concentration (<2.55) is the best method of differentiating anaemia of chronic disease from anaemia of chronic disease associated with iron deficiency anaemia (see Table 28.3).[41] However, there does not appear to be much advantage of these newer, more expensive methods over measuring total iron-binding capacity.[40] A report showed that reticulocyte haemoglobin content (CHr) is sensitive enough to distinguish iron-deficient erythropoiesis even in iron-replete volunteers receiving erythropoietin.[42] An increase in absolute reticulocyte count and CHr begins after oral iron therapy(324 mg by mouth twice per day) for 2 weeks and these two indices increase well in advance of the usual increase of 1 g of haemoglobin after 1 month.

Normocytic morphology is most often associated with anaemia of chronic disease. Anaemia of chronic disease is associated with the presence of renal insufficiency, cancer, congestive heart failure, hepatitis C, inflammation, diabetes, rheumatoid arthritis, osteoarthritis, hypertension, stroke and chronic obstructive lung disease. Also there is an elevation of proinflammatory cytokines such as IL-1, IL-6 and TNF-α. In many older people, IL-6 is chronically elevated and therefore the relationship between anaemia and elevated IL-6 requires further investigation. A recent report suggested that anaemia of chronic disease is associated with a increase in inflammatory cytokines/markers including IL−6.[28,43] In studies of anaemia of chronic disease, renal insufficiency accounts for about 27% of cases. Most of these patients have an erythropoietin deficiency. Figure 28.1 lists

Table 28.2 The WHO classification for MDS.

Refractory anaemia (RA)	Anaemia but white blood cell and platelet counts are normal and bone marrow has <5% blasts
Refractory anaemia with ringed sideroblasts (RARS)	Anaemia similar to those with RA but >15% of the red blood cells as sideroblasts and a normal white blood cell count and platelet count
Refractory cytopenia with multilineage dysplasia (RCMD)	<5% blasts and <15% sideroblasts in the bone marrow and at least two of the blood cell counts are low
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Same as RARS but at least two blood cell counts are low
Refractory anaemia with excess blasts (RAEB)	5–20% blasts in the bone marrow and <5% blast cells in the blood. Often also have a low white blood cell count and platelet count
Myelodysplastic syndrome, unclassified (MDSU)	Pancytopenia but do not show characteristics of other subtypes of MDS
MDS associated with isolated del(5q)	Anaemia and <5% blasts and loss of genetic material from chromosome 5

Adapted from Jaffe ES, Harris NL, Stein H and Vardiman JW (eds). *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues*, IARC Press, Lyon, 2001, pp. 47–8.

Table 28.3 Comparison of anaemia of chronic disease and iron deficiency anaemia.

Property	Iron deficiency anaemia	Anaemia of chronic disease
Mean corpuscular volume	Normal or decreased	Decreased or normal
Serum iron	Decreased	Decreased
Total iron-binding capacity	Increased	Normal or decreased
Serum ferritin	Decreased	Increased
Soluble transferritin receptor	Increased	Decreased

the anaemia of renal insufficiency separately, since this anaemia is common and has a distinct therapy.

In chronic kidney disease, there is blunted erythropoietin response, downregulating the response of the erythron to erythropoietin stimulation and probably reducing the survival time of erythrocytes. Hence there is a compensatory increase in erythropoietin levels in an attempt to normalize the haemoglobin concentration. In more advanced stages, this compensation fails, leading to low haemoglobin levels.[44] Anaemia of chronic kidney disease is diagnosed by recognizing renal insufficiency in association with a low erythropoietin level. The Cockcroft–Gault equation is usually used for calculation of estimated creatinine clearance[45] and has been shown to be strongly correlated with more accurate measures of glomerular filtration rate (GFR) measured creatinine clearance.[46]

If the serum creatinine is greater than 2 mg l^{-1}, it is usually unnecessary to measure erythropoietin levels. However, older persons can have a declining GFR in the face of a relatively normal serum creatinine. This results from the loss of lean mass (sarcopenia) associated with ageing or disease-related cachexia, reducing the source of serum creatinine. For example, an 85-year-old woman with a haemoglobin concentration of 100 g l^{-1} who weighs 55 kg and has a serum creatinine of 1.3 mg l^{-1} (normal range) will have a creatinine clearance calculated by the Cockcroft–Gault equation of 27.5 ml min^{-1}. For this reason, a creatinine clearance should be calculated in all older persons with anaemia to determine their renal status. The Cockcroft–Gault equation will demonstrate that the majority of older women with a creatinine of 1.2 mg l^{-1} or greater have severe renal impairment.

Primary bone marrow failure due to drug effects, alcoholism, radiation therapy, chemical exposure and recent trauma or surgery, aplastic syndromes and myelodysplastic syndrome may produce a normocytic morphology. Haemolytic anaemias and, on occasion, nutritional anaemia may present with normocytic morphology and should be excluded.

Haemolytic anaemia

In haemolytic anaemia, increased cell destruction is suggested by an increased lactic acid dehydrogenase, and increased haemoglobin catabolism is suggested by increased levels of indirect bilirubin. Increased clearing of haemoglobin is suggested by decreased levels of haptoglobin, while the bone marrow response is gauged by reticulocytosis. None of these tests are specific or able to distinguish among the various causes of haemolytic anaemia. The causes of a haemolytic anaemia can be classified into disorders of the structure or synthesis of haemoglobin, deficiencies of enzymes that provide the red cell with energy or protect it from chemical damage and disorders of the red cell's membrane.

Defects in haemoglobin structure

Haemoglobinopathies, the inherited diseases of haemoglobin, are very common. Haemoglobinopathies usually result from genetic alterations in the production of haemoglobin; for example, the sickle cell mutation results in a single amino acid substitution in the β-globin chain. Sickle cell disease consists of the homozygous state for the sickle cell gene (HbSS) or a compound heterozygous state for the sickle cell gene combined with either HbC (a β-chain variant) or β-thalassaemia (HbSC disease or sickle cell β-thalassaemia). Heterozygotes have one normal and one affected β-chain gene and produce about 60% HbA and 40% HbS. Homozygotes produce mainly HbS with small amounts of HbF. Compound heterozygotes for HbS and HbC produce almost equal amounts of each variant, whereas those who inherit the sickle cell gene from one parent and β-thalassaemia from the other make predominantly sickle haemoglobin. Sickle cell anaemia should be suspected in any patient with a haemolytic anaemia. It can be confirmed by a sickle cell test, although this does not distinguish between heterozygotes and homozygotes. A definitive diagnosis requires haemoglobin electrophoresis and the demonstration of the sickle cell trait in both parents. The median life expectancy for men and women with homozygous sickle cell anaemia is 42 and 48 years, respectively. In men and women who are heterozygous for HbSC, mean life expectancy is 60 and 68 years, respectively, while a few patients survive into their 70s.[47]

Defects in haemoglobin synthesis

The thalassaemias are classified as α- or β-thalassaemias, depending on which pair of globin chains is synthesized inefficiently. Both β- and δ-chain production are affected in rarer forms of thalassaemias. Patients with the homozygote state for the β-synthesis usually develop severe anaemia in the first year of life. The HbF level is always raised. Severe ineffective erythropoiesis results in erythroid marrow expansion to as much as 30 times the normal level and leads to skeletal changes and hepatosplenomegaly.[48] Transfusion may result in normal growth and development. However, accumulation of iron may lead to damage to the myocardium, pancreas and liver and to infection and folic acid deficiency. Milder forms of β-thalassaemia (thalassaemia intermedia) can be associated with similar bone changes, anaemia, leg ulcers and delayed development in children. Heterozygote β-thalassaemia persons are asymptomatic, with hypochromic microcytic red cells, a low mean corpuscular haemoglobin and low mean cell volume. The HbA2 level is about twice normal. Homozygote persons for α-thalassaemia (Hb Bart's) develop hydrops fetalis syndrome, characterized by the stillbirth of a severely oedematous fetus in the second half of pregnancy. HbH disease is associated with a moderately severe haemolytic anaemia. Carrier states for α-thalassaemia result in a mild hypochromic anaemia with normal HbA2 levels. Other anaemias with an important inherited component include Fanconi's anaemia (hypoplastic anaemia with skeletal deformities), Blackfan–Diamond anaemia (red cell aplasia) and several forms of congenital dyserythropoietic anaemia.

Defects in red cell enzymes

Red cells utilize two main metabolic pathways, either anaerobic metabolism of glucose or reduction of glutathione to protect against injurious oxidants. A large number of inherited enzyme defects have been described. Defects in the pyruvate kinase pathway can cause haemolytic anaemia. Glucose-6-phosphate dehydrogenase deficiency involves a pathway that is critically important to prevent haemolysis.

Precipitated haemoglobin may form a Heinz body, an erythrocyte inclusion that is detected by staining with Crystal Violet. Glucose-6-phosphate dehydrogenase deficiency is gender linked and affects males predominantly. It affects millions of people worldwide, mainly the same groups that are affected by the thalassaemias. Neonatal jaundice, sensitivity to fava beans and haemolytic responses to oxidant drugs are clues to glucose-6-phosphate dehydrogenase deficiency. Several drugs, including Methylene Blue, naphthalene, nitrofurantoin, phenazopyridine, primaquine, sulfonamides and sulfones, Toluidine Blue and trinitrotoluene, have been associated with haemolytic anaemia in persons with glucose-6-phosphate dehydrogenase deficiency.[49]

Defects in the red cell membrane

The red cell membrane is required to maintain the integrity of the cell. There are many inherited defects of the membrane proteins, some of which cause haemolytic anaemia. Hereditary spherocytosis is due to a structural change that makes the cells more leaky and can be treated by splenectomy. Other inherited varieties of elliptical or oval red cells can produce chronic haemolysis and respond to splenectomy.

Accelerated destruction of red cells

The diagnosis of autoimmune haemolysis is based on demonstrating that autoantibodies or complement components are bound to the red cells and are associated with a shortened red cell lifespan. Anaemia results when the rate of red cell destruction exceeds the regenerative capacity of the bone marrow. The direct antiglobulin test was introduced by Coombs *et al*. in 1945 and remains the hallmark in the laboratory diagnosis of autoimmune haemolytic anaemia.[50] The Coombs test demonstrates the presence of immunoglobulins or complement bound to the erythrocyte membrane. The antibodies can be classified into warm, cold and mixed types, depending on the thermal characteristic of the autoantibodies.[51] The diagnosis may be complicated when the haemolysis is associated with another type of anaemia, haemorrhage or blood transfusions or is minor.[52] A large number of conditions have been associated with an autoimmune haemolytic anaemia (see Table 28.4).

Aplastic anaemia

Aplastic anaemia is a failure of the bone marrow. Erythrocytes, granulocytes and platelets decrease to dangerously low levels. The pathophysiology of aplastic anaemia is thought to be immune mediated, with active destruction of blood-forming cells by lymphocytes. The aberrant immune response may be triggered by chemicals and drugs (see Table 28.5), viral infections or by endogenous antigens generated by genetically altered bone marrow cells. Anaemia leads to fatigue, dyspnoea and cardiac symptoms, while thrombocytopenia leads to bruising and mucosal bleeding and neutropenia leads to sharply increased susceptibility to infection.[53]

Aplastic anaemia can be effectively treated by stem cell transplantation or immunosuppressive therapy. Transplantation is curative but is best used for younger patients who have histocompatible sibling donors. Antithymocyte globulin and ciclosporin restore haematopoiesis in approximately two-thirds of patients. However, recovery of blood cell

Table 28.4 Conditions associated with autoimmune haemolytic anaemias.

Warm antibody	Cold antibody
Chronic lymphocytic leukaemia	Primary atypical pneumonia
Hodgkin's disease	Ebstein–Barr virus infection
Non-Hodgkin's lymphomas	Leprosy
Thymomas	
Multiple myeloma

Infectious disease/childhood viral disorders	
Hypogammaglobulinaemia	
Dysglobulinaemias	
Ulcerative colitis	
Ovarian dermoid cysts	
Immune deficiency syndromes	
Drug-induced (α-methyldopa)	

count is often incomplete, recurrent pancytopenia requires retreatment and some patients develop late complications (especially myelodysplasia).[54]

Paroxysmal nocturnal haemoglobinuria (PNH) is intimately related to aplastic anaemia because many patients with bone marrow failure have an increased population of abnormal cells. These abnormal haematopoietic stem cells lack an entire class of distinctive cell surface proteins, which may convey a selective advantage in resisting immune attack. PNH may be related to aplastic anaemia and myelodysplasia. PNH cells have been identified in 42% of patients with aplastic anaemia and 23% of those with myelodysplasia early in the disease process and before any treatment.[55] Finding a non-immune haemolysis with haemosiderinuria should lead to an investigation for PNH. PNH should be investigated in cases of aplastic anaemia or a venous thrombosis. PNH is a rare disease with the annual incidence of only about four per million persons.[56]

Management

Anaemia due to vitamin B_{12} or folate deficiency is treated by the replacement of the vitamin. Vitamin B_{12} can be replaced either by injections (1000 μg weekly for 1 month, then monthly thereafter), orally (1000 μg daily, which should not be given with food) or intranasally. Folate 1 mg should be used to treat folate deficiency and should be used during the first few weeks of vitamin B_{12} deficiency.

In persons with iron deficiency, the recommended treatment is iron sulfate 325 mg three times per day, providing 195 mg of elemental iron per day.[57–59] The sulfate moiety can cause gastrointestinal distress and, if this occurs, iron in the form of gluconate or fumarate may be helpful. Some experts suggest that iron sulfate once per day may have a similar effect to three times per day dosing if absorption is normal. The duration of iron therapy may be longer when once per day dosing is used. Whatever the chosen dose, a reticulocyte count should be obtained 1 week after starting iron. If there is not a robust reticulocyte response, intravenous iron should be considered. Iron therapy may be discontinued when the ferritin level is normalized (see Table 28.6). Iron should be considered replaced when serum ferritin is maintained above 100 ng ml^{-1}. Once a ceiling ferritin level of 800 ng ml^{-1} has been reached, no more iron should be administered.

Since the introduction of human recombinant erythropoietin in 1989, the treatment of anaemia due to chronic disease has been revolutionized. A linear relationship between GFR and anaemia has been demonstrated. In patients with chronic renal insufficiency, the evaluation of anaemia should begin in women with a haemoglobin concentration of 110 g l^{-1} or less and in men with a haemoglobin concentration of 120 g l^{-1} or less. Anaemia can develop relatively early in the course of a chronic renal failure and has been associated with a serum creatinine as low as 2.0 mg l^{-1}.[60]

Significant anaemia has been noted when the calculated GFR is less than 20–35 ml min^{-1}.[61,62] In patients with an impaired renal function and a normochromic, normocytic anaemia, it is rare for the serum erythropoietin level to be elevated. Therefore, measurement of erythropoietin levels in such patients is not likely to guide clinical decision-making or therapy. While the majority of persons on dialysis receive erythropoietin, there are many persons who have chronic renal insufficiency who do not receive erythropoietin. This is particularly true among older persons.

As may be expected with increased blood volume, erythropoietin therapy increases blood pressure, necessitating close monitoring in patients with known cardiovascular disease. The haemoglobin level should not exceed 120 g l^{-1} in correcting anaemia in renal insufficiency.

Erythropoietin has been shown to increase the haemoglobin concentration in patients with anaemia associated with surgical blood loss, cancer, chemotherapy, anaemia associated with drug therapy for AIDS or hepatitis C virus, myelodysplastic disease and the anaemia of chronic disease, especially when associated with rheumatoid arthritis. Several conditions may result in an inadequate response to erythropoietin therapy, including coexisting iron, vitamin B_{12} or folate deficiency, acute or chronic infections, inflammatory diseases, chronic blood loss, haemoglobinopathies, multiple myeloma, malnutrition, haemolysis, malignancy, hyperparathyroidism and hypogonadism. Failure to respond to erythropoietin should trigger an evaluation for these conditions (see Table 28.7).

Table 28.5 Drugs associated with aplastic anaemia.

Group 1: marrow aplasia expected	Group 2: marrow aplasia idiosyncratic
Antineoplastic drugs	Antiarthritics (gold salts, D-penicillamine, colchicine)
Alkylating agents (busulfan, cyclophosphamide, melphalan, nitrogen mustard)	Antibiotics (sulfonamides)
Antimetabolites (fluorouracil, mercaptopurine, methotrexate)	Anticonvulsants (carbamazepine, hydantoins, felbamate)
Cytotoxic antibiotics (daunorubicin, doxorubicin, mitoxantrone)	Antidysrhythmics (quinidine, tocainamide)
Benzene	Antihypertensives (nifedipine)
Benzene-containing chemicals	Antiplatelets (clopidogrel, ticlodipine)
Kerosene	Antithyroids (carbimazole, methimazole, propylthiouracil)
Carbon tetrachloride	Diuretics (acetazolamide, chlorothiazide, furosemide)
Stoddard's solvent	Non-steroidal anti-inflammatory drugs (butazones, indomethacin, ibuprofen)
Toluene	Hypoglycaemics (chlorpropamide, tolbutamide) Psychotropics (chlordiazepoxide, chlorpromazine, other phenothiazines)

Table 28.6 Approach to the management of anaemia.

Diagnosis	Treatment
Iron deficiency	Ferrous sulfate 325 mg 1–3 times daily
Vitamin B_{12} deficiency	Vitamin B_{12} 1000 μg orally or intramuscularly
Folate deficiency	Folate 1 mg daily
Anaemia of chronic kidney disease	Epoetin alfa 10 000 U weekly or darbepoetin alfa 60 μg every 2 weeks to target haemoglobin 100–120 g l^{-1}
Anaemia of chronic disease	Treat underlying condition; consider epoetin alfa weekly or darbepoetin alfa every 2 weeks to target haemoglobin 100–120 g l^{-1}

Table 28.7 Potential causes for inadequate response to erythropoietin therapy.

Iron/vitamin B_{12}/folate deficiency
Infection/inflammation (e.g. access infections, surgical inflammation, AIDS, systemic lupus erythematosus)
Chronic blood loss
Osteitis fibrosa
Haemoglobinopathies (e.g. α- and β-thalassaemias, sickle-cell anaemia)
Multiple myeloma
Malnutrition
Haemolysis
Aluminium toxicity
Malignancy
Hyperparathyroidism
Hypogonadism
Other: angiotensin-converting enzyme inhibitors (reported, but not verified)

The target haemoglobin for optimum outcomes with erythropoietin therapy has been the focus of several trials. The Normal Haemoglobin Trial[63] found a 30% increase in death and non-fatal myocardial infarction in patients who had clinical evidence of heart failure and who were receiving dialysis and who received erythropoietin to maintain a haematocrit of 42% versus a similar group who maintained a haematocrit of 30%.

The Correction of Haemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial evaluated patients with chronic kidney disease for a mean duration of 16 months.[64] Patients had a mean haemoglobin level of 101 g l^{-1} and a mean GFR of 27 ml min^{-1} and about 50% were diabetic at baseline. Patients were randomly assigned to receive a dose of epoetin alfa targeted to achieve a haemoglobin level of 135 g l^{-1} or to receive a dose targeted to achieve a haemoglobin level of 113 g l^{-1}. The primary endpoint was a composite of death, myocardial infarction, hospitalization for congestive heart failure and stroke. The use of a target haemoglobin level of 13.5 g dl^{-1} (as compared with 11.3 g dl^{-1}) was associated with increased composite risk and no incremental improvement in the quality of life.

In the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE) trial, patients with stage 3–4 chronic kidney disease and mild to moderate anaemia (haemoglobin 110–125 g l^{-1}) were randomized to treatment with epoetin beta to a target haemoglobin range of either 130–150 or 105–115 g l^{-1}.[65] The primary outcome was a composite of eight cardiovascular events. After following these patients for 3 years, the investigators found that there was no significant difference in cardiovascular event rates or in all-cause mortality between the two groups, but an increase in blood pressure was noted in the normalization group.

The Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT)[66] randomized subjects with diabetes,

chronic kidney disease and moderate anaemia who were not undergoing dialysis to darbepoetin alfa to achieve a haemoglobin level of 130 g l^{-1} or to placebo with rescue darbepoetin alfa if the haemoglobin level was less than 90 g l^{-1}. The primary endpoint of the study was a composite outcome of death or a cardiovascular event (non-fatal myocardial infarction, congestive heart failure, stroke or hospitalization for myocardial ischaemia) and of death or end-stage renal disease. This study showed that the normalization of the haemoglobin by use of darbepoetin alfa did not reduce the risk of either death or a cardiovascular event or death or a renal event and was associated with a higher risk of stroke.

A meta-analysis of the 27 trials selected demonstrates that a higher haemoglobin target is associated with increased risks for stroke [relative risk (RR) 1.51], hypertension (RR 1.67) and vascular access thrombosis (RR 1.33) compared with a lower haemoglobin target. No statistically significant differences in the risks for mortality (RR 1.09), serious cardiovascular events (RR 1.15) or end-stage kidney disease (RR 1.08) were observed, although point estimates favoured a lower haemoglobin target.[67]

Blood transfusions are often given to older persons who become symptomatic, drop their haemoglobin concentration below 80 g l^{-1} or who have an acute bleed. However, despite adequate careful cross-matching of blood, complications are common. Transfusion reactions can lead to haemolysis and fever. Transfusions are often associated with circulatory overload in older persons.

Since the original description of blood-borne hepatitis A, numerous infections including AIDS have been transmitted to patients during blood transfusions. For these reasons, attempting to maintain haemoglobin concentration by other approaches is very important in the long-term care resident. Human recombinant erythropoietin administration can reduce blood transfusion requirements.[22]

Erythropoietin stimulates bone marrow and reduces transfusion requirements during chemotherapy or radiotherapy. However, data from a meta-analysis of 53 trials in cancer patients receiving erythropoietin during active chemotherapy treatment found increased mortality during the active study period (combined hazard ratio 1.17) and a slight increase in overall mortality during the active study period and a slight decrease in subsequent overall survival.[68] Because of the findings, a black box warning was added to erythropoiesis-stimulating agent labels in 2008 stating that these agents shorten survival and increase risk for cancer progression in patients with breast, non-small-cell lung, head and neck, lymphoma and cervical cancers. Prescription of erythropoiesis-stimulating agents is limited in patients with cancer. Guidelines for the use of erythropoiesis-stimulating agents in patients with cancer are shown in Table 28.8 and are available at http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/default.htm.

Table 28.8 Guidelines for use of erythropoiesis-stimulating agents in patients with cancer.

1. Erythropoiesis-stimulating agents (ESAs) are indicated for the treatment of anaemia due to the effect of concomitantly administered chemotherapy based on studies that have shown a reduction in the need for red blood cell transfusions in patients with metastatic, non-myeloid malignancies
2. ESAs are not indicated for patients receiving myelosuppressive therapy when the anticipated outcome is cure
3. Use ESAs only for treatment of anaemia due to concomitant myelosuppressive chemotherapy
4. ESA therapy should not be initiated at haemoglobin levels $\geq$10 g dl^{-1} and dosing should be adjusted to maintain the lowest haemoglobin level sufficient to avoid red blood cell transfusion
5. Discontinue ESAs following the completion of a chemotherapy course
6. ESAs have not been demonstrated in controlled clinical trials to improve symptoms of anaemia, quality of life, fatigue or patient wellbeing
7. ESAs are not indicated for use in patients receiving hormonal agents, therapeutic biological products or radiotherapy unless receiving concomitant myelosuppressive chemotherapy

Conclusion

The positive clinical outcomes for treating anaemia, such as reduction in transfusion requirement, suggest that a haemoglobin concentration of less than 120 g l^{-1} should be investigated and treated whenever possible. The differential diagnosis of anaemia is complex, including inherited or acquired anaemias that persist into older age. Chronic kidney disease and its associated anaemia are very likely underdiagnosed in older persons. Erythropoietin should clearly be considered in all anaemic older adults with chronic kidney disease whose serum creatinine is greater than 2 mg l^{-1}. A calculated creatinine clearance should be done to identify patients with chronic renal failure whose creatinine may be less than 2 mg l^{-1}. The availability of recombinant erythropoietin and newer products with a longer half-life make the goal of correcting anaemia and improving patient outcomes a priority.

Key points

- Anaemia has been associated with frailty, functional impairment, falls and increased mortality.

- Positive clinical outcomes for treating anaemia demand investigation and treatment whenever possible.
- The differential diagnosis of anaemia is complex.
- Anaemia associated with chronic kidney disease remains underdiagnosed in older persons.
- Newer treatment modalities facilitate the goal of correcting anaemia and improving patient outcomes.

CHAPTER 29

Disorders of haemostasis

Kingsley K. Hampton
Royal Hallamshire Hospital, Sheffield, UK

Introduction

Bleeding causes or contributes to the death of about 5% of the elderly population. This is primarily due to intracranial and subarachnoid haemorrhage, ruptured aortic aneurysm and gastrointestinal bleeding from peptic ulcer and gastric or colonic malignancy. Bleeding due to primary disorders of haemostasis in the elderly is relatively rare. Severe congenital bleeding diatheses are usually diagnosed at a young age, with the majority of them now being treatable and carrying a normal life expectancy, while acquired disorders of haemostasis are an uncommon cause of death except as part of the syndrome of multiorgan failure. Most bleeding in the elderly is localized and the result of a specific underlying pathology, frequently malignancy. Bleeding disorders can be classified as being due to abnormalities of platelet number or function, disorders of the coagulation cascade and disturbances of the vascular endothelium and connective tissues.

Thrombotic disorders are far more significant causes of morbidity and mortality in the elderly age group. Arterial thrombosis and atheroma cause cardiovascular disease, cerebrovascular disease and peripheral vascular disease. Likewise, venous thromboembolism is primarily a disease of older age and is now recognized as being due to a combination of both circumstantial and underlying genetic factors. Ageing itself does not result in either any major or significant changes in the range of the common coagulation tests, such as the activated partial thromboplastin time (APTT), prothrombin time (PT) or thrombin time (TT), or in the level of fibrinogen or other specific coagulation factors and inhibitors. Likewise, the platelet count does not alter with age. There is, however, convincing evidence from sensitive markers of coagulation activation that background turnover of the proteins is increased with age.[1] Although there are no major changes in haemostasis that occur with increasing age, diseases that may result in bleeding problems or thrombosis are more common and their consequences more serious in the elderly (Table 29.1).

Disorders of platelet number

The normal platelet count is between 140 and 400 $\times 10^9\,l^{-1}$. There is, however, some reserve and haemostasis is normal with a platelet count of above 80 $\times 10^9\,l^{-1}$, assuming normal platelet function. If the platelet count falls below this value, the bleeding time progressively prolongs but spontaneous haemorrhage, in particular intracerebral haemorrhage, does not occur until the platelet count falls below 20 $\times 10^9\,l^{-1}$. Platelet numbers can be decreased by three mechanisms: decreased production in the bone marrow, increased peripheral destruction, immune consumption and splenic pooling in gross splenomegaly with hypersplenism. In addition, adverse effects of drugs should always be considered as a possible cause in any case of thrombocytopenia.[2]

Decreased platelet production

Decreased platelet production can be due to any condition that causes infiltration and replacement or aplasia of the bone marrow, for example, aplastic anaemia, leukaemia, lymphoma, carcinoma and myelodysplasia or deficiency of vitamin B_{12} and folate in megaloblastic anaemia.

Increased peripheral destruction

In childhood, immune thrombocytopenic purpura (ITP) is usually an acute self-limiting condition, frequently precipitated by a viral infection, which spontaneously remits. In adults, ITP often has an insidious onset without an obvious precipitant cause and runs a chronic course over many months and years, occasionally being extremely refractory to treatment. ITP is due to the production of an autoantibody against platelets, usually directed against the platelet membrane-specific glycoproteins. The binding of the antibody to the platelet surface antigen results in the uptake of the platelet–antibody complex by the reticuloendothelial system and premature destruction of

the platelet. Destruction occurs primarily in the spleen and also in the liver and bone marrow and platelet survival is decreased from the normal 7–10 days to only a few hours. Diagnosis is based on the finding of true thrombocytopenia, together with a normal bone marrow showing normal or increased numbers of megakaryocytes, the progenitor cells of platelets and an absence of an alternative cause of excessive peripheral platelet destruction. A low platelet count from an automated blood cell analyser should always be repeated and the blood film should be examined to exclude artefactual thrombocytopenia due either to the sample having clotted or to platelet clumping caused by the anticoagulant. The clotting screen should be normal. ITP in adults, unlike in childhood, seldom remits spontaneously. The initial treatment is with prednisolone, $1\,mg\,kg^{-1}$ daily or intravenous immunoglobulin $0.4\,g\,kg^{-1}$ daily for 5 days. The condition is usually steroid responsive but frequently steroid dependent, and attempts to withdraw the steroids result in recurrence of thrombocytopenia. Often, the platelet count will stabilize at an acceptable level of above $50 \times 10^9\,l^{-1}$ on no steroids or only a minimal dose, and in the absence of symptoms this is often well tolerated for many years. If there is no response to steroids or an unacceptably high dose is required to maintain a satisfactory platelet count, alternative therapies include intravenous immunoglobulin, $400\,mg\,kg^{-1}$ per day for 3–5 days, which usually raises the platelet count for around 3 weeks and sometimes results in a sustained remission and splenectomy, which, although it does not prevent autoantibody production, does prevent premature platelet destruction by the spleen. A splenectomy is successful in achieving complete remission in about 50–75% of cases progressing as far as surgery. Splenectomy should not, however, be undertaken lightly as it is not without hazard, particularly in the thrombocytopenic patient. In addition to the operative risks, there is the risk of subsequent overwhelming postsplenectomy sepsis: preoperative pneumococcal *Haemophilus influenzae*, a meningococcal vaccination and postoperative penicillin prophylaxis should therefore be given. For those in whom a splenectomy is contraindicated or fails, immunosuppressive therapy with azathioprine or cyclophosphamide is sometimes effective. Danazol, vitamin C, interferon and ciclosporin have all been tried with varying efficacy, as has extracorporeal absorption of the antibody with a protein A column. New thrombopoietin agonists are becoming available which may have a role in the management of severe symptomatic or refractory ITP. In difficult and refractory cases, none of these therapies is frequently or consistently successful.[3]

Increased pooling of platelets

Under normal circumstances, 25% of the peripheral platelet pool is sequestered within the spleen at any one time. With increasing and massive splenomegaly, this can increase to more than 90%, resulting in a peripheral platelet count falling even to $50 \times 10^9\,l^{-1}$. Bleeding, however, is rare as the platelets appear to be mobilized during haemostatic challenge and the platelet mass is usually normal.[4]

Thrombocytopenia due to drugs

Drugs can cause thrombocytopenia by direct bone marrow suppression, for example, cytotoxic drugs, alcohol and chloramphenicol or by inducing an immune response – those most commonly being implicated are aspirin, paracetamol, antibiotics, anticonvulsants, diuretics and other miscellaneous drugs such as tolbutamide, quinine and quinidine. Heparin causes a characteristic syndrome of heparin-induced thrombocytopenia (HIT), which, unlike other drug-induced causes of thrombocytopenia, is associated not only with decreased platelet survival and thrombocytopenia but also with platelet activation and hence arterial and venous thrombosis.

Consequently, this condition is associated with severe morbidity, due to severe venous or arterial thrombosis and a mortality of around 30%. It is more common with unfractionated heparin than with low molecular weight heparin,

but can occur with either. Patients receiving heparin for both prophylactic and therapeutic indications should have their platelet counts regularly monitored to anticipate this serious complication. Treatment of suspected HIT involves immediate withdrawal of heparin and commencement of an alternative method of anticoagulation, such as hirudin or heparan but not warfarin.[5]

Functional platelet defects

By far the most common platelet functional defect (Table 29.2) is that acquired following treatment with aspirin. Aspirin works by irreversibly acetylating the platelet enzyme prostaglandin synthase and thereby decreases platelet reactivity and aggregation for the platelet's entire lifespan. Aspirin prolongs the skin bleeding time. In recent years, aspirin has become established in the treatment of acute arterial thrombotic events, such as unstable angina and myocardial infarction, and in the secondary prophylaxis of myocardial infarction and transient ischaemic attack and stroke. There is a trend towards decreasing the dose of aspirin, which not only decreases gastrointestinal toxicity but also results in the platelet being irreversibly acetylated by aspirin in the portal circulation; with low total dose, aspirin is then deacetylated within the liver, resulting in no systemic bioavailability of aspirin and thus in no inhibition of the beneficial effects of endothelial cell prostacyclin production. Clopidogrel is another orally active anti-platelet agent which acts by irreversible inhibition of the platelet ADP receptor. Other drugs that affect platelet function include non-steroidal anti-inflammatory drugs (NSAIDs), high doses of penicillin and cephalosporins and some antidepressants and anaesthetics. Abnormal platelet function can occur in any of the myeloproliferative disorders, namely primary proliferative polycythaemia, essential thrombocythaemia, chronic myeloid leukaemia and myelofibrosis, leading to both bleeding and thrombosis. Bleeding is paradoxically more common with raised platelet counts, especially when greater than $1000 \times 10^9\ l^{-1}$.

Similarly, in myelodysplastic syndromes, in addition to the frequent thrombocytopenia, abnormal platelet function is common and bleeding can cause severe morbidity, requiring platelet transfusion; bleeding and infection are the most common causes of death. Abnormalities of platelet function leading to a prolonged bleeding time frequently occur in uraemia. This improves with dialysis and can be specifically treated, if necessary, with both cryoprecipitate and desmopressin (DDAVP). An acquired platelet function defect, due primarily to proteolytic degradation of platelet surface glycoproteins by plasma, occurs during extracorporeal circulation in cardiopulmonary bypass. It can be ameliorated by the use of the fibrinolytic inhibitor aprotinin, but may on occasion require platelet transfusion in addition. Congenital functional platelet defects are extremely rare, with an incidence of less than one per million of the population. Deficiency of the platelet-specific glycoprotein Ib, which allows interaction with the von Willebrand factor, occurs in Bernard–Soulier syndrome and deficiency of the platelet surface glycoprotein IIb/IIIa occurs in Glanzmann's thrombasthenia. Deficiency of platelet alpha and dense granules, which are usually released upon platelet aggregation and are involved in recruitment of large numbers of platelets into the platelet plug, are deficient in storage pool disease.[6]

Hereditary coagulation defects

Severe deficiency (<0.01 IU ml^{-1}) of factor VIII (haemophilia A) or factor IX (haemophilia B) will have been diagnosed at a young age and management of these conditions is highly specialized and age independent. Spontaneous bleeding into muscles and joints is frequent and is managed by infusions of appropriate clotting factor concentrates (Figure 29.1). In addition, many of the older patients have severe complications of advanced haemophiliac arthropathy and often hepatic impairment due to chronic infection with hepatitis viruses, especially hepatitis C virus. Haemophilia A and B both have gender-linked inheritance and occur in males. Mild (>0.05 IU ml^{-1}) and moderate ($0.01–0.05$ IU ml^{-1}) cases may have escaped diagnosis until a later age and will not present until they have a severe haemostatic challenge such as surgery, which can occur at any age. These patients will have a long APTT and specific factor assays will reveal the diagnosis. They can usually be managed with desmopressin, a long-acting synthetic analogue of vasopressin, the antidiuretic hormone, rather than with clotting factor concentrates, with the attendant savings on cost and reduced risk of viral transmission. Female carriers of haemophilia A and B usually have around half the normal levels of the respective clotting factor, although, owing to the randomness of the lyonization effect (random inactivation of one X chromosome in all female cells), up to 30% of carriers will have factor VIII or factor IX levels sufficiently low to require treatment at times of surgery; conversely, many carriers have entirely normal levels of factor VIII and factor IX, and, therefore, carrier status cannot be determined accurately simply by measuring

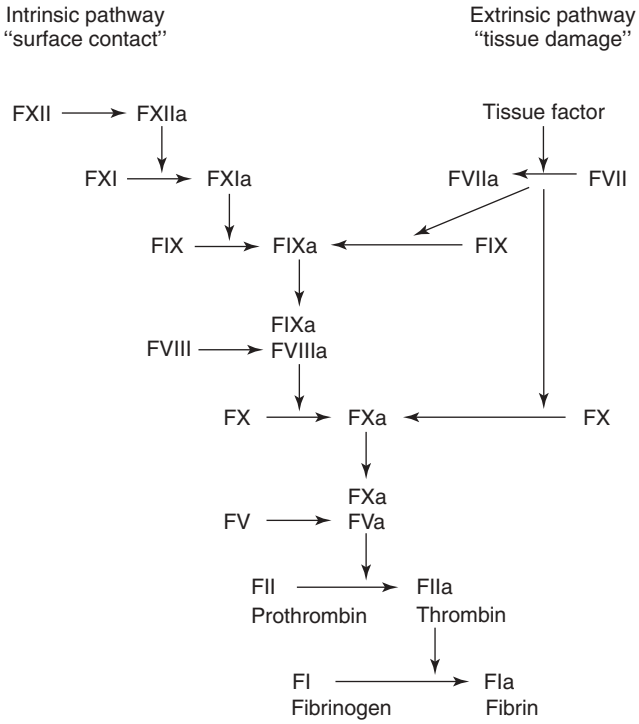

Figure 29.1 Coagulation cascade.

the appropriate factor levels but instead requires genetic analysis.

Von Willebrand's disease is extremely common and has an incidence of up to 1% in the general population. It is autosomally dominantly inherited and, therefore, occurs in males and females equally. The majority of cases are mild; the condition is significantly underdiagnosed and in milder cases bleeding occurs only with significant haemostatic challenges. Consequently, mild von Willebrand's disease can present and be diagnosed at any age. Von Willebrand's disease is due to a decreased concentration of the protein von Willebrand factor, which is important in mediating platelet adhesion to the subendothelium; von Willebrand factor also circulates non-covalently bound to coagulation factor VIII and so protects factor VIII from premature proteolytic degradation. Therefore, in von Willebrand's disease, diminished levels of the von Willebrand factor result in both a mild platelet defect and a mild defect of the coagulation cascade consequent upon the diminished amounts of factor VIII. Unlike in haemophilia, the skin bleeding time is increased and bleeding tends to be primarily mucocutaneous, with epistaxis, gum bleeding, gastrointestinal bleeding and menorrhagia. Diagnosis and classification require the determination of factor VIII concentration, the von Willebrand factor antigen and the von Willebrand factor activity, by use of the ristocetin cofactor activity or collagen binding activity and analysis of the von Willebrand factor multimer distribution. Mild type I cases can usually be treated with desmopressin prior to significant haemostatic challenge, whereas the rarer, more severe forms of von Willebrand's disease usually require treatment with clotting factor concentrates, which should contain both factor VIII and the von Willebrand factor.[7]

Acquired coagulation defects

Probably the most commonly acquired coagulation defect (Table 29.3) in the elderly is iatrogenic, because of the use of the anticoagulants heparin and warfarin. Heparin is given parenterally and acts by potentiating the action of antithrombin to inhibit thrombin. It is a difficult drug to use, with a narrow therapeutic range, complicated pharmacokinetics and significant interpatient variation in dose requirements. Insufficient heparin will result in thrombosis or extension of previously existing thrombosis, while excess treatment rapidly precipitates haemorrhage, which is potentially life threatening. Heparin infusion should be monitored by use of the APTT; the therapeutic range is a ratio of between 1.5 and 2.[8] All the active drugs are now being used for thromboprophylaxis and will shortly be used for the treatment of venous thromboembolism. Dabigatran is an orally active direct thrombin inhibitor and rivaroxaban is an orally active direct factor Xa inhibitor for use in prophylaxis of high-risk surgery and is already proven to be beneficial and it is likely they will be used in the treatment of deep venous thrombosis (DVT) and pulmonary embolism (PE) and replace warfarin for the majority of cases of patients in atrial fibrillation. There are no data yet as to whether they can be used in patients with recurrent thrombosis or thrombophilia or patients with prosthetic heart valves. The introduction of low molecular weight heparins for both prophylaxis and treatment of venous thrombosis has the significant advantages of a longer half-life, increased bioavailability and more predictable pharmacokinetics, and consequently they can be given by once-daily subcutaneous injection without the need for monitoring, even in the doses required for treatment. Since low molecular weight heparin has a greater effect on factor Xa than on thrombin (IIa), it cannot be monitored with the APTT but instead requires an antifactor Xa

Liver disease
Specific coagulation factor inhibitors
Disseminated intravascular coagulation
Paraproteins

assay. However, in overdosage, even low-molecular weight heparin will prolong the APTT and bleeding under these circumstances may require neutralization of the heparin with protamine sulfate.[9]

Warfarin, likewise, is a drug with a narrow therapeutic range, complicated pharmacokinetics and multiple drug interactions, and significant haemorrhagic consequences if given in overdose. Warfarin also requires careful monitoring. There are well-established guidelines for the treatment of venous thrombosis, these being an international normalized ratio (INR) of 2–3 for uncomplicated thrombosis and 3–4 for recurrent and complicated thrombosis or in patients with the presence of artificial prosthetic heart valves or similar.

Liver disease is a common cause of an acquired coagulation disorder. In addition to being the site of synthesis of the majority of coagulation proteins, the liver is also extremely important in the clearance of activated clotting factors. In addition, liver disease is often also associated with dysfibrinogenaemia, due to increased deposition of sialic acid residues on fibrinogen resulting in charge repulsion and failure to polymerize, and hypofibrinogenaemia, due to failure of synthesis. Furthermore, liver disease often causes portal hypertension and hypersplenism with consequent thrombocytopenia due to splenic pooling of platelets. The coagulation defect in liver disease first manifests as a prolongation of the PT and initially is due to decreased production of the active forms of the vitamin K-dependent clotting proteins, factors II, VII, IX and X. Consequently, vitamin K may be of some use in correcting the coagulation defect in early liver disease. Vitamin K takes a minimum of 6 h to work and its effect is maximal at 24 h. In more advanced liver disease, there is a decreased production of all clotting factors and fibrinogen, except for factor VIII, and vitamin K is usually not effective.[10] Disseminated intravascular coagulation is caused by a wide variety of triggering factors and mechanisms and is discussed elsewhere.

Thrombotic thrombocytopenic purpura presents as a classic pentad of fever, thrombocytopenia, neurological and renal involvement and a microangiopathic haemolytic anaemia with red cell fragmentation. It has recently become clear that the majority of cases of TTP are due to an autoimmune deficiency of ADAMST13, an enzyme present in the plasma, that cleaves high molecular weight von Willebrand factor multimers. These ultra-high von Willebrand factor multimers are released from endothelial cells and are usually processed by ADAMST13. If ADAMST13 is deficient, these ultra-high von Willebrand factor multimers are able to cause spontaneous aggregation of platelets to the endothelial cells causing microvascular thrombosis and hence the symptoms of TTP. High-volume plasma exchange results in removal of the antibody and the ultra-high molecular weight multimers, while replacement with plasma results in the patient receiving active enzyme and normal von Willebrand factor multimers. The autoimmune component can be treated either with prednisolone or, more recently, infusions of rituximab. The coagulation tests, however, usually remain normal or only very mildly deranged, in contradistinction to the case in disseminated intravascular coagulation, where thrombocytopenia is accompanied by profound disturbances of coagulation. The treatment is with aggressive, large-volume plasma exchange and plasma transfusion and will involve liaison with haematologists and renal physicians.[11]

Acquired factor VIII inhibitors are rare but their incidence is increasing as the population ages. They can occur spontaneously or in association with an underlying autoimmune or lymphoproliferative disorder. Their management involves both treatment of the active bleeding episode and subsequent efforts to remove or neutralize the antibody. The latter usually involves immunosuppression, although occasionally acquired inhibitors will resolve spontaneously. Treatment of bleeding episodes may require high doses of factor VIII and the use of activated prothrombin complex concentrates or recombinant factor VIIa. Data from the United Kingdom Haemophilia Centre Doctors Organisation has recently shown that the mortality from acquired haemophilia is surprisingly low and that in the elderly patient group sepsis, an effect of immunosuppression, actually causes more death than bleeding.

Paraproteinaemias can affect coagulation either by non-specific inhibition of fibrin polymerization by the paraprotein, which can occur in myeloma, Waldenström's macroglobulinaemia and other lymphoproliferative disorders or by the paraprotein having specific activity against one or more of the proteins of the coagulation cascade. This is a relatively rare phenomenon, but activity against factor VIII, giving acquired haemophilia, and von Willebrand factor, giving acquired von Willebrand's disease, is recognized.[12]

Vascular disorders

In these disorders (Table 29.4), coagulation tests and platelet number and function are normal. The defect lies in the vascular endothelium and supporting tissues.[13] Senile purpura is relatively common and occurs on the extensor surfaces of the forearms and hands in particular. It is due to decreased amounts of collagen supporting the small blood vessels, which rupture with minor trauma or apparently spontaneously. The process is considerably accelerated by long-term treatment with corticosteroids. There is no specific treatment and, other than being cosmetically disturbing, it does not constitute a significant haemorrhagic diathesis. Hereditary haemorrhagic telangectasia is an autosomally dominantly inherited disease with multiple telangectasia of the lips, conjunctiva and the oral cavity associated with telangectasia throughout the gastrointestinal tract and also

Table 29.4 Haemorrhagic vascular defects.

Senile purpura
Steroid purpura
Hereditary haemorrhagic telangiectasia
Gastrointestinal angiodysplasia
Ehlers–Danlos syndrome
Henoch–Schönlein purpura

with pulmonary arteriovenous malformations. The condition tends to become progressively more severe with age and frequently presents in later life, usually as chronic iron deficiency anaemia. Troublesome gastrointestinal bleeding can usually be managed by iron supplementation but may require a chronic transfusion regimen. The fibrinolytic inhibitor tranexamic acid and estrogens have been used with some success. Owing to the widespread nature of the lesions, surgery is not usually a feasible treatment option.[14]

Scurvy (vitamin C deficiency) is associated with purpura and widespread bleeding, particularly from mucosal surfaces and subperiostally. It is due to both abnormal collagen synthesis and a defect in platelet function but is rare in the Western world, except in association with malnutrition and alcoholism. Amyloidosis may be primary or complicate paraproteinaemias, collagen vascular disorders and chronic infection. The deposition of amyloid protein in the blood vessels leads to fragility and consequently purpura is common. Cases of a specific coagulation defect due to absorption of the coagulation factor X by the amyloid protein have occasionally been reported. Ehlers–Danlos syndrome, especially type IV with a deficiency of type III collagen, results in structural weakness of major blood vessels with a tendency to rupture and consequent severe haemorrhage. Henoch–Schönlein purpura is rare in the elderly, being primarily a condition of childhood. It is an anaphylactoid purpura with cutaneous petechia and urticaria, associated with joint swelling, abdominal colic and melena. Despite the purpura, which is usually a manifestation of severe thrombocytopenia, the platelet count remains normal in this condition. Precipitating drugs should be withdrawn; steroids give relief from the joint and abdominal symptoms.

Thrombotic disorders

Although arterial thrombosis is a major cause of morbidity and mortality, its prevention is not possible at present; likewise, its pathophysiology is not well characterized. Smoking, hyperlipidaemia and a raised fibrinogen concentration are associated with accelerated atheroma, which accounts for the majority of arterial disease (*see* **Chapter 43, Peripheral arterial disease**). In addition, atrial fibrillation (*see* **Chapter 36, Arrhythmias**) and valvular cardiac defects are associated with arterial embolization, but a full understanding of arterial thrombosis does not exist at present.[15]

The situation with venous thrombosis is somewhat different and there have been rapid advances in the understanding, diagnosis and management of venous thrombosis (*see* **Chapter 44, Venous thromboembolism**) over the last few years. Venous thrombosis is primarily a disease of old age; until recently, it was thought that in the majority of cases the cause was circumstantial, with predisposing factors being immobilization and surgery, particularly to the hip, knee and pelvis, together with accessory factors such as obesity and malignancy. It has become clear, however, that in up to 50% of cases of venous thrombosis, there is an additional underlying genetic predisposition to thrombosis that becomes manifest under the above circumstances. The importance of thromboembolic prophylaxis of both surgical and medical patients at medium and high risk of developing thrombosis is increasingly being recognized and practiced. Likewise, the need for objective diagnosis of venous thrombosis by ultrasound examination or venography in the lower limb, and ventilation–perfusion lung scanning and pulmonary angiography in cases of suspected pulmonary embolus, has become established. Objective validation of the diagnosis of venous thromboembolic disease should always precede the initiation of treatment. Treatment should initially be with heparin, either unfractionated or low molecular weight heparin, and subsequently with oral warfarin. Warfarin in the elderly is not without hazards, there being an increased chance of drug interactions and in general the dose required in elderly patients is somewhat lower than in younger patients. Furthermore, the risk of bleeding is increased both at high INRs and also at normal INRs because of the increased incidence of underlying pathology, such as peptic ulcer, gastrointestinal malignancy and angiodysplasia. Consequently, it is important that recommended target ranges and duration of anticoagulation are adhered to and patients are not anticoagulated without good cause (Table 29.5).[16]

Thrombophilia

The proteins of the natural anticoagulant pathway act to limit and regulate thrombin generation. Deficiency of these proteins results in increased thrombin generation and consequently increased fibrin formation and venous thrombosis (Table 29.6). Deficiencies of antithrombin, protein C and protein S are rare but significant conditions do exist. They are autosomally dominantly inherited and only occur in the heterozygous form, the homozygous form being incompatible with life. These conditions usually present with venous thrombosis, which may be unusually widespread or occur at an unusual site, sometimes occurring spontaneously but often following a recognized predisposing factor. They may

Table 29.5 INR ranges in various conditions.

Antiphospholipid syndrome (lupus anticoagulant)

be recurrent and there is often a positive family history of venous thrombosis. Although patients may well present at a younger age, they can be diagnosed at any age and certainly second or recurrent episodes of thrombosis will occur in old age. The diagnosis of these conditions can be somewhat problematic as the concentrations of all these proteins fall during active thrombosis, and antithrombin levels fall during heparin therapy, while protein C and S levels fall during warfarin therapy.

Consequently, patients should ideally be investigated when they have neither active thrombosis nor are on anticoagulants. The finding of a deficiency state should lead to family screening as other family members are at risk. In the absence of a first episode of thrombosis, management should consist of adequate thromboprophylaxis at times of increased risk, such as surgery and immobilization. After a first episode of thrombosis, reasonable management is to anticoagulate for 3–6 months with warfarin with a target range of 2–3; after recurrent thrombosis, lifelong anticoagulation should be considered, initially with a target range of 2–3 but increasing this to 3–4 should further episodes of thrombosis occur while patients are already anticoagulated.[17]

A new thrombophilic defect of resistance to activated protein C (APCR) has recently been described. APCR is part of the natural anticoagulant pathway and usually acts to degrade activated factors V and VIII, thereby causing feedback inhibition of the coagulation cascade (Figure 29.2). Patients with APCR do not show the expected prolongation of the APTT following the addition of exogenous APCR and consequently have a low-activated protein C ratio. It has been shown that the basis of this defect is a single base substitution at position 1691 of the factor V heavy chain, resulting in a substitution of the amino acid glutamine for an arginine residue. This abolishes an APCR cleavage site and results in a factor V molecule that can be activated by thrombin but can no longer be inactivated by APCR; consequently, there is enhanced and prolonged activation of the coagulation cascade, increased thrombin generation and hence a predisposition to thrombosis. This condition can therefore be diagnosed both by a plasma assay and by genetic analysis of the factor V gene. The condition is autosomally dominantly inherited and is extremely common, occurring at an incidence of between 2 and 10% in the Caucasian population, although it appears to be rare or absent in non-Caucasian populations. Unlike the other thrombophilic conditions, individuals with both heterozygous and homozygous forms of this condition exist and the lifelong incidence of thrombosis appears to be somewhat less than antithrombin, protein C and S deficiency. Indeed, a significant proportion of patients with this condition may never have a thrombotic event. The frequency with which

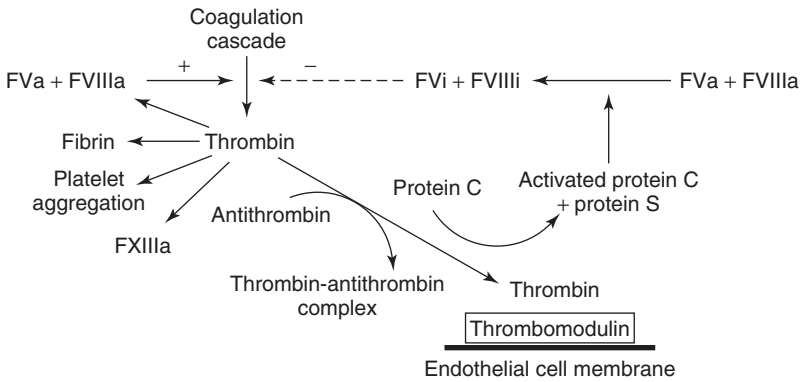

Figure 29.2 The natural anticoagulant pathway directly inhibits and negatively regulates the formation of thrombin by the coagulation cascade.

it occurs within the Caucasian population suggests that in evolutionary terms it must have some, as yet obscure, evolutionary advantage, but with life expectancy increasing and surgery becoming more frequent nowadays, it is clear that this condition is a major predisposing factor contributing to venous thrombosis. Indeed, between 40 and 60% of patients having a first episode of thrombosis have this condition, a 12-fold increase over the incidence within the background population. Although still not fully validated, management should parallel the management of other hereditary thrombophilic conditions.[18]

Lupus anticoagulant

The lupus anticoagulant is a laboratory diagnosis based on the finding of a prolonged APTT that is not due to a deficiency of a specific coagulation factor or a specific inhibitor of any coagulation factor, but to an autoantibody apparently directed against phospholipids, but in reality directed primarily against proteins that are intimately associated with phospholipids. Since the reactions of the coagulation cascade are phospholipid dependent, these antiphospholipid antibodies decrease the efficiency of the coagulation cascade and prolong the clotting time. The diagnosis can be confirmed using the dilute Russell viper venom test (DRVVT), in which the test is optimized so that phospholipid availability is rate limiting and this accentuates the effect of antiphospholipid antibody. Confirmation is achieved by showing that the clotting time returns to normal when excess phospholipid (in the form of freeze-fractured platelets) is added to quench the antibodies and that the test is not corrected by the addition of normal plasma that contains only additional coagulation factors.

The name lupus anticoagulant is somewhat unfortunate. The lupus refers to systemic lupus erythematosus (SLE) and it was in patients with this condition that the phenomenon was first observed. However, it has subsequently become clear that the majority of patients do not have SLE. Likewise, although it appears to be anticoagulant *in vitro* by prolonging the activated partial thromboplastin time (APTT), *in vivo* some lupus anticoagulants are associated with an acquired predisposition to thrombosis and bleeding does not occur. Consequently, the finding of a lupus anticoagulant may be an indication for thromboprophylaxis or even anticoagulation.

The significance of the finding of a lupus anticoagulant can be very variable. Transiently positive tests frequently occur after infections and many drugs can precipitate these antibodies, as can chronic infection such as syphilis. In these circumstances, the antibody does not appear to be associated with an increased incidence of either arterial or venous thrombosis. In patients with an underlying collagen vascular disease or in whom a primary antiphospholipid syndrome is diagnosed, there is an association between the finding of a positive test and recurrent arterial or venous thrombosis. The primary antiphospholipid syndrome consists of a positive lupus anticoagulant test and an association with livedo reticularis, thrombocytopenia and recurrent miscarriages in females. The lupus anticoagulant can precipitate both arterial and venous thrombosis and, within an individual, the site of second and subsequent thrombosis tends to occur in the same system; these patients may require long-term anticoagulation. There is no evidence that the antibodies causing the prolongation of the APTT *in vitro* are those that cause thrombosis; indeed, they may be an epiphenomenon, as a wide range of autoantibodies are found in these conditions, including antibodies against cardiolipin, which can be IgG or IgM, and are detected by a solid-phase enzyme-linked immunosorbent assay (ELISA).[19]

Key points

- Bleeding can be due to disorders of the coagulation cascade, platelets or blood vessels.
- Bleeding disorders can be congenital or acquired, the latter being more common.
- Drugs are a common cause of bleeding disorders.
- Thrombin disorders, both arterial and venous, are common in the elderly.
- Recurrent, severe or unusual episodes of venous thrombosis suggest thrombophilia.

CHAPTER 30

Disseminated intravascular coagulation

Kingsley K. Hampton
Royal Hallamshire Hospital, Sheffield, UK

Introduction

Disseminated intravascular coagulation (DIC) is a failure of haemostatic homeostasis (Figure 30.1). The haemostatic system comprises five components: the coagulation cascade, the fibrinolytic cascade, platelets, the natural anticoagulant pathway and vascular endothelial cells. It is a complex system which normally maintains blood fluidity when blood is confined within the intravascular vessels, but is able to trigger rapid and localized coagulation if vascular integrity is breached. The intravascular space usually contains no exposed tissue factor but all cells outside the vascular system express tissue factor in their cell membranes which initiates coagulation through the extrinsic pathway. In DIC there is unregulated and uncontrolled activation of the coagulation cascade and platelets resulting in blockage of the microvascular system of critical organs. Simultaneously, there is activation of the fibrinolytic cascade generating plasmin and consequently fibrin and fibrinogen degradation, together with depletion of components of the natural anticoagulant pathway which contribute to the systemic bleeding diathesis.[1,2] Hence the paradox of DIC is that the clinical manifestations are of bleeding while the patient suffers serious morbidity and mortality due to organ damage due to microvascular thrombosis. DIC usually has an acute onset with bleeding manifestations dominating the clinical picture; however, a chronic form can occur, the manifestations of which are very different, usually with presentation as thrombosis, and the management of this form of condition likewise differs.

Pathophysiology

DIC is a pathophysiological syndrome characterized by clinical manifestations of generalized bleeding together with laboratory features of severe coagulopathy. It is not a discrete pathological entity but a final common pathway for a variety of triggers and precipitating factors and can be initiated by a number of different mechanisms (Table 30.1). DIC is characterized by great variation both between patients and within the same patient over time. It is a dynamic condition that will progress if untreated but can rapidly improve if appropriate treatment of the underlying cause and support haemostatic factors is given. Consequently, it has been difficult to perform adequate randomized controlled trials in the management and treatment of DIC, although there have been several recent advances in its early diagnosis and treatment.[3]

The primary triggers of DIC in the elderly are sepsis and malignancy, particularly disseminated malignancy. Other causes include massive trauma and major surgery, and ABO-incompatible blood transfusions and snake bites are rarer but recognized causes. DIC may be precipitated by activation of the coagulation cascade following tissue factor exposure, for example, as in massive trauma and major surgery; activation of the fibrinolytic cascade, for example, the liberation of plasminogen activators by leukaemic blasts in acute promyelocytic leukaemia or carcinoma of the prostrate; intravascular platelet activation, for example, heparin-induced thrombocytopenia; and by endotoxins in Gram-negative sepsis and meningococcal septicaemia or by direct proteolytic cleavage of circulating haemostatic proteins, as occurs in pancreatitis and with some snake venoms (Table 30.1). In addition to uncontrolled activation of the platelets and the coagulation cascade, there is depletion of the proteins of the natural anticoagulant pathway. Depletion of these further enhances the microvascular thrombosis and also leads to activation of the complement system, resulting in an inflammatory response and generation of vasoactive peptides, such as bradykinin. DIC also provokes a poorly characterized neuroendocrine response involving elevated catecholamines and glucocorticoids.[4]

Clinically, DIC manifests as simultaneous bleeding and microvascular thrombosis leading to multiple organ dysfunction including renal failure and adult respiratory distress syndrome (ARDS) and is often associated with fever, hypotension, acidosis, hypoxia and proteinuria. While bleeding is the most obvious and commonly

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

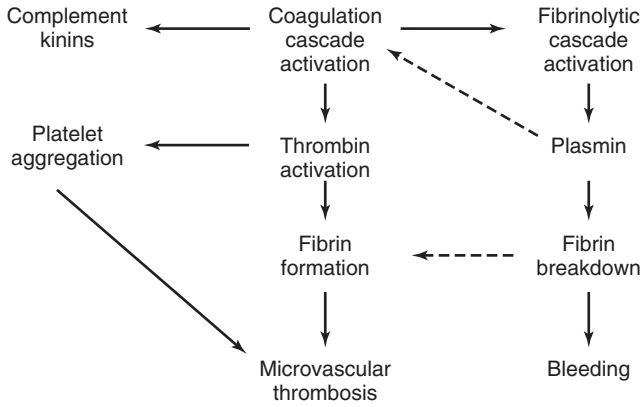

Figure 30.1 Mechanism of microvascular thrombosis and bleeding in DIC. Broken lines indicate inhibition.

Table 30.1 Mechanisms and precipitating factors in DIC.

Mechanism	Example
Coagulation cascade activation	Tissue factor exposure in trauma and extensive surgery
Fibrinolytic cascade activation	Plasminogen activators liberated in acute promyelocytic leukaemia
Intravascular platelet aggregation	Haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura
Endothelial cell activation	Gram-negative sepsis, malignancy
Direct proteolytic cleavage of haemostatic proteins	Pancreatitis, snake venoms

recognized manifestation, death by exsanguinations is rare due to the appropriate use of blood and platelet transfusions. The usual cause of death in DIC is multiorgan failure as a consequence of the microvascular thrombosis, which is not so clinically obvious. Treatment of multiorgan failure, which is a consequence of anoxia and ischaemic necrosis of vital organs, is far more difficult to treat satisfactorily.[5]

The bleeding in DIC is multifactorial in origin as a result of depletion of fibrinogen and all coagulation factors as a consequence of consumption due to uncontrolled and excessive activation of the coagulation cascade, diminished platelet number due to consumption and an additional or acquired platelet defect consequent to a proteolytic degradation of platelet surface glycoproteins and partial degranulation of α and dense platelet granules. Hyperfibrinolysis leads to elevated levels of fibrin and fibrinogen degradation products (FDP and D-dimers) which act as competitive inhibitors of fibrin polymerization. The uncontrolled generation of free thrombin and plasmin degrades fibrin, fibrinogen and coagulation factors, particularly factors V and VIII. Consequently, there is a systemic bleeding diathesis resulting in bleeding not only from local surgical incisions or traumatic wounds, but also generalized bruising, petechiae and purpura, together with bleeding from sites of venepuncture, arterial lines, drains, catheters and endotrachial tubes. There is also frequent gastrointestinal bleeding, haemoptysis, haematuria and even intramuscular or intracerebral bleeding. Excessive bleeding from a single site, particularly following surgery, is usually more indicative of failure of local haemostasis than DIC and requires specific local measures. The microvascular thrombosis results in anoxic damage and ischaemic infarction of vital organs, including lungs, kidneys, brain, pituitary, liver, adrenal, heart and skin.[6]

Diagnosis

The diagnosis of DIC is made in the presence of a predisposing cause, the clinical manifestations of systemic bleeding and multiorgan dysfunction and from appropriate laboratory investigations (Table 30.2). The haemoglobin is usually reduced owing to intravascular red cell fragmentation resulting in a microangiopathic haemolytic anaemia (MAHA) and there is profound thrombocytopenia. Coagulation times are abnormal with a prolongation of the activated partial thromboplastin time (APTT), prothrombin time (PT) and thrombin time (TT) and depletion of fibrinogen, all due to consumption. In addition, there is evidence of fibrinolytic activation and fibrin degradation with elevations of serum FDPs or plasma D-dimers. In addition to these rapid and readily available tests, recent studies have shown that waveform analysis of the coagulation profile on automated machines can have both diagnostic and prognostic significance and laboratory abnormalities can be included in a validated scoring system for DIC. In addition to consumption of the coagulation factors and prolongation of the clotting times, levels of natural anticoagulant pathway proteins, namely, antithrombin, protein C and protein S, are also significantly reduced, contributing to the microvascular thrombosis.[7]

As DIC is a dynamic condition, it is preferable to perform the simple clotting tests frequently, both before and

Table 30.2 Laboratory diagnosis of DIC.

Test	Result
APTT	Prolonged
PT	Prolonged
TT	Prolonged
Fibrinogen	Low, usually $<1\ g\ l^{-1}$
Platelets	Low, usually $<50 \times 10^9\ l^{-1}$
FDPs	Raised
D-dimer	Raised

after clinical interventions, to judge their efficacy and the need for further blood product replacement therapy or interventions. The role of thromboelastography (TEG) and endogenous thrombin potential in monitoring DIC remains to be clarified. These tests are invariably abnormal but whether they can be used to direct interventional therapy is as yet unclear.

Management

The first principle of management of DIC should be towards resuscitation of the patient to achieve adequate oxygenation, blood pressure, circulation and renal perfusion. Once resuscitation is complete, then aggressive treatment of the underlying precipitating cause of the DIC should be addressed. Most frequently this is sepsis and aggressive broad-spectrum antibiotic therapy following the taking of appropriate microbiological samples is necessary. A few causes of disseminated malignancy, such as acute promyelocytic leukaemia and hormone-responsive breast and prostatic carcinoma, may also be amenable to treatment but the prognosis in DIC secondary to disseminated malignancy is usually poor; indeed, mortality overall remains high at 25–75% in various series.

There is considerable controversy about the place of blood product support in DIC. Clearly, red cells and platelet support, together with plasma product support, is indicated in patients who are actively bleeding. In patients who are not actively bleeding or requiring surgical or other intervention, the use of transfused clotting factors and platelets serves only to make the microvascular thrombosis worse unless the underlying precipitating factors have been treated. However, once these issues have been addressed and if the patient is bleeding, it is appropriate to transfuse red cells to achieve a haemoglobin of above $10\,g\,l^{-1}$ or haematocrit above 30%, to transfuse platelets to achieve a platelet count of $>80 \times 10^9\ l^{-1}$ to transfuse FFP ($10–15\,ml\,kg^{-1}$) to correct the PT and APTT to no more than 10% prolonged above the upper limit of normal and to increase the fibrinogen to $>1\,g\,l^{-1}$ through the appropriate use of cryoprecipitate (cryoprecipitate is particularly rich in fibrinogen) or fibrinogen concentrate. Following blood product intervention, the clotting screen should be repeated to assess the response to therapy and the need for additional future therapy.

In DIC due to sepsis, there is now evidence that depletion of the natural anticoagulant pathway proteins, such as antithrombin, protein C and protein S, contribute not only to microvascular thrombosis but also to the systemic inflammatory response and to a poorer prognosis. Activated protein C concentrate is licensed for use in severe sepsis and there is evidence in meningococcal meningitis that supplementation of depleted protein C improves outcome and recombinant human activated protein C is now licensed for use in severe sepsis with beneficial effects on mortality. The use of antithrombin concentrates is widespread in countries other than the UK but their efficacy has not yet been proven in an appropriate prospective randomized trial.

The use of heparin is even more controversial.[8,9] There are no adequate controlled trials to support its use and although it would appear logical to use an anticoagulant in a condition where the major morbidity and mortality are due to thrombosis, the use of a systemic anticoagulant in patients either with active bleeding or at high risk of catastrophic bleeding is troublesome. Furthermore, there are considerable problems in determining the duration of treatment and monitoring of heparin therapy in the presence of severely prolonged clotting times, and as heparin works by potentiating the activity of antithrombin, which is usually severely depleted in DIC, its efficacy is uncertain. Fibrinolytic therapy with tranexamic acid is contraindicated in DIC, unless the trigger mechanism is hyperfibrinolysis and the use of aprotinin, prostacyclin and antiplatelet drugs remains controversial and unproven. There is evidence that human recombinant activated FVIIa may be useful in uncontrolled life-threatening haemorrhage, but it should be recognized that the product is not licensed for this indication and its use in systemic bleeding disorders outside of haemophilia and platelet disorders is associated with a significant increase in arterial thrombotic events, particularly heart attacks and cerebrovascular accidents.

Chronic disseminated intravascular coagulation

Chronic DIC manifests very differently from acute DIC. The cause is usually, but not exclusively, disseminated malignancy, which may be manifest but may often remain occult for weeks or months after the initial presentation. Patients usually present with bruising from thrombocytopenia and on further investigation are found to have, in addition to thrombocytopenia, hypofibrinogenaemia and elevated FDPs or D-dimers. Bleeding is a rare manifestation of this condition, although bruising is common, while thrombosis in the form of superficial thrombophlebitis and deep venous thrombosis is common. Furthermore, a sterile nonbacterial endocarditis is well recognized, which can result in presentation with arterial embolization.[10]

Thus, the hallmarks of this condition are arterial and venous thrombosis rather than bleeding. The condition will usually resolve if the underlying cause can be successfully treated. If it cannot, the cautious application of anticoagulation rather than blood product support is the mainstay of treatment. Warfarin is notoriously difficult to use in this condition and low molecular weight heparin is the treatment of choice, in terms of both efficacy and improving overall outcome.

Key points

- DIC presents with haemorrhage, but it is the microvascular thrombosis that causes the multi-organ damage.
- DIC is commonly due to sepsis or disseminated malignancy.
- Diagnosis requires a blood count and a clotting screen.
- Treatment should address the underlying cause first, especially if sepsis, and only then may blood product support be indicated.
- Chronic DIC presents with thrombosis, rather than haemorrhage.

CHAPTER 31

Anticoagulants

Hamsaraj G.M. Shetty[1] and Philip A. Routledge[2]

[1]University Hospital of Wales, Cardiff, Wales, UK
[2]Cardiff University School of Medicine, Cardiff, Wales, UK

Introduction

Thromboembolism in the arterial and venous circulation is more frequent with increasing age. The elderly are also more likely to have conditions such as colonic neoplasms and peptic ulcers that make them more susceptible to bleeding with anticoagulant therapy. Because of age-related changes in cardiovascular and renal homeostasis and concomitant (often multiple) medical problems, they do not tolerate haemorrhage well. They are more sensitive to anticoagulants such as warfarin. It is also likely that chronological age itself is associated with increased risk of anticoagulant-associated bleeding. This chapter will discuss the benefits/risks and methods to optimize anticoagulant therapy in the elderly.

The elderly are more prone to thromboembolism

The elderly are more prone to arterial as well as venous thromboembolism, and thrombotic disease is the commonest cause of hospital admission, disability and death in patients over 50 years of age in the developed world.

The incidence of deep vein thrombosis (DVT) and pulmonary embolism (PE) and thus venous thromboembolism (VTE) increases with increasing age. Between 65 and 69 years of age, annual incidence rates per 1000 for DVT and PE are 1.3 and 1.8 respectively, and rise progressively to 2.8 and 3.1 in individuals aged between 85 and 89 years. PE is more likely to occur in older men than women of similar age. About 1.7% of older people develop PE and 8% develop recurrent PE within one year of treatment for DVT.[1] The diagnosis of PE is often missed in elderly people and it is more often diagnosed only after death.[2]

The elderly are particularly likely to have concomitant conditions that substantially increase the risk of VTE. Thus the incidence of hip fracture increases from 116 (women) and 0 (men) per 100 000 person-years in the 60–64 year age group to 2597 (women) and 1187 (men) per 100 000 person-years in the 85+ year age group. The elderly are about eight times more likely to develop VTE in hospitals, nursing homes or other chronic care facilities. About 3% of patients with DVT and 21% of those with PE die in hospital. One-year mortality associated with DVT is 21% and that with PE is 39%. Elderly patients are more likely to have a new DVT at the time of admission to hospital with an acute non-surgical illness.[3,4]

As a result of the factors described above, the effective prevention of this common and life-threatening condition could produce major benefits. In 2005, the UK House of Commons reported that more than 25 000 patients in England died every year from VTE acquired in hospital; which is more than the combined annual total of deaths from breast cancer, AIDS and traffic accidents, and more than twenty-five times the number who die from MRSA each year.[5]

In the arterial circulation, the risk of thrombosis and embolism also increases with increasing age. Thus, thrombotic and embolic strokes are more frequent with increasing age. One reason for this is that non-valvular atrial fibrillation (AF) is much more common in the elderly and is associated with a fivefold increased risk of stroke.[6] The prevalence of AF rises from 0.5% in the fifth decade of life to 8.8% in the eighth.[6] Such individuals who do have an acute stroke are two- to threefold more likely to die than those with acute stroke who are in sinus rhythm.[7] The association with age is sufficiently important that the three commonly applied risk algorithms used to consider the risk–benefit of antithrombotic therapy in AF (CHADS2, NICE and ACCOP) all incorporate age >75 years into the risk calculation.[8]

Over 100 years ago, Virchow identified three main factors for development of thrombosis. The first was reduction in blood flow, which may be a factor in heart failure, a condition seen more frequently in the elderly. The second factor was changes in the vessel wall, which occurs with

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

atherosclerosis and therefore with increasing age. Finally, changes in blood coagulability were cited by Virchow. Increases in clotting factor concentration, in platelet and clotting factor activation and a decline in fibrinolytic activity are all seen in the elderly.[9]

Anticoagulant response differs in the elderly

Several studies have confirmed the original findings of Eccles that oral anticoagulant requirements decline with age.[10] In one study, Routledge and co-workers showed that warfarin requirements fell with increasing age so that patients aged less than 35 required a mean of 8.1 mg per day, more than twice as much to maintain the same international normalized ratio (INR) as in patients aged 75 years or over. The relationship between age and warfarin requirements was rather weak, however, indicating that other factors may be more important in determining warfarin dose than chronological age itself.[11] These findings have been confirmed in a retrospective longitudinal study in 104 patients aged between 31 and 74 years when warfarin was started and followed for a median of 10 years. This suggests that the decline in dose is not related to a birth cohort effect but does occur in individuals as they grow older.[12] The average decline in dose (1.4% per year) in the study was very similar to the rate of decline observed in the much larger cross-sectional study discussed earlier.[11]

A similar reduced dose requirement in the elderly has also been reported with other coumarin anticoagulants such as acenocoumarol, bishydroxycoumarin and phenprocoumon. The reason for the increased sensitivity to oral anticoagulants is still not fully known, although most studies indicate a pharmacodynamic sensitivity rather than any major change in the pharmacokinetics of warfarin.[13,14] However, one study has reported an age-related decline in warfarin clearance.[15]

Increased age was also associated with an increased risk of haemorrhage in patients receiving unfractionated heparin (UFH) therapy intravenously with age greater than 70 years being associated with a significant increased risk of major bleeding.[16] It is not known what contribution pharmacokinetic and pharmacodynamic differences make to this increased risk. Low molecular weight heparins (LMWHs) are predominantly eliminated by renal excretion, which on average declines with increasing age. Age appears to be one factor predicting the occurrence and severity of bleeding or major bruising events in association with the widely used LMWH, enoxaparin, when given in therapeutic doses for the treatment of thromboembolic disease.[17] However, the manufacturers state that no dosage adjustments are necessary in the elderly unless kidney function is impaired.

Two new oral antithrombotic agents, dabigatran etexilate (an orally active inhibitor of both free and clot-bound thrombin) and rivaroxaban (an orally active inhibitor of both the 'free' and prothrombinase complex-bound forms of activated factor X) have received marketing authorization in Europe for the prevention of thromboembolic events following major orthopaedic surgery (e.g. total hip and knee replacement). Both are cleared in significant part by renal elimination (around 80% and 65% respectively), and as stated earlier, renal function does decline overall in the elderly. The manufacturers of dabigatran (but not rivaroxaban) recommend a reduced dose in patients aged over 75 years.[18]

The elderly are more prone to haemorrhage

The elderly are more prone to develop haemorrhage, even when not receiving anticoagulants. Life-threatening haemorrhage is most likely to occur in the gastrointestinal tract or intracranially. Although duodenal ulcer is more common at younger ages, gastric ulcer and gastrointestinal bleeding due to non-steroidal anti-inflammatory drugs (NSAIDs) are both more common with increasing age. In addition, the mortality from gastrointestinal bleeding is higher in the elderly. Intracranial bleeding (intracerebral and subdural) in the absence of anticoagulant therapy is also more frequent in the elderly.

Schulman has comprehensively summarized the increasing body of evidence indicating that age is an independent risk factor for major bleeding in patients receiving oral anticoagulant therapy with an average twofold increase in major bleeding among the elderly.[19]

Increased age also appears to be a risk factor specifically for intracranial haemorrhage. A case-control study compared 170 patients (median age, 78 years) with non-valvular AF who developed intracranial bleeding while on warfarin with 1020 matched controls (median age, 75 years) who were also receiving warfarin for non-valvular AF but did not develop intracranial bleeding.[20] The risk of intracranial bleeding was found to be increased in patients aged 85 years or over (adjusted odds ratio, 2.5; 95% CI, 1.3–4.7) and at INRs between 3.5 and 3.9 (adjusted odds ratio, 4.6; 95% CI, 2.3–9.4).The odds ratio for intracranial bleeding increased to 8.8 (95% CI, 4.6–17) at INRs greater than 4 but INRs less than 2 were not associated with a decreased risk (adjusted odds ratio, 1.3; 95% CI, 0.8–2.2). The incidence of bleeding in the elderly has been shown to be higher in the first 90 days of anticoagulation both due to poor control of anticoagulation and unmasking of an occult lesion.[21,22]

However, the incidence of intracranial bleeding in patients receiving oral anticoagulant therapy is still very low. Meta-analysis of six AF trials of warfarin versus placebo, involving 2900 patients, showed an intracranial

bleeding rate of 0.3% per year during anticoagulation and 0.1% per year in association with placebo.[23] Intracerebral haematomas account for 70% of intracranial bleeds associated with anticoagulation and are associated with a mortality rate of up to 60%. Most of the remaining episodes are subdural haematomas, which are less often fatal. The elderly are more likely to have cerebrovascular disease, leukoaraiosis and cerebral amyloid angiopathy which increase the risk of intracerebral bleeding. Poor mobility may predispose the elderly for recurrent falls that may increase the risk of both subdural and intracerebral bleeding.

The elderly are more likely to be on multiple drugs that may interact with warfarin, increasing the risk of bleeding. Particular agents include NSAID drugs, including aspirin, which markedly increase the risk of gastrointestinal bleeding when co-administered with warfarin. The nearly 13-fold increase in the risk of developing haemorrhagic peptic ulcer disease in concurrent users of oral anticoagulants and NSAIDs aged over 65 years is much greater than the sum of the risks of the same problem with each of these groups of medication used separately. The use of antiplatelet drugs (e.g. aspirin or clopidogrel) also increases risk hospitalization for major bleeding among users of coumarins.[24]

An Outpatient Bleeding Risk Index has been shown to be successful in classifying patients into low-, intermediate- and high-risk groups.[25] The index included four risk factors for major bleeding (attracting 1 point each in the index): age over 65 years, history of gastrointestinal bleeding, history of stroke, and one or more specific comorbid conditions (recent myocardial infarction, haematocrit of less than 30%, presence of diabetes mellitus and serum creatinine of greater than 1.5 mg dl^{-1}). A score of zero indicated low risk, 1–2 was classified as medium risk and a score of 3–4 was suggested to indicate high risk (23% in 3 months and 48% in 12 months). Although this may be a potentially useful tool in some circumstances, it automatically places all people aged over 65 years in the medium-risk category, which we believe is not always the case. It is important to recognize that under-usage of anticoagulants should not be encouraged in elderly patients, since treatment has been shown to be highly effective in this group (see below).

Anticoagulants are effective in the elderly

Heparin and warfarin are as effective in elderly patients as they are in younger ones in the treatment of venous thromboembolism. A fixed oral dose of dabigatran (150 mg bid) in patients with acute VTE (age range 18–93 years, median 56 years), has been shown to have similar efficacy and safety as warfarin.[26]

Six studies of oral anticoagulation for the prevention of thromboembolic events in patients with non-valvular AF, have shown a reduction in events in patients over a wide age-range.[23] Adjusted-dose warfarin reduced stroke by 62% (95% CI, 48–72%). The absolute risk reduction for primary prevention was 2.7% per year and 8.4% per year for secondary prevention. The Danish AFASAK Study included subjects with AF who were aged between 38 and 91 years, in whom anticoagulant therapy reduced the relative risk of stroke by 54%.The Boston Area Anticoagulation Trial showed an 86% reduction in stroke in an elderly population (mean age 68 years). A mixed retrospective and prospective cohort study of 13 559 adults with non-valvular atrial fibrillation has reported that adjusted net clinical benefit of warfarin therapy was greatest for patients who were over 85 years of age (2.34% per year; 95% CI, 1.29–3.30%).[27]

More recently, the Birmingham Atrial Fibrillation Treatment of the Aged Study (BAFTA) assigned 973 patients aged 75 years or over (mean age 81.5 years, SD 4.2) with AF randomly to warfarin (target INR 2–3) or aspirin (75 mg per day). There were 24 primary events (21 strokes, two other intracranial haemorrhages, and one systemic embolus) in people assigned to warfarin and 48 primary events (44 strokes, one other intracranial haemorrhage, and three systemic emboli) in individuals assigned to aspirin. This supports the view that the benefits of warfarin over aspirin therapy remain in the elderly and were not offset by an increased risk of intracranial haemorrhage.[28]

One study in patients with AF (mean age 71 years) has shown dabigatran at a dose of 110 mg to be associated with similar rates of stroke and systemic embolism, lower rates of major haemorrhage and at a dose of 150 mg, to be associated with lower rates of stroke and systemic embolism but similar rates of major haemorrhage as compared with warfarin.[29]

The risk–benefit equation: how to optimize it in the elderly

The most important factors associated with risk of bleeding while on anticoagulants are: (a) degree of anticoagulation; (b) the presence of potential bleeding site; and (c) duration of anticoagulant therapy.

Degree of anticoagulation

As discussed previously, several studies have reported a curvilinear relationship between the degree of anticoagulation and the risk of bleeding (Figure 31.1).[30] Thus the bleeding risk rises threefold between INRs 2 and 3 and a further three fold between 3 and 4.[21] Since a high INR is one of the most important factors determining the bleeding risk, dwarfing any possible age-related effects, it is essential that the lowest effective intensity of anticoagulation is maintained in the elderly.

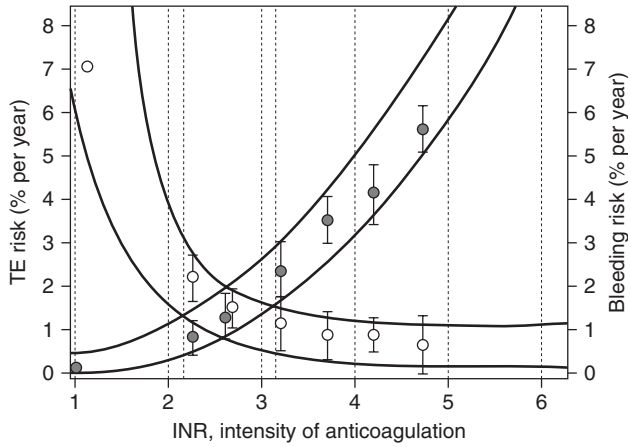

Figure 31.1 Relationship between intensity of anticoagulation and risk of thromboembolism (TE) and bleeding in 1865 patients receiving oral anticoagulants after insertion of St Jude prosthetic heart valves. The single open circle represents 12 patients who received only antiplatelet agents because of contraindications to warfarin therapy. INR = international normalization ratio. Reproduced from Horstkotte *et al.*[30] by permission of *The Journal of Heart Valve Disease*.

Figure 31.2 Severe bleeding into the breasts of a 70-year-old lady receiving warfarin after insertion of a prosthetic heart valve. More than 500 ml of blood was drained from the left breast and she was eventually controlled carefully between an INR of 2.5 and 3.0 without recurrence of bleeding.

In major studies of primary stroke prevention in non-valvular AF, target INRs ranged from 1.5 to 4.5. There was no evidence that the most intensive anticoagulation reduced stroke risk more and it may well have increased bleeding risk. The higher intensities of anticoagulation used in the past may well have contributed to the reports of higher incidence of anticoagulation-related bleeding. The recommended ranges of anticoagulation for many indications have fallen over the recent years and this should improve the safety of anticoagulant therapy. A target INR of 2.5 is therefore recommended for treatment of venous thromboembolism, primary and secondary stroke prevention in individuals with non-valvular AF.[31] A higher intensity of anticoagulation may be needed under specific circumstances, such as prevention of thromboembolism in those with prosthetic heart valves, or those with recurrent thromboembolism.

Presence of potential bleeding site

When bleeding occurs, it is usually from a pathological site, often in the bladder or bowel, or from an abnormal intracranial blood vessel. Even in apparently spontaneous bleeding, for example into the skin, this may be related to the atrophic changes that occur with increasing age (Figure 31.2). As has been mentioned earlier, some episodes of haemorrhage may result in the discovery of potentially remediable (including malignant) lesions at an earlier stage than would otherwise have occurred. Certainly *all* patients who bleed should be investigated for underlying pathology, even if the bleeding episode occurred when the INR was excessive. Clinicians should also consider the possibility of occult bleeding in any patient with unexplained symptoms or signs while receiving warfarin. Alveolar haemorrhage may present with unexplained anaemia or dyspnoea, for example. Other presentations that may pose diagnostic difficulties include retroperitoneal haemorrhage, rectus sheath haematoma and spontaneous intramural intestinal haematoma (which may present as small intestinal obstruction).

Duration of anticoagulant therapy

Many elderly patients are prescribed warfarin for stroke prevention in non-valvular AF or to prevent thromboembolism from a prosthetic heart valve. Both these situations require long-term anticoagulation. A duration of three months is recommended for treatment of first episode of unprovoked (idiopathic) DVT and PE.[31] Long-term anticoagulation is recommended in patients with recurrent DVT or PE. The decision about the duration of anticoagulation in a given patient will be dictated by the specific clinical circumstances in that particular individual.

The risk of bleeding continues as long as an individual is on anticoagulant therapy. As discussed earlier, the risk of bleeding is higher during the initial weeks and months of anticoagulation. One study, which included 712 patients with venous thromboembolism, found that the overall risk of serious haemorrhage was six per 1000 patient-months; all but nine such episodes occurred in the first month and none in the next two months.[32] This early occurrence of a significant proportion of major haemorrhage is supported by other studies.[21,22] Therefore, older patients need closer monitoring during the first month of anticoagulation.

Perhaps the most difficult time is during initiation of anticoagulants. Because of their sensitivity to warfarin,

the elderly may be excessively anticoagulated at this time, particularly if standard rather than tailored induction doses are used. The original tailored regimen[33] used a first dose of 10 mg, adjusted thereafter according to the INR, which was measured daily. Siguret and colleagues have since devised a regimen for patients aged over 70 years.[34] This involved giving 4 mg daily for three successive days and was shown to be safe and accurate in elderly hospitalized patients.

Conclusions

Anticoagulants are now widely used in elderly patients. The view that they are lethal drugs in the elderly has been shown to be unjustified.[35] The introduction of INR, downward revision of therapeutic ranges and the production of guidelines for initiation and maintenance therapy have helped to improve the risk–benefit equation positively.[33] The use of computer-assisted anticoagulation and near-patient INR testing have improved monitoring of anticoagulation even further. Newer oral anticoagulants such as dabigatran and rivaroxaban appear to be similar to warfarin in terms of efficacy and safety. Other oral anticoagulants are currently under investigation.

Education of patients and carers on important aspects of anticoagulant therapy is likely to improve the control of anticoagulation and compliance. A small study of compliance (adherence or concordance) found no decline in compliance in elderly ambulant patients.[36] A combined retrospective and prospective cohort study, which included 323 patients aged over 80 years on oral anticoagulant therapy, found that the rate of major bleeding was 2.4 events per 1000 patient-months.[37] This study found no association between an increased rate of bleeding and socioeconomic, cognitive variables or functional impairments. However, insufficient education in anticoagulant therapy as perceived by the patient or caregiver [odds ratio (OR), 8.83], polypharmacy (OR, 6.14), and INR values above the therapeutic range (OR, 1.08) were found to be significant predictive factors for bleeding complications.

A careful analysis of risk versus benefit in every patient before commencing anticoagulant therapy is likely to minimize the incidence of serious complications. Most importantly, careful monitoring to maintain the lowest effective INR, avoid dangerous drug interactions, and to detect and manage haemorrhagic complications promptly will further enhance the benefits of anticoagulants in the elderly.

Key points

- The elderly are more prone to venous and arterial thromboembolism.
- Ageing is associated with increased sensitivity to anticoagulants.
- Intracranial haemorrhage is more likely to occur in individuals aged 75 years or over.
- The risk of all haemorrhage is greatest in the first month after commencement of anticoagulation, but persists throughout the course of treatment.
- The risk of all haemorrhage increases disproportionately with increasing intensity of anticoagulation.
- Nevertheless, when they are used appropriately, anticoagulants are highly effective drugs in the elderly.

CHAPTER 32

Myelodysplasia

Martha Wadleigh, David S. Rosenthal and Richard M. Stone
Harvard Medical School, Boston, MA, USA

Introduction

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal stem cell disorders characterized by dysplasia, ineffective haematopoiesis and potential risk of transformation into acute leukaemia.[1,2] These disorders are sporadic and arise *de novo* or may result following toxin, radiation and chemotherapy exposure (secondary MDS).[3,4] MDS primarily affects older patients, with an increased incidence with advancing age.[5,6] Disease onset prior to the sixth decade is uncommon, although not unheard of, especially with treatment-related or secondary MDS. As the demographics in developed countries shift towards older patient populations due to increased longevity and better quality of healthcare and more people are receiving intensive chemotherapy, the prevalence of MDS will likely increase.

MDS may easily be overlooked in elderly patients. It can present simply as a chronic macrocytic anaemia and there may be a tendency to 'leave well enough alone' in an older patient with multiple comorbidities. However, our understanding of MDS continues to improve and better treatment strategies have been developed which can prolong life and also delay transformation to acute leukaemia. Therefore, it is important to evaluate carefully any cytopenia in older patients.

Epidemiology and clinical presentation

The exact incidence of *de novo* MDS remains unclear but appears to be greater than the incidence of acute myelogenous leukaemia (AML).[7] In a recent analysis of the SEER database from 2001 to 2004, the age-adjusted incidence rate was 3.3 per 100 000.[8] A sharp increase in the incidence of MDS was observed with age: for those aged 80 years and older the incidence was five times that of those aged 60–69 years (35.5 compared with 7.1 per 100 000).[8] The age-adjusted incidence of MDS is slightly higher among males than females. However, these are likely underestimations of the true incidence of this disease owing to the underdiagnosis of MDS in the past. The incidence rate appears to have increased from 3.3 per 100 000 per year in 2001 to 3.56 per 100 000 in 2004.[9] This increase is probably due in part to an increasing population of people over age 65 years, and also increased recognition and diagnosis of the disease by haematologists and oncologists with the development of more effective therapies.

There are several well-known risk factors for the development of MDS, including exposure to organic solvents, ionizing radiation and prior chemotherapy. The incidence of therapy-related myelodysplasia is also increasing. Therapy-related MDS can result from prior exposure to ionizing radiation or chemotherapy. Prior exposure to alkylating agents is associated with the highest risk of MDS and has very distinct cytogenetic abnormalities, such as loss of the long arm of chromosomes 5 and/or 7. The risk for developing therapy-related MDS or AML has been described in long-term survivors of cancers treated with semustine (methyl-CCNU). The actuarial risk is between 6 and 9% in patients treated for Hodgkin's disease and 17% in patients treated for multiple myeloma. The risk of developing MDS increases with the use of regional radiation therapy following treatment for common cancers such as breast cancer, small cell lung cancer and testicular cancer. Topoisomerase II inhibitors, such as epipodophyllotoxins and anthracyclines, have also been associated with therapy-related AML, but usually without an MDS prodrome, and commonly involve chromosomal abnormalities such as 11q23, 3q26 and 21q22.[10]

The clinical presentation of MDS is varied. Symptoms for the most part are non-specific and depend upon the number and severity of cytopenias present. The majority of patients with MDS have a macrocytic anaemia with or without additional cytopenias. Patients with anaemia may have profound symptoms of dyspnoea on exertion, fatigue, lethargy, malaise, dizziness and even angina.[11] Neutropenic patients may develop severe systemic infections and infection represents a primary cause of death

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

in many cases of MDS.[12] Increased infectious risk may be a result of neutrophil dysfunction secondary to impaired chemotaxis and/or microbial killing.[12,13] T-Cell function is thought to remain intact and therefore patients with MDS less commonly develop viral or mycobacterial infections in the absence of treatment with immunosuppressive agents.[12] Other symptoms may include easy bruising or bleeding, a common manifestation of thrombocytopenia and dysfunctional platelets.

The physical findings of MDS are likewise non-specific and usually reflect underlying cytopenias if present. Of note, patients with chronic myelomonocytic leukaemia (CMML) may have splenomegaly, an unusual finding in patients with other subtypes of MDS.

Diagnosis

Blood and bone marrow examination

MDS is diagnosed in patients with one or more cytopenias and depends upon the finding of dysplastic features within the bone marrow in one or more lineages. A peripheral blood smear is helpful in demonstrating a normocytic or a macrocytic anaemia, but alone is insufficient for diagnosis. In order to make the diagnosis, a bone marrow aspirate and biopsy are required. An aspirate is necessary to evaluate morphology, quantify the number of myeloblasts, and assess for cytogenetic abnormalities. A core bone marrow biopsy is used to assess the bone marrow cellularity, which is typically hypercellular and indicative of ineffective haematopoiesis in the setting of peripheral cytopenias.

The morphological features of red cell precursors in the bone marrow aspirate include megaloblastic (asynchronous maturation of the nucleus and cytoplasm) or binucleate or multinucleated cells. Ring sideroblasts may also be identified. These are red cell precursors with iron-laden mitochondria and are defined by the presence of five or more Prussian Blue-staining iron granules encircling more than one-third of the nucleus in more that 15% of the erythroblasts. Erythroid hyperplasia may also be prominent and is associated with ineffective erythropoiesis (a hallmark of MDS).

Abnormalities in the myeloid series can include a left shift with a predominance of immature myeloid cells, hypogranulation and hypolobulation of the nucleus in mature granulocytes. A classic finding is the presence of pseudo-Pelger–Huet cells, which are granulocytes with a bilobed nucleus in a *pince-nez* configuration. A typical feature in the bone marrow of MDS patients is the presence of >5% myeloblasts. The proportion of myeloblasts has both diagnostic and prognostic information (see below) and is important in differentiating AML from MDS.

The megakaryocytes may likewise be dysplastic and may have not only a quantitative but also a qualitative defect. Examination of the peripheral smear may reveal giant or agranular platelets. In the bone marrow, the megakaryocytes may be small and hypolobulated.

Dysplasia in the bone marrow is not sufficient to establish the diagnosis of myelodysplasia. Deficiencies of vitamin B_{12} and folate, hypothyroidism, viral infections such as Epstein–Barr and the human immunodeficiency virus and exposure to antibiotics and other chemicals such as ethanol, chemotherapy and benzene can result in dysplasia. These other causes must be ruled out systematically by a careful history and physical and laboratory examination.

Cytogenetics

A critical component of the bone marrow aspiration is the cytogenetic examination of the bone marrow, which not only may help to establish the diagnosis, but also yields important prognostic information (see below). Roughly 60% of patients with MDS have a normal karyotype, but the presence of a common cytogenetic abnormality may establish the diagnosis in difficult cases.[14] In addition, new cytogenetic abnormalities may document an evolution to a more clinically aggressive state (i.e. transformation to acute leukaemia). The sensitivity of cytogenetic analysis has been greatly increased by the utilization of fluorescent *in situ* hybridization (FISH), which uses specific DNA probes to identify rapidly individual chromosomes in hundreds of cells and does not depend upon cell division. The drawback of this approach is that the analysis is restricted to already known and well-established cytogenetic abnormalities.

One series found that cytogenetic abnormalities were more common in the advanced stages of MDS compared with the less advanced MDS subtypes.[15] The more common abnormalities are trisomy 8 and deletions of the long arms of chromosomes 5, 7, 11, 13 and 20. Complex karyotypes, defined as three or more cytogenetic abnormalities, are found in 15% of cases and confer a poor prognosis. [15,16] A sole abnormality involving deletion of 5q is seen commonly in patients with refractory anaemia and represents a distinct clinical syndrome, the '5q syndrome'. This syndrome, seen most often in elderly women, is characterized by a prolonged clinical course, which does not typically progress to acute leukaemia. The anaemia is typically profound, but neutropenia is usually mild and platelets are typically elevated. It must be understood that a normal karyotype does not exclude the diagnosis of MDS and is seen in approximately half of the cases of MDS.

Therapy-related MDS is also associated with specific chromosomal abnormalities. In particular, partial or complete loss of chromosome 5 or 7 have been seen after exposure to alkylator therapy, and patients exposed to topoisomerase II inhibitors typically present with a monocytic leukaemia without antecedent MDS and typically

have rearrangements of the mixed lineage leukaemia gene located on 11q23.[17]

Other genetic events

Over the past few years, our understanding of the genetic basis for MDS has expanded significantly. Pivotal work by Ebert *et al*. identified that haploinsufficicny of the ribosomal gene RPS14 cooperates with the loss of micro-RNAs miR-145 and miR-146 which result in key features of the 5q phenotype.[18] Mutations in the Ten-Eleven Translocation-2 gene (TET2) were recently identified in MDS and other myeloid neoplasms.[19–21] TET2 mutations occur in 10–26% of MDS patients. The enzyme converts methylcytosine to hydroxymethylcytosine and thus may play a role in DNA methylation and may predict response to hypomethylating agents.[22] Other recurrent mutations in RUNX1, ASXL1 and TP53 have also been discovered in a substantial proportion of MDS cases. Active investigation is ongoing to determine which of these mutations are causative in the pathogenesis of MDS and which play a role progression of the disease and or may be therapeutically relevant to predict response to therapy.

Classification

The current term MDS was adopted by the French, American and British (FAB) Cooperative Group in 1976 in their classification scheme of these disorders. The WHO classification was proposed as a modification of the FAB system.[23] Notably, the criterion for AML was lowered from 30% blasts in the bone marrow to 20% blasts, which eliminated the category of RAEB-t of the FAB classification. Patients with refractory anaemia (RA) with or without ring sideroblasts were divided based upon the presence of unilineage or multilineage dysplasia. Multilineage dysplasia has been shown to impart an inferior prognosis. The category of refractory anaemia with excess blasts was divided into two categories based upon the percentage of blasts. Furthermore, in this classification system MDS associated with a del(5q) was assigned its own category and is associated with a prolonged life expectancy. A new category, MDS-unclassifiable, was introduced to incorporate patients with significant unilineage dysplasia without meeting other criteria for the diagnosis. In addition, chronic myelomonocytic leukaemia has been removed from the MDS category and placed within the myeloproliferative neoplasms category. The WHO was updated in 2008 (Table 32.1).[24] Important changes include three categories of refractory cytopenia with unilineage dysplasia, RA, refractory neutropenia (RN) and refractory thrombocytopenia (RT), which reduced the number of cases referred to as unclassifiable.[24]

Prognosis

The WHO classification scheme is useful for the diagnostic categorization of patients with MDS, but these diagnostic groups represent heterogeneous patient populations with varied prognoses. Several prognostic systems have been devised to predict the outcome of individual patients better. The most widely used and accepted is the International Prognostic Scoring System, from the International Myelodysplastic Syndrome Risk Analysis Workshop[6] (Table 32.2). In this analysis based on over 800 patients, the important predictors for overall prognoses were cytogenetic abnormalities, percentage of myeloblasts in the bone marrow and the number of lineages that exhibited cytopenias. Favourable cytogenetics includes the loss of the Y, 5q or 20q chromosomes or the presence of a normal karyotype. Adverse cytogenetic changes were those with three or more cytogenetic abnormalities or any abnormalities involving chromosome 7. Number scores are attributed to each variable, thus dividing patients into four categories based on the sum of scores for each variable. The median survival for the categories were 5.7, 3.5, 1.2 and 0.4 years for the low-, intermediate-1-, intermediate-2- and high-risk groups, respectively[25] (Table 32.3). The time for 25% of the patients in each of the four risk groups to evolve into acute leukaemia was 9.4, 3.3, 1.1 and 0.2 years, respectively. This schema provides very useful prognostic information for patients and counselling regarding treatment options such as haematopoietic stem cell transplantation. However, the usefulness of the IPSS is limited by the fact that patients with secondary MDS were excluded from the analysis and the information only pertains to patients at the time of diagnosis and cannot be used to estimate the real-time risk for patients. Furthermore, it may underestimate the impact of cytogenetics. In this analysis, rare, non-complex cytogenetic abnormalities were placed in the intermediate-risk karyotype group.

Haase *et al*. reviewed the cytogenetic data for over 2124 patients with MDS in Austria and Germany.[16] Given the large number of patients, cytogenetic risk groups could be further refined. The median survival was 53.4 months for patients with normal karyotypes and 8.7 months for those with complex anomalies. Thirteen rare abnormalities were identified with good, intermediate and poor prognostic impact (Table 32.4).

In an attempt to incorporate dynamic variables such as transfusion burden, the WHO prognostic scoring system (WPSS) was developed.[26] This model takes into account WHO subgroups, karyotype and transfusion requirement to classify patients into five risk groups with variable median survivals (12–103 months) and also probability of leukaemia conversion. The advantage of the WPSS is that it is a dynamic prognostic scoring system which can be used for patients at any time during the course of their disease.

Table 32.1 2008 WHO Classification and Criteria of MDS.

Type	Peripheral blood	Bone marrow
Refractory cytopenias with unilineage dysplasia (RCUD) Refractory anaemia (RA) Refractory neutropenia (RN) Refractory thrombocytopenia (RT)	Unicytopenia or bicytopenia <1% or rare blasts	Unilineage dysplasia >10% of the cells in one myeloid lineage <5% blasts ≤15% of erythroid precursors are ring sideroblasts
Refractory anaemia with ring sideroblasts (RARS)	Anaemia No blasts	Erythroid dysplasia only <5% blasts ≥15% ring sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Bi- or pancytopenia No/rare blasts No Auer rods Monocytes $<1000\,\mu l^{-1}$	Dysplasia in ≥10 % of cells in two or more myeloid cell lines No Auer rods ±15% ringed sideroblasts <5% blasts
RAEB-1 (refractory anaemia with excess blasts-1)	Cytopenias <5% blasts No Auer rods	Uni- or multilineage dysplasia 5–9% blasts No Auer rods
RAEB-2 (refractory anaemia with excess blasts-2)	Cytopenias 5–19% blasts Auer rods may be present	Unilineage or multilineage dysplasia 10–19% blasts Auer rods
MDS-U (MDS unclassified)	Cytopenias No or rare blasts	Unequivocal dysplasia in <10% of cells in one or more myeloid cell lines when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS No Auer rods <5% blasts
5q-Syndrome	Anaemia <5% blasts Platelets normal or increased	Normal to increased megakaryocytes with hypolobulated nuclei No Auer rods <5% blasts Isolated del(5q)

Adapted from *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*, IARC Press, Lyon, 2008.[24]

Table 32.2 International Prognosis Scoring System (IPSS) in MDS.[6,25]

	Score				
Variable	0	0.5	1.0	1.5	2.0
BM blasts (%)	<5	5–10		11–20	21–30
Karyotype[a]	Good	Intermediate	Poor		
Cytopenias[b]	0/1	2/3			

[a]Karyotype definitions: good,–Y,–5q,–20q, normal; poor, chromosome 7 abnormalities or complex karyotypes (three or more abnormalities); intermediate, all others.
[b]Cytopenia definitions: haemoglobin, $<10\,g\,dl^{-1}$; absolute neutrophil count, $<1800\,\mu l^{-1}$; platelet count, $<100\,000\,\mu l^{-1}$.

It has been externally validated and demonstrated to be very helpful particularly for determining the prognosis of patients with low-risk disease.[27]

To overcome some of the limitations of the IPSS which excludes patients with t-MDS, proliferative chronic myelomonocytic leukaemia and those who have received prior therapy, a group at the University of Texas M.D. Anderson Cancer Center developed a new prognostic scoring system that included all of these patients.[28] This model was able to identify four prognostic groups based upon a prognostic score which included features such as age, performance status, platelet count, haemoglobin, white blood cell count, complex karyotype or chromosome 7 abnormality and prior transfusions.

Table 32.3 IPSS Survival for MDS and Evolution to AML.

Risk category	Score	Median survival (years) in the absence of therapy	25% AML progression (years) in the absence of therapy
Low	0	5.7	9.4
Intermediate-1	0.5–1.0	3.5	3.3
Intermediate-2	1.5–2.0	1.1	1.1
High	2.5	0.4	0.2

Adapted from Greenberg *et al.*[6]

Table 32.4 Prognosis of rare cytogenetic abnormalities.

Risk group	Cytogenetic abnormality
Good-prognosis cytogenetics	del(9q)
	+1/+1q
	t(1q)
	t(7q)
	del(12p)
	Chromosome 15 anomalies
	t(17q)

Treatment

The management of patients with MDS requires consideration of several variables, including comorbidities, patient age, severity of cytopenias and the fact that the older patient population in general do not tolerate or respond to conventional therapy. The treatment for MDS is divided into two categories, high and low intensity. High-intensity treatment in general requires hospitalization and includes intensive chemotherapy and haematopoietic stem cell transplant. In contrast, low-intensity treatments are defined as those which can be performed in an outpatient setting, including haematopoietic growth factors, differentiation agents, low-intensity chemotherapy and transfusion support. Key factors in determining high- versus low-intensity treatment are a patient's age, performance status and IPSS score. High-intensity therapies are usually considered for patients <60 years old, who have good performance status and who fall into the intermediate-2- or high-risk categories. High-intensity treatment may be considered for patients >60 years old who have good performance status and who are in the higher risk categories, but generally patients >60 years of age are considered for low-intensity therapy. Patients >60 years of age in the low- or intermediate-1-risk category are usually considered for supportive care or low-intensity therapy.

Supportive care

Transfusion support and iron overload

Supportive care is an integral part of the management of all patients with MDS regardless of risk category. Supportive care includes treatment with antibiotics for infection and transfusion support for anaemia and thrombocytopenia. In order to lessen isoimmunization, viral infections and febrile transfusion reactions, leukoreduced and irradiated products are encouraged. In some cases, patients may receive well over 50 units of packed red blood cells. With each unit of blood containing 250 mg of iron, patients may develop iron overload. High levels of iron may lead to secondary haemachromatosis and its resultant adverse hepatic, pancreatic, gonadal and cardiac effects.[29] Iron chelation with deferoxamine[30] may be administered to these patients; however, this therapy is difficult. Deferoxamine only chelates ~25 mg of iron per day, must be administered subcutaneously and can lead to chronic skin irritation and cataracts. Two oral iron chelators are now available, deferiprone and deferasirox. Deferiprone reduced hepatic and cardiac iron content in thalassaemia patients, but its utility in MDS is limited by the risk of agranulocytosis and it is not currently approved in the USA.[31] Deferasirox is administered once daily and is approved for secondary iron overload in transfusion-dependent anaemias. It has been tested in MDS and found to decrease serum ferritin significantly at 1 year in heavily transfused MDS patients, but exactly what impact that has on total body iron stores or even survival in MDS is unclear.[32] Side effects typically include mild nausea and diarrhoea and careful surveillance of renal and hepatic function should be done as nephrotoxicity and hepatotoxicty have been described. Furthermore, baseline hearing and vision tests are recommended prior to initiating the drug and yearly thereafter because of the risk of auditory and ophthalmological disturbances.

Several international guidelines on iron chelation for MDS have been published.[33–37] Many patients with MDS rarely live long enough to develop the complications of iron overload, hence iron chelation as a therapy should be reserved for those patients with lower risk disease with an expected survival of more than 1 year, which is fairly consistent across the various guidelines. Once patients have received anywhere from 20 to 50 units of red blood cells and if the serum ferritin is >1000–2500 ng ml^{-1}, the recommendation is to initiate iron chelation therapy.[31]

In addition to requiring periodic red blood cell transfusions, some patients with more advanced MDS may have severe chronic thrombocytopenia with associated bleeding. This can be life threatening if significant bleeding occurs in the brain or gastrointestinal tract. Platelet transfusions can be administered, but should be given judiciously as many patients become alloimmunized and then fail to respond to subsequent platelet transfusions.[38] Similarly to red blood cell transfusions, platelets should be irradiated.[38,39]

Erythroid-stimulating agents

Erythroid-stimulating agents (ESAs) are not approved by the FDA for MDS, but they are commonly used to treat MDS patients to reduce transfusion requirements. Recombinant erythropoietin (EPO) is given subcutaneously 1–3 times weekly. Darbopoietin-α (DAR) is a pegylated form of EPO and is given in doses of 150–300 μg per week. A meta-analysis compared treatment with EPO and DAR and concluded that the drugs have similar response rates in MDS patients.[40] The serum EPO level is usually elevated in MDS patients; nonetheless, ~25% of patients with MDS respond to treatment. ESAs tend to have the greatest effect in patients with low transfusion requirements, low baseline serum EPO levels and low- or intermediate-1-risk MDS without excess blasts.[41,42] Response to ESAs may take time. In one study, response rates more than doubled from 12 to 26 weeks, hence a long trial of the agent is generally required. The combination of EPO and granulocyte-colony stimulating factor (G-CSF) has been shown to increase the haematocrit and the number of circulating neutrophils and the combination may be synergistic. A predictive model for response can be utilized to identify patients who have a low, intermediate or high probability of responding to ESAs and G-CSF (Table 32.5). The combination of G-CSF and EPO appears to be particularly synergistic in patients with refractory anaemia with ring sideroblasts.[42–44]

Randomized trials have demonstrated an increased risk of thromboembolic complications and inferior survival in patients with solid tumours receiving ESAs.[45,46] Two independent retrospective analyses comparing MDS patients treated with ESAs with MDS patients not treated with ESAs have demonstrated a survival benefit for those treated with ESAs.[44,47] This benefit probably arises because of they minimize transfusion and hence decrease iron overload. However, another retrospective study demonstrated no survival benefit for MDS patients treated with ESAs.[48] The Eastern Cooperative Oncology Group conducted a prospective randomized trial comparing the efficacy and long-term safety of EPO with or without G-CSF plus supportive care versus supportive care alone for the treatment of anaemic patients with lower-risk MDS.[49] With a median follow up of 5.8 years, no differences were found in overall survival of patients in the EPO versus the supportive care arm or in the incidence of transformation to acute myeloid leukaemia. Response rates in this trial were 36% in the EPO-alone arm versus 9.6% in the supportive care arm. One patient developed a deep venous thrombosis in the EPO arm. Hence EPO can be effective in those patients with lower risk MDS, is considered safe and is not associated with an increased risk for mortality or leukaemic transformation.

Table 32.5 Predictive model for response to erythroid stimulating agent and G-CSF in myelodysplastic syndromes.

Variable	Probability of response (%)
Transfusions >2 units per month and serum erythropoietin >500 units l^{-1}	7
Only one of the above criteria	23
Neither criterion	74

Platelet growth factors have been an area of active research and investigation. Thrombopoietin is the endogenous hormone responsible for maintaining normal platelet counts. A pegylated derivative, megakaryocyte growth and development factor (MGDF), has been tested as an adjunct to supportive care in patients with AML induction therapy.[50,51] Its use did not decrease bleeding complications or reduce platelet transfusions in AML. Furthermore, when tested in healthy volunteers, it resulted in antiplatelet antibodies and thrombocytopenia, halting further development of this compound. Low doses of recombinant human interleukin-11, a thrombopoietic cytokine, have been tested in patients with MDS and bone marrow failure.[52] Five of 11 evaluable patients with MDS had an increase of platelet counts with a median duration of 12–30 weeks. Side effects even at low doses included fluid retention, peripheral oedema, conjunctival injection and myalgias. Romiplostin, a peptibody found to increase platelet production through the thrombopoietin (TPO) receptor c-Mpl, has been tested in clinical studies involving healthy volunteers and patients with chronic immune thrombocytopenia and found to increase the platelet count.[53] In a phase 1 study using this agent as part of supportive care in patients

with lower risk MDS, with baseline platelet counts of $\leq 50 \times 10^9 l^{-1}$,[54] durable platelet responses were achieved in 19 of 44 patients (46%). Bleeding events and platelet transfusions were reduced in those patients who had sustained responses. One thrombotic event was noted and reticulin grade in the marrow was increased in seven patients, unchanged in 10 patients and decreased in seven patients. No neutralizing antibodies to either romiplostim or endogenous TPO were found. Of concern was that two patients progressed to AML in the study and four cases of transiently increased blast counts were noted. No changes in cytogenetics were noted for patients with baseline and end-of-study cytogenetics available. Romiplostim has been tested in patients with low- or intermediate-risk MDS receiving azacitidine therapy, as an adjunct to supportive care.[55] There was no statistically significant difference seen in the groups receiving romiplostim 500 or 750 μg or placebo in terms of clinically significant thrombocytopenic events or platelet transfusions. However, romiplostim 750 μg significantly raised the median platelet count during cycle 3 on day 1 and at the nadir compared with the placebo.

Eltrombopag is an oral small-molecule non-peptide agonist of the thrombopoietin receptor. In a phase 1 placebo-controlled clinical trial of 73 healthy male subjects, eltrombopag given once daily in doses ranging from 5 to 75 mg resulted in a dose-dependent increase in the platelet count. There were no adverse events in the subjects receiving drug or placebo.[56] It is currently being studied in patients with high-risk MDS.

Pyridoxine, androgens, vitamins

The rationale for the use of pyridoxine in MDS is the potential improvement in ineffective erythropoiesis. Pyridoxine is a non-toxic cofactor required for haem biosynthesis and is usually given for 3 months in patients with anaemia from MDS, but responses are rare. There is no clear role for androgens, danzaol or vitamins in the therapy of MDS.

Immunosuppressive therapy

In the past, it was not uncommon to treat MDS patients with corticosteroids. Given the immunosuppression associated with the steroids, their routine use is not recommended although they may result in transient improvement in cytopenias. There is evidence that patients with hypocellular bone marrows (i.e. hypocellular MDS) have an immune or T-cell-mediated process.[57–59] In these patients, treatment with equine or rabbit antithymocyte globulin, a treatment commonly used for aplastic anaemia, has been found to be effective with response rates of >50%.[60] It is worth mentioning that a randomized trial comparing equine with rabbit antithymocyte globulin in patients with severe aplastic anaemia demonstrated superior results in terms of response and toxicity for the equine-treated arm.[61] Patients who typically respond are young and have low platelet counts and HLA-DR 15 histocompatibility antigen.[62] Although originally it was thought that only those with hypoplastic MDS would respond, it now seems clear that bone marrow hypoplasia is not a requirement for response.[63]

The success of immunosuppressive therapy in MDS is offset in part by the toxicities that can be associated with the antithymocyte globulin and the prolonged administration of ciclosporin. An alternative immunosuppressive regimen using the anti-CD52 antibody alemtuzumab was tested in patients with MDS who were judged likely to respond to immunosuppressive therapy based on HLA-DR status and time of red blood cell transfusion dependence.[64] In this small study, alemtuzumab 10 mg per day was administered intravenously over 10 days and response rates of 77% (17/22) in intermediate-1 patients and 57% (4/7) in intermediate-2 patients were observed with a median time to response of 3 months. At 12 months, five of nine patients who responded had normal blood counts and seven of nine patients were transfusion independent. Infections were the primary complications with 23% of participants reactivating cytomegalovirus and 68% reactivating Epstein–Barr virus. This study suggests that alemtuzumab may be a viable treatment for MDS patients judged likely to respond to immunosuppressive therapy.

Hypomethylating agents

Azacitidine (5-azacytidine, 5-aza, Vidaza) is a pyrimidine nucleoside analogue of cytidine, whose mechanism of action is thought to be DNA hypomethylation in addition to a direct cytotoxic effect on the haematopoietic elements of the bone marrow. A phase 3 clinical trial comparing azacitidine with best supportive care in 191 patients with MDS demonstrated a 60% response rate in those patients who received azacitidine 75 mg m^{-2} subcutaneously for 7 days every 28 days.[65] Importantly, only 7% were complete remissions; the other responses were partial remissions or haematological improvements. The benefit of azacitidine was seen in all risk groups of MDS patients. Complete and partial response rates were 23% versus 0% for the azacitidine and the supportive care arms, respectively. The median time to leukaemic transformation or death was 21 versus 13 months, respectively. In addition, there was a companion quality of life analysis that demonstrated azacitidine to be superior to supportive care.[66] Survival could not be adequately looked at because of the crossover design. Nonetheless, this regimen is well tolerated and can be administered on an outpatient basis. Major side effects include nausea and vomiting and also myelosuppression.

A large European study then compared azacitidine with conventional care in a phase 3 randomized trial in higher risk patients with MDS.[67] Conventional care consisted of

best supportive care, low-dose cytarabine or intensive or AML-type induction chemotherapy, as selected by participating investigators prior to randomization. The patients assigned to the intensive chemotherapy arm were more likely to be younger than 65 years, to have high-risk disease and to have AML by WHO criteria. Azacitidine treatment was continued in the absence of progression or unacceptable toxicity and the median number of cycles administered was nine. In this pivotal study, complete and partial remission rates for the azacitidine arm were superior to conventional care, at 29% versus 21%, respectively. With a median follow-up of 21.1 months, the median overall survival was 24.5 months for the azacitidine arm compared with 15 months for the conventional care arm ($p = 0.0001$). The favourable results with azacitidine seen in this trial compared with conventional care and prior azacitidine trials may be due in part to the long duration of therapy (median duration of therapy of >9 months) and to the appropriate selection of patients in the higher risk MDS category.

Another hypomethylating agent, decitabine (5-aza−2′-deocytidine), has also demonstrated promise as an agent for MDS. Chemically it is closely related to azacitidine. A phase 2 trial performed in Europe[68] demonstrated that decitabine has significant activity in MDS. In this multicentre trial of 66 patients with MDS, decitabine was given at 15 mg m^{-2} i.v. over 4 h every 8 h on days 1, 2 and 3, with cycles repeating every 6 weeks. With this schedule, the overall response rate was 25, 48 and 64% for those in the intermediate-1-, intermediate-2- and high-risk groups, respectively. The median survival time from the start of treatment for the high-risk patients was 1.2 years, compared with an expected survival of 0.5 years. In addition, 31% of patients with abnormal pretreatment cytogenetics had major cytogenetic responses. Toxicity associated with this drug includes fever, infection, sepsis, neutropenia, anaemia and thrombocytopenia. A phase 3 multicentre trial randomized 170 patients with MDS to decitabine 15 mg m^{-2} every 8 h for a nine doses every 6 weeks or supportive care with transfusions, antibiotics and growth factors.[69] The overall response rate in the decitabine arm was 17%, with 9% complete remissions, 8% partial responses and 13% haematological improvements. There was a significant trend towards delay in progression to AML or death in patients with intermediate-2- or high-risk disease, but disappointingly there was no survival benefit to decitabine in this trial.

A phase 3 study in higher risk MDS patients was conducted in Europe, which compared 119 patients treated with decitabine at 15 mg m^{-2} every 8 h for nine doses with 114 patients treated with best supportive care.[70] The response rate was 34% (13% complete response, 6% partial response and 15% haematological improvement). Again, no difference in overall survival or time to progression to AML was seen in the decitabine arm. Azacitadine and decitabine are chemically similar compounds with similar biological activity. The difference in survival benefit seen with one drug versus the other may be attributed to an inadequate number of cycles of decitabine being administered. In the European trial, a median of only four cycles of decitabine were administered compared with nine cycles in the European azacitidine trial for high-risk MDS patients.

In an attempt to decrease the toxicity associated with this agent, an alternative schedule for prolonged exposure has been explored and had a demonstrated efficacy of 65% in patients with haematological malignancies in a phase 2 trial.[71] Using a Bayesian design, patients were randomized among the following doses and schedules: 20 mg m^{-2} i.v. for 5 days, 20 mg m^{-2} subcutaneously for 5 days and 10 mg m^{-2} i.v. for 10 days. Decitabine 20 mg m^{-2} i.v. for 5 days was found to be the optimal dose and schedule with a complete remission rate of 39%. This is not the registration dose of the drug but represents a dose and schedule that are easily administered in the outpatient setting. The ADOPT trial confirmed the efficacy of this dose and schedule of decitabine for patients with MDS with an IPSS score of ≥ 0.5.[72] In this large, multicentre trial, 99 patients were enrolled. The overall response rate was 32% with 17 complete responses plus 15 marrow complete responses and a 51% overall improvement.

At this time, azacitidine and decitabine are approved for the treatment of patients with MDS. Azacitadine improves the survival of higher risk patients. In general, both agents should be given for 4–6 cycles before the treatment is considered a failure. Failure of response would be lack of any sort of response, including haematological improvement, complete response or partial response, progression to AML or toxicity that precludes further treatment. These agents are recommended for patients who are not candidates for high-intensity therapy, and also for patients as a 'bridge' prior to allogeneic stem cell transplant.

Lenalidomide

Lenalidomide, a thalidomide analogue, is approved by the FDA for the treatment of transfusion-dependent, low- and intermediate-1-risk MDS with a del(5q). In a multicentre phase 2 study,[73] 148 patients were treated with lenalidomide 10 mg daily for 21 days of a 28 day cycle (46 patients) or 10 mg daily every day (102 patients). Importantly, patients had the del(5q) alone or with other abnormalities, were transfusion dependent and had an absolute neutrophil count >500 μl^{-1} and a platelet count >50 000 μl^{-1}. At 24 weeks, 112/148[74] had a response; 99 patients (67%) became transfusion independent and another 13 patients had a reduction in their transfusion burden by 50%; 85 patients had adequate cytogenetic results at time of entry and at 24 weeks and a 45% complete cytogenetic response rate

was noted. Importantly, grade 3 and 4 neutropenia and thrombocytopenia were the most frequent toxicities seen and monitoring of blood counts weekly during the first 8 weeks or so of treatment is recommended. The median duration of response is ~2 years. Resistance has been seen and typically the re-emergence of the del(5q) clone is seen in conjunction with recurrent anaemia and or transfusion dependence. Features predicting response include age, shorter duration of disease, lower transfusion burden and treatment-related thrombocytopenia.

Lenalidomide activity has been seen in non-del(5q) MDS patients. A multicentre phase 2 study evaluated lenalidomide in transfusion-independent low- or intermediate-1-risk MDS patients without del(5q).[75] Again, eligible patients had to have adequate peripheral blood counts defined as an absolute neutrophil count $>500\,\mu l^{-1}$ and a platelet count $>50\,000\,\mu l^{-1}$ and had to have documented transfusion dependence. A total of 214 patients were treated with 10 mg of lenalidomide daily or 10 mg for 21 days of a 28 day cycle. Again, the most common grade 3 and 4 toxicities were neutropenia (30%) and thrombocytopenia (25%). A total of 56/114 patients (26%) achieved transfusion independence after a median duration of 4.8 weeks of treatment with a median duration of response of 41 weeks.

Lenalidomide has been tested in higher risk MDS patients with del(5q).[74] In a phase 2 study of 47 patients with intermediate-2- or high-risk MDS with a del(5q), lenalidomide 10 mg was administered for 21 days of a 28 day cycle. Thirteen patients (28%) had a response, including seven patients (15%) with a complete remission. Those patients who had a complete remission tended to have higher platelet counts at baseline and a del(5q) alone or with one other abnormality.

Interestingly, none of the phase 2 studies have demonstrated a survival benefit for lenalidomide in MDS patients. Because of reports of leukaemic transformation in patients with low-risk MDS being treated with lenalidomide, the European Medicines Agency (EMEA) did not approve the drug in Europe, pending more data on safety and the rate of leukaemic transformation.

Intensive therapy

Induction chemotherapy

For the most part, intensive and aggressive antileukaemic chemotherapy as is used for acute myelogenous leukaemia has not been as effective when used in patients with MDS. In a retrospective study from the University of Texas M.D. Anderson Cancer Center, outcomes with AML induction regimens were compared among those treated for AML, RAEB and RAEB-t.[76] This study demonstrated that patients with MDS (RAEB or RAEB-t) did equally as poorly or as well as those with AML after controlling for age and cytogenetics.[76] No data are available regarding the benefit of post-remission consolidation with high-dose ara-C in these patients, as older adults with AML do not benefit from this intensive approach as do younger adults with *de novo* AML.[77,78] The lack of benefit for intensive chemotherapy in these patients is due to a decreased capacity to tolerate intensive chemotherapy. Furthermore, the stem cell defect in MDS occurs in a very early or proximal stem cell, which is more likely to be resistant to chemotherapy due to the overexpression of the multi-drug resistant P-glycoprotein (MDR-1). This protein acts to confer resistance to chemotherapy. Several studies using modulators of MDR-1 plus standard induction regiments for AML have been performed on in patients with advanced MDS or AML from MDS in order to circumvent this mode of resistance. In one study, quinine was used as an MDR modulator in combination with mitoxantrone and cytarabine which resulted in a 52% complete response rate in those patients who expressed the P-glycoprotein compared with 18% for those patients who did not receive the quinine.[79] In another study using PSC833, no difference was seen in remission rates or overall survival between those who did and did not receive the MDR modulator.[80]

Haematopoietic stem cell transplantation

Because the defect in MDS occurs in an early haematopoietic precursor, allogeneic transplant represents a potentially curative option. Many studies have suggested that low-risk MDS patients and also those with high-risk disease experience a long-term disease-free survival from a matched related donor allogeneic transplant.[81–83] Unfortunately, many patients do not have this option of treatment either because of age, comorbidity or lack of a sibling donor. The use of non-myeloblative or reduced-intensity conditioning in older patients is growing. This treatment modality seeks to maximize the immune effect of graft versus leukaemia while minimizing the toxicity associated with ablative conditioning regimens. Non-myeloablative transplantation has a low short-term mortality rate in patients with MDS up to age 70–75 years with overall survival rates comparable to those for ablative transplantation, mainly due to the higher risk of relapse seen.[84] In a large retrospective series of 1333 MDS patients aged >50 years who received a transplantation within the European Group for Blood and Marrow Transplantation (EBMT), 449 (34%) were >50 years of age.[85] Overall survival for the entire cohort was 31% with a 4 year estimate of non-relapse mortality of 36% for all patients. For those >60 years of age, the overall survival was 27% and the non-relapse mortality was 36%. In another study examining the effect of age on the outcome of reduced-intensity haematopoietic cell transplantation in older patients with AML or with MDS, age was not found to have a significant impact on non-relapse mortality, relapse, disease-free survival or overall survival.[86] In

this series, HLA mismatch, unfavourable cytogenetics and pre-stem cell transplant performance status were predictors for improved 2 year overall survival.

Key points

- Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal stem cell disorders characterized by dysplasia, ineffective haematopoiesis and potential risk of transformation into acute leukaemia.
- In MDS, the important predictors for overall prognoses are cytogenetic abnormalities, percentage of myeloblasts in the bone marrow and the number of lineages that exhibit cytopenias.
- Because the defect in MDS occurs in an early haematopoietic precursor, allogeneic transplant represents a potentially curative option.

CHAPTER 33

Management of myelodysplastic syndromes and acute leukaemia

Heidi D. Klepin and Bayard L. Powell
Wake Forest University School of Medicine, Winston-Salem, NC, USA

Introduction

Myelodysplastic syndromes (MDS) encompass a heterogeneous group of disorders characterized by ineffective haematopoiesis typically resulting in cytopenias. MDS is clearly a disease of ageing patients and will be commonly encountered in primary care and geriatric practices. MDS may behave as an indolent disease or progress to bone marrow failure or acute leukaemia. Acute leukaemias are clonal disorders characterized by a proliferation of immature myeloid [acute myeloid leukaemia (AML)] or lymphoid [acute lymphocytic leukaemia (ALL)] cells. Accumulation of leukaemic cells impairs the normal haematopoietic function of the bone marrow, resulting in cytopenias with or without leukocytosis. While relatively uncommon, the incidence of acute leukaemias, particularly AML, increases with age. In addition, management issues are increasingly complex in older adults due to the aggressive nature of both the disease and the treatments required for cure. This chapter outlines key diagnosis and management issues for older adults with MDS and acute leukaemias.

Myelodysplastic syndromes

The myelodysplastic syndromes (MDS) represent a broad group of clonal haematopoietic disorders characterized by ineffective haematopoiesis resulting in peripheral blood cytopenias. In these diseases, cells of the affected lineage are unable to undergo maturation and differentiation, resulting in cytopenias. The major clinical significance is the morbidity associated with profound cytopenias and the potential to evolve into AML.

MDS are clearly diseases of ageing patients, with a median age at diagnosis of 76 years.[1] It is estimated that over 80% of the 10–15 000 patients diagnosed in 2010 will be over age 60 years.[2] Unfortunately, survival for MDS has been poor with a reported three-year overall survival rate of 35%.[3] Complications of bone marrow failure are a leading cause of death for these patients. The incidence of these disorders is likely to rise with the ageing of the US population making this an increasingly important public health concern.

Advanced age is the primary risk factor for developing MDS. Most patients diagnosed with MDS have no other known predisposing risks. Exposures that have been associated with subsequent development of MDS include chemotherapy, radiation, agricultural chemicals (i.e. pesticides), solvents and tobacco smoking. Of these, exposure to alkylating agent chemotherapy (i.e. melphalan) has been most well defined. Alkylating agent associated MDS typically presents within five to seven years after exposure and is characterized by abnormalities in chromosomes 5 and 7.

Diagnosis and prognosis

Diagnosis of MDS relies primarily on peripheral blood and bone marrow findings. The diagnosis should be suspected in individuals presenting with persistent cytopenia. Careful attention should be paid to consistent decreases in blood counts over time in an older adult which may signify early developing MDS. A frequent presentation can be progressive macrocytic anaemia in an older adult. Many patients are asymptomatic at the time of diagnosis. However, careful history-taking should include questions regarding recurrent infections, bruising, bleeding, duration of cytopenia and need for red cell transfusion. The differential diagnosis for suspected MDS includes megaloblastic anaemia (B12 and folate deficiency), AML, aplastic anaemia, copper deficiency, viral infections (HIV), large granular lymphocytic leukaemia, paroxysmal nocturnal haemoglobinuria (PNH), and heavy metal poisoning.

The initial workup includes a CBC with differential, reticulocyte count, RBC folate, serum B12, iron studies and review of the peripheral smear. Classic peripheral blood

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

findings associated with MDS include macrocytosis and hypogranular, hypolobated neutrophils (pseudo-Pelger-Huet anomaly). A bone marrow biopsy with cytogenetic analysis is necessary to confirm the diagnosis. The bone marrow is typically hypercellular with dysplastic features. The percentage of myeloblasts in the marrow helps differentiate between an MDS and AML. Cytogenetic abnormalities play an increasingly important role in the diagnosis and prognosis of MDS. Clonal chromosomal abnormalities can be detected in approximately 50% of patients with MDS.[4] Diagnosis of certain MDS subtypes (such as the 5q minus syndrome) is entirely dependent upon detection of specific cytogenetic abnormalities. Cytogenetic testing, therefore, should be performed as part of bone marrow evaluation in all patients with suspected MDS to inform the diagnostic workup, prognosis and treatment options.

The classification of MDS has evolved. Historically, the French-American-British (FAB) Cooperative Group classification system was used which included five diagnostic categories based on peripheral blood and bone marrow characteristics. Categories included refractory anaemia (RA), RA with ring sideroblasts (RARS), RA with excess blasts (RAEB), RAEB in transformation (RAEBT), and chronic myelomonocytic leukaemia (CMML). A more recent classification scheme was proposed and updated by the World Health Organization (WHO) which incorporates cytogenetic abnormalities.[5] This classification scheme is presented in Table 33.1 and reflects the heterogeneity of MDS.

The natural history of patients with MDS syndromes is quite variable. It is well established that mutagen-induced MDS is associated with a poor prognosis and that increased age is also a negative prognostic factor. However, the

Table 33.1 WHO Classification of peripheral blood and bone marrow findings in myelodysplastic syndromes.

Disease	Blood findings	Bone marrow findings
Refractory cytopenias with unilineage dysplasia (RCUD)	Unicytopenia or bicytopenia	Dysplasia in ≤10% of cells in one myeloid lineage
Refractory anaemia Refractory neutropenia Refractory thrombocytopenia	No or rare blasts	<5% blasts <15% ringed sideroblasts
Refractory anaemia with ringed sideroblasts (RARS)	Anaemia No blasts	≥15% ringed sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias No or rare blasts (<1%) No Auer rods $1 \times 10^9\ l^{-1}$ monocytes	Dysplasia in ≥10% of the cells of two or more myeloid cell lines <5% blasts in marrow No Auer rods ±15% ringed sideroblasts
Refractory anaemia with excess blasts-1 (RAEB-1)	Cytopenias <5% blasts No Auer rods $1 \times 10^9\ l^{-1}$ monocytes	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
Refractory anaemia with excess blasts-2 (RAEB-2)	Cytopenias 5–19% blasts Auer rods ± $1 \times 10^9\ l^{-1}$ monocytes	Unilineage or multilineage dysplasia 10–19% blasts Auer rods ±
Myelodysplastic syndrome-unclassified (MDS-U)	Cytopenias ≤1% blasts	Dysplasia <10% of cells in one or more myeloid cell lines accompanied by a cytogenetic abnormality that is characteristic for MDS <5% blasts
MDS associated with isolated del (5q)	Anaemia Usually normal or increased platelet count <1% blasts	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts Isolated del(5q) cytogenetic abnormality No Auer rods

Table 33.2 International Prognostic Scoring System (IPPS) for MDS.

(a) IPSS Scoring System	**0**	**0.5**	**1.0**	**1.5**
Bone marrow blasts (%)	<5	5–10	–	11–20
Karyotype[a]	Good	Intermediate	Poor	–
Cytopenias	0/1	2/3	–	–

(b) IPPS Risk Category	Overall score	Median survival (years)
Low	0	5.7
Intermediate-1	0.5–1.0	3.5
Intermediate-2	1.5–2.0	1.2
High	≥2.5	0.4

[a]Karyotype definitions: Good risk = normal, -Y, del(5q), del (20q); Poor risk = ≥3 abnormalities, abnormal chromosome 7; Intermediate risk = all other abnormalities.
Adapted from Greenberg *et al.*[6]

heterogeneity of this disease has complicated accurate prognostication in *de novo* MDS. The International Prognostic Scoring System (IPSS) (Table 33.2(a)) was developed to risk stratify patients at the time of diagnosis based on cytogenetic, morphological and clinical data. The IPSS for MDS was developed based on an analysis of 816 patients which demonstrated that specific cytogenetic abnormalities, the percentage of blasts in the bone marrow, and the number of haematopoietic lineages involved in the cytopenia were the most important variables in disease outcome.[6] Risk scores are determined based on these variables, and a categorization of low risk, intermediate-1, intermediate-2, and high risk is assigned (Table 33.2(b)). The IPSS demonstrated improved prognostic discrimination over earlier classification schemes and has been incorporated into clinical practice and subsequent trial design.

There are multiple known prognostic factors that are not included in the IPSS classification. For example, chronological age is not incorporated into the IPSS score. The prognostic impact of increasing age, however, differs by IPSS risk group. In the original analysis used to develop the IPSS, survival for high-risk patients appeared to be independent of age. This suggests survival was driven primarily by tumour biology in these patients.[6] Survival for low-risk patients was strongly dependent on age with median survival of 9.0 years versus 3.9 years for age groups <70 and ≥70 years respectively. Therefore additional factors such as comorbid disease may influence survival in the setting of more indolent MDS.

The IPSS classification system has several limitations: (1) it does not account for duration of disease; (2) subjects who received prior therapy or had secondary MDS were excluded; and (3) it does not account for performance status or comorbid disease. Additional classification schemes have been proposed which include prognostic factors such as poor performance status, older age, prior transfusions and time elapsed from diagnosis.[7] Despite its limitations, the IPSS classification remains a useful tool in clinical practice.

Treatment

Treatment strategies for MDS have been evolving in recent years to target higher risk MDS and subgroups defined by specific cytogenetic abnormalities. Treatment goals include managing cytopenias, decreasing progression to AML, improving overall survival while maintaining quality of life. Current treatment recommendations for MDS involve a risk-adapted therapeutic approach. In general, the National Comprehensive Cancer Center (NCCN) guidelines recommend classifying patients into relatively low risk (IPSS Low or Intermediate-1 categories) and higher risk (IPSS Intermediate-2 and High categories).[8] Supportive care aimed at controlling symptoms related to cytopenias is the mainstay of treatment for: (1) low-risk patients and (2) patients with poor functional status or limiting comorbid conditions regardless of IPSS classification. Higher risk patients with good functional status and manageable comorbid conditions should be considered for low-intensity chemotherapy along with best supportive care.

Supportive care typically constitutes red cell and platelet transfusions, antibiotics for infection, haematopoietic growth factors such as recombinant erythropoietin (epoetin alpha) for selected patients, and iron chelation. Patients with symptomatic anaemia, or transfusion-dependent anaemia, may benefit from epoetin alpha or a longer acting form darbepoetin alpha. Response rates in studies are approximately 50% (major response is defined by haemoglobin increase $>2\,g\,dl^{-1}$ or transfusion independence, minor response is defined by haemoglobin increase $1–2\,g\,dl^{-1}$ or 50% reduction for transfusion-dependent patients).[9] Patients most likely to respond to use of erythropoietin are those with IPSS score low/intermediate-1, serum erythropoietin level <500, and transfusion requirement of <2 units of red cells per month.[10] The NCCN recommends a target haemoglobin of $\leq 12\,g\,dl^{-1}$. Granulocyte colony stimulating factor (G-CSF) may have a synergistic effect in combination with epoetin for treatment of anaemia. Low dose G-CSF dosed three times per week can be added to erythropoietin if response is inadequate to epoetin alone. Use of growth factors for symptomatic anaemia has been associated with improved quality of life and decreased transfusion requirement without increased risk of progression to AML.[8,11] However, no improvement in survival has been attributed to this intervention. Responses in haemoglobin levels are typically evident within 6–8 weeks of treatment.

Ongoing treatment is not indicated if no response is detected during this time period.

Over time, most patients become transfusion dependent, increasing the risk of iron overload. Secondary iron overload negatively affects survival in transfusion-dependent patients.[12] Current consensus guidelines recommend iron chelation therapy for those patients most likely to suffer negative consequences from chronic iron overload.[8] The patients most likely to benefit from chelation are those with lower risk MDS, ongoing transfusion dependence, and anticipated survival of greater than one year. For these patients, initiation of iron chelation therapy should be considered after transfusion of 20–30 units of red cells or the serum ferritin exceeds $2500\,\mu g\,l^{-1}$. Serum ferritin can be used to monitor efficacy of chelation with goal ferritin $<1000\,\mu g\,l^{-1}$ on treatment. Chelation agents include deferoxamine or the oral agent deferasirox.

Patients in the higher risk IPSS categories are more likely to experience morbidity related to cytopenias and to progress to acute leukaemia in a shorter time interval from diagnosis. For patients who present with high-risk disease or show evidence of progression to high-risk disease during follow-up, treatment with low-intensity chemotherapy should be considered. The low-intensity chemotherapeutic agents which have demonstrated efficacy in treatment of MDS are the hypomethylating agents 5-azacytidine and decitabine.

The first chemotherapy agent to demonstrate efficacy in treatment of MDS was 5-azacytidine. A randomized controlled trial of 191 patients which compared treatment with 5-azacytidine to supportive care alone for high-risk MDS demonstrated significant improvements in response, time to AML progression, and survival.[13] Eligible patients (median age 68) met FAB classification criteria for MDS and were considered high risk. The 5-azacytidine was administered at a dose of $75\,mg\,m^{-2}$ for 7 consecutive days on a 28-day cycle. The response rate (complete and partial) was 23% in the treatment arm with median time to leukaemic progression 21 versus 13 months for supportive care ($p = 0.007$). After controlling for the effect of crossover from placebo to active treatment, there was a survival advantage detected in treated patients.

Importantly, this study also evaluated quality of life outcomes.[14] Treatment with 5-azacytidine was associated with significant improvement in fatigue, dyspnoea, self-reported physical functioning and psychological distress. Quality of life differences were maintained after controlling for the number of transfusions received. The improvements in both disease-related outcomes and quality of life established the use of 5-azacytidine as a standard of care for treatment of high-risk MDS. Another randomized controlled international trial of 358 patients confirmed an overall survival benefit favouring 5-azacytidine over physician-directed conventional care.[15]

Based on treatment experience from these randomized studies it is generally recommended to treat for approximately 4–6 cycles if tolerated to determine response for individual patients. Treatment protocols typically recommend treating for an additional three cycles after achieving complete remission or for as long as a treatment benefits persist in patients with a lesser response.

Decitabine, a second pyrimidine nucleoside analogue of cytidine which inhibits DNA methylation, is also FDA approved for the treatment of higher risk MDS. A randomized study of 170 patients (median age 70) compared decitabine versus supportive care for patients who met FAB classification for MDS and had an IPSS score ≥ 0.5.[16] The dose schedule was $15\,mg\,m^{-2}$ given intravenously every 8 hours for 3 days on a 6-week cycle. Patients treated with decitabine had a 17% overall response rate with an additional 13% demonstrating haematological improvement. Patients with intermediate-2 or high-risk disease by IPSS classification demonstrated improvement in progression to AML (12 months versus 6.8 months). In this study the median number of treatment cycles administered was three with responding patients receiving a median of six cycles (range 2–8). Temporary dose reduction or delay was required in 35% of patients on treatment. Evaluation of quality of life demonstrated improvements in global health status, fatigue, and dyspnoea favouring active treatment.

A follow-up randomized study evaluated different treatment dosing schedules of decitabine.[17] A five-day intravenous schedule which had the highest dose intensity was determined to be optimal. This dosing schedule is convenient for outpatient treatment and has become an acceptable option in clinical practice. At the present time there is no randomized clinical trial data that compares decitabine directly to 5-azacytidine. These agents are generally considered to be similar in efficacy although documentation of overall survival benefit favours 5-azacytidine. Current evidence would suggest that the patients most likely to benefit from these agents are those with intermediate-2 or high-risk classification by IPSS.

While these medications are associated with toxicity, they represent the mainstay of treatment for older adults with higher risk MDS who have a good performance status. The primary toxicity seen is myelosuppression. Often cytopenias will worsen in the first few months of treatment prior to demonstrating evidence of response. Consequences of myelosuppression can be managed in older adults with temporary increased use of transfusion support, growth factor support and prophylactic antibiotics for neutropenia. Higher intensity therapy such as allogeneic transplantation, to date the only curative therapy for MDS, is generally restricted to younger adults with acceptable donors due to the high morbidity and mortality associated with the therapy itself.

Treatment options have expanded for patients with MDS associated with chromosome 5q deletion. The 5q- syndrome is a specific MDS subset defined by deletion of the long arm of chromosome 5 as the sole abnormality without excess bone marrow blasts. The 5q- syndrome typically manifests as refractory anaemia, often with normal or even increased platelet counts, and is considered a more favourable MDS subset because a large percentage of patients do not progress to acute leukaemia. Lenalidomide, an oral immunomodulatory drug, has demonstrated efficacy in this setting. In a phase 2 clinical trial of 148 patients, significant decrease in transfusion requirements and reversal of cytogenetic abnormalities was demonstrated.[18] Eligible patients met FAB criteria for MDS, had a chromosome 5q31 deletion that was either in isolation or combined with additional cytogenetic abnormalities, low or intermediate-1 IPSS score, and transfusion-dependent anaemia. The majority of patients (64%) had isolated 5q deletion. Lenalidomide was dosed 10 mg daily orally for 21 days of a four-week cycle. Transfusion independence was achieved in 67% of participants. Median time to response was rapid at 4.6 weeks. The primary toxicity in this study was myelosuppression with neutropenia and thrombocytopenia. This typically occurred within the first eight weeks of treatment. Dose adjustment was required in the majority (84%) of patients. This drug has become the standard of care for treatment of transfusion-dependent, lower risk patients with chromosome 5q deletion and reinforces the clinical and therapeutic importance of cytogenetic evaluation in MDS.

Despite recent advances in pharmacological treatment options, there are unresolved clinical questions related to the treatment of older adults with MDS. One major issue is patient selection. Clinical trials in MDS have included a substantial number of older adults. However, most studies included only patients with good functional status.[13,16] Many older adults with MDS in clinical practice present with functional impairments. It is unclear if the beneficial results seen in clinical trials can be extrapolated to older adults with impaired performance status. This results in a substantial proportion of older adults for whom there is no evidence-based treatment recommendation.

Clinical experience suggests that some older adults with poor performance status may benefit from low-intensity chemotherapy, particularly those whose functional decline was related to disease progression. Alternatively, some older adults with impaired functional status may experience increased morbidity with active treatment. The interaction between presence of specific comorbidities and treatment benefit has also been understudied. Clinical trials targeting older adults with impaired performance status are needed which emphasize both disease-specific outcomes and quality of life.

Another issue for treatment of MDS in older adults is the balance between ongoing maintenance therapy for disease control and quality of life. It is unclear how long older adults who respond to hypomethylating agents should remain on treatment. Studies would suggest continuing treatment until intolerance or progression. Over time, many older adults can develop toxicities and functional decline due to ongoing therapy. The impact of continuous treatment versus sequential treatment strategies on disease control and quality of life is unknown.

There are multiple new therapeutic approaches for MDS under investigation. There is an increasing focus on development of targeted therapies that is informed by improved understanding of biological mechanisms underlying the MDS syndromes. Future treatment algorithms will likely differentiate specific disease subtypes such as the 5q- syndrome which are susceptible to targeted therapeutic approaches. Combining novel agents with hypomethylating agents to improve efficacy is another investigational approach. Finally, improved patient-assessment strategies will help identify which older patients with high-risk MDS may benefit from more aggressive treatment approaches such as reduced-intensity allogeneic transplantation.

Acute myelogenous leukaemia (AML)

AML is a disease of older adults, with a median age at diagnosis of 67 years.[2] The American Cancer Society estimated that 12 330 patients would be diagnosed with AML in 2010 with an anticipated 8950 dying of the disease.[2] The incidence of AML increases dramatically with age (Figure 33.1) and there is a persistent age-related survival disparity (Figure 33.2). Multiple factors contribute to poor treatment outcomes in older adults including aggressive tumour biology and poor tolerance to aggressive therapies due to functional limitations and comorbid conditions.

The primary risk factors for developing AML are increasing age and a history of prior MDS. Less common risk factors include exposure to certain chemotherapy drugs (alkylating agents, topoisomerase 2 inhibitors, and nitrosoureas), radiation or benzene exposure, and a history of Down syndrome.

Diagnosis and prognosis

The clinical signs and symptoms of AML can be varied and non-specific. However, in contrast to MDS, symptoms are typically acute in onset and often prompt medical evaluation. Common symptoms include fatigue, bleeding, fever and infection. Symptoms are typically related to cytopenias, often pancytopenia due to leukaemic infiltration of the marrow. Less commonly, older adults with AML may present with severe leukocytosis, which can produce symptoms of leukostasis due to the large peripherally circulating blast fraction. Leukostasis symptoms include altered mental status, shortness of breath, or chest pain. Occasionally patients

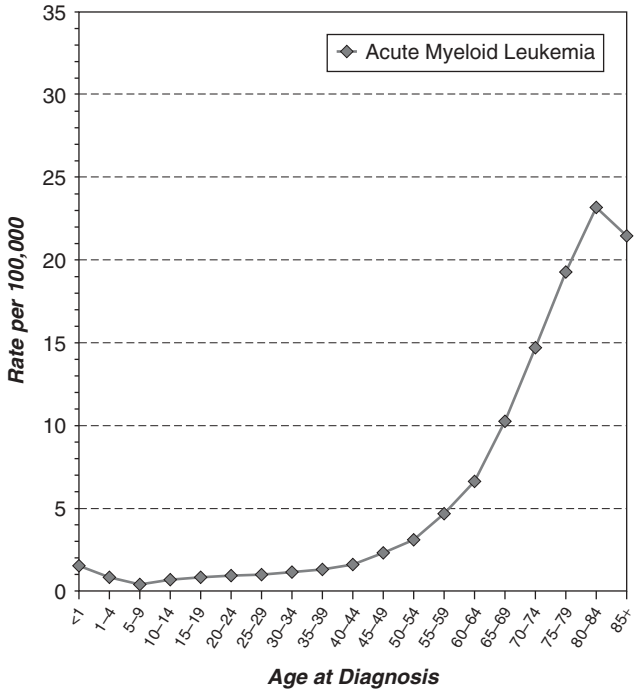

Figure 33.1 The incidence of AML as a function of age: 2000–2007 SEER (Surveillance Epidemiology and End Results) data. Source: http://seer.cancer.gov.

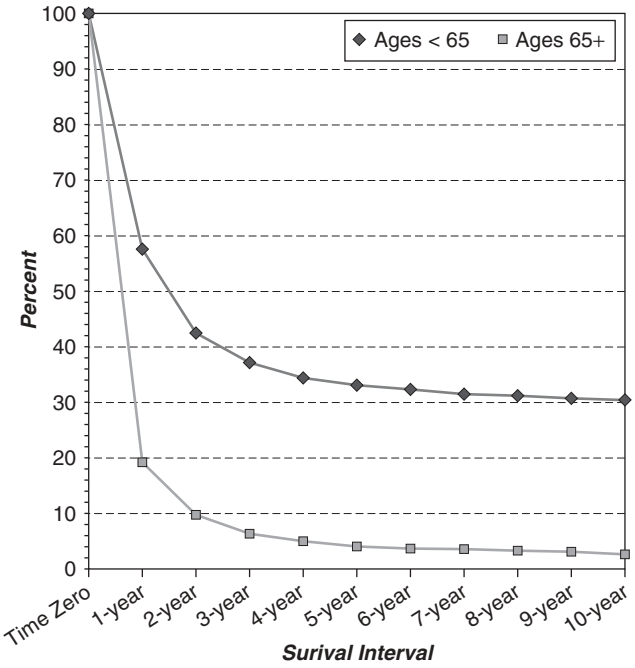

Figure 33.2 Relative survival by age group from Surveillance Epidemiology and End Results (SEER) data 1988–2006. Source: http://seer.cancer.gov.

may present with leukaemic infiltration of tissues outside the bone marrow such as the liver, spleen, lymph nodes, skin or central nervous system which can produce a variety of site-specific symptoms. Initial peripheral blood findings range from pancytopenia with or without circulating blasts cells to severe leukocytosis (primarily blasts) with accompanying anaemia and pancytopenia.

The diagnosis of AML is established by bone marrow biopsy when the percentage of leukaemic blasts of myeloid lineage is ≥20%.[19] Morphological evaluation can be aided by immunohistochemical and flow cytometry techniques to confirm myeloid versus lymphoid origin. For patients who present with leukocytosis, flow cytometry alone can establish the diagnosis. The historical international classification system (FAB) details subtypes of AML (M1 through M7) based on morphology, histochemical characteristics, and immunophenotyping. The more recently proposed WHO classification of AML (Table 33.3) highlights the importance of a cytogenetic classification for prognosis and treatment and has become the standard classification scheme. It has become increasingly clear in recent years that AML encompasses a group of distinct diseases with a broad range of tumour biology. Subsets of AML defined by specific cytogenetic abnormalities have been shown to be associated with improved prognosis such as the core binding factor leukaemias [inv(16), t(8;21), t(16;16)], and acute promyelocytic leukaemia (APL) [t(15;17)]. Treatment strategies targeting specific AML subtypes have been developed to maximize clinical outcomes and minimize toxicity based upon cytogenetic classification.

Table 33.3 WHO (2008) Classification of acute myeloid leukaemias and related precursor neoplasms.

Acute myeloid leukaemia with recurrent genetic abnormalities[a]
Acute myeloid leukaemia with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukaemia not otherwise specified (NOS)
Myeloid sarcoma
Myeloid proliferation related to Down syndrome
Blastoid plasmacytoid dendritic neoplasm

[a]Examples include core binding factor leukaemias[i.e. t(8;21), inv(16)], and acute promyelocytic leukaemia with t(15;17).
Adapted from Vardiman *et al.*[5]

If untreated or unresponsive to chemotherapy, AML may be rapidly fatal (median survival <2 months). The major causes of death are overwhelming infection and haemorrhage related to the disease-associated cytopenias. Survival for AML is age-dependent, with five-year survival rates as low as 5% among patients ≥65 years compared to approximately 30% for those <65.[2] This age-related outcome disparity is also seen in clinical trials. In addition, older adults are more likely to experience treatment-related toxicity. Due to concerns regarding inferior outcomes, a

large proportion of older adults in the United States are not referred for chemotherapy treatment of their disease.

Age-related changes in tumour biology are a major determinant of poor outcome in older adults with AML.[20,21] Older patients have a higher percentage of unfavourable cytogenetic abnormalities (i.e. chromosomes 5 and 7 abnormalities, and complex karyotypes) and a lower percentage of favourable cytogenetic abnormalities [i.e. t(8;21), and inv(16)] compared to younger patients. Unfavourable cytogenetic abnormalities are associated with decreased remission rates and shortened overall survival. Intrinsic drug resistance, mediated by the expression of a multidrug resistance phenotype (MDR1), is also more common in older AML patients. This provides an advantage to the leukaemia cells when treated with conventional agents such as anthracyclines. Finally, older adults are more likely to present with secondary AML arising in the setting of myelodysplastic syndrome (MDS), which is less responsive to standard therapies. While each of these poor prognostic features can individually influence remission rates, the combination of poor prognostic features is dramatically associated with lower remission rates with standard therapies. For example, older adults with the combination of *de novo* AML, MDR1 negative phenotype, and favourable/intermediate cytogenetics may have a complete remission (CR) rate as high as 81% compared to a CR rate of only 12% in those with MDR positive phenotype, secondary AML, and unfavourable cytogenetics.[22]

Despite the impact of tumour biology, striking differences in treatment outcomes persist between older and younger adults after stratifying for cytogenetic risk group.[20] Older adults with favourable cytogenetic profiles continue to experience inferior outcomes relative to younger patients with the same disease. Patient-specific factors, such as comorbidity and functional impairment, influence an older adult's ability to tolerate tumour burden and aggressive treatments. Increased comorbidity burden has been independently associated with lower remission rates, increased treatment-related mortality and poor overall survival. In one study, treatment-related death among older adults was 3% for patients who screened negative for comorbid conditions compared to 30% for those screening positive for majority comorbidity using a validated comorbidity index.[23]

Similarly, physical function at the time of diagnosis is strongly associated with prognosis. Older adults who present with poor performance on the Eastern Cooperative Oncology Group (ECOG) Performance Scale (score >2, spending more than 50% of the day resting) are at increased risk for treatment-related mortality and poor survival. The prognostic importance of poor performance status increases significantly with chronological age. For example, clinical trial evidence suggests that the treatment-related mortality rate is approximately 30% for patients aged 56–65 years with poor performance status (ECOG score >2) compared to 80% for those >75 years of age with a poor performance status.[20]

Treatment

There is significant debate regarding optimal treatment for older adults with AML. While selected older adults can benefit from standard aggressive therapies, many experience increased morbidity and poor treatment response. Curative treatment for AML typically involves induction and consolidation chemotherapy. Initial (induction) chemotherapy is given in the hospital and is associated with long hospital stays (mean 20+ days) due to expected complications of myelosuppression including transfusion dependence and infections. The goal of this intensive chemotherapy is to produce marrow aplasia, followed in a few weeks by reconstitution of bone marrow. Remission requires recovery of peripheral blood counts and <5% myeloid marrow blasts. Post-remission chemotherapy (consolidation) is required for cure.

Standard induction therapy for AML is combination chemotherapy that includes cytosine arabinoside (Ara-C) and an anthracycline such as daunorubicin. A landmark randomized study by Löwenberg *et al*. demonstrated improved survival in selected patients ≥65 years of age treated with induction therapy versus supportive care alone.[24] In addition, there was no difference in time spent hospitalized between the two groups. This study paved the way for considering curative therapy options for older adults.

Unfortunately, many subsequent studies have failed to improve upon the suboptimal treatment outcomes seen in the older population. While complete remission rates range from 40–60%, median survival remains less than a year on clinical trials. Dose-attenuated treatments, designed to minimize toxicity, have not resulted in substantial improvement in outcomes. Haematopoietic growth factors including granulocyte colony stimulating factor (G-CSF) and granulocyte macrophage colony stimulating factor (GM-CSF) have not consistently been shown to improve response rates or survival; likewise they do not clearly decrease costs. To date, no induction chemotherapy regimen tailored to the older adult population has clearly demonstrated improvement in clinical outcomes.

Optimal post-remission therapy for older adults also remains unclear. It is generally accepted that post-remission therapy or consolidation is required to eradicate residual leukaemia after induction. Typical post-remission treatment includes high-dose Ara-C or haematopoietic stem cell transplantation. In a randomized study of low-, intermediate- and high-dose Ara-C for consolidation in patients who had achieved complete remission, younger patients benefited from dose escalation

while older patients experienced more cerebellar toxicity and no benefit in disease-free survival.[25] In elderly specific trials, lower dose Ara-C regimens as a single agent or in combination with an anthracycline have been tested. In this population, there is no clear evidence to date that multiple courses of consolidation or maintenance therapy improve outcomes when compared to a single course of consolidation therapy.

Haematopoietic stem cell transplantation is another post-remission therapy option. In younger adults, high-dose chemotherapy followed by autologous stem cell transplantation can be considered for patients with intermediate-risk cytogenetics. Autologous haematopoietic stem cell transplantation is feasible in highly selected older adults with AML.[26] However, there is no randomized trial data to suggest superiority of this strategy over conventional chemotherapy and treatment-related mortality remains high (15–30%).

Allogeneic stem cell transplantation remains a standard post-remission treatment option with potential for long-term survival in younger adults with poor-risk cytogenetics. Traditional allogeneic haematopoietic cell transplantation (allo-HCT) is associated with very high treatment-related mortality in older adults and is therefore not recommended as post-remission therapy for most patients >60 years of age. Use of reduced-intensity allogeneic transplantation regimens ('non-myeloablative regimens') have resulted in a trend towards increased allogeneic transplantation in adults over age 50. This type of transplantation utilizes the graft versus leukaemia effect and reduces acute toxicities associated with use of myeloablative therapies. While this therapy may be feasible in highly selected older adults, it is yet unclear if this treatment strategy is superior to conventional approaches.

Post-remission therapy for older adults is further complicated by a higher likelihood that patients will no longer be candidates for additional treatment due to functional impairment or end organ damage resulting from induction therapy. In many cases a curative treatment approach must be aborted due to poor performance status that precludes post-remission treatment. In randomized trials, up to 20% of older adults may not go on to receive any consolidation therapy after achieving complete remission.[27] Attrition is much higher for older adults considered for post-remission transplantation.

Treatment recommendations differ for patients with acute promyelocytic leukaemia (APL). APL is characterized by a translocation between chromosomes 15 and 17 leading to the fusion of the promyelocytic leukaemia (*PML*) gene with the retinoic acid receptor α (*RAR*α) gene, resulting in disruption of normal cell differentiation.[28] While less common among older adults, this fulminant disease has a very high response and cure rate with current therapies that include use of all-*trans* retinoic acid (ATRA) which overcomes the differentiation block. A unique clinical feature of APL is presentation with bleeding secondary to disseminated intravascular coagulation and requires emergent treatment. Haemorrhage is a frequent cause of early mortality, particularly if untreated. When suspected, treatment with ATRA should begin immediately. Curative treatment includes induction with anthracycline and ATRA therapy followed by consolidation and maintenance therapy. The treatment course may span 1–2 years with remission rates ranging between 75–90%. In addition, relapsed patients may respond to arsenic trioxide, with a high proportion achieving a second remission. This subtype of AML should be treated aggressively in older adults given the high probability of response.

Regardless of AML subtype, supportive care is a key component of treatment for AML. Improvements in survival for AML over the past decades have been largely attributed to improved supportive care during induction. Older adults referred for AML therapy should be treated at high-volume centres with standard supportive care algorithms in place. Key components of supportive care include aggressive treatment of neutropenic fever (absolute neutrophil count <1000, temperature >100.5°F) and transfusion support. Patients with neutropenic fever should be started on broad spectrum intravenous antibiotics with gram negative coverage regardless of symptoms. Cultures are often negative but should be obtained routinely. Antibiotic regimens should be broadened to include antifungal coverage if fevers persist despite use of appropriate antibacterial therapy. Transfusion support is also a critical part of supportive care for patients with AML. During induction and consolidation therapy red cell transfusions are regularly required due to marrow hypoplasia. In addition, platelet transfusions are indicated for bleeding or prophylactically to prevent spontaneous intracranial bleeding using a threshold of $<10\,000\,\mu l^{-1}$.

In summary, treatment recommendations for older adults with AML need to be individualized based on tumour biology and an assessment of physiologic age rather than chronological age alone. While optimal therapy for older adults as a group remains debated, there is some evidence to guide decision-making for individual patients. Older adults with newly diagnosed AML who present with any of the following characteristics are more likely to experience toxicity and less likely to benefit from standard induction chemotherapy: an ECOG score >2, significant comorbidity (Charlson Comorbidity Index score >1), and poor-risk cytogenetics. It would be reasonable to offer these patients supportive care alone, low-intensity therapy or a clinical trial investigating novel agents. Alternatively, older adults with good functional status (ECOG <2, no impairment in IADLs), minimal comorbidity, and good-risk cytogenetics are likely to benefit from curative therapies. Optimal treatment for the large population of older adults who fall

between these two extremes is unclear. Prospective studies are needed to validate the added prognostic value of risk stratification based on factors other than chronological age and cytogenetic risk group.

Future directions

Investigation of novel agents to be used in addition or as a supplement to standard induction may improve outcomes for older adults with AML in the future. Development of less toxic more targeted agents may provide treatment alternatives for the large proportion of the elderly AML population who have less than optimal functional status, limiting comorbidities or unfavourable tumour biology. Clinical trials are in development that target treatments to specific biological subsets of AML in the elderly. In addition, clinical trials are also evaluating the use of geriatric assessment techniques to improve risk stratification among this patient population. Finally, supportive care strategies are being developed that focus attention on the maintenance of functional status and quality of life for those patients who are treated with aggressive therapies.

Acute lymphoblastic leukaemia (ALL)

Approximately 4000 cases of ALL are diagnosed yearly in the United States, with only one third of these cases in adults.[2] There is a bimodal incidence peak between ages 2 and 5 years, and again after age 50 years. With available therapy today, childhood ALL is curable in the majority of patients. ALL in adults is not the same as the childhood disease. First, the frequency of complete response is lower −70–75% in adults as opposed to more than 90% in children. Second, the remission duration and curability using the same therapy is considerably less.

ALL is broadly classified according to WHO criteria as follows: (1) precursor B-cell ALL; (2) precursor T-cell ALL; and (3) mature B-cell leukaemia (Burkitt leukaemia). Precursor B-cell ALL represents the majority of cases. Within these categories, several subgroups are identified based on cytogenetic abnormalities which have prognostic significance. These lymphoblastic neoplasms can present as either leukaemia or lymphoma. They are classified as leukaemia if there are >25% bone marrow blasts.

Common clinical manifestations at diagnosis include symptoms of pancytopenia (fatigue, bleeding, bruising, infection), and constitutional symptoms (fevers, night sweats, weight loss). Central nervous system involvement is common particularly in precursor B-cell ALL. In contrast to AML, hepatosplenomegaly and lymphadenopathy may be seen in up to half of adult patients. Precursor T-cell ALL, which is typically seen in younger patients, often presents with an anterior mediastinal mass. Diagnosis is made by bone marrow biopsy with morphologic and immunophenotypic analysis.

Important prognostic features for outcome in the treatment of ALL include older age, cytogenetics, and immunophenotype. Poor prognosis is especially associated with the presence of chromosomal translocations such as Philadelphia (Ph+) chromosome t(9;22), t(4,11), t(8;14), t(2;8), or t(8;22), and with a phenotype indicating mixed lymphoid-myeloid leukaemia (also called biphenotypic leukaemia). Poor prognosis tumour biology, particularly Ph+ ALL is more common among older adults, seen in up to 50% of older ALL patients.

The initial goal of therapy for adult ALL is to correct problems secondary to bone marrow failure; that is, to treat anaemia with blood transfusions, treat documented or suspected infection, and control bleeding. Specific anti-leukaemia treatment is then directed toward the achievement of a complete remission. Induction chemotherapy therapy for ALL, very different from that for AML, usually includes the use of prednisone, vincristine, daunorubicin, and asparaginase.[29] While these drugs are well tolerated in children, increasing age is associated with poorer drug tolerance. Mortality, usually from infection and/or bleeding during the induction process, may occur in 10–20% of elderly patients.

It is widely accepted that patients with ALL require therapy after complete remission (CR).These phases of treatment once the patient is in CR have been referred to as intensification (consolidation) therapy and maintenance therapy. The optimal therapy after remission and the duration of such therapy in older patients are not clearly defined. Most programmes use multiple drugs administered in a cyclic fashion over a two-year period; the more intensive therapy is given over about six months after CR is achieved (intensification or consolidation), followed by a less-intensive outpatient maintenance regimen for approximately 18 months.

Directed treatment to the craniospinal axis [central nervous system (CNS) prophylaxis] is standard practice in the treatment of childhood ALL. While the incidence of CNS leukaemia is lower in adults than in children, treatment to the CNS is also part of ALL therapy in adults. This usually consists of intrathecal methotrexate in conjunction with high-dose systemic therapy such as high-dose methotrexate and Ara-C, or cranial radiation.

With the above intensive treatment plan, the median duration of remission is approximately two years, with 35–45% of adult patients disease-free at five years. However, prognosis is poorer for older adults with long-term survival <20% with treatment.[30] One contributing feature to this poorer response duration in adults as opposed to children is the inability to deliver optimal chemotherapy at maximal doses due to comorbid diseases and increased

susceptibility to toxicity. This is evident both in the induction phase and during intensification post-remission with high treatment-associated mortality.[30]

Identification of targeted therapeutic approaches may improve outcomes for older adults with ALL. One example of this is the shifting treatment paradigm for the Ph+ ALL subtype. Outcomes for all patients with this poor prognosis variant have improved with the addition of imatinib mesylate to combination chemotherapy.[31] Imatinib mesylate inhibits the constitutively active abl tyrosine kinase which is seen in approximately half of older adults with ALL. Use of imatinib with steroids alone has demonstrated activity among older adults[32] and provides an option for patients who may not be candidates for aggressive chemotherapy due to comorbidity or poor functional status.

In summary, ALL is an uncommon disease that requires aggressive and prolonged chemotherapy for cure. Outcomes remain poor among older adults and treatment decision- making should be individualized based on tumour biology, estimated reserve capacity in response to treatment, and life expectancy. Standard multidrug chemotherapy (with imatinib for Ph+ ALL) should be considered for older adults with minimal comorbid disease and good functional status. The risks of treatment morbidity and mortality increase for older adults with poor functional status and/or limiting comorbid conditions. In this setting, palliative treatment with steroids, low-intensity chemotherapy, and imatinib for Ph+ ALL may be appropriate.

Conclusion

Myelodysplastic syndromes are common among older adults and the natural history varies greatly. Older adults with low-risk disease can be managed with supportive care alone for many years while those with higher risk disease, and good functional status should be considered for low-intensity therapy. The goal of therapy is to maximize quality of life, delay progression to AML and improve survival. AML is an aggressive disease requiring rapid initiation of multiagent chemotherapy for cure. While treatment outcomes remain suboptimal for older adults, selected older patients can benefit and be cured of disease. Older adults with good functional status and minimal comorbid conditions should be referred for treatment of AML. Similarly, selected older adults can benefit from treatment of ALL, although treatment courses are protracted. Curative and palliative treatment options have expanded for ALL with the use of targeted imatinib therapy for Ph+ ALL. Ongoing research aimed at identifying less toxic therapies targeted to tumour biology will likely expand treatment options for each of these disease entities for older adults.

Key points

- Myelodysplastic syndromes (MDS) are common and have a varied natural history.
- Older adults with low-risk MDS can be managed supportively.
- Treatment with low-intensity chemotherapy (i.e. 5-azacytidine or decitabine) should be considered for older adults with high-risk MDS and adequate functional status.
- Older adults with AML are more likely to present with aggressive tumour biology and treatment outcomes remain poor.
- Treatment for AML should be individualized. Older adults with favourable/intermediate tumour biology and good functional status can benefit from curative therapy.
- ALL is uncommon in older adults. Curative treatment is protracted but should be considered for those with good functional status. Imatinib should be part of curative or palliative therapy for Ph+ ALL.

SECTION 4

Cardiovascular Diseases and Health

CHAPTER 34

Epidemiology of heart disease

Ahmed H. Abdelhafiz
Rotherham General Hospital, Rotherham, Yorkshire, UK

Introduction

Epidemiology is defined as the study of occurrence and distribution of disease in human populations. Epidemiological research can be used to study benefits of interventions to prevent and decrease the burden of disease or to predict requirements for trained healthcare professionals, caregivers for disabled or older people, and service planning. Coronary heart disease (CHD) is an important cause of morbidity and mortality. Incidence and prevalence of CHD both rise steeply with increasing age. The older population is growing and the world's population ≥60 years old is estimated to reach 2 billion by 2050 (three times that in 2000). The development and progression of atherosclerosis is not just a function of ageing but is determined by the distribution of cardiovascular (CV) risk factors related to specific lifestyles. Heart disease may affect quality or quantity of life or both. As the population suffering from heart disease becomes older, their functional ability becomes more important. Mortality cannot be the only outcome relevant to older people but quality of life, cognitive and functional capacities are equally important endpoints. While CHD is a major cause of mortality, other heart diseases may have a significant impact on quality of life due to limitation of exercise tolerance. This chapter discusses epidemiological features of the most common heart diseases affecting older people including CHD, heart failure, valvular heart disease and rhythm disorders (Box 34.1).

Box 34.1 Common heart diseases in older people

- Coronary heart disease
- Heart failure
- Valvular heart disease
  - *Degenerative valve disease*
  - *Infective valve disease*
- Rhythm disorders
  - *Atrial fibrillation*
  - *Sudden cardiac death*

Coronary heart disease

The CHD epidemic started in the 1950s affecting firstly western countries. Prior to the 1920s CHD was not common and caused only <10% of all deaths in the United States. However, by the 1950s this had escalated to >30% and it is now the leading cause of death. While its mortality has fallen by 50%, its incidence has decreased little or hardly at all. Mortality from CHD has also decreased among elderly persons, but information on changes in incidence in the elderly is limited. The main reasons for the decline in morbidity and mortality are due to changes in risk factors as well as improvement of treatment. Survival after myocardial infarction has improved and significant advances have also been made in the surgical and medical treatment of CHD.

Risk factors and prevention

Major risk factors for atherosclerosis have been well established. Epidemiological studies concluded that the causes for this epidemic are due to genetic factors in addition to other considerations such as age, smoking, hypertension, obesity, diabetes and cholesterol. Variations in disease occurrence in different nations still remain far from being fully explained. No single factor is responsible for CHD. It is a multifactorial disorder that is likely to be due to subclinical inflammation that many factors can contribute to, such as chronic infection, increased clotting tendencies and other irritants.

Genetics

It is believed that CVD results from many genes, each with a relatively small effect working alone or in combination with other modifier genes and/or environmental factors. Familial hypercholesterolaemia and hyperhomocystinuria are well-described examples. Insulin-like growth factor-1

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

(IGF-1) is believed to influence ageing and may be involved in the pathogenesis of CHD; however, a causative association is lacking. In the prospective (four-year) case-control study nested within the British Women's Heart and Health Study, IGF-1 was inversely correlated with waist:hip ratio, fasting insulin, C-reactive protein, triglycerides and systolic blood pressure, and was positively correlated with HDL cholesterol but there was no evidence of CHD risk reduction in older women (60–79 years old).[1] However, in another study high IGF-1 was independently associated with increased all-cause mortality and risk of development of heart failure in an elderly cohort of 642 individuals, aged 50–89 years, followed up for five years.[2] Telomere length is another genetic factor associated with CV health and ageing. Telomere attrition is associated with elevated blood homocysteine and increased endothelial cell inflammatory markers and may underlie early fetal origins of CVD. The identification and characterization of genes that enhance prediction of disease risk and improve prevention and treatment of atherosclerosis need further genetic epidemiological studies.

Age and sex

Prevalence of CHD increases with age from 2% for males and 0.5% for females at age 40–44 to peak at 18% and 12% respectively at age 85–89. Median age at onset is 67.5 years for males and 77.5 years for females. Lifetime risk is 35% for males and 28% for females. Prevalence of CHD decreased in individuals <65 and increased among those ≥75 years especially in women. CHD accounts for 22% of male deaths and 17% female deaths at all ages. Largely, epidemiology of CHD is changing from a fatal disease of middle-aged men to a more chronic condition of elderly women. CHD is intimately related to normal ageing in that its incidence continues to increase indefinitely with age. In a prospective study to investigate the influence of increasing age on incidence of CVD in 22 048 male physicians aged 40–84 who were free of major disease, incidence of CVD continued to increase to age 100 over 23 years of follow-up.[3] Beginning at age 80, CVD was more likely to be diagnosed at death. The remaining lifetime risk of CVD at age 40 was 34.8%, 95% confidence interval (CI), 33.1–36.5% and at age 90 was 16.7% (95% CI, 12.9–20.6%). These findings suggest that people aged ≥80 may be living with a substantial amount of undiagnosed CVD. Additional research is needed to determine if continued screening and detection of CVD up to and beyond age 80 might help improve health in later life.

Ethnicity and race

Prevalence of CHD and related risk factors vary among different ethnic groups. The pattern of this variation is complex, and could be related to genetic or socioeconomic differences. For example, populations of African descent living in Europe and the United States have a higher incidence of stroke and lower incidence of CHD than in their white counterparts. They have higher rates of hypertension, which may explain their high rate of stroke. Similarly, in China mortality from CHD is still lower than in western countries while mortality due to stroke is several times higher largely due to the high prevalence of hypertension. The lower rate of CHD may be explained by low rates of other risk factors including smoking.[4] In the Indian subcontinent CVD is expected to increase rapidly and it will be the host of >50% of cases of heart disease in the world within the next 15 years. Risk factors for this epidemic are similar to those elsewhere in the world; however, ~50% of CHD-related deaths occur in people <70 years compared with only 22% in the west. Also Asians living in western countries have a 50% greater premature mortality risk from CHD than the general population.

Diet

Dietary factors are related to the risk of CHD through several biological mechanisms. For example: (i) Fish consumption provides cardio-protective benefits through favourable effects on lipid profile, threshold for arrhythmias, platelet activity, inflammation, endothelial function, atherosclerosis and hypertension. Consumption of fish 1–2 times per week or at least 5–10% of energy from polyunsaturated fatty acids reduces the risk of CHD in older people relative to lower intakes.[5] (ii) Antioxidants present in fruit and vegetables improve endothelial function, inhibit platelet activation and lower blood pressure. (iii) High salt consumption is directly related to hypertension, myocardial infarctions and strokes. Modest reductions in salt lower systolic blood pressure by at least 2 mmHg reducing the prevalence of hypertension by 17%, cardiac events by 30% and overall mortality by 20%. Older people will gain the greatest advantage from lowering their salt intake, most likely because they are more salt sensitive. (iv) Alcohol intake has a U-shaped relationship with the risk of CHD. 'Moderate drinking' defined as one drink for women and two drinks for men per day reduces the risk of CHD by 25%. Data relating to multivitamin use and the risk of CVD are inconsistent. Broader adherence to recommendations for daily intake of fruit, vegetables, low salt, alcohol in moderation and fish may take away 20–30% of the burden of CVD and result in one extra life-year if started early by the age of 40 years.[6]

Cholesterol

Cholesterol is a risk factor for CVD in the middle aged but appears to be less potent at older ages. However, dietary cholesterol is more detrimental in people with diabetes, regardless of age, because of dyslipidaemia and increased insulin resistance. In the Health, Ageing and Body Composition Study of 1941 community-dwelling elderly people

aged 70–79, there were no significant associations between dietary fats and CVD risk, hazard ratio (HR) 1.47, 95% CI, 0.93–2.32 for the upper versus lower tertile, p for trend 0.10 after nine years of follow-up. However, dietary cholesterol was associated with increased CVD risk among older people with diabetes (3.66, 1.09–12.29).[7] Possible reasons for these results are attenuated association between lipids and CV risk among older people, differences in baseline CV risk between old and young, or selective survivorship of older people leading to a population sample less vulnerable to environmental factors such as dietary fat.

Exercise

Although few studies have been conducted in the elderly, most have reported physical activity to be beneficial in preventing premature mortality but with some concerns about adverse effects especially in frail elderly with comorbidities. Physical activity may trigger sudden death and may have a higher risk of injury. However, in a Japanese study of 10 385 elderly (aged 65–84), most of whom were under treatment for pre-existing disease, every physical activity was associated with a reduced risk of all causes and CVD mortality after seven years of follow-up. Hazard ratios (95% CI) for CVD mortality among participants with ≥5 days of physical activity per week for the total sample and those with pre-existing diseases were 0.38 (0.22–0.55) and 0.35 (0.24–0.52) respectively, compared with no physical activity. In spite of possible adverse effects, this study indicated that elderly people with a pre-existing disease benefit from any level of physical activity in a dose-response relationship to mortality.[8]

Obesity

Obesity is a risk factor for CHD, poor health and excess mortality. Thresholds for normal weight or obesity defined as body mass index (BMI) were primarily based on evidence from studies in younger adults. In older people the relationship between weight and CV risk is more complex. It remains unclear whether overweight and obese cut points are overly restrictive measures for predicting mortality in older people. In a study to examine all cause and cause-specific mortality associated with underweight (BMI <18.5), normal weight (BMI 18.5–24.9), overweight (BMI 25.0–29.9), and obesity (BMI > or = 30.0) in an elderly cohort of 4677 men and 4563 women aged 70–75, mortality risk was lowest for overweight participants after 10 years of follow-up. Risk of death for overweight participants was 13% less than for normal weight participants (HR 0.87, 95% CI, 0.78–0.94). Minimum mortality risk was found at a BMI of 26.6 (95% CI, 25.7–27.5) in men and 26.26 (95% CI, 25.5–26.9) in women. Risk of death was similar for obese and normal weight participants (HR 0.98, 95% CI, 0.85–1.11).[9] It appears that extreme obesity is harmful but overweight older people are not at greater mortality risk, and there is little evidence that dieting in this age group confers any benefit.

Smoking

Smoking is a major modifiable risk factor for CVD and causes 11% of all CVD-related mortality. Smoking contributes to the pathogenesis of CHD through promotion of atherosclerosis, triggering of coronary thrombosis, coronary artery spasm, cardiac arrhythmias and the reduced capacity of blood to deliver oxygen. The magnitude of the burden produced by smoking increases rather than decreases with ageing. While relative risk for smoking on CHD is similar in the elderly and middle aged, there is a twofold increase in excess absolute risk in the elderly. Benefits of cessation for older smokers are similar in magnitude to those of younger smokers who quit. The risk of CHD drops by 50% one year after smoking cessation and approaches that of a person who has never smoked within 3–4 years, even in individuals older than 60 years. Smoking cessation is highly cost-effective and should be viewed as a therapeutic rather than just a preventive intervention regardless of age.[10]

Socioeconomic factors

There is an inverse relationship between socioeconomic status (SES) and prevalence of CV risk factors. People with lower SES tend to adopt unhealthier behaviours, such as smoking and unhealthy dietary habits, and seem to have an increased prevalence of CV risk factors resulting in socioeconomic inequalities in CV health. Although there is a strong social class gradient in CHD risk in middle age, the evidence in old age is limited. In a population-based study of 3761 British men aged 60–79 years there was a graded relationship between social class and CHD incidence after 6.5 years of follow-up. The HR for CHD incidence comparing social class V (unskilled workers) with social class I (professionals) was 2.14 (95% CI, 1.06–4.33; p for trend = 0.11) after adjustment for behavioural factors. Absolute difference in CHD risk between highest and lowest social classes was 4%. Socioeconomic inequalities in CHD persist in the elderly and are at least partly explained by behavioural factors. Improving behavioural factors (especially smoking) could reduce these inequalities by one third.[11]

Hypertension

Hypertension is a major risk factor for CVD in elderly. It reduces life expectancy by seven years. Prevalence of hypertension is 20% in developed countries. However, prevalence is significantly higher in older people affecting 70% of those >80 years. Black Americans develop hypertension earlier in life and it tends to be more severe than in the white population. There is a strong but complex association between blood pressure (BP) and

age. Up to 50 years of age, systolic and diastolic BP rise in tandem. After age 50, systolic BP continues to rise, whereas diastolic BP tends to fall. Below age 50, diastolic BP is the major predictor of CHD risk, whereas above age 60, systolic BP is more important. There is also an enhanced risk for CHD associated with increased pulse pressure. The risk of a fatal CHD event doubles for every 20/10 mmHg increment above 115/75 mmHg. Absolute risk of adverse outcomes increases with age reaching 16-fold higher for persons 80–89 years than for those 40–49 years. A 10 mmHg reduction of systolic BP would predict a 50–60% lower risk of stroke death and a 40–50% lower risk of CHD death. In very old individuals (≥85 years old) the association between hypertension and mortality is weaker and treating hypertension reduces risk of death by 21%, risk of stroke by 30% and risk of cardiac failure by 64%. The target for BP is <140/90 mmHg in general and <130/80 mmHg in individuals with diabetes or chronic kidney disease. Evidence that excessive lowering of diastolic BP in older hypertensive individuals with wide pulse pressures may compromise cardiac outcomes (J curve) is inconsistent and no consensus exists regarding the minimum safe level of diastolic BP in these individuals.[12]

Diabetes mellitus

Diabetes has been recognized as an independent major CV risk factor. In spite of various known metabolic and microvascular complications of diabetes, cardiovascular disease remains the most common cause of death in diabetic persons of all age groups affecting around 65–80%. Diabetes itself, in the absence of associated CHD constitutes a risk similar to those of non-diabetic individuals with a previous history of myocardial infarction. Increased risk of CVD in diabetes is not fully explained by traditional risk factors and could be related to increased insulin resistance. Risk of CHD and myocardial infarction rises by 30% and 14% respectively for every 1% increase in HbA1c. Whether hyperglycaemia itself is a risk for CHD is not very clear. Hyperglycaemia leads to an increase in oxidative stress which, in combination with other risk factors, may cause an accelerated progression of atherosclerosis.

Metabolic syndrome

Metabolic syndrome is a constellation of central obesity, impaired fasting glucose, hypertension, high triglycerides and low HDL cholesterol. Pathophysiology of metabolic syndrome includes decreased physical activity and increased inflammation. In older people vitamin D deficiency,[13] leading to increased parathyroid hormone and insulin resistance, in combination with low testosterone, leading to increased waist:hip ratio, are other contributing factors. Metabolic syndrome affects >40% of persons >60 years old and is more common in men. Comparative utility of metabolic syndrome versus its individual components for predicting adverse outcomes in older populations is not well established. In an Italian study of 2910 subjects aged ≥65 years, metabolic syndrome was associated with increased all-cause mortality in all subjects (HR 1.41, 95% CI, 1.16–1.72, $p < 0.001$), in men (1.42, 1.06–1.89, $p < 0.017$), and in women (1.47, 1.13–1.91, $p < 0.004$). It was also associated with increased CV mortality in all subjects (1.60, 1.17–2.19, $p < 0.003$), in men (1.66, 1.00–2.76, $p < 0.051$), and in women (1.60, 1.06–2.33, $p < 0.025$). Among metabolic syndrome components, all-cause mortality is better predicted by high glucose in all subjects (1.27, 1.02–1.59, $p < 0.037$) and in women (1.61, 1.16–2.24, $p < 0.005$) and by low HDL cholesterol in women (1.48, 1.08–2.02, $p < 0.014$), whereas CV mortality is better predicted by high glucose (2.17, 1.28–3.68, $p < 0.004$) and low HDL cholesterol (1.78, 1.07–2.95, $p > 0.026$) in women.[14] In a similar US study of 4258 older people ≥65 years free of CVD, those with metabolic syndrome had a 22% higher mortality, relative risk (RR) 1.22, 95% CI, 1.11–1.34 compared with persons without metabolic syndrome after multivariable adjustment. Higher risk with metabolic syndrome was confined to persons having an elevated fasting glucose level >6.1 mmol l^{-1} (RR 1.41, 95% CI, 1.27–1.57) or hypertension (RR 1.26, 95% CI, 1.15–1.39) as one of the diagnostic criteria of metabolic syndrome. Persons having metabolic syndrome without high fasting glucose or metabolic syndrome without hypertension did not have higher risk (RR 0.97, 95% CI, 0.85–1.11 and 0.92, 0.71–1.19 respectively). Persons having both hypertension and high fasting glucose had 82% higher mortality (RR 1.82, 95% CI, 1.58–10.9).

In older people individual components of metabolic syndrome predict CVD mortality with equal or higher HR when compared with metabolic syndrome. Therefore, these findings suggest that the metabolic syndrome concept is a marker of CVD risk, but may not have any more advantage in predicting cardiac risk than its individual components.[15]

Frailty and disability

Frailty is a geriatric syndrome of increased vulnerability to stress factors due to decline in function in multiple interrelated systems. Frailty is distinct from related concepts of (i) comorbidity: the burden of coexisting medical illnesses, and (ii) disability: the limited ability for self-care (Figure 34.1). Frailty reflects biological rather than chronological age leading to substantial variability in the outcomes of older people. The relationship between frailty and CVD is mutual; frailty may lead to CVD just as CVD may lead to frailty. In other words frailty is associated with CVD as a risk factor and as an outcome. Around 7% of the US population >65 years and 30% of octogenarians are frail. Domains to define frailty include mobility, strength, balance, motor processing, cognition, nutrition, endurance

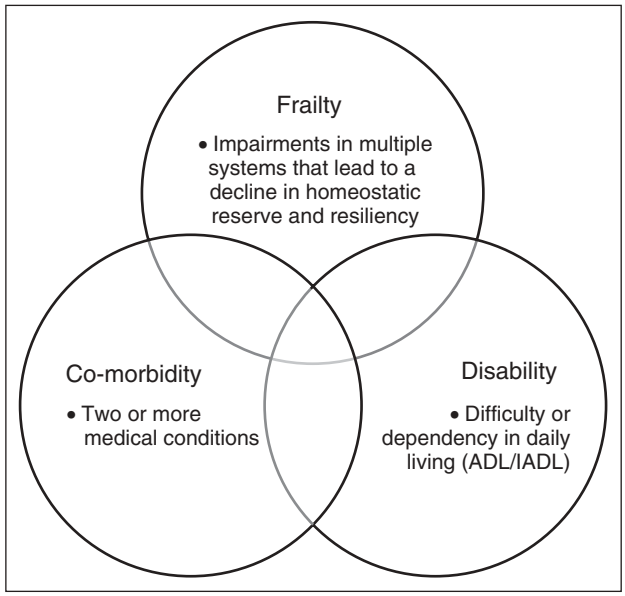

Figure 34.1 Overlap between frailty, comorbidity, and disability. ADL, activities of daily living (basic self-care tasks); IADL, instrumental ADL (household management tasks). Reprinted from Afilalo *et al.*[16] Copyright 2009, with permission from Elsevier.

and physical activity. Frailty reduces patients' ability to maintain homeostasis in the face of acute stress, predicts mortality and heralds transition to disability. In a systematic review of frailty in patients with CVD, nine studies were included encompassing 54 250 elderly patients with a mean follow-up of 6.2 years. In community-dwelling elders, CVD was associated with an odds ratio (OR) of 2.67 to 4.1 for prevalent frailty and an OR of 1.47 for incident frailty in those who were not frail at baseline. Gait velocity (a measure of frailty) was associated with an OR of 1.61 for incident CVD. In elderly patients with documented severe CHD or heart failure, the prevalence of frailty was 50–54%, and this was associated with an OR of 1.62 to 4.0 for all-cause mortality after adjusting for potential confounders (Table 34.1). It is likely that underlying abnormalities in haematological, inflammatory and metabolic systems in frail older patients are linked to increased CV risk. Compared with non-frail counterparts, frail patients had significantly higher levels of factor VIII, D-dimers, C-reactive protein, leukocytes, fibrinogen, glucose, low vitamin D and low haemoglobin. The close correlation between frailty and biomarkers of inflammation and thrombosis resembles the correlation between CVD and these same biomarkers. This common biological pathway may explain why frailty and CVD are interrelated at clinical level. Reasons to consider frailty in older people with CVD include its early identification and anticipation of care after major cardiac events. There is overlap of frailty with comorbidity and disability. Unintended weight loss, disability in activities of daily living and presence of multiple comorbid conditions in a complex cardiac patient should alert physicians to the possibility of associated frailty. Screening of frailty may include simple tests, such as grip strength, gait speed or quadriceps strength. Early recognition of frailty will need comprehensive geriatric assessment combined with multidisciplinary interventions to slow or reverse functional decline, improve physical performance and quality of life.[16] Disability, on the other hand, is a common condition in older people and has been associated with prevalent CHD and shorter longevity. It is less clear whether disability is a risk factor for atherosclerosis development or a prognostic factor for CHD outcome. In a French multicentre prospective population-based cohort of 9294 subjects free of CVD (aged $\geq$65 years), the mean level of CV risk factors increased gradually with severity of disability. After a median follow-up of 5.2 years, 264 first coronary events, including 55 fatal events, occurred. After adjustment for CV risk factors, participants with moderate or severe disability had a 1.7 times (95% CI, 1.0–2.7) greater risk of overall CHD than non-disabled subjects, whereas those with mild disability were not at greater CHD risk. An association was also found with fatal CHD, for which risk increased gradually with severity of disability (HR 1.7, 95% CI, 0.8–3.6 for mild disability, 3.5, 1.3–9.3 for moderate to severe disability, p for trend = 0.01). This result reflected a specific association between disability and fatal but not with non-fatal CHD. The lack of association between disability and non-fatal CHD suggests that disability has little impact on atherosclerosis development. In other words disability even of mild severity has more to do with prognosis rather than with occurrence of CHD (Figure 34.2). However, this prognostic function of disability could be related to the possibility that disabled subjects suffering from an acute

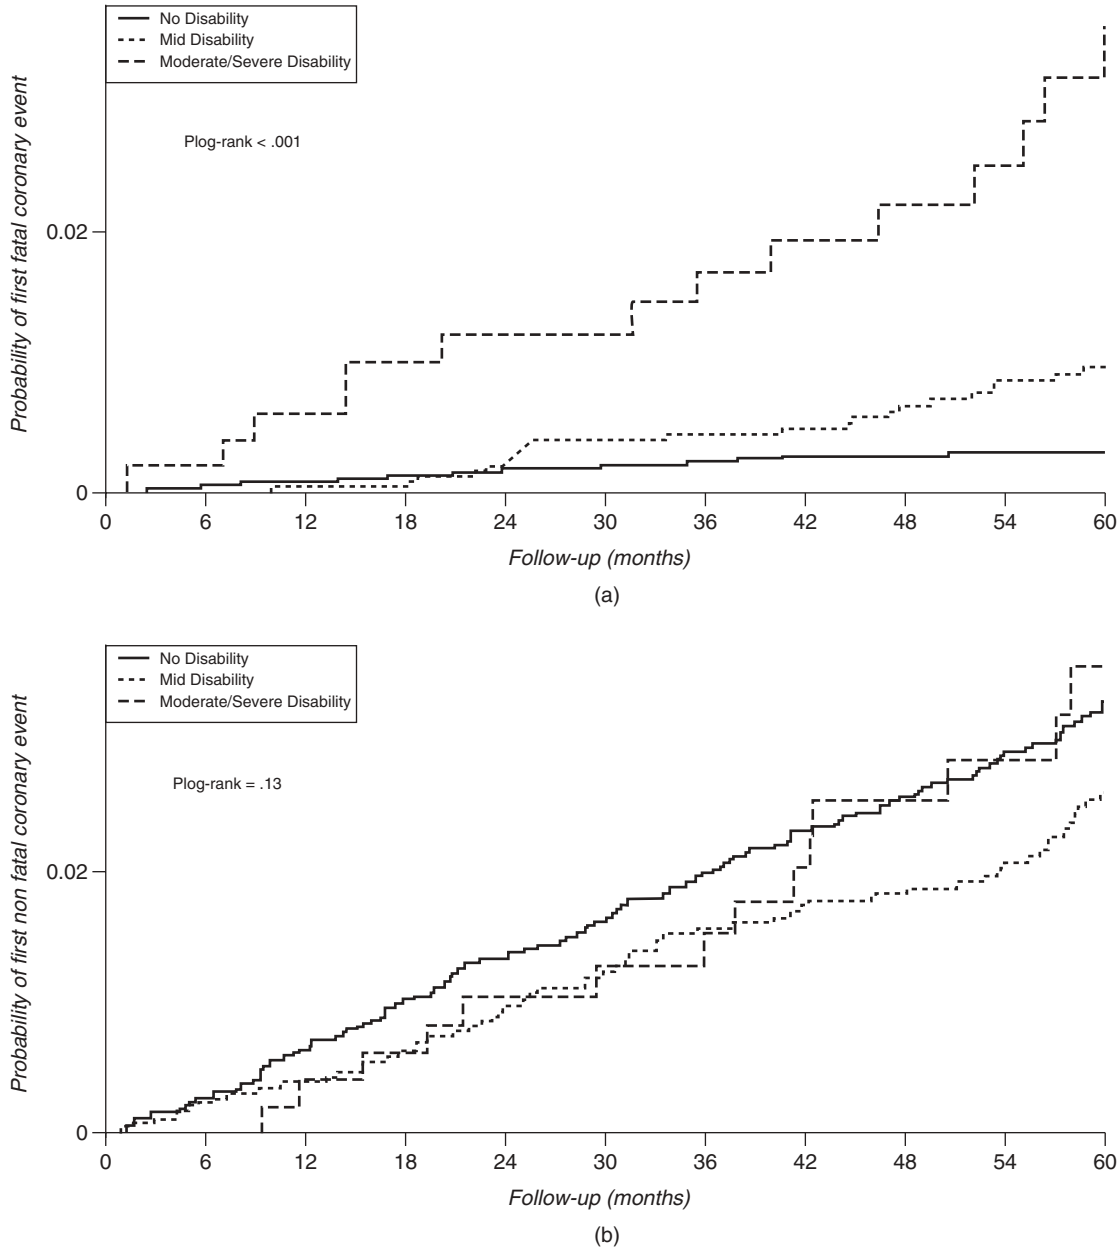

Figure 34.2 (a) Unadjusted Kaplan-Meier cumulative probability of incident fatal coronary heart disease over six years of follow-up according to baseline degree of disability. The Three-City Study. (b) Unadjusted Kaplan-Meier cumulative probability of incident non-fatal coronary heart disease over six years of follow-up according to baseline degree of disability. The Three-City Study. No disability (n = 54 080); mild disability: disability in mobility only (n = 52 712); moderate or severe disability: disability in mobility plus activities of daily living, instrumental activities of daily living, or both (n = 5562). Reproduced from Plichart *et al.*[17] with permission from Wiley-Blackwell.

event might be treated less aggressively, too frail to cope with a vascular event and likely to die, or simply disability is associated with severe CHD with a worse prognosis. Therefore, in this population, promotion of regular physical activity seems appropriate, because physical activity has been associated with less severe acute coronary syndrome, lower in hospital mortality, better short-term prognosis and less disability.[17]

Risk factors in the cognitively impaired

Little is known about CV risk factor profile for older people with dementia. As many CV risk factors are treatable by lifestyle changes, confirmation of the risk factor profile for older people with dementia could substantially impact upon preventive health practices for this group of patients. People with dementia often lack the ability to notice or address symptoms of disease and may not be

able to understand or be appropriately concerned about vascular risk factors and may need a more active approach than the general population does. In a cross-sectional study of 470 older people with dementia (age 50–90 years), healthy behaviour was low with 98.9% of participants having an unhealthy diet and 68.3% a lack of exercise. Smoking (13.6%) and alcohol abuse (0.3%) were relatively minor problems. Abdominal overweight (70.4%), hypertension (36.8%), hypercholesterolaemia (31.8%) and diabetes (8.7%), were highly prevalent.[18] In another study of 155 individuals attending a specialized ageing clinic, risk factor assessments found 18% with hypertension, 8% with elevated glucose, 27% with elevated total cholesterol, 70% overweight or obese, 11% current or ex-smokers and 96% with inadequate daily exercise. The prevalence of hypertension and smoking increased significantly with age.[19] These profiles have important implications in determining the risk of CVD in these patients. Campaigns to promote health should consider the introduction of preventive screening programmes in patients with dementia.

Reverse epidemiology

Reverse epidemiology refers to paradoxical epidemiological associations between survival outcomes and traditional CV risk factors such as obesity, hypertension and hypercholesterolaemia. It has been observed in chronic wasting disease states such as chronic heart failure, dialysis patients, advanced malignancies and in advanced age. The relation between these traditional risk factors and poor outcomes exists but in the opposite direction. For example, higher BMI, higher blood pressure, as well as high cholesterol are associated with improved heart failure outcomes. In patients with diabetes and heart failure tight diabetes control (HbA1c < 7%) is associated with higher mortality in comparison to HbA1c > 7% in accordance with reverse epidemiology phenomenon. Relative risk associated with higher BMI decreases substantially in older age groups. Reverse epidemiology with respect to cholesterol levels has been demonstrated in the elderly; however, hypertension and poor glycaemic control in older people with diabetes remain associated with increased morbidity and mortality. In a study of 400 hospitalized individuals >60 years old, obesity did not show independent survival value. Obesity, higher blood pressure and serum cholesterol, besides being related to lower mortality both in hospital and after discharge, were associated with better nutrition and functional capacity, less intense acute phase reaction and organ dysfunction, and lower incidence of high mortality diseases such as dementia, pneumonia, sepsis or cancer. These associations may explain why obesity and other reverse epidemiology data are inversely related to mortality. The increased mortality is related to under-nutrition and frailty manifested by low cholesterol and low BP. In hospitalized patients, weight loss and malnutrition are frequent and must be attributed to disease and to inflammatory response. Diseases such as cancer, dementia or heart failure cause malnutrition, a predisposing condition for sepsis which is often the final cause of death. Patients with BMI <30 who died in hospital showed more weight loss than those who survived; the lower the BMI, the greater the weight loss. In contrast, patients with BMI >30 who died in hospital gained more weight than those who survived; the higher the BMI, the greater the weight gain. When BMI was <30, patients who died had lost more weight than survivors. However, above 30 the situation was the opposite: patients who died in hospital had gained more weight than those who survived. This change at 30 of the prognostic meaning of weight variation indicates a limit on the obesity paradox or a U-shaped relation.[20] Weight gain in patients with a BMI higher than 30 is unhealthy (since it is related to mortality) as is weight loss in patients with lower BMI. The U-shaped relationship between obesity and survival was also observed in community-dwelling older patients with heart failure. In a study to determine all-cause mortality for 1236 patients, mean (SD) age 71 (12) years with a prior diagnosis of heart failure and a preserved ejection fraction (≥50%) survival was better for groups with higher BMI up to a BMI >45 where the mortality increased. After adjustment for patient age, history, medications, and laboratory and echocardiographic parameters, the HR for total mortality (relative to BMI 26–30) were 1.68 (95% CI, 1.04–2.69) for BMI <20, 1.25 (95% CI, 0.92–1.68) for BMI 20–25, 0.99 (95% CI, 0.71–1.36) for BMI 31–35, 0.58 (95% CI, 0.35–0.97) for BMI 36–40, 0.79 (95% CI, 0.44–1.4) for BMI 41–45, and 1.38 (95% CI, 0.74–2.6) for BMI >45 ($p < 0.0001$) (Figure 34.3). Thus, despite the benefit of weight loss in the prevention of CHD and heart failure, there is a lack of data to support a survival benefit from weight loss in patients with established heart failure.[21] The mechanism for reverse epidemiology is not clear. It appears that malnutrition and inflammation are characteristics shared by populations exhibiting reverse epidemiology. In heart failure weight loss associated with increased inflammation is termed cardiac cachexia. In that sense heart failure is a 'systemic inflammatory disease'. It is also likely that low BMI, low cholesterol and low blood pressure associated with other factors such as low serum albumin and low serum iron are simply markers of poor health and chronic comorbid conditions which lead to poor outcomes. Clinical implication of this is not yet clear but more attention should be focused on optimal management of under-nutrition and inflammation. It is early to conclude that withdrawal of proven medications with survival benefits such as angiotensin-converting enzyme inhibitors or beta-blockers is recommended. Statins may have an anti-inflammatory effect that can be beneficial in management of inflammation irrespective of cholesterol-lowering effects. Reverse epidemiology questions the limits of normal

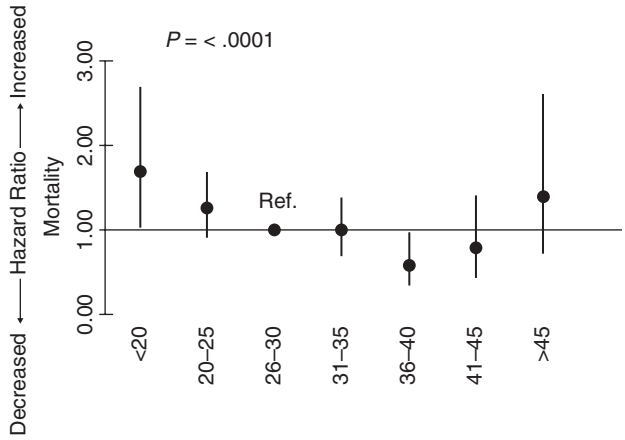

Figure 34.3 Hazard ratios for mortality by BMI after adjustment for age, history, medications, laboratory and echocardiographic findings (all $p < 0.0001$). A U-shape relationship persists between BMI and mortality. Reprinted from Kapoor *et al.*[21] Copyright 2010, with permission from Elsevier.

BMI (20–25) for ageing and chronic diseases. It seems appropriate, in diseased individuals, to restrain weight loss by improving feeding and maintaining physical activity to preserve muscle mass. Further research is still needed to clearly understand the mechanisms of reverse epidemiology to better care for these frail patients (Box 34.2).

Box 34.2 Summary – CHD

Epidemiologic features

- Incidence increases indefinitely with age.
- Relationship with obesity is U-shaped and inverse with socioeconomic status.
- Hypertension-related risk is 16-fold in persons 80–89 compared to 40–49 years.
- Metabolic syndrome does not add advantage in predicting CV risk above its individual components.
- Frailty is a non-conventional risk factor with a mutual relationship to CVD.
- Disability is a poor outcome indicator for CHD.
- In frail older people a paradoxical relation exists between traditional risk factors and outcome. The mechanism of this reverse epidemiology is related to malnutrition and inflammation.
- Reverse epidemiology questions the limits of normal BMI (20–25 kg m^{-2}) for ageing and chronic diseases.

Clinical implications

- Benefits of quitting smoking persist in older people.
- A 10 mmHg reduction in systolic BP would reduce CHD mortality by 50%.
- Early recognition of frailty is important to slow or reverse functional decline, improve physical performance and quality of life through multidisciplinary interventions.
- Attention should be focused on optimal management of under-nutrition and inflammation. It seems appropriate, in diseased individuals, to restrain weight loss by improving feeding and maintaining physical activity to preserve muscle mass.
- Physical activity has a positive impact on mortality in a dose-response relationship.

Heart failure

Heart failure is characterized by systolic or diastolic ventricular dysfunction associated with evidence of circulatory failure manifested by fatigue and fluid retention. It is becoming increasingly common and is the end product of CHD, hypertension and valvular heart disease. Therefore heart failure epidemiology is related to prevalence, incidence and outcomes of these CV diseases (Figure 34.4). It mostly affects elderly people as >75% of patients are >65 years old and mean age is 75 years. In developed countries the biggest factor boosting heart failure prevalence is increasing growth of an elderly population. In the United States, the number of elderly (>65 years) is expected to grow from 35 million in the year 2000 to 70.3 million in 2030. In the United Kingdom the number of people aged >65 years has increased by 50% and those >85 has increased threefold in the last 40 years. Even if incidence remains constant, the total number of people with heart failure is expected to double increasing its prevalence. Prevalence and incidence of heart failure in those aged 80–89 years is 10 times prevalence and incidence in those aged 50–59 years. In the United States 550 000 new cases of heart failure occur each year. More than 20 million people have heart failure worldwide of whom 5 million are in America and 6.5 million in Europe. Heart failure is the leading cause of hospitalization affecting >20% of acute hospital admissions of individuals >65 years. Age-adjusted annual incidence of heart failure is 0.14% in women and 0.23% in men, with better survival among women. Lifetime risk for developing heart failure at age 40 years is 21% for men and 20% for women. Several factors contribute to the increased burden of heart failure. Improved care of acute myocardial infarctions and of those patients already diagnosed with heart failure have combined to foster a growing epidemic. Age-adjusted survival rates have improved and risk of death has declined 12% per decade. However, heart failure still carries a grave prognosis. The two- and five-year mortality rates are 60% and 75% respectively. Mortality in heart failure is as high as in many common types of cancer such as bowel cancer in men and breast cancer in women. It is associated with a comparable number of expected life-years lost (6.7 years per 1000 in men and 5.1 years per 1000 in women).[22]

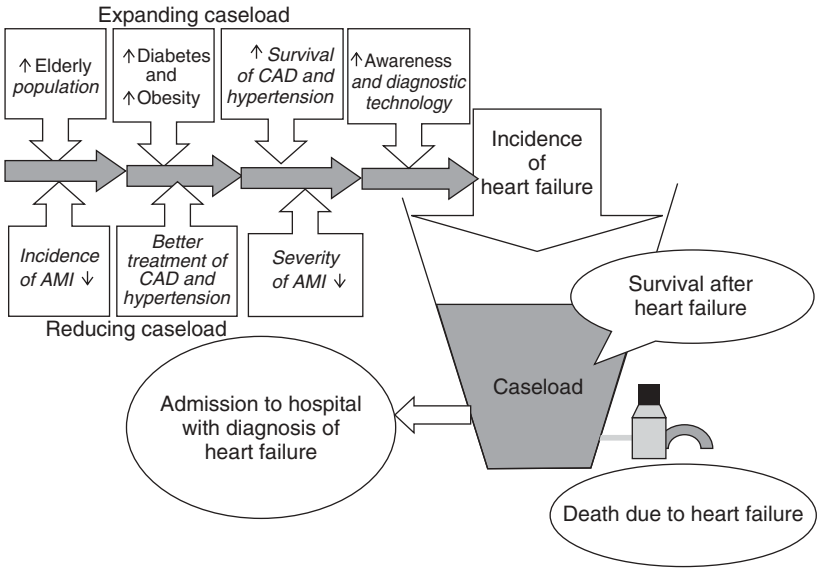

Figure 34.4 Epidemiology of heart failure. AMI, acute myocardial infarction; CAD, coronary artery disease. Reprinted from Najafi *et al*.[22] by permission of Oxford University Press.

Ethnic variations

In developing countries ischaemic aetiology for heart failure is less common. Other causes such as rheumatic (Africa, Asia, Latin America), Chagas disease (Latin America) and hypertension (African) are more prominent. Hypertension, rheumatic heart disease, cardiomyopathy, chronic lung disease and pericardial disease are the main contributors to the aetiology of heart failure in Africa, accounting for >90% of cases. In Arabic populations prevalence of heart failure is common and increases with age from 1 per 1000 in individuals <45 years to 25 per 1000 in those ≥65 years. Common causes are similar to those in western countries such as CHD and hypertension. However, idiopathic dilated cardiomyopathy is relatively more prevalent than reported in the West. Valvular heart disease and lung diseases causing heart failure are less common. Incident heart failure before 50 years of age is more common among blacks than among whites. Diastolic hypertension, obesity, lower HDL cholesterol and kidney disease are independent predictors. Although CHD and its complications remain uncommon in developing countries, the situation is changing due to modifications in lifestyle, diet, cultural attitudes and other consequences of rapid urbanization which will lead to a global rise in incidence and prevalence of heart failure.[23]

Risk factors and prevention

A large proportion of heart failure risk is attributed to modifiable risk factors. In the Health, Aging and Body Composition Study, 2934 participants were enrolled, mean (SD) age 73.6 (2.9) years, 47.9% men, 58.6% white, and 41.4% black and assessed for incidence of heart failure, population attributable risk (PAR) of independent risk factors for heart failure, and outcomes. During a median follow-up of 7.1 years, 258 participants (8.8%) developed heart failure (13.6 cases per 1000 person-years, 95% CI, 12.1–15.4). Men and black people were more likely to develop heart failure. No significant sex-based differences were observed in risk factors. CHD (PAR 23.9% for white and 29.5% for black) and uncontrolled hypertension (PAR 21.3% for white and 30.1% for black) carried the highest PAR in both races. Among black participants, six risk factors (smoking, increased heart rate, CHD, left ventricular hypertrophy, uncontrolled hypertension, and reduced glomerular filtration rate) had >5% higher PAR compared with that among white participants, leading to a higher overall proportion of heart failure attributable to modifiable risk factors in black compared to white participants (67.8% vs. 48.9%). Participants who developed heart failure had higher annual mortality (18.0% vs. 2.7%). No racial difference in survival after heart failure was noted; however, rehospitalization rates were higher among black participants (62.1 vs. 30.3 hospitalizations per 100 person-years, $p < 0.001$).[24] In another population-based case-control study of 962 Olmsted County residents with heart failure (mean age 75.4 years; 53.7% women who were older than men 78.3 vs. 72.1 years respectively, $p < 0.001$) mean (SD) number of risk factors for heart failure per case was 1.9 (1.1) and increased over time ($p < 0.001$). Hypertension was most common (66%), followed by smoking (51%). Risk of heart failure was particularly high for CHD and diabetes (OR 3.05, 95% CI, 2.36–3.95 and 2.65, 1.98–3.54) respectively (Table 34.2). However, PAR was highest for CHD and hypertension, each accounted for 20% of heart failure cases in the population, although CHD accounted for the greatest proportion of cases in men (PAR 23%) and hypertension was of greatest importance in women (PAR 28%). Preventing CHD and hypertension will have

Table 34.2 Association between heart failure and risk factors from case/control analysis.

			Population Attributable Risk (95% CI)		
Risk Factor	**OR (95% CI)**	***p* Value**	**Overall**	**Women**	**Men**
CHD	3.05 (2.36–3.95)	<0.001	0.20 (0.16–0.24)	0.16 (0.12–0.20)	0.23 (0.16–0.30)
Hypertension	1.44 (1.18–1.76)	<0.001	0.20 (0.10–0.30)	0.28 (0.14–0.42)	0.13 (0.00–0.26)
Diabetes	2.65 (1.98–3.54)	<0.001	0.12 (0.09–0.15)	0.10 (0.06–0.14)	0.13 (0.08–0.18)
Obesity	2.00 (1.57–2.55)	<0.001	0.12 (0.08–0.16)	0.12 (0.07–0.17)	0.13 (0.07–0.19)
Ever smoker	1.37 (1.13–1.68)	0.002	0.14 (0.06–0.22)	0.08 (0.00–0.15)	0.22 (0.07–0.37)

the greatest population impact in preventing heart failure. Sex-targeted prevention strategies might confer additional benefit.[25]

Diastolic heart failure

Diastolic heart failure is defined by the presence of signs and symptoms of heart failure, normal ejection fraction and evidence of abnormal left ventricular diastolic function. Echocardiographic studies in the community show that 50% of all patients with heart failure have preserved left ventricular systolic function. Prevalence of diastolic heart failure increases more sharply with age more than systolic heart failure. It is likely that age-related changes in diastolic function lower the threshold for expression of diastolic heart failure in elderly. Ageing is associated with a stiffening of large vessels and concentric hypertrophy of left ventricular myocardium with reduced early diastolic relaxation and filling rates. This combined ventricular-vascular stiffening may contribute to increased prevalence of diastolic heart failure in elderly persons. This ventricular-vascular stiffening occurs more steeply in women. It is very likely that systolic hypertension plays an important role in the genesis of diastolic heart failure by increasing both vascular and ventricular stiffness. Compared to those with reduced systolic function, patients with preserved systolic function are older, more often female, more likely to have hypertension associated with left ventricular hypertrophy and less likely to have CHD. Mortality rates are higher in these patients compared to age-matched controls without heart failure, but not as high as those in patients with reduced systolic function. In contrast, morbidity, as measured by hospitalization and re-admission, is substantial and comparable to that of patients with systolic heart failure.

Complexity and care for heart failure

Heart failure and cognition

Heart failure results in losses in memory, psychomotor speed, and executive function in 25% of patients. In a study to determine types, frequency and severity of cognitive deficits among patients with heart failure compared with age and education matched healthy participants and participants with major medical conditions other than heart failure in a sample of 414 participants (249 heart failure, 63 healthy and 102 medical participants), heart-failure patients had poorer memory, psychomotor speed, and executive function compared with healthy and medical participants. Significantly more heart-failure patients (24%) had deficits in three or more domains and heart failure severity was associated with more cognitive deficits. Multiple comorbidity, hypertension, depressive symptoms and medications were not associated with cognitive deficits. Older patients with more severe heart failure have more problems in executive function.[26] Future studies are needed to identify mechanisms for cognitive deficits in heart failure and to test interventions to prevent cognitive loss and decline. On the other hand, the presence of heart failure in a cognitively impaired individual further increases heart failure-related morbidity and affects functional outcomes and need for institutional care.

Heart failure and geriatric conditions

There is a high prevalence of geriatric conditions among older people with heart failure including urinary incontinence, falls and dementia. Each of these conditions suggests the presence of a high degree of disability. Geriatric conditions are strongly and independently associated with short- (30 days) and long-term (5 years) mortality among older patients hospitalized for heart failure. In a study of 62 330 hospitalized heart-failure patients, mean (SD) age 79.6 (7.8), mortality rates were 9.8% at 30 days and 74.7% at 5 years. Dementia and mobility disability, were among top predictors of short (OR 1.86, 95% C I, 1.73–2.01 and 1.96, 1.81–2.12, respectively) and long-term mortality (2.01, 1.84–2.19 and 1.78, 1.70–1.87, respectively). These results enhance the relevance of cognitive and physical disabilities in heart-failure patients.[27] Despite the ageing population and the fact that heart failure primarily affects older persons in whom many complex conditions coexist, current studies and guidelines have not incorporated routine assessment or management of geriatric conditions.

Heart failure in care homes

Prevalence of heart disease in care homes is expected to be higher than in the general population due to older and frailer populations living in these settings. Little data is available because care home residents are often excluded from epidemiological studies. In a systematic review of 10 studies, prevalence of heart failure was 20% (range 15–45%). This figure is higher than in the general population (3–13%); however it could be underestimated as both undetected and incorrect diagnosis of heart failure was common. The mean age of study populations ranged between 79–89 years. CHD and atrial fibrillation were the most common causes of heart failure. The level of associated comorbidities (dementia 9–73%, diabetes mellitus 11–38%, chronic obstructive pulmonary disease 12–36%, and hypertension 8–55%) among these patients was also high.[28] Accurate diagnosis of heart failure in these settings is difficult and hampered by concomitant comorbidity which often shows characteristic signs and symptoms similar to those of heart failure (e.g. breathlessness, ankle swelling and fatigue) making interpretation difficult. Early diagnosis and treatment may prevent progression of the disease and lead to improvement of disabling symptoms, ultimately resulting in an overall improvement in quality of life.

Care needs for heart failure

Older people with heart failure have higher rates of disability, geriatric conditions, nursing home admission, and often require a multifaceted approach of care. Promoting care delivery systems that provide a coordinated, multidisciplinary approach to older people with heart failure will be necessary to optimize care. It is important to recognize associated physical and cognitive dysfunction in heart failure patients in order to optimize care and outcome. Although geriatric conditions are chronic and incurable, physical therapy and exercise may improve mobility, and increased caregiver and nursing support can be implemented to help patients with dementia adhere to medications. Benefits of interventions to address mobility and dementia may also enhance patients' abilities to avoid or cope with other medical conditions such as falls. Older patients with severe heart failure may be severely distressed with poorly controlled symptoms. There is a growing realization that palliative and supportive care may play an important role in treatment and underpin services to improve quality of life.

Caregiver burden

Heart failure imposes a significant burden on patients, families, and the long-term care system. However, social support is associated with better outcomes of heart failure. Mechanism for such better outcomes could be due to social support for enhanced self-care such as adherence to medication and healthy behaviour. Social isolation and living alone on the other hand are associated with increased heart-failure mortality, morbidity and psychosocial distress independent of possible contributing factors such as depression and severity of heart failure. The responsibilities of providing care for heart failure patients can be overwhelming, and may lead to exhaustion and depression in caregivers who may have multiple health problems of their own. Caregivers may also experience distressing symptoms such as sleep difficulties related to patient's sleep problems. Caregiver outcomes are also important, which should include both their physical and emotional health (Box 34.3).

Box 34.3 Summary – Heart failure

Epidemiologic features

- Heart failure is the end product of CHD, hypertension, and valvular heart disease.
- Older people are main sufferers (mean age 75 years).
- Prevalence and incidence in people 80–89 is 10 times those 50–59 years.
- Increasing growth of older population and improved care for CHD is leading to a growing epidemic of heart failure.
- In spite of improved survival, heart failure still carries a grave prognosis.
- Ischaemic aetiology is less common in developing countries.
- Heart failure risk is attributed to modifiable risk factors particularly CHD in men and hypertension in women.
- Diastolic heart failure is more common in older women who are likely to have hypertension, left ventricular hypertrophy and less likely to have CHD. It carries similar morbidity but less mortality than systolic heart failure.

Clinical implications

- Preventing CHD and hypertension will have an impact on reducing heart failure.
- Complex conditions tend to coexist with heart failure and are independently associated with mortality. Guidelines should incorporate routine assessment and management of these geriatric conditions.
- Prevalence in care homes is high and associated with a high level of disability. Early diagnosis and treatment in these settings may prevent progression and improve quality of life.
- Heart failure imposes a significant burden on families. It will need a multifaceted care. Caregiver outcomes are also important, and should include both their physical and emotional health.

Valvular heart disease

Prevalence and incidence of rheumatic heart disease have declined in the developed world but are still common in developing countries mainly affecting younger populations. The most common valve diseases in the elderly are either degenerative or infective.

Degenerative valve disease

The aortic valve is most commonly affected and prevalence of degenerative aortic valve disease (DAVD) rises as life expectancy increases. About 95 000 valve procedures are performed each year in the United States, and DAVD is responsible for >25 000 annual deaths. Traditional risk factors associated with atherosclerosis such as age, diabetes and cholesterol have been implicated in the development of DAVD. Early stages of DAVD are similar to the active inflammatory process of atherosclerosis including basement membrane disruption, inflammatory cell infiltration, lipid deposition and calcification. Visceral obesity also has a role in the development and progression of DAVD. In addition, visceral obesity in combination with other metabolic risk factors has been associated with degenerative changes in bioprosthetic heart valves. It seems that DAVD is related to an atherosclerotic process where interactions between lipids, inflammation and valvular tissue play an important role in the development of valvular calcification. This concept is referred to as 'valvulo-metabolic risk'. Despite these common risk factors only 50% of patients with DAVD have significant CHD, and most patients with CHD do not have DAVD suggesting that some other factors are contributing to the development of DAVD. Association of these risk factors may have implications for therapeutic interventions such as statins or angiotensin-converting enzyme inhibitors that may delay or prevent progression of DAVD. However, although 60–70% of patients with DAVD have dyslipidaemia and are already receiving statins, a substantial percentage of these patients show rapid progression. This suggests that, targeting dyslipidaemia alone may not be sufficient but targeting whole metabolic risk could be more effective in slowing valve degeneration progression.

Infective valve disease

Valve infection or infective endocarditis affects patients with predisposing valvular abnormalities traditionally caused by rheumatic carditis, and streptococcus viridans is the most common pathogen. This presentation is still seen in developing countries where rheumatic heart disease is prevalent. In the western world the incidence of infective endocarditis is rising in the elderly population >65 years reaching around four times that of the general population. Factors accounting for this increase include the high prevalence of undiagnosed degenerative valve disease and increased use of invasive procedures and implanted medical devices. Infective endocarditis has a predilection for males, but the proportion of females affected progressively increases with age. Despite progress in diagnosis and treatment, mortality rates remain high reaching twice that of younger patients. Diabetes, gastrointestinal and genitourinary tract cancers are predisposing risk factors. Although the prevalence of *S. aureus* decreases with age, enterococci and *S. bovis* are emerging as major players of infective endocarditis in elderly patients.[29] The evaluation of gastrointestinal and genitourinary tract lesions frequently requires invasive procedures, which remain an important risk. These findings might affect antibiotic prophylaxis strategy by taking into account patient age in global risk assessment (Box 34.4).

Box 34.4 Summary – Valvular heart disease

Epidemiologic features

- Prevalence of DAVD increases with age.
- Traditional risk factors are associated with DAVD and referred to as 'valvulo-metabolic risk'.
- Incidence of infective endocarditis in elderly population is four times and mortality is twice that of younger patients. The high prevalence of DAVD and increased use of invasive procedures and implanted medical devices are the main risks.
- Gastrointestinal and genitourinary tract cancers are predisposing factors for bacteraemia (enterococci and *S. bovis*) causing endocarditis.

Clinical implications

- Targeting metabolic risk factors may have an effect on slowing valve degeneration progression.
- Antibiotic prophylaxis strategy should take into account patient age in patients undergoing invasive gastrointestinal or genitourinary procedures.

Rhythm disorders

Abnormal heart rhythm increases with age even in those with normal hearts. Prevalence rates of atrial and ventricular ectopy reach up to 100% in older people. Left ventricular dysfunction is associated with increased prevalence of ventricular ectopy. However, there is no association between the extent or complexity of ventricular ectopy and the presence or absence of significant CHD in the absence of left ventricular dysfunction, and prognosis is good. Epidemiological features of two important rhythm disorders are discussed in this section: atrial fibrillation and sudden cardiac death believed to be due to ventricular tachycardia.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia. It is characterized by uncoordinated atrial activation with consequent loss of atrial mechanical function. Hypertension is the most important single risk factor for AF, conferring a 1.5-fold increased risk in men and a 1.4-fold increased risk in women. AF affects 10% of

people >80 and 20% of people ≥90 years. In developed nations, overall prevalence is 0.9% and number of people affected is projected to more than double over the next two decades. Incidence is 3 per 1000 person-years in men and 2 per 1000 person-years in women aged 55–64 years but increases exponentially with advancing age to 20–30 per 1000 patient-years in individuals ≥85 years. AF is 1.5 times more common in men than in women. However, onset of AF in women occurs at a later age than in men (65 vs. 60 years respectively). Life-time risk of AF is 1 in 4 for both sexes from age 40 years onwards. The incidence pattern of AF may show racial and geographical variations with white subjects having twice the incidence rate of African Americans. Also incidence and prevalence appear to be lower in Asia than in the United States or Europe. The number of people with AF may reach 12.1 million by 2050 assuming no further increase in incidence, and 15.9 million assuming the continued increase in incidence rate is present. This may still be an under-estimation as prevalence of sustained silent AF in people >65 years is believed to reach up to 60%. AF is associated with a doubling of mortality ranging from 1.3–1.8-fold for men and 1.9–2.8-fold for women. Thromboembolic stroke is the most serious complication, risk of which is increased five times in patients with AF. AF is responsible for 15% of cases of strokes. Annual risk of stroke due to AF is 1.5% among patients aged 50–59 years and increases to 23.5% in those >80 years with a similar AF-related stroke mortality rates. AF also increases risk of heart failure by 2–7-fold. As a result of increasing age and improved survival rates in patients with CHD, heart failure and hypertension, an increase in prevalence of AF is likely to be exponential and sustained in the foreseeable future. Prognosis of AF is likely to be influenced by appropriate treatment strategies such as the use of anticoagulation to reduce stroke risk as well as rate or rhythm control to prevent tachycardia-induced cardiomyopathy and heart failure.

Sudden cardiac death

Sudden cardiac death (SCD) refers to death from abrupt cessation of cardiac function due to cardiac arrest. It results from a lethal arrhythmia and usually occurs in a background of structural abnormality or CHD. The most accepted definition is sudden and unexpected death within an hour of symptom onset. Incidence of SCD is 4–5 million cases per year worldwide and 60% of cases are males. There are two well-established peaks in age-related prevalence of SCD, one during infancy representing sudden infant death syndrome and the second in the geriatric age group, between ages 75–85 years. Approximately 80% of SCD are attributed to CHD. Two major mechanisms of fatal ventricular arrhythmias could result in SCD: (i) Polymorphic ventricular tachycardia resulting from acute coronary ischaemia associated with plaque rupture and occlusion of one or more main coronary arteries in patients with relatively normal left ventricular function. (ii) Monomorphic ventricular tachycardia resulting from re-entrant loops around areas of scarred myocardium in patients with established ischaemic cardiomyopathy. Either arrhythmia, if untreated, will eventually degenerate into ventricular fibrillation and SCD. A diagnosis of severe left ventricular dysfunction is the best available predictor of SCD risk and ejection fraction remains the major criterion to stratify patients for defibrillator implantation. An implantable cardiovertor defibrillator is effective therapy in the prevention of SCD. However, severe left ventricular dysfunction affects <30% of all SCD cases in the community. Almost 50% of SCD cases has normal left ventricular function and the remaining 20% have either mildly or moderately decreased left ventricular systolic function (ejection fraction >0.35 and <0.50). Impaired kidney function, as measured by cystatin C, has an independent association with SCD risk among elderly persons without clinical CVD.[30] Risk of SCD in patients with CHD is multifactorial and one major factor is rupture of atherosclerotic plaque. By stabilization of vulnerable plaque with cholesterol lowering and anti-platelets medications or by coronary artery bypass surgery and percutaneous angioplasty significant decline in ejection fraction may be less common in the future. However, specific clinical risk predictors for patients with vulnerable plaque that is prone to rupture still need further studies (Box 34.5).

Box 34.5 Summary – Rhythm disorders

Epidemiologic features

- AF is the most common sustained cardiac arrhythmia.
- Hypertension is the most important risk factor for AF.
- AF affects 10% of people >80 and 20% of people ≥90 years.
- AF is 1.5 times more common in men than in women.
- It increases risk of thromboembolic stroke by 5 times, heart failure by 2–7 times, and mortality by 2 times.
- As a result of increasing age and improved survival in patients with hypertension, an increase in prevalence of AF is expected.
- Incidence of SCD is 4–5 million per year and 60% of cases are males.
- Approximately 80% of SCD are attributed to CHD.
- Ventricular tachycardia degenerating into ventricular fibrillation is the most likely cause of SCD precipitated by rupture of atherosclerotic plaque.

Clinical implications

- Prognosis of AF is likely to be improved by appropriate treatment strategies such as use of anticoagulation to reduce stroke risk as well as rate or rhythm control to prevent tachycardia-induced cardiomyopathy and heart failure.
- Stabilization of vulnerable plaques by treatment of risk factors, or by coronary interventions may reduce incidence of SCD.

Conclusion

The incidence and prevalence of heart disease are increasing. As a result of the growth in an older population, combined with improvement in treatment, an increase in the number of older people living with cardiac conditions is expected. With increasing urbanization and modification of lifestyle in developing countries, the increase in heart disease is global. Unconventional risk factors are emerging in older people such as frailty and disability, which have both a predictive and prognostic effect. In the very old and frail individuals there is reversal of the effect of traditional risk factors such as obesity, hypercholesterolaemia and hypertension. The mechanism of this reverse epidemiology is likely to be due to inflammation and malnutrition. This will have clinical implications in treating malnutrition and avoiding weight loss in this group of patients with promotion of physical activity. Once heart disease is established it is likely to be associated with both physical and cognitive dysfunction and a high risk of institutionalization. Targeted care for older patients with heart disease that is multidisciplinary in nature with a focus on the whole person and outcomes relevant to them such as quality of life is needed.

Key points

- Epidemiology of heart disease is shifting from middle-aged men to elderly women.
- As the older population is growing combined with improvements in treatment, as well as increasing urbanization in developing countries, a global rise in prevalence of heart disease is expected.
- Once heart disease is established it is likely to be associated with physical and cognitive disability and increased risk of institutionalization.
- Care needs for older people with heart disease should take into account their complex needs and outcomes relevant to them considering illness in the context of the whole patient rather than as a solitary entity.

CHAPTER 35

Cardiac ageing and systemic disorders

David J. Stott and Terence J. Quinn
Academic Section of Geriatric Medicine, Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow Royal Infirmary, Glasgow, Scotland, UK

Introduction

Ageing is a highly heterogeneous process and deterioration in organ function, including the heart, often does not correlate well with chronological age. A complex mix of influences combine to influence cardiovascular function in older people, including intrinsic ageing, the cumulative effect of multiple underlying diseases, and many environmental or external influences (such as frequency and intensity of exercise, cigarette smoking and diet). Separating the effects of intrinsic ageing from subclinical disease is challenging, and teasing out the additional contributions of environmental and lifestyle exposures even more problematic. Accepting these difficulties, it is still important to have a basic knowledge and understanding of the effects of intrinsic ageing on the heart to enable accurate interpretation of the effect of systemic disease on cardiovascular function in older people (see Figure 35.1). 'Healthy' or intrinsic cardiac ageing is associated with gradual decline in organ function and homeostatic reserve. The effects include reduced maximal aerobic exercise capacity and a decreased threshold for clinical expression of many age-related cardiac and non-cardiac diseases. However, healthy cardiac ageing by itself should not cause symptoms or limit usual activities of daily living.

Although there is no uniform ageing heart phenotype, some general principles are apparent, and we have attempted to summarize these. In this regard there are established and emergent data from multiple sources including *in vitro* work, animal models and clinical studies. This chapter aims firstly to summarize effects of ageing on cardiac structure, function and homeostatic reserve. The potential impact of these changes on the manifestation of various systemic (non-cardiac) diseases is then considered.

Changes in cardiac structure with ageing

For most solid organs age-related atrophy is the norm; however, magnetic resonance imaging (MRI) studies of the ageing heart show approximately 10% increase in cardiac mass from the age of 20 to 80 years in both men and women;[1] the 'healthy' older left ventricle is characterized by an increased mass-to-volume ratio.[2] Autopsy series confirm a high prevalence of left ventricular hypertrophy (LVH) in elderly subjects.[3–5] This hypertrophy is caused mainly by increased impedance to left ventricular ejection due to reduction in elasticity and compliance of the aorta and large arteries with resultant higher systolic arterial pressures; age-related degenerative aortic valve disease with sclerosis and thickening of valve leaflets and proximal bulging of the interventricular septum may also contribute; however, the contribution of these changes to LVH has not been definitively proven.

Data on cardiac changes in very elderly subjects are limited, with small numbers studied and often apparently contradictory results. Varying results are at least in part explained by differing rates of underlying disease, with coronary artery disease particularly common in males and hypertension in females.[6] As a result, in unselected very elderly subjects, reduced left ventricular systolic function and wall motion abnormalities are over-represented in males while females are particularly likely to have ventricular hypertrophy, atrial dilatation and moderate-to-severe mitral and tricuspid valve dysfunction.

Studies in older populations comprehensively screened for cardiovascular disease, particularly hypertension and coronary artery disease, have generally shown that the morphological cardiac changes described above are less marked in disease-free older hearts.[6] For example in the longitudinal Framingham cohort study, the association of LVH with increasing age was explained mainly by higher blood pressure, overweight, smoking and diabetes mellitus.[7] These findings reinforce how difficult it is to distinguish between cardiac changes secondary to intrinsic ageing and changes as a result of disease or environmental exposures. It is likely that certain structural changes classically thought to be primarily manifestations of intrinsic ageing are in fact also influenced by lifestyle or environmental factors;

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

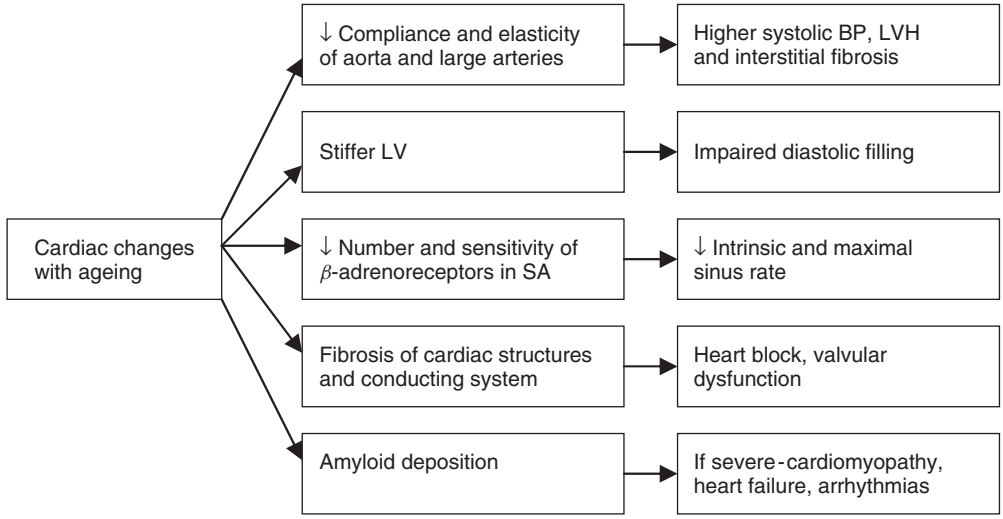

Figure 35.1 Changes in cardiovascular system with healthy ageing.

reports of partial reversal of age-associated changes with interventions such as exercise lends further credence to this hypothesis.[8,9]

Microscopic changes in the ageing heart are well described and include a decrease in number of myocytes with hypertrophy of remaining cells. Convincing mechanistic explanations for these changes are lacking although tissue hypoxia secondary to reduced capillary density has been postulated.[10] Contrary to previous belief, adult myocardial cells remain capable of active division and this has been demonstrated *in vitro* in response to myocardial injury.[11] There is an age-associated increase in other cardiac cell types and materials including interstitial fat, lipofuscin pigment and fibroblast numbers (and activity).[11] The magnitude and functional importance of cardiac interstitial fibrosis is debated[12] but age-related valvular fibrosis and calcification is common. The latter often causes valvular regurgitation or stenotic gradients, manifest on echocardiography or clinically as murmurs on auscultation. Previously thought to be benign, 'senile aortic sclerosis' is now recognized to be associated with significant increases in cardiovascular and total mortality.[13]

Intracellular deposits of amyloid are common in the older heart. Distinct patterns of atrial appendage amyloid and more generalized deposition are recognized.[14] In post-mortem studies amyloid deposits have been found in the majority of aged hearts with the highest prevalence (80–100%) reported in Japanese populations.[15] Although most elderly patients do not have symptoms from cardiac amyloid, some will develop extensive infiltration resulting in a clinical cardiomyopathy that can in turn be associated with heart failure and arrhythmias.[15] The electrocardiograph (ECG) may show low voltage complexes and on echocardiography, the myocardium has a characteristic bright 'speckling' appearance with other features of a restrictive physiology. In advanced cases virtually every cardiac structure can be infiltrated. Age-related reduction in the number of functional pacemaker cells in the sinoatrial node and myocyte cells in specialized conducting tissues are well described and are clinically manifest by ECG changes and predisposition to dysrhythmias such as 'sick sinus syndrome'.[16]

Biochemical changes with age have been reported including alterations in sarcoplasmic reticulum and Ca^{2+} uptake across membranes. In isolated senescent cardiac tissue slower myosin isoenzymes and decreased adenosine triphosphatase activity are also described.[17] These biochemical alterations result in prolongation of isovolumetric relaxation. These changes may be of functional importance, particularly with regard to reduced diastolic function and cardiac failure with preserved ejection fraction.

Changes in cardiac physiology with ageing

Healthy ageing is associated with little change in systolic function or cardiac output at rest. However, age-related changes in diastolic function are apparent on echocardiography or cardiac MRI.[18] There are progressive changes in the pattern of left ventricular filling, with numerous indirect measures of diastolic function showing deterioration with advancing age; the early phase of diastolic ventricular filling is delayed and maximal flow rate across the mitral valve is reduced; as a result a much greater proportion of ventricular filling occurs late in diastole during atrial contraction. These changes in diastolic function seem to be largely independent of disease. However, their precise aetiology and

in particular the role of reduced left ventricular compliance and myocardial relaxation patterns remains to be definitively established.[2,19] For most older people these changes are not of major consequence. However, the development of atrial fibrillation (AF) (and loss of the late ventricular filling phase) has much more severe adverse consequences in the older heart, with greatly reduced cardiac homeostatic reserve and maximum aerobic exercise capacity.

There is an age-related reduction in cardiac responsiveness to adrenergic stimuli, resulting in a decrease in both intrinsic and maximal sinus heart rate.[20] During exercise or other stressful stimuli, the increase in heart rate is attenuated in older people; at any given submaximal work-rate the heart rate rise is reduced and the older heart relies on dilatation and increased stroke volume to increase cardiac output (working on the physiological principles of the Starling curve). This compensatory response is effective at low or moderate workloads; however, cardiac reserve is reduced, with a reduction in maximal cardiac output in the older heart. These changes appear to be due to a reduction in both the number and sensitivity of cardiac β-receptors; the age-related changes described are akin to the effects of pharmacological β-blockade.

Arterial baroreceptors responses are slowed with increasing age. As a result, aged individuals typically exhibit increased arterial pressure variability with decreased cardiac heart rate variability and responsiveness.[21] It has been postulated that these changes predispose to postural hypotension and syncope in the elderly.

It could be argued that discussion of intrinsic ageing and the disease-free heart is a somewhat academic exercise. The reality is that most older people, at least in the developed world, have clinically relevant ischaemic cardiac disease. Atherosclerosis begins in adolescence and the incidence and prevalence of ischaemic heart disease increase dramatically with age.[22] Up to 30% of the over 65s have symptoms of ischaemic heart disease with angina or previous acute myocardial infarction. However, it has been estimated that a further 30% have clinically significant but covert or unrecognized disease. A variety of factors contribute to this hidden burden of disease. There may be barriers to communication or reporting such as chronic cognitive impairment. Symptoms may be masked by comorbidities that reduce exercise capacity, or cause other more clinically obvious symptoms. In addition ageing is associated with impaired perception of ischaemic cardiac pain; on exercise there is a delay from onset of myocardial ischaemia to symptoms of angina in older people. As a result when cardiac symptoms occur they may be vague or atypical.[23] Myocardial infarction may present as a confusional state or 'collapse', while myocardial ischaemia may provoke non-specific lethargy and reduced physical capacity. Therefore, ischaemic heart disease is a common cause of reduced cardiac homeostatic reserve in older people and in the event of a physiological stressor such as systemic illness, adverse clinical consequences such as myocardial ischaemia, heart failure or cardiac arrhythmias can readily occur. The presentation, diagnosis, and treatment of coronary artery disease in older people are discussed in detail in Chapter 37, Ischaemic heart disease.

Cardiac manifestations of non-cardiac disease

The brain

Cerebrovascular disease

Acute strokes in older people, including infarction, subarachnoid and intracranial haemorrhage are often associated with cardiac rhythm or conduction disturbances, and the 12-lead ECG may show repolarization patterns resembling acute myocardial infarction. Elevation in serum cardiac enzymes, particularly troponin, is seen in approximately 20% of patients with acute stroke and is associated with ECG changes and increased mortality. Although some patients will have underlying coronary thrombosis, these ECG and biomarker changes can occur in the absence of significant coronary arterial disease.[24] In this situation the underlying process may be a stress response with activation of the sympathoadrenal system causing patchy focal myocardial damage known as myocytolysis.[25]

Many older subjects with ischaemic cerebrovascular disease have comorbid coronary artery disease. Cardiac disease is the commonest cause of death in the first months following ischaemic stroke, with 2–6% of patients dying from cardiac causes. Risk is highest in the first days immediately post-ictus. Predictors include diabetes, LV dysfunction, renal impairment, long QTc and severe neurological impairment.[26]

Dementia and cognitive decline

Increasingly it is recognized that vascular disease is an important and potentially preventable contributor to dementia and cognitive decline in later life. Post-mortem studies have shown that Alzheimer's pathology on its own is often not sufficient to cause major cognitive decline. However, the combination of Alzheimer's pathology and ischaemic cerebrovascular disease (particularly small vessel ischaemia) carries particular risk of dementia.[27] Longitudinal population studies have shown that vascular risk factors, particularly hypertension, diabetes mellitus and cigarette smoking, are associated with increased risk of dementia.[28,29] Congestive cardiac failure (CCF) may also contribute to late-life cognitive impairment. Dementia is over-represented in CCF patients; predictors include left ventricular systolic dysfunction and arterial blood pressures below 130 mmHg.[30] A variety of mechanisms have been proposed including occult cerebral infarction,

low-grade small vessel ischaemia, activated thrombosis and blood pressure variability and altered cerebrovascular reactivity. A degree of cognitive dysfunction occurs in most older patients after cardiac surgery including coronary artery bypass grafting.[31] Those with pre-existing small vessel cerebral ischaemia are at particular risk. Low blood pressure during surgery and small cerebral embolic events are thought to be the main contributors.

The respiratory system

Cardiac failure and atrial fibrillation (AF) are common complications of serious respiratory illness in older people. Chronic obstructive pulmonary disease and reduced lung function (FEV1, forced expiratory volume) are independent risk factors for arrhythmias including AF. Respiratory infections such as influenza and respiratory syncytial virus are associated with increased risk of hospitalization for heart failure and sudden death.[32] Potential mechanisms include infection-induced rises in cytokines that have negative cardiac inotropic effects, and sympathetic nervous system activation.

While there is a considerable body of research focusing on the ageing left ventricle and aorta, age-associated changes in the right heart and pulmonary circulation are less well described. Population-based studies have suggested modest increases in pulmonary systolic pressure independent of respiratory disease; greater pulmonary pressures are associated with increased risk of cardiovascular events and mortality.[33]

Gastrointestinal system

Age is an independent risk factor for circulatory collapse and death after acute gastrointestinal haemorrhage. This is likely to be due to reduced homeostatic cardiac reserve.[34] Circulatory problems to the bowel are fortunately uncommon; however, the incidence does rise markedly with increasing age. Potential mechanisms include atherosclerosis of mesenteric arteries or cardio-embolism, particularly in AF. Symptoms are usually of pain, altered bowel habit and haematochezia although clinical presentation can range from mild transient symptoms to fulminant acute abdomen with gangrenous bowel.[35] For milder cases a conservative approach is often recommended with pharmacological treatment of underlying vascular risk factors. Older age is a predictor of poor outcome.[36]

Exposure to helicobacter pylori infection becomes increasingly common with advancing age. In young subjects it has been suggested that helicobacter may be a contributory cause of ischaemic heart disease, in association with raised fibrinogen levels. However, no convincing link has been confirmed with ischaemic heart disease in elderly subjects; observational studies claiming that helicobacter eradication therapy decreases fibrinogen levels in coronary heart disease are likely to be confounded by regression to the mean.[37]

The association of aortic valvular disease (particularly aortic stenosis) with gastrointestinal angiodysplasia, the 'Heyde Syndrome' has been recognized for many years. However, the nature and strength of the link has been debated as both conditions are relatively common, particularly in older age. A biological mechanism for this association involving activation of clotting factors has been postulated.[38]

Renal system

Deterioration in renal and cardiac function often occurs together in older people. Renal impairment in older people is associated with increased risk of ischaemic cardiovascular disease. The risk is inversely related to glomerular filtration rate and is significantly increased by the time biochemical alterations in serum creatinine are apparent.[39] This association is partly due to common aetiologies, including hypertension and atherosclerosis.

A cardio-renal 'vicious circle' is well recognized in older patients wherein impaired natriuretic ability of the ageing nephron results in fluid overload and CCF, while the older, diseased heart is unable to maintain adequate cardiac output and perfusion pressure to the kidneys leading to further deterioration in renal function. When elderly patients with chronic heart failure develop impaired renal function, this is an adverse prognostic factor for hospitalization and death.

Cardiovascular disease remains the leading cause of death in patients with end-stage renal disease, accounting for around half of all deaths. The risk remains elevated even after renal transplantation.[40] An association between renal impairment and modest increases in serum levels of cardiac biomarkers such as troponin has also been reported. Studies detailing the cardiac phenotype of patients with end-stage renal failure and raised troponin have shown increased incidence of cardiac risk factors and LV impairment but no excess of coronary artery disease or demonstrable ischaemic damage.[41,42] Nonetheless, elevated troponin in renal failure is associated with increased cardiovascular risk.[41]

Endocrine abnormalities and the cardiovascular system

Thyroid

Hyperthyroidism is common in older people, with cardiovascular manifestations dominating the clinical presentation; palpitations, dyspnoea, sinus tachycardia, arrhythmias, and systolic hypertension are common features. Heart failure is particularly likely if pre-existing heart disease is present. The risk of AF (paroxysmal or

chronic) is increased in older patients. In the absence of underlying heart disease, AF may revert to sinus rhythm when a euthyroid state is achieved. However, in older patients or when AF has been present for a long duration, the rate of reversion is lower.[43] Cardiovascular complications remain the principle cause of death, even after treatment of hyperthyroidism.

Hypothyroidism also has important cardiac manifestations in older people. Bradycardia, non-pitting peripheral oedema, pericardial effusion, CCF and low-voltage complexes on ECG are all recognized.[43] Exertional dyspnoea and easy fatigability are common complaints, resulting from a combination of systolic and diastolic dysfunction on effort.[44] Endothelial dysfunction may increase the risk of hypertension and arterial thrombotic events and there is increased risk of atherosclerosis due to hypertension and atherogenic lipid profile. Decreased metabolic demand on the myocardium and low physical activity levels in hypothyroidism make symptoms of angina less frequent even in the presence of significant coronary artery disease. Many of these cardiac manifestations of hypothyroidism reverse with thyroxine replacement therapy. However, it is recommended that extra caution is exercized in the elderly while initiating treatment to avoid precipitating acute myocardial infarction and heart failure, as they are likely to have underlying ischaemic heart disease. The initial dose of thyroxine should normally be ~25% of the anticipated replacement dose, increased in a stepwise fashion at 6–8 week intervals.[45]

Subclinical thyroid dysfunction is common in older patients, with a prevalence of asymptomatic (biochemical) hypothyroidism of ~10% and hyperthyroidism in 1.5%. These laboratory endocrine abnormalities are associated with detrimental cardiovascular effects; prospective longitudinal studies have shown that subclinical hypothyroidism, with thyroid stimulating hormone (TSH) levels greater than $10\,mU\,l^{-1}$, is associated with increased incidence of heart failure.[46] Subclinical hyperthyroidism (with low serum TSH levels) is associated with approximately two- to threefold increase risk of developing AF.[47,48] In this context this arrhythmia may be a more benign phenomenon than in primary cardiac disease.[47] However, there is some evidence that low TSH is associated with increased cardiovascular morbidity and mortality.[49] Thyroid hormones have positive inotropic and chronotropic effects and cardiac benefits for hypothyroid subjects from hormone replacement would seem likely; this is supported by imaging studies which have suggested reversal of cardiac dysfunction in patients rendered biochemically euthyroid.[50] However, no adequately powered randomized controlled trials using cardiac endpoints are available.[51] It is not certain that active treatment of subclinical hypo- or hyperthyroidism to achieve a euthyroid state prevents cardiac complications.

Other hormones

Acromegaly and associated growth hormone excess is associated with cardiac enlargement and hypertension. Chronic overproduction of growth hormone also impairs carbohydrate metabolism and leads to a state of hyperinsulinaemia and insulin resistance with consequent increased risk of diabetes mellitus. Elderly people with acromegaly are more likely to develop acromegalic cardiomyopathy with cardiac enlargement and chronic heart failure that is often refractory to treatment. Older patients with hypopituitarism and low serum levels of growth hormone also appear to be at risk of cardiac complications, including acute myocardial infarction. Growth hormone replacement therapy may ameliorate this risk.[52]

The potential link of low levels of sex hormones with cardiovascular disease has attracted considerable attention. Despite apparent beneficial effects on traditional vascular risk factors, prospective studies have shown that estrogen replacement in post-menopausal women is associated with increased incidence of vascular events.[53] In males, low serum testosterone has also been associated with cardiovascular risk factors but definitive evidence of a beneficial cardiac effect of replacement is lacking.[54]

Diabetes mellitus (see Chapter 101, Diabetes mellitus)

A high index of suspicion is necessary for detection of myocardial ischaemia in the elderly with diabetes mellitus as they are more likely to have silent or atypical disease, particularly in females. The reported incidence of arteriosclerotic coronary heart disease in older diabetic patients is likely to be an underestimate as most studies have excluded the elderly with renal dysfunction or other comorbidities.[55] Elderly diabetics are more likely to have multivessel coronary artery disease (often unsuitable for percutaneous revascularization procedures or coronary artery bypass grafting), and have an increased risk of CCF. Diabetes is also associated with LVH independent of other common risk factors.[56] In addition, diabetic cardiomyopathy associated with small vessel disease has been described.

Metabolic syndrome

The concept of the metabolic syndrome was developed to improve understanding of links between insulin resistance and vascular disease. The components of this prediabetic state include raised BMI, elevated triglycerides and blood sugar, low high-density lipoprotein, and hypertension. However, it appears that diagnosis of the metabolic syndrome carries limited clinical utility in older age; while it is associated with increased risk of type-2 diabetes it

has weak or no associations with vascular risk in elderly populations.[57]

Systemic infections and the heart

A variety of acute and chronic systemic infections have been suggested to increase the risk of acute ischaemic vascular events. Even minor acute infections are associated with myocardial infarction and stroke. Although various specific infective agents have been implicated, the process seems most likely to be a generic systemic response to any viral or bacterial infection.[58] Factors such as dehydration, immobility and increased blood coaguability are likely to be responsible. The evidence for a strong causal link between chronic infection and vascular disease is less compelling.[59] There is a modest association between periodontal disease and risk of ischaemic vascular events (including acute myocardial infarction and stroke); the mechanism could involve systemic inflammation contributing to atherosclerosis and thrombosis. However, absence of a standard definition for periodontal disease complicates interpretation of results. In addition there are multiple potential confounding risk factors common to both conditions. Additional large-scale longitudinal epidemiologic and intervention studies are necessary to validate this association and to determine causality.[60]

Cancer

Cardiac neoplasms may be primary or metastatic and although rare, as with most solid organs tumours, an age-related association is apparent. Autopsy series have found that the majority of cardiac tumours are due to secondary spread from primary neoplasms in lung, breast or from haematological malignancy.[61] Primary cardiac myxomas may present with cardiac symptoms or neurological manifestations particularly ischaemic stroke.[62]

Nutrition and cardiovascular system in the elderly

Symptomatic heart failure, especially in the elderly, can affect food intake, leading to malnourishment. A syndrome of cardiac cachexia is recognized and is associated with poor outcomes, independent of severity of heart failure. The weight loss seen in these patients is greater than would be expected from poor diet alone and metabolic, neurohormonal and immune abnormalities may play a role.[63] Besides presenting with significantly more comorbidity, patients with low BMI are at higher risk of postoperative complications following cardiac surgery.[64]

Conclusions

Cardiac manifestations of systemic disease are common in older people. Healthy ageing is associated with a reduction in cardiac homeostatic reserve, increasing the risk of cardiac arrhythmias and heart failure with many non-cardiac illnesses. In addition clinically significant ischaemic heart disease is present in the majority of over 65s in the developed world, further reducing cardiac reserve, and increasing the risk of myocardial ischaemia in response to almost any severe systemic non-cardiac disease. Ischaemic heart disease is linked to dysfunction in numerous other organ systems, and the classic scenario of multiple pathologies in an older person often includes cardiac disease. Optimal management of the older patient requires that the multiple interacting contributors to symptoms or functional decline are identified to allow key modifiable factors to be prevented or treated.

Key points

- Ageing is associated with a marked reduction in cardiac homeostatic reserve due to a combination of intrinsic ageing, and a high prevalence of underlying cardiac disease (particularly ischaemic heart disease).
- This reduced homeostatic reserve greatly increases the risk of cardiac dysfunction (including heart failure and arrhythmias) with non-cardiac disease in older people.
- Cardiac dysfunction in older people also places other organ systems at risk. Examples include increased risk of dementia with both atrial fibrillation and chronic heart failure.
- Frequently there is a complex interaction between different organ systems. For example deterioration in renal and cardiac functions often occur together in older people.
- Optimal management of the older patient requires that these multiple interacting contributors to symptoms or functional decline are recognized, and key modifiable contributors prevented or treated.

CHAPTER 36

Arrhythmias

Abhay Bajpai and A. John Camm
St George's, University of London, London, UK

The population is ageing and, as the heart ages, pathophysiological changes occur that predispose to numerous rhythm disturbances. Prognostic improvements made in the management of heart disease have further increased the burden by prolonging exposure to conditions that promote the development of arrhythmias. Arrhythmias are associated with a substantial risk of morbidity and mortality and the management of arrhythmias in the elderly presents important challenges. Clinical presentation can vary from one extreme (asymptomatic incidental finding) to the other (acute haemodynamic collapse) and includes a myriad of non-specific symptoms common to many disorders. The general principles of arrhythmia management in the elderly are the same as with other ages, but plans must be individualized as there is a vast scope amongst the elderly for comorbidity, polypharmacy, impaired cognition, poor exercise tolerance and other factors that modify the risk–benefit ratio. This chapter reviews arrhythmias in the elderly and their associated morbidity and mortality, with increased emphasis on the commonest rhythm disorder, atrial fibrillation.

The elderly heart

Ageing of the heart is associated with the deposition of amyloid in the atrial myocardium, a gradual loss of the specialized pacemaker myocytes of the sinoatrial (SA) node and the deposition of collagen and fibrous tissue in the specialized ventricular conduction tissue. These ageing processes are associated with a pathological outcome in some patients. For instance, loss of SA node pacemaker cells contributes to the development of sick sinus syndrome. This process is augmented by pathological changes secondary to cardiovascular disease such as hypertension and coronary atherosclerosis, both of which increase in incidence with age. In reviewing 12-lead and 24 h electrocardiogram (ECG) survey findings in the elderly, it can be difficult to distinguish between whether purely ageing or pathological processes are responsible.

12-Lead and ambulatory ECG surveys

Findings of a prolonged PR interval, left-axis deviation and bundle branch block (BBB) are more common in the elderly. First-degree heart block, as a lone finding in an asymptomatic patient, is not associated with an adverse prognosis. Left-axis deviation is associated with cardiovascular disease but in the absence of clinical disease does not carry a worse prognosis. Increases in left ventricular hypertrophy and left BBB with age correspond to the increased incidence of cardiovascular disease and clearly are associated with an increased mortality. Right BBB is more common than left in the elderly, but has no prognostic impact *per se*.

In the absence of medication, a sustained bradycardia is not a normal finding in the elderly. However, elderly subjects do show a significant reduction in 24 h heart rate variability.[1] A survey of 500 asymptomatic individuals aged 50–80 years[2] found no association between heart rate and age, and a study of 1372 individuals aged 65 years and older[3] found no association between bradycardia and age. Various studies have shown a small decline in mean heart rate with age,[4] but even in healthy subjects aged 80–99 years, mean heart rate is still >70 bpm.[1] A persistent and significant bradycardia should alert the clinician to the possibility of sinus node disease. There is a low incidence of sinus arrhythmia in the elderly, but ectopic activity is considerably increased. Specific brady- and tachyarrhythmias are discussed individually below.

Symptomatic bradycardias

Cardiac impulse originates in the SA node, propagates through the atria and is normally conducted to the ventricles via the atrioventricular (AV) node and bundle of His. Bradycardia can result from abnormalities at any level: dysfunction of SA node automaticity, conduction disturbances within the AV node or bundle of His. These are discussed individually below. Bundle branch or fascicular blocks may

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

prolong ventricular depolarization (QRS complex width) or cause electrical axis deviation, but will not result in a bradycardia unless conduction through all fascicles is interrupted, equivalent to complete AV block. The autonomic nervous system regulates sinus node automaticity and AV nodal conduction. The balance of parasympathetic and sympathetic tone is subject to influence from a host of extrinsic factors: physiological [e.g. sleep (see Chapter 54, Sleep apnoea and sleep disorders)], pathological [e.g. hypothyroidism (see Chapter 98, Thyroid disorders)] and iatrogenic (e.g. medication). The causes of a bradycardia are summarized in Table 36.1.

Presentation

Episodes of bradycardia are common in all age groups. However, a sustained bradycardia is not a normal finding in the elderly and, as discussed above, implies pathology. The presence or absence of symptoms is principally determined by the heart's ability to compensate for a bradycardia. Cardiac output is the product of heart rate and left ventricular stroke volume. If the latter cannot increase sufficiently to match demand and peripheral and/or cerebral perfusion falls, this will result in symptoms. These vary from understated symptoms such as lack of concentration, fatigue, poor memory, dizziness and myalgia to more pressing concerns of syncope and heart failure.

Assessment

Documentation of a bradycardia (rhythm strip, 12-lead ECG or ambulatory monitoring) is not sufficient. The symptoms described above are all non-specific and differential diagnoses are extensive, especially in the elderly. It is essential to establish a correlation between the patient's symptoms and the occurrence of bradycardia, otherwise treatment of the arrhythmia may be successful (e.g. pacemaker implantation), but without any symptomatic benefit. History, examination and investigations should be targeted at confirming the presence of arrhythmia, its association with symptoms, to differentiate physiology from pathology and to recognize reversible risk factors (such as medication, hypothyroidism, sleep apnoea).

Sinus node dysfunction (sick sinus syndrome)

The term sick sinus syndrome confers the impression of a constellation of multiple electrocardiographic manifestations such as sinus bradycardia, inappropriate sinus node response to exercise (chronotropic incompetence), sinoatrial block and periods of sinus arrest, particularly occurring after paroxysms of atrial tachyarrhythmias ('tachybrady syndrome'). Dysfunction may progress to the stage that no sinus beats occur (Figure 36.1). Both paroxysmal and chronic atrial fibrillation are commonly associated with sinus node disease. Sinus node dysfunction is primarily

Table 36.1 Causes of bradycardia.

System	Cause
Cardiovascular	Ischaemia/infarction
	Infiltrative disorders (e.g. sarcoid, amyloid, haemochromatosis)
	Inflammatory disorders (e.g. systemic lupus erythaematosus, rheumatoid)
Respiratory	Obstructive sleep apnoea
Medication	β-Blockers (including topical eye preparations)
	Anti-arrhythmics (e.g. digoxin, amiodarone)
	Antihypertensives (e.g. calcium channel antagonists)
Iatrogenic	Valve replacement

Endocrine	Hypokalaemia
	Hyperkalaemia
	Hypothyroidism
Neurological	Raised intracranial pressure
	Increased vagal tone (e.g. micturition, defecation, coughing)
	Carotid sinus hypersensitivity
Infectious disease	Infective endocarditis
	Lyme disease
	Chagas disease
Miscellaneous	Hypothermia
	Metastatic disease

SLE, systemic lupus erythaematosus.

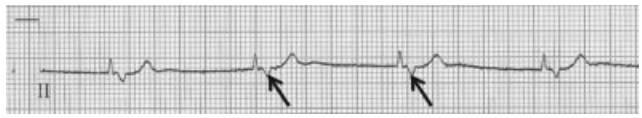

Figure 36.1 Junctional bradycardia: failure of sinus beats has resulted in a junctional escape rhythm. The junctional impulses are seen conducting antegradely causing ventricular depolarization, but also retrogradely into the atria causing inverted P waves, seen immediately after the QRS complex (arrows).

a disease of the elderly resulting from degenerative or ischaemic causes which may also affect other conductive tissue including the AV node. The majority of patients experience recurrent syncope from sinus pauses with inadequate escape rhythm or marked sinus bradycardia. Mortality appears to be unaffected by sinus node dysfunction[5] and survival is influenced by associated pathology such as ischaemic heart disease.

The main indications for pacing in sinus node dysfunction are as follows:[6]

- Sinus node dysfunction with documented symptomatic bradycardia, symptomatic chronotropic incompetence or where bradycardia is the result of medication necessary to treat other medical conditions, such as in the treatment of tachyarrhythmias (class I recommendation).
- Sinus node dysfunction and heart rate <40 bpm, where an association between symptoms consistent with bradycardia and the presence of bradycardia has not been clearly established; syncope of unknown origin in presence of significant sinus node abnormalities on electrophysiological testing (class IIa recommendations).

Atrioventricular blocks

First-degree heart block

The PR interval (time from onset of P wave to onset of QRS complex) corresponds to the time from initiation of atrial depolarization, conduction through the atria and into the bundle branch system via the AV node and bundle of His. A prolonged PR interval (>0.2 s) with preservation of 1:1 AV conduction is termed *first-degree heart block*. The incidence of first-degree AV block increases with ageing. Moderate prolongation of the PR interval in this fashion is a benign condition,[7] but PR intervals >0.3 s can be symptomatic.[8] Marked first-degree AV block could cause loss of synchrony between the atria and the ventricles leading to incomplete atrial and ventricular filling and increased capillary wedge pressure.

Indications for pacing in first-degree AV block are as follows:[6]

- First-degree heart block associated with symptoms of a delay in AV synchronous contraction or haemodynamic compromise (class IIa recommendation).
- First-degree heart block in association with neuromuscular diseases due to unpredictable progression of AV disease; drug-related AV block where the block is expected to persist even after withdrawal of the drug (class IIb recommendation).

Second-degree heart block

This is an intermittent failure of atrial depolarization to result in ventricular depolarization and tends to occur in various patterns. Mobitz type I second-degree heart block (Wenckebach) is present when there is progressive lengthening of the PR interval with each beat until an atrial depolarization is not conducted, resulting in a dropped beat. The PR interval resets and the cycle resumes. Mobitz type II second-degree heart block occurs when atrial depolarizations are intermittently blocked without preceding progressive PR interval prolongation. AV conduction occurring in a 2:1 fashion (or higher) represents another pattern of second-degree heart block. If block of two or more consecutive P waves occurs, this is termed *advanced second-degree heart block* (see Figure 36.2).

Indications for pacing in second-degree AV block are as follows:[6]

- Any form of second-degree heart block associated with symptomatic bradycardia or ventricular arrhythmias presumed to be secondary to the AV block (class I recommendation).
- Advanced second-degree AV block in symptom-free patients with documented significant periods of pauses or asystole lasting ≥3.0 s or any escape rhythm of rate <40 bpm in an awake patient (class I recommendation).
- Advanced second-degree AV block associated with arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia (class I recommendation).
- Unresolving advanced second-degree block following cardiac surgery or catheter ablation of AV junction (class I recommendation).
- AV block during exercise in the absence of myocardial ischaemia.
- Type II second-degree heart block with a wide QRS complex (class I recommendation).
- Asymptomatic type II second-degree heart block with narrow QRS complex (class IIa recommendation).

Figure 36.2 Rhythm strip showing advanced second-degree heart block. The second ventricular complex is a junctional escape beat.

• Associated with symptoms of a delay in AV synchronous contraction or haemodynamic compromise (class IIa recommendation).
• In association with neuromuscular diseases due to unpredictable progression of AV disease; drug-related AV block where the block is expected to persist even after withdrawal of the drug (class IIb recommendation).

Third-degree heart block (complete heart block)

Third-degree heart block is a complete block of conduction between the atria and ventricles resulting in regular atrial activity and the presence of an independent escape rhythm. The escape rhythm is generally ventricular in origin with a wide QRS complex and rate of ~30–40 bpm. Nodal or junctional escape rhythms imply that the anatomical level of block is higher within the AV node or the bundle of His (Figure 36.3). The lower the origin of the escape rhythm, the less specialized and hence less reliable is the conduction tissue.

Indications for pacing in complete AV block are as follows:[6]

• Third-degree heart block with one of the following features: symptomatic bradycardia; documented asystole ≥3.0 s or any escape rhythm of rate <40 bpm in symptom-free awake patients; unresolving block following cardiac surgery or catheter ablation of AV junction; asymptomatic third-degree heart block, especially in the context of LV dysfunction or cardiomegaly; AV block during exercise in the absence of myocardial ischaemia (class I recommendations).
• Asymptomatic heart block in the absence of cardiomegaly (class IIa recommendation).
• Drug-related AV block where the block is expected to persist even after withdrawal of the drug (class IIb recommendation).

Choice of pacemaker

Once the decision to implant a pacemaker has been made, consideration should be given to the appropriate pacemaker mode. The choice lies between single-chamber ventricular-only pacing (VVI/R), dual chamber atrial plus ventricular pacing (DDD/R) or single-chamber atrial-only pacing (AAI/R). DDD or AAI pacing allow the preservation of normal physiology by maintaining AV synchrony. Single-chamber AAI pacing is indicated in patients with pure sinus node disease with no evidence of either existing or future development of disease elsewhere in the conduction system. However, elderly patients, who may initially present with apparently pure sinus node dysfunction, have a greater likelihood of more widespread conduction system involvement and therefore generally will not benefit from atrial-only pacing. Physiological pacing may improve haemodynamics, but dual-chamber systems can be technically more challenging as two leads are required with greater potential for late complications. A series of large prospective, randomized trials have compared ventricular pacing (VVI/R) with physiological systems (DDD/R or AAI/R) for sinus node dysfunction or AV block (see Table 36.2 for a summary of these trials). A key limitation of these trials is that a significant number of patients either crossed over between treatment arms or dropped out of their assigned pacing mode. Meta-analysis of these five trials shows that there is no difference in overall mortality between ventricular and physiological pacing systems and no difference in new-onset heart failure or improvement or progression of any existing heart failure.[9]

However, a statistically significant reduction in the development of AF was found with physiological pacing, particularly in the Mode Selection Trial (MOST) and Canadian Trial Of Physiological Pacing (CTOPP) trial. There was borderline reduction in thromboembolic stroke with physiological pacing. Some cross-over studies with intra-patient comparison between the two pacing modes have shown improved functional capacity and increased patient preference for dual-chamber pacing.[10]

Therefore, elderly patients with sinus node dysfunction who require pacing should be considered for a dual chamber system. No clear evidence exists for benefit of dual-chamber pacing over simple ventricular pacing for AV block in the elderly, but given the overall findings from trials, physiological pacing should be considered for those likely to be pacemaker dependent. Active elderly patients over 70 years of age appear to benefit from DDD pacing in terms of improvement in quality of life.[11] However, the final decision in the elderly depends on an individual basis after taking into account patient preferences, co-morbidities and the available resources.

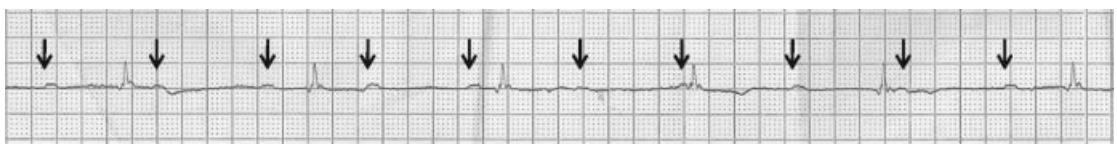

Figure 36.3 Complete heart block. Rhythm strip showing P waves (arrows) that are independent and unrelated to QRS complexes. The QRS complexes are relatively narrow, suggestive of junctional escape rhythm.

Table 36.2 Characteristics of trials comparing ventricular and physiological pacing.

Trial[a]	*n*	Age (years)	Indication[a]	Follow-up (years)	Results
CTOPP	2568	73	SND or AVB	3.1	No significant difference in stroke, cardiovascular death or hospitalization for heart failure Annual rate of AF significantly lower in physiological group, but higher perioperative complication rate
CTOPP (long-term)	2568	73	SND or AVB	6	No significant difference in cardiovascular death, stroke or total mortality Persistent significantly lower rate of AF in physiological group
MOST	2010	74 (median)	SND	2.8	No significant difference in death, non-fatal stroke or hospitalization for heart failure Incidence of AF significantly lower in physiological group
PASE	407	76	SND or AVB	2.5	No significant difference in stroke, stroke or all-cause mortality, stroke, death or hospitalization for heart failure No significant difference in the development of AF
UKPACE	2021	80	AVB	4.6	No significant difference in all-cause mortality No significant difference in secondary end-points of AF or heart failure

[a]CTOPP, Canadian Trial Of Physiologic Pacing:[13] CTOPP (long-term), Canadian Trial Of Physiologic Pacing long-term follow-up:[14] MOST, Mode Selection Trial:[15] PASE, pacemaker selection in the elderly:[16] UKPACE, United Kingdom Pacing and Cardiovascular Events; SND, sinus node dysfunction: AVB, atrioventricular block.

Complications of pacemaker implantation

Complications can occur during implantation and include pneumothorax (1–2% with subclavian vein approach; <0.1% with cephalic or axillary vein approach), bleeding, myocardial perforation and tamponade (<0.2%), lead dislodgement and failure to sense or capture. Post-procedure complications are bruising, wound haematoma, infection (<1%), device erosion, lead fracture and box or lead dislodgement. In a recent series, early complications (within 2 weeks of implantation) occurred in 6.7% of patients and late complications in 7.2% of patients.[12] The majority of these patients required an invasive correction of the complication. Despite the reduction in size of the modern pacemaker, special considerations have to be made for elderly patients. Devices are generally implanted subcutaneously between the skin and the pectoral muscle in the infra-clavicular region, but skeletal deformities resulting from osteoarthritis or osteoporosis of the shoulder, spine or pectoral region may occasionally prevent this. In addition, wound healing and device erosion through the skin are more likely to occur with cachexia and thinning skin. In such patients, the pacemaker may be better positioned under the pectoral muscle. Clearly, as with any procedure, a risk–benefit assessment has to be made on an individual basis.

Atrial tachyarrhythmias

Atrial ectopic beats

These are a common finding in the elderly and, if frequent, can result in a pulse that could be confused with AF. No specific treatment is required, but if symptomatic, patients generally respond to β-blocker therapy.

Atrial tachycardia

Short bursts of atrial tachycardia are common in the elderly (Figure 36.4). In many cases, no symptoms are associated and no treatment may be needed. Sometimes the atrial tachycardia triggers AF or causes rapid ventricular rates when treatment of the tachycardia may become necessary. Most elderly patients will achieve symptomatic benefit from β-blocker therapy, and some may require anti-arrhythmic medication (e.g. amiodarone, sotalol) or urgent direct current cardioversion (DCC) if haemodynamically unstable. Percutaneous catheter ablation utilizing radiofrequency or cryo energy is increasingly used, but success rates are generally higher in younger patients and therefore not currently a preferred option in the elderly.

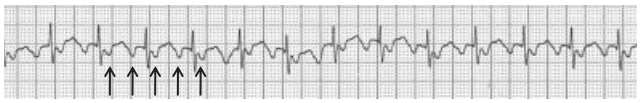

Figure 36.4 Atrial tachycardia. Abnormal, inverted P waves are seen (arrows) with 2:1 conduction to the ventricles. The tracing may appear like atrial flutter, but note that the P wave rate or cycle length is less than the typical flutter cycle length of 300 bpm.

Multifocal atrial tachycardia (MAT)

Another common atrial arrhythmia in the elderly, multifocal atrial tachycardia (MAT), is characterized by the appearance of diverse P wave morphologies as complexes originate from different foci within the atria. This can result in irregular R–R intervals and hence clinically mimic AF. There is an association with chronic airways disease and drug toxicity (digoxin, theophyllines and tricyclic antidepressants). Treatment should be aimed at the underlying cause.

Atrial flutter

Atrial flutter and AF are two ends of the same spectrum. Whereas the atria are activated in a chaotic manner in AF, atrial flutter consists of organized atrial activation seen on the ECG as a regular saw-tooth pattern of flutter waves with typically a flutter-wave rate of ~300 bpm (see Figure 36.5). A physiological 2:1 AV block frequently occurs and atrial flutter should always be suspected when a patients with a ventricular rate of 150 bpm. In the elderly, variable 4:1, 8:1 or other AV ratios may also be seen. Vagal manoeuvres or intravenous adenosine can temporarily increase the AV block, making flutter waves more visible. With typical (counterclockwise) atrial flutter, flutter waves are seen inverted in the inferior limb leads, giving rise to the characteristic saw-tooth appearance on the ECG. Atrial flutter commonly occurs in patients with AF and vice versa. Antiarrhythmic medication prescribed for AF can convert the AF into atrial flutter. Management of the two conditions is essentially similar and although the stroke risk associated with atrial flutter may not be as high as for AF, there is still a substantial risk[17] and a high likelihood of coexisting AF requiring the use of anticoagulation. In a given elderly patient, unlike other atrial arrhythmias, catheter ablation of typical atrial flutter may be performed with relative ease and high curative rates.

Atrial fibrillation

AF is characterized by disorganized atrial activity confirmed on the ECG by the substitution of regular P-wave activity by rapid fibrillatory waves varying in shape, amplitude and timing. If AV node conduction is intact,

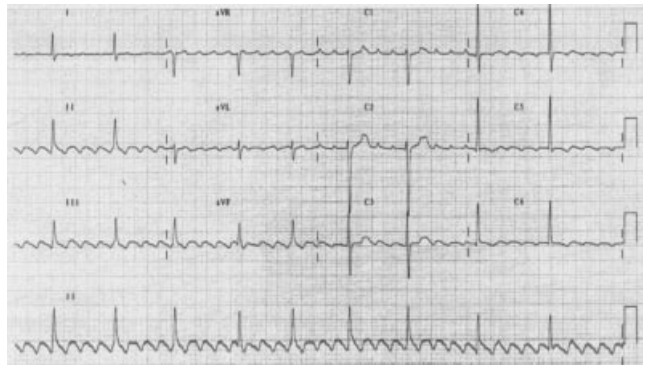

Figure 36.5 12-Lead ECG of typical atrial flutter with variable AV block. Note the inverted P waves (flutter waves) in the inferior leads II, III and aVF. The flutter wave cycle length is 300 bpm.

Figure 36.6 Rhythm strip of patient in AF with a slow ventricular response.

Figure 36.7 Lead II rhythm strip of a patient with chronic AF who presented with syncope. The rhythm is regular with fibrillatory baseline and absence of P waves, suggestive of complete heart block in the setting of AF.

the chaotic atrial activation will result in a rapid and irregular ventricular response. In the elderly, AV conduction may be impaired. A slower ventricular rate is common and sometimes verges on a symptomatic bradycardia (see Figure 36.6). The presence of regular rhythm on the ECG with a fibrillatory baseline implies development of complete AV block in a patient with AF, the regularity arising from the escape rhythm (Figure 36.7).

Classification

AF can be classified into five types based on the presentation, duration and choice of treatment strategy. When the first episode is detected, it is important to understand that its duration may be uncertain and there may have been previous episodes, which were not symptomatic, remembered or documented. After first detection, AF is then subclassified into the following categories according to its time course and intervention: *paroxysmal (PAF), persistent, long-standing persistent* and *permanent* atrial fibrillation. PAF is characterized by recurrent episodes of AF alternating with

sinus rhythm. The characteristic feature of PAF is that the episodes terminate spontaneously, usually within 48 h. If the episodes of fibrillation continue for more than 7 days or patients require intervention to restore sinus rhythm, this is termed persistent AF. When AF has lasted for ≥1 year and when it is decided to adopt a rhythm-control strategy, AF is termed long-standing persistent AF. Permanent AF is more a statement of intent rather than a duration or pathological based description and is reserved for patients in whom AF is resistant to conversion or accepted for rate control by the patient and there are no further attempts to achieve sinus rhythm. Permanent AF is redesignated long-standing persistent AF if there is a change of plan towards adopting a rhythm-control strategy.[18]

Epidemiology

AF affects 1–2% of the general population and is the commonest sustained arrhythmia in the elderly. The true prevalence of AF may be closer to 2% as many patients remain asymptomatic and may never present to a hospital. The prevalence of AF increases with age from <0.5% at 40–50 years to 5–15% at 80 years.[19]

Men are more often affected than women. An analysis of 1.4 million patients registered with 211 general practices in England and Wales showed that prevalence rates increased with age from <1 in 1000 in those under 35 years of age to >100 in 1000 in those aged 85 years and older.[20] The prevalence of AF is estimated to double in the next 50 years.[21]

We are in part a victim of our own success owing to prognostic improvements made in coronary heart disease and heart failure, conditions known to predispose to the development of AF. This, together with an ageing population, has led to the description of a near-epidemic of AF.[22] AF increases the risk of stroke fivefold. In 2000, the projected direct cost of AF to the UK National Health Service (NHS) was calculated at £459 million, 0.98% of total NHS expenditure,[23] a conservative estimate as costs related to stroke rehabilitation and anticoagulant-related haemorrhage were not considered.

Aetiology

Valvular AF

It is essential to make a distinction between valvular and non-valvular AF because of the consequence for stroke risk. Valvular heart disease is present in about 30% of patients with AF.[24]

Mitral stenosis and/or regurgitation, and in its later stages aortic stenosis, cause left atrial dilatation leading to AF. Rheumatic heart disease is now relatively rare in developed nations. In the Framingham Study, patients with rheumatic heart disease and AF had a 17-fold increase in stroke risk compared with age-matched controls.[25]

Non-valvular AF

AF occurring in the absence of rheumatic mitral stenosis or a prosthetic heart valve is termed *non-valvular AF*,[18] which can then be further subdivided as follows.

With associated cardiovascular disease

Hypertension (see Chapter 40, Hypertension), diabetes requiring medical treatment, heart failure (see Chapter 41, Heart failure), cardiomyopathies, coronary artery disease (Chapter 37, Ischaemic heart disease) and congenital heart defects such as atrial septal defect are commonly associated with AF. Of these, heart failure carries the highest predictive risk for the development of AF.[26] Hypertension is identified as a risk factor for AF and related complications such stroke and thromboembolism.

Hypertension, when associated with left ventricular hypertrophy by electrical criteria on the ECG, strengthens its contribution towards predicting development of AF. Coronary artery disease can be both a reversible risk factor (ongoing ischaemia or infarction) or irreversible (scar formation from prior infarction).

Other causes

Other identifiable and potentially reversible causes include obesity and obstructive sleep apnoea, electrolyte disturbance, sepsis, stress, hyperthyroidism, pulmonary disease, hypoxia and alcohol binge drinking. These factors need to be considered both in a first detected episode of AF and for the patient with a recent compromise in rate control.

Lone AF

Patients with a structurally normal heart in whom no identifiable cause can be found for their AF are denoted as having lone AF. This is probably rare in the elderly since almost all patients will have a degree of underlying heart disease by this stage and such a diagnosis of exclusion should only be made with caution in the elderly. In a small number of younger patients, sympathetic or vagal overstimulation may trigger AF and could influence the choice of anti-arrhythmic medication.

Consequences of AF

AF independently increases the mortality by twofold and is associated with stroke, other systemic thromboembolic disease, heart failure and related morbidity, leading to poor quality of life. Only antithrombotic treatment has been shown to reduce AF-related mortality.[27]

Atrial remodelling

It is a common finding for patients presenting with PAF to cardiovert spontaneously to sinus rhythm within 24 h of its onset.

The success of electrical or chemical cardioversion and the subsequent maintenance of sinus rhythm are generally higher with AF of a shorter duration. These observations are consistent with the concept that AF itself is capable of inducing an electrical remodelling of the atria, which in turn sustains the arrhythmia. Electrophysiological artificial maintenance of AF in animal models has been shown to induce reversible atrial changes (shortened atrial refractoriness) that lead to the perpetuation of AF[28] and eventually to histological (cellular dedifferentiation, fibrosis) and gross structural changes (atrial dilatation).

Haemodynamic function

With the chaotic activation inherent in AF, synchronous atrial mechanical function is not possible. The left ventricle in AF can only fill passively in the absence the late diastolic contribution from atrial contraction. This in turn can lead to a 5–15% decrease in cardiac output, an effect that is more pronounced in patients with reduced ventricular compliance (e.g. hypertensives) in whom ventricular filling is significantly reliant on the atrial contribution. Further deterioration in haemodynamic function results from high ventricular rates due to shortening of the diastolic filling time and additionally tachycardia-related myopathy (tachycardiomyopathy) at rates persistently above 120–130 bpm. Restoration of atrial mechanical function after successful ventricular rate control or cardioversion leads to quantifiable improvements in left ventricular function.[29] However, the return of atrial contraction may be delayed or insufficient if AF has been present for a substantial period of time.

Thromboembolism

The risk of stroke in non-rheumatic AF patients is 5.6 times greater than in age matched controls with an identical blood pressure distribution.[25] Thrombus formation, often in the left atrial appendage (LAA), is responsible for embolic stroke and systemic embolism in the context of AF. Stroke risk consistently and significantly increases with age from 6.7% in those aged 50–59 years to 36.2% for those aged 80–89 years.[30] Asymptomatic cerebral infarction based on computed tomography (CT) findings has been found in 14.7–48% of AF patients.[31-33] The large variation in incidence is probably due to the use of different radiological definitions of infarction and study size. The two largest studies[31,32] showed statistically significant associations of silent infarction with increasing age. Compared with non-AF strokes, those occurring in the context of AF have a greater mortality and survivors are more likely to suffer a recurrence and greater disability.[34] Asymptomatic AF carries the same thromboembolic risk as symptomatic AF. PAF has been shown also to have similar rates of ischaemic stroke and predictors as sustained AF.[35,36]

Multivariate analysis from antithrombotic trials in AF have demonstrated several clinical risk factors for stroke in non-rheumatic AF: increasing age, history of hypertension, previous stroke or transient ischaemic attack (TIA) and diabetes.[37] A pooled analysis of echocardiographic data from three of these trials demonstrated that left ventricular systolic dysfunction (as defined by global or regional wall motion abnormalities shown on 2D transthoracic echo) is an independent risk factor for stroke in AF.[38] Recent 2010 ESC guidance additionally suggests vascular disease and sex category (female) as additional important risk factors (CHA_2-DS_2-VASc scoring system; see below). Moreover, increased left atrial diameter (measured by m-mode echocardiography) is an independent predictor of thromboembolism.[39] The presence of thrombus in the LAA and its precursor, the appearance of spontaneous echo contrast, are also associated with thromboembolism.[40] Therefore, patients with AF can be risk stratified for stroke on the basis of clinical and echocardiographic data.

Clinical manifestations

AF can have a diverse clinical presentation, whether symptomatic or asymptomatic. Patients may report experiencing palpitations, dyspnoea or chest pain. Release of atrial natriuretic peptide (ANP) can be associated with polyuria, although this is relatively uncommon in the elderly. Patients may only present with the consequences of disease: thromboembolic complications, heart failure secondary to the tachycardia-induced cardiomyopathy or symptoms secondary to reduced cardiac output (lightheadedness, fatigue). Cognitive impairment secondary to cerebral hypoperfusion or recurrent thromboembolism is important to distinguish as this would identify a potentially treatable cause of impairment. Syncope is not a common presentation of AF and generally indicates additional pathology such as conduction system disease or aortic stenosis.

History and examination

There needs to be a focused workup concentrating on the following points.

Confirmation of arrhythmia

The clinician should elucidate any prior history of palpitations and associated symptoms. A review of medication past and present, for warfarin or anti-arrhythmics, should be undertaken and response/tolerance to these agents noted. On examination, there is an irregularly irregular pulse and variation in loudness of the first heart sound. There is good evidence that manual pulse check with ECG follow-up of an irregular pulse is a sensitive screening method.[41] A 12-lead ECG is essential, as this

can provide evidence of prior myocardial infarction, left ventricular hypertrophy and AV node or bundle branch conduction disease.

Aetiology of arrhythmia

It is essential to identify any possible reversible triggers that may be responsible for a new episode of AF or deterioration in previously well-controlled disease. An assessment of associated cardiovascular disease should also be made both for aetiology and stroke risk assessment.

Effect of arrhythmia on the patient

It is important to identify a clear pattern of symptoms attributable to the arrhythmia and any indication of cardiovascular compromise. Evidence of end-organ effects such as heart failure or stroke should also be sought, as this may influence treatment decisions such as anticoagulation.

Patient assessment for management options

A balanced decision regarding rate versus rhythm control and the risks and benefits of anticoagulation should be made. It is imperative that any potential bleeding risks (such as previous haemorrhage or history of falls) are identified. A social history (emphasizing exercise tolerance, living conditions, access to support and cognitive function) is important. A review of medication will establish potential risks of drug interactions and polypharmacy. Issues of non-compliance should be explored as medication, particularly warfarin, will require stable and consistent administration.

Imaging

Transthoracic echocardiography (TTE) is an essential investigation in any patient with AF, regardless of age. It provides an assessment of the left atrium, mitral valve and left ventricular function and dimensions, thus providing information regarding aetiology and stroke risk assessment. TTE has its limitations since it cannot reliably exclude the presence of thrombus in the LAA. Transoesophageal echocardiography (TOE) is the imaging of choice to examine the LAA for thrombus or its precursor spontaneous echo contrast. Its role in cardioversion is discussed below.

Other tests

A chest X ray and lung function tests are required when lung disease is suspected. A CT head scan is indicated if there is any evidence of cerebrovascular disease which may be important in making a decision regarding anticoagulation. Relevant blood and urine tests include those to rule out infection or inflammatory disorders, liver and renal functions, thyroid functions, full blood count and coagulation profile.

Management

There are two aims in the management of AF: to prevent thromboembolism and to control the arrhythmia (rate or rhythm control). The classification of AF into paroxysmal, persistent, long-standing persistent and permanent is clinically useful as it gives a clear guide to a management strategy for each patient. In PAF, the aim is to maintain sinus rhythm and control the ventricular rate when AF does occur. For a patient with permanent AF, the decision has been made to accept the arrhythmia and instead symptomatic improvement is attained with ventricular rate control. Persistent AF may presents the clinician with a dilemma: standard practice has been to strive for sinus rhythm by electrical or pharmacological means with symptom control, improved haemodynamics and reduced risk of thromboembolism being the proposed rationale. However, rhythm control medication could pose the problem of pro-arrhythmia and randomized controlled trials[42–47] have not shown superiority of rhythm control over rate control; these are summarized in Table 36.3.

The conclusion to draw from these trials is that for relatively asymptomatic elderly patients with persistent AF, rate control is generally no worse an option than rhythm control. In a first detected episode of AF, one should consider an attempt at rhythm control, cardioversion being the first-line therapy for acute haemodynamic compromise related to AF. However, in elderly patients who are tolerating the arrhythmia, accepting rate control should not be viewed as a failure. Acceptable methods of rate and rhythm control for the elderly are described in the following section. Anticoagulation to prevent thromboembolism needs to be considered whichever strategy is chosen. How a patient is anticoagulated will depend upon the options available, duration of anticoagulation and a risk–benefit analysis for each patient.

Rate control

As has already been discussed, bradycardia is not a normal finding for the elderly and similarly a slow ventricular rate in an elderly patient with untreated AF implies underlying conduction system disease.[48] The aim of rate control is to maintain a patient's heart rate at what is physiologically appropriate for the level of exertion. This must not be at the expense of symptomatic pauses or bradycardia. Therapy must be tailored to the individual, but rates of 60–80 bpm at rest and 90–115 bpm during moderate exercise have been suggested as a target.[49] This can be achieved through medication and/or non-pharmacological methods, although not infrequently no specific rate control therapy is needed in the elderly. The recent RACE II trial[50] showed that in patients with fast ventricular rates, but without severe symptoms,

Table 36.3 Randomized controlled trials of rate versus rhythm control in AF.

Trial[a]	No. of patients	Mean age (years)	Follow-up (years)	Outcome
AFFIRM AF + risk factor for stroke	4060	69.7	3.5	No difference on overall mortality or quality of life Increased hospitalization in rhythm control group
PIAF Persistent AF + symptoms	252	61	1	No difference in symptoms or quality of life Increased hospitalization in rhythm control group Increased walking distance in rhythm control group
RACE Persistent AF or flutter post-cardioversion	522	68	2.3	No difference in composite end-points (cardiovascular death, heart failure, thromboembolism, bleeding, severe drug adverse effects, pacemaker implantation)
STAF Persistent AF + symptoms + LVEF <45%	200	65	1.6	No difference in composite end-points (death, cerebrovascular event, systemic embolization, cardiopulmonary resuscitation) Increased hospitalization in rhythm control group
HOT-CAFÉ First clinically overt persistent AF	205	60.8	1.7	No difference in composite end-points of death, thromboembolic events, intracranial or major haemorrhage
AF–CHF AF + symptoms of heart failure + LVEF ≤ 35%	1376	66	3.1	No difference in cardiovascular deaths

stringent rate control (resting heart rate <80 bpm) conferred no symptomatic benefit over lenient rate control (resting heart rate <110 bpm).

Digoxin

Digoxin, a muscarinic agonist, slows AV nodal conduction. This is sufficient to produce adequate rate control for elderly patients with low levels of exertion. This action can be overwhelmed when faced with high sympathetic stimulation, which explains why digoxin is less effective during exercise and why patients with previously well-controlled AF present with inadequate rate control in the context of an acute illness.[51] Although digoxin can be considered as first-line therapy for an inactive elderly patient, it should not be solely relied upon in the presence of high sympathetic tone (i.e. sepsis, pain, β-agonist medication). Digoxin also blocks the sodium/potassium ATPase exchange pump by occupying the potassium binding site (hence digoxin toxicity is potentiated in hypokalaemia) and can act as a mild positive ionotrope (although probably not in the context of AF). Digoxin has not been shown to be of prognostic benefit in heart failure[52] but it can be safely used in patients with heart failure. In comparison with β-blockers and the non-DHP calcium channel antagonists used for rate control, digoxin has a relatively slow onset of action of the order of hours compared with minutes.[48] This is acceptable if there is no urgency for rate control to be achieved. Digoxin compared with placebo produces a small but statistically significant reduction in the frequency of symptomatic episodes of PAF,[53] probably via a significant reduction in ventricular rate, recorded during patient-activated recordings. However, 24 h ambulatory ECG monitoring during this period failed to show any reduction in frequency, duration of AF or ventricular rate. Digoxin was well tolerated by these patients and so is not believed to be detrimental in PAF, although its benefit is questionable. Concerns have been expressed regarding its use in PAF, as digoxin has been shown to augment the shortening in atrial effective refractory period that can predispose to further episodes of AF.[54] Digoxin has no role to play in cardioversion. Neither oral[55] nor intravenous[56] preparations have been shown to be more effective than placebo. Digoxin is excreted in an unchanged form via the kidneys. Serum level monitoring and dose adjustment will be required in renal dysfunction. To reduce the risk of toxicity, a lower dosage than that required in younger patients should initially be used. The dose may then be up-titrated if the response is inadequate. There is an age-related decline in glomerular filtration rate and impaired renal function can easily develop with acute illness or changes to medication, such as introduction of a diuretic.

β-Blockers

β-Receptor antagonists block the action of catecholamines and hence are particularly useful in the context of high sympathetic drive. This may on occasion also be to their detriment as a decrease in maximum exercise tolerance has been reported,[57] as have measured reductions in $VO_{2\,max}$ and cardiac output during exercise.[58] A reduction in exercise tolerance is not universal, however, and β-blockers remain the most effective agent for controlling ventricular rate during exertion. They should also be considered as first-line treatment in the context of hypertension, ischaemic heart disease or stable LV dysfunction, although usually more β-blockade is needed for rate control than for heart failure and so β-blocker monotherapy is not useful for patients with both conditions. These agents have a rapid onset of action, but their use is restricted by bronchospasm. In cases of acute pulmonary oedema, they should only be considered where there is no doubt that it is has been precipitated by decompensated AF (not an easy diagnosis to be certain of) and used in small, titrated doses.

Non-dihydropyridine calcium channel antagonists

Verapamil and diltiazem act directly on the AV node, slowing conduction. Both have a rapid onset of action similar to that of β-blockers and are a useful alternative in the context of airways disease. These too should be used with caution in pulmonary oedema and do not have the prognostic benefits enjoyed by β-blockers in heart disease.

Amiodarone

In cases where amiodarone fails to cardiovert AF chemically, significant improvements in ventricular rate control can occur.[59] This is clinically useful where rapid control of AF is required to relieve symptoms and effective rate control can provide a significant benefit, even if cardioversion is unsuccessful. However, for the purposes of rate control, the agents discussed above are a more practical long-term option as the use of amiodarone maybe limited due to severe extracardiac side effects, including thyroid dysfunction.

Dronedarone

This is a new multichannel blocker that is used for maintaining sinus rhythm, but also has anti-adrenergic activity and is effective as a rate-controlling agent during rest as well as exercise. It can be added to other rate-controlling agents and effectively reduces heart rates in AF relapses (not currently approved for permanent AF).[60]

Combination of rate control agents

A combination of β-blocker and non-DHP calcium channel antagonists is to be used only with caution. These are both negative ionotropes, which together can cause life-threatening hypotension or bradycardia. In addition, verapamil and diltiazem both inhibit the metabolism of propranolol and metoprolol and hence if used together can result in synergistic detrimental effects.[61] Verapamil can cause a significant and unpredictable elevation in plasma digoxin levels and should not be used together. There are, however, no significant interactions of digoxin with diltiazem,[62] making it a preferred option over verapamil. Digoxin can also be used in combination with β-blockers, but vigilant follow-up is required for any of these combinations as the risk of conduction disease and hence the potential for bradyarrhythmias are more common in elderly patients. Amiodarone causes significant elevation in the plasma levels of digoxin, necessitating halving of the digoxin dose if used simultaneously with amiodarone.[61]

Recommendations for rate control

Monotherapy for ventricular rate control should be chosen on an individual basis: digoxin is recommended for relatively sedentary patients with low levels of exertion, β-blockers for active patients or those with ischaemic heart disease, and calcium channel antagonists (diltiazem or verapamil) if β-blockers are not tolerated or are contraindicated.

Combination therapy of the above may be required to achieve adequate rate control at rest and during exercise, with careful monitoring to avoid bradycardia. Amiodarone is also an effective rate-controlling agent and may be suitable for some patients when other drugs are unsuccessful. In certain situations, such as heart failure, combination of a β-blocker with digoxin may be beneficial.

For acute rate control in patients without heart failure or hypotension, intravenous β-blocker or calcium channel antagonist (diltiazem or verapamil) can be used. In patients where adequate rate control cannot be achieved or medication is not tolerated, non-pharmacological methods should be considered.

Non-pharmacological rate control

Permanent pacemaker

In the elderly, AF may be a part of wider conduction system disease ('tachy-brady syndrome', sick sinus syndrome) and adequate rate control may only be achieved at the expense of intolerant bradycardia. Implantation of a permanent pacemaker may then become necessary to allow continuation or up-titration of rate-control medication.

Ablate and pace strategy

If the ventricular response is refractory to medical rate control therapy or a patient is intolerant to drug therapy and other non-pharmacological treatments such as catheter-based or surgical ablation of AF are not indicated, the option of catheter-based ablation of AV node/bundle of His should be considered. The main benefits of this

approach are a reduction in symptoms and improved quality of life.[63] This involves irreversible destruction of normal AV conduction tissue, an irreversible process that renders the patient permanently pacemaker dependent. Cardiac resynchronization therapy (biventricular pacemaker) may provide additional long-term benefit in patients with severe heart failure symptoms (NYHA functional class III or IV) and LV ejection fraction ≤35%.

Rhythm control

Urgent DC cardioversion (DCC)

Patients with acute, uncontrolled AF who become haemodynamically compromised or experience evolving myocardial ischaemia/infarction require urgent synchronized electrical DCC under short-acting general anaesthetic or conscious sedation. Unless AF duration is <48 h or if the patient is not already anticoagulated within the therapeutic range, then the procedure should be preceded by an intravenous bolus of unfractionated heparin followed by either continuous infusion or subcutaneous low molecular weight heparin (LMWH). A prospective study of 357 patients (mean age 68 years) presenting with AF of duration that was clinically estimated at <48 h and without prior anticoagulation demonstrated a low incidence of thromboembolism with cardioversion.[64] If the duration of arrhythmia is uncertain or when there is high risk of left atrial/atrial appendage thrombus, transoesophageal echocardiography can be performed prior to urgent cardioversion. Electrical cardioversion can cause temporary disruption of left atrial mechanical function, which can lead to the development of spontaneous echo contrast and thrombus formation. Therefore, despite the low incidence of thrombus formation in AF of <48 h duration, thromboembolic risk becomes evident in the period after cardioversion. The duration of risk is uncertain, especially in cases of cardioversion for acute AF. A retrospective, pooled analysis of studies of electrical cardioversion of AF of various durations demonstrated that 98% of embolic episodes occurred within 10 days of cardioversion.[65] Current recommendations are to commence oral anticoagulation with warfarin and maintain an international normalized ratio (INR) of 2–3 for at least 4 weeks after cardioversion, except when AF is of recent onset and no other thromboembolic risk factors are present.[18]

Elective DC cardioversion

Elective cardioversion should be considered for patients with AF who are stable and do not have severe underlying heart disease. At least 3 weeks of adequate anticoagulation with warfarin is mandatory prior to attempted cardioversion of AF of >48 h duration. This been shown successfully to resolve preformed atrial thrombus and results in an 87% improvement in the incidence of thromboembolism at cardioversion.[66] Some trials have shown that an alternative strategy of transoesophageal echo-guided cardioversion to exclude the presence of LAA thrombus obviates the need for prior anticoagulation, is safe, reduces the time to cardioversion, is associated with fewer haemorrhagic events[67] and is cost-effective.[68] Timing of recovery of left atrial mechanical function is related to duration of prior AF.[29] If the patient remains in sinus rhythm at 4 weeks post-cardioversion, anticoagulation may be stopped depending on long-term thromboembolic risk. However, as discussed above, the duration of thromboembolic risk still remains uncertain. In the Rate Control versus Electrical Cardioversion trial,[44] 17% of all thromboembolic complications occurred in the rhythm control arm when warfarin therapy was ceased. Electrolyte imbalances must be excluded prior to an attempt at cardioversion. Cardioversion generally achieves high success rates,[69] but relapse rates can be high with age, hypertension, AF duration, previous recurrences, enlarged left atrium, presence of coronary disease, pulmonary or mitral valve disease and NYHA functional class III or IV predicting long-term failure of electrical cardioversion.[70] In the event of relapse, further attempts at cardioversion with pretreatment with anti-arrhythmic medication are recommended.[49] Amiodarone would be a suitable choice for the elderly patient, but consideration must be paid to the risks of such a strategy (pro-arrhythmia/systemic side effects) as compared with accepting rate control for each individual patient.

Pharmacological cardioversion and rhythm control

The risk of thromboembolism is present irrespective of the method of cardioversion employed, requiring anticoagulation use with pharmacological attempts at rhythm control. The choice of agents that can be used in elderly patients is more restricted than that for younger patients with AF. This is because of the increased comorbidity in the elderly population and the side-effect profile of medication used.

Amiodarone

This Vaughan Williams class III anti-arrhythmic, along with sotalol and dofetilide, blocks potassium channels, thereby slowing repolarization and prolonging the QT interval. It also affects calcium and sodium channels and has an extensive half-life (~50 days) due to protein binding. It has a broad side-effect profile but a practical safety profile, permitting its use in LV dysfunction and ischaemic heart disease. It is indicated for both cardioversion and maintenance of sinus rhythm. Amiodarone is metabolized by the cytochrome P450 system and so the dosage may have to be increased when used concomitantly with enzyme inducers such as rifampicin or carbamazepine. Amiodarone itself is an enzyme inhibitor, resulting in increased drug levels of phenytoin or warfarin if used in combination. It is important to consider that because of its long half-life, side

Table 36.4 Factors which increase the risk of sotalol-induced QT prolongation and pro-arrhythmia.

- Women
- Marked left ventricular hypertrophy (>1.4 cm)
- Severe bradycardia
- Ventricular arrhythmias
- Renal dysfunction
- Hypokalaemia
- Hypomagnesaemia

effects or interactions may persist for some time, even after discontinuation of the amiodarone. Risk of drug-induced pro-arrhythmia (QT prolongation and polymorphic ventricular tachycardia), although less in comparison with other anti-arrhythmic drugs, requires regular monitoring of QT interval.

Sotalol

Another potassium channel blocker, sotalol has additional β-blocking action (class II) that predominates over the class III action at low doses. This may limit its efficacy in the elderly population where intolerance of substantial β-blocker action may prevent high enough dosing for the class III effect to manifest. Sotalol appears to be as effective as amiodarone in patients with ischaemic heart disease (SAFE-T study[71]) and should be used as first-line agent in these patients.

Sotalol prolongs the QT interval, which should be closely monitored and the drug stopped or reduced if the QT interval is >500 ms (Table 36.4).

β-Blockers

β-Blockers are only modestly effective in preventing recurrent AF, except if it is related to thyrotoxicosis or is exercise induced. The 'anti-arrhythmic' effect may also be due in part to better rate control during paroxysmal episodes rendering these recurrences less symptomatic or silent.

Flecainide

The class 1C anti-arrhythmic flecainide is a sodium channel blocker that delays depolarization and can lead to prolongation of the QRS width. In suitable patients with AF <24 h, intravenous flecainide has 67–92% efficacy in converting AF to sinus rhythm, but is less effective in AF of longer duration. In the light of the Cardiac Arrhythmia Suppression Trial (CAST), where flecainide in post-infarct patients was associated with increased mortality,[72] concern has been expressed regarding its safety for use in the elderly, who will generally have a degree of ischaemic heart disease. Flecainide should be avoided in patients with coronary artery disease or left ventricular impairment. The drug prolongs the QRS duration, and thereby the QT interval, and should be stopped if the QRS duration has increased by >25% of the baseline.

Dofetilide/ibutilide

These are a newer class III agents that may be effective in recent-onset AF. Ibutilide is more effective in conversion of atrial flutter than AF. However, a high incidence of ventricular arrhythmias currently limits their use in elderly patients.

Dronedarone

Dronedarone is a new multichannel blocker that is less toxic than amiodarone, in terms of systemic side effects, and may be of use to maintain sinus rhythm in stable patients without structural heart disease or heart failure. In comparison with placebo, dronedarone appears to reduce significantly all-cause mortality, cardiovascular hospitalizations and stroke risk (independent of antithrombotic treatment) in patients with paroxysmal or persistent AF or flutter (ATHENA study[73]).

Similarly to sotalol and flecainide, dronedarone is less effective than amiodarone in maintaining sinus rhythm.[74] However, it may be more important from a general perspective, especially in the elderly, to have less cardiovascular hospitalizations or stroke risk than maintenance of sinus rhythm when other relevant therapies for rate control and anticoagulation are well maintained. Dronedarone can be safely prescribed in patients with NYHA class I–II heart failure, but there is increased mortality when used in symptomatic patients with NYHA class III–IV heart failure due to worsening of heart failure (ANDROMEDA study[75]). Although studies included patients with a history of risk factors such as hypertension and coronary disease, no definitive data exist for its use in patients with LVH or in those who are asymptomatic to justify routine prescribing.

Recommendations for rhythm control

Urgent electrical cardioversion should be considered for AF resulting in haemodynamic compromise, myocardial ischaemia or heart failure. Elective electrical or pharmacological cardioversion should be considered for patients with stable AF where there is a reasonable chance of long-term maintenance of sinus rhythm. Premedication with anti-arrhythmic medication increases the success rate in maintaining sinus rhythm after electrical cardioversion. The choice of pharmacological agent for long-term control is limited in the elderly due to underlying heart disease. β-Blockers should be considered for rhythm (plus rate) control in patients with a first episode of AF. Amiodarone is suitable for patients with left ventricular dysfunction, whereas sotalol is preferred in patients with ischaemic heart disease in the absence of significant left ventricular hypertrophy or impairment. Dronedarone use is limited to patients without significant structural heart disease, but

should be considered in order to reduce cardiovascular admissions in patients with paroxysmal/persistent AF and cardiovascular risk factors.

Non-pharmacological rhythm control

A number of non-pharmacological options have been explored to control and prevent AF, with varying degrees of success. Currently these procedures are not widely suitable for an elderly population, but can be considered on an individual basis.

Ablation procedures (surgical and catheter based)

For its continuation, AF needs a critical mass of atrial tissue to allow the spread of multiple waves of depolarization.[76] The maze operation has been developed and refined whereby multiple atrial incisions are made to interrupt abnormal conduction pathways, but maintain a route for sinus impulses from the SA node to pass to the AV node. The procedure achieves maintenance of sinus rhythm at 3 months in >90% of selected patients[77] and freedom from AF for up to 15 years in 75–95%. The major drawback is the requirement for median sternotomy and the use of cardiopulmonary bypass. This has limited its use to patients who are already requiring cardiac surgery for another indication such as valve replacement. Catheter-based approaches have attempted to duplicate the maze procedure without requiring extensive surgery and procedures targeting the left atrium have had more success than those in the right atrium.[49] The potential application of catheter ablation has grown since the detection of ectopic beats originating from pulmonary veins that are capable of instigating AF. Short-term studies have shown success in the mapping and ablation of foci for PAF.[78,79] Refinements need to be made to the localization of foci and choice of energy source used (radiofrequency, laser or cryoablation). The procedure is time consuming; there is a substantial risk of pulmonary vein stenosis, thromboembolism and damage to adjacent structures,[80] but it may prove useful in selected patients with non-permanent AF. With improvements in technology and our understanding of mechanisms of AF, catheter ablation is assuming an increasing role in AF management. Recent meta-analysis found a 77% success rate for catheter ablation versus 52% for anti-arrhythmic therapy.[81]

Nevertheless, the success rates are generally higher in younger patients with relatively normal hearts. Unlike younger patients, factors that initiate and maintain AF in the elderly are not just limited to triggers found within the pulmonary veins, but also within the atrial substrate requiring more extensive ablation and repeat procedures. Currently, most of the elderly population may not benefit from catheter-based techniques. Atrial flutter commonly coexists with AF, but can be more symptomatic than AF. Catheter ablation of atrial flutter, on the other hand, is relatively safer and quicker with high success rates even in the elderly population.

Atrial pacing

It has been reported that atrial (including dual-chamber) pacing has reduced the incidence of AF versus ventricular pacing alone in patients receiving a permanent pacemaker for sick sinus syndrome. Large trials have had conflicting results with reports of reduced incidence of AF[13,15,82] and no reported differences (UKPACE[16]). No trial has yet shown a statistically significant reduction in mortality. Therefore, in those patients receiving a pacemaker for sinus node dysfunction, atrial pacing could be considered to reduce the incidence of AF. This does not translate to AF patients who do not require a pacemaker for another clinical indication. The importance of the site of atrial pacing and multisite atrial pacing is being investigated and may find a future role in patients with symptomatic, drug-refractory AF.[83]

Anticoagulation

A large body of evidence exists for the use of antithrombotic therapy in AF to prevent thromboembolic stroke. Current options for thromboprophylaxis are vitamin K antagonists (VKA) such as adjusted-dose warfarin (INR 2–3) or antiplatelet agents such as aspirin (75–325 mg daily). A recent meta-analysis demonstrated that adjusted-dose warfarin reduced the relative risk of stroke by 64%.[84] Antiplatelet therapy, aspirin being the most commonly studied agent, reduces stroke risk by 22%. Aspirin 75 mg achieves near-complete platelet inhibition and is safer than higher doses in terms of bleeding risk. The benefits are consistent for both primary and secondary prevention.

Adjusted-dose warfarin or aspirin?

A meta-analysis of nine clinical trials comparing VKA and aspirin revealed significant superiority of VKA over aspirin with a relative risk reduction (RRR) of 39%. In the Birmingham Atrial Fibrillation Treatment of the Aged study (BAFTA[85]), VKA (INR 2–3) was superior to aspirin 75 mg daily by 52% in reducing primary endpoints of ischaemic or haemorrhagic strokes or systemic embolism. There was no difference between VKA or aspirin in risk of major haemorrhage.

In the ACTIVE trials, anticoagulation was superior to combined aspirin–clopidogrel (ACTIVE-W, RRR 40%) with no difference in bleeding rates.[86] In the ACTIVE-A study (aspirin–clopidogrel versus aspirin alone), combination therapy reduced the stroke risk by 28% at the expense of a 2% increase in major bleeding events.[87a]

Table 36.5 CHA_2DS_2-VASc risk factor-based scoring system.

Risk factor	Score[a]
*C*ongestive cardiac failure	1
*H*ypertension	1
*A*ge >75 years	2
*D*iabetes mellitus	1
*S*troke/TIA/thromboembolism	2
*V*ascular disease (myocardial infarction/peripheral arterial disease/aortic plaques)	1
*A*ge 65–74 years	1
*S*ex category (i.e. female sex)	1

[a]Maximum score 9 as age may score 0, 1 or 2.

VKA treatment should be considered for all patients with AF or flutter, including elderly patients, with ≥1 stroke risk factors in the absence of contraindications after assessment of risk–benefits and patient preferences. It is important to note that the type of AF does not influence the decision for thromboprophylaxis. The choice between VKA and aspirin (or other antiplatelet drugs) depends on the number of risk factors for thromboembolic events present in a given patient. The $CHADS_2$ scoring system is widely used and serves as a simple tool to guide antithrombotic treatment (1 point each for *C*ardiac failure, *H*ypertension, *A*ge >75 years and *D*iabetes and 2 points for history of *S*troke). A score of ≥2 requires use of VKA, with aspirin or VKA for score 1 and aspirin or no antithrombotic therapy for score 0. Age >75 years independently carries a worse prognosis for stroke and mortality over other risk factors. The $CHADS_2$ system can underestimate the stroke risk, placing some patients in the 0–1 category who may significantly benefit from anticoagulation. Recent AF guidelines have addressed this issue and advise a more comprehensive risk-factor-based approach using a modified scoring system (CHA_2DS_2-VASc; see Table 36.5) in patients who score 0–1 on the $CHADS_2$ system (ESC guidelines for AF[18]).

Underuse of warfarin in the elderly

There is considerable evidence for the under use of warfarin, especially in the elderly, due to presumed risk of bleeding. In a survey of the prevalence of AF and eligibility for anticoagulation in Newcastle, UK, only 17% of patients aged over 75 years with AF and no irreversible contraindications were receiving warfarin.[88] A prospective study of 1138 stroke patients admitted to a neurology unit observed that only 12% of patients with AF who suffered a recurrent stroke were receiving warfarin prior to their recurrence.[89] An American physicians' survey reported that not only was older age a deterrent to providing anticoagulation, but also a lower intensity of anticoagulation was sought.[90]

Anticoagulation issues in the elderly

Risk of bleeding and warfarin dose

Bleeding risk has inconsistently been associated with increasing age. Recent studies show considerably lower rates of intracranial haemorrhage between 0.1 and 0.6% in the elderly population on anticoagulation maintained on INR 2.0–3.0.[91] While taking warfarin, most episodes of thrombosis occur at INR levels of <2,[92] but intracranial bleeding increases significantly with INR values >3.5–4.0. The SPAF III study[93,94] investigated the efficacy of low-intensity fixed-dose warfarin (INR 1.2–1.5) plus aspirin 325 mg versus adjusted-dose warfarin. The low-dose regimen was associated with a significantly higher incidence of stroke or thromboembolism. The Primary prevention of Arterial Thromboembolism in patients with non-valvular Atrial Fibrillation (PATAF) study[95] showed no difference between aspirin 150 mg, adjusted-dose warfarin and low-dose warfarin, but excluded patients aged over 78 years from the study, so the results cannot be applied to the elderly.

The key hurdle, however, is trying to maintain a patient's INR within the range 2–3. In the SPAF III study, only 61% of INR measurements were in that range.

Practicalities of regular monitoring in the elderly

Standard monitoring of INR has taken place in the haematology-based anticoagulation clinic. Like most hospital outpatient clinics, these can be extremely busy, have inflexibility in appointment times and dates and can represent a significant challenge for the elderly patient. Where difficulties are perceived, this may even influence the decision to anticoagulate a patient with warfarin. This need not be the case and availability and ease of use can be improved by disseminating the responsibility for monitoring into the community. Reliable and portable machines for measuring prothrombin times are available[96] and dose adjustments can be made by general practitioners or non-clinicians such as pharmacists[97] at practices or visiting nursing homes.

Pharmacokinetics of warfarin in the elderly

Cross-sectional and longitudinal[98] studies have both reported a fall in warfarin dose requirements with increasing age. Conclusive mechanisms are yet to be fully elucidated, but reduced drug clearance will play a role in the elderly. Although this does not influence the achievement of a steady state of anticoagulation, it does affect how the anticoagulation is induced. The commonly used Fennerty regimen[99] was first described in patients with a mean age of 52 years. A low-dose induction regimen has been shown to induce fewer INR measurements >4.5 and spend more time within the therapeutic range for

patients aged over 75 years.[100] This was achieved at the expense of an increase in mean time to reach therapeutic INR, which although on average was less than a single day,[100] may present an unacceptable delay in discharge from hospital.

Pharmacodynamics of warfarin the elderly

Issues of non-compliance or inconsistencies in consumption of tablets in elderly patients with dementia are a particular concern for warfarin, a drug with considerable individual variation and a narrow therapeutic window where a greater or lesser effect both carry significant risk. In a study of long-term care facilities, those patients with AF who were also diagnosed as having dementia were less likely to receive warfarin.[101] Clearly, dementia can encompass a wide range of degrees of cognitive impairment and no one would argue that in the presence of end-stage dementia the benefits of anticoagulation for AF would outweigh the discomfort and inconvenience of regular monitoring and minor bleeding. However, in the context of multi-infarct dementia, the benefits of anticoagulation to halt the stepwise decline become more apparent. Indeed, a supervised residential facility provides an environment where compliance issues can be managed.

Risks associated with polypharmacy

Numerous interactions have been reported with warfarin. Table 36.6 lists common agents involved, but is not intended as a comprehensive list. The anticoagulant effect will be reduced by foods that are high in vitamin K such as parsley, broccoli and liver. Polypharmacy and the risk of falls have to be considered with sedative medication or postural hypotension secondary to antihypertensives.

Upcoming anticoagulants

Several new oral anticoagulants are being developed which are at least as effective as VKA, with less drug interaction and better pharmacokinetics negating the need for regular INR monitoring. These include direct thrombin inhibitors (e.g. dabigatran) and factor Xa inhibitors (e.g. rivaroxaban, apixaban). In the RE-LY study, dabigatran 110 mg b.i.d. was similar to VKA in stroke prevention with lower bleeding rates. Higher dose of 150 mg b.i.d. further lowered the risk of thromboembolic stroke with similar major bleeding rates to those with VKA.[87b] AVERROES study compared apixaban against aspirin in patients unsuitable for VKA and showed significant reductions in stroke and systemic embolism with an acceptable safety profile.[102]

Non-pharmacological possibilities to prevent stroke

As LAA is the major site for development of atrial thrombus, mechanical occlusion of LAA may reduce the risk of stroke in patients with AF. Catheter-based occlusion of the LAA (WATCHMAN device) in high-risk patients who are unsuitable for VKA showed non-inferiority to VKA, but at higher rates of adverse events, mainly due to procedure-related complications.[103] More evidence is needed to allow the routine use of such devices.

Other supraventricular arrhythmias

As discussed above, the most common supraventricular arrhythmia in the elderly is atrial fibrillation. Paroxysmal atrioventricular nodal reciprocating tachycardia (AVNRT) is more common in the younger age groups than in the elderly. AVNRT may commonly manifest at later ages in association with coronary disease, perioperatively or chest infection. AVNRT is recognized on the ECG as rapid, narrow, complex tachycardia. Small, inverted P waves are generally seen superimposed on the terminal portion of the QRS complex. The diagnostic challenge is when a supraventricular tachycardia presents as a broad complex tachycardia due to aberrant conduction from partially blocked right or the left bundle branches, when it will need to be distinguished from a ventricular tachycardia (VT). Both arrhythmias can be asymptomatic or symptomatic and it is safer to assume all broad complex tachycardias to be ventricular in origin until proven otherwise. In general, dissociate atrial and ventricular activity (including fusion or capture beats), concordant QRS pattern in precordial leads, prominent R wave in V1, QRS morphology similar to previously noted ventricular ectopy, electrolyte disturbances and presence of acute myocardial ischaemia favour the diagnosis of VT.

Patients with SVT and haemodynamic instability require urgent DCC. In stable patients, vagal manoeuvres such as

Table 36.6 Common medication which interact with warfarin.

System	Potentiate anticoagulation	Decrease anticoagulation
Cardiovascular	Amiodarone, simvastatin, fibrates	Spironolactone
Endocrine	Thyroxine, steroids	
Gastrointestinal	Cimetidine, omeprazole	Cholestyramine
Nervous	Chlorpromazine, tricyclic antidepressants	Barbiturates, carbamazepine
Malignancy	Tamoxifen	
Antimicrobials	Aminoglycosides, metronidazole, clarithromycin	Rifampicin

carotid massage or the valsalva manoeuvre could terminate the tachycardia, failing which intravenous β-blockers, non-dihydropyridine calcium channel blockers (verapamil, diltiazem) or adenosine may be necessary. In patients without any history of severe asthma or obstructive airway disease, adenosine is preferred due to its short half-life and rapid onset of action. For long-term management and prevention of future recurrences, the choice generally lies between β-blockers, verapamil and diltiazem. Amiodarone or sotalol may be considered in selected patients, but increase the risk of systemic side effects or pro-arrhythmia.

Ventricular arrhythmias

Ventricular arrhythmias are common in the elderly and the incidence increases with advancing age and the presence of structural heart disease.[104] A ventricular ectopic beat or premature ventricular contraction (PVC) is a depolarization that originates in the ventricles, has a wide QRS complex and is followed by a normal compensatory pause (see Figure 36.8). Three or more consecutively occurring PVCs with a rate in excess of 120 bpm is termed *ventricular tachycardia* (VT). VT is defined as non-sustained (NSVT) if lasting <30 s (see Figure 36.9) and sustained if lasting >30 s or requiring immediate cardioversion. VT is characterized by an ECG appearance of a broad, complex tachycardia with QRS duration >0.12 s (an important differential to consider is supraventricular tachycardia with aberrant conduction). VT is monomorphic if the QRS morphology remains stable or polymorphic if QRS morphology is variable (e.g. torsades de pointes – polymorphic VT with changing QRS axis). Complex ventricular arrhythmias include VT and paired, multiform or frequent PVCs. Ventricular fibrillation is rapid (>300 bpm), irregular complexes with marked variation in rate, amplitude and morphology (Figure 36.10).

Ventricular arrhythmias can be found in 70–80% of people over 60 years of age. Complex ventricular ectopy is common in the elderly, but many often remain asymptomatic. Incidence of sudden cardiac death (SCD) increases with age and 80% of SCDs from cardiac causes can be attributed to coronary heart disease, other common causes being dilated or hypertrophic cardiomyopathy and valvular heart disease. In the peri-infarction period, age >75 years appears to be independently associated with higher in-hospital cardiac arrest.[105] Channelopathies, such as congenital long QT or Brugada syndromes, are uncommon in the elderly age group.

Prognosis

PVDs and non-sustained VT in the absence of heart disease are not associated with an increase in coronary disease or mortality and do not require treatment with anti-arrhythmic medication.[106] In contrast, polymorphic VT

Figure 36.8 Rhythm strip showing single and paired ventricular ectopic beats followed by normal compensatory pauses.

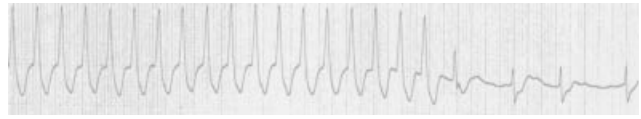

Figure 36.9 Rhythm strip showing non-sustained ventricular tachycardia.

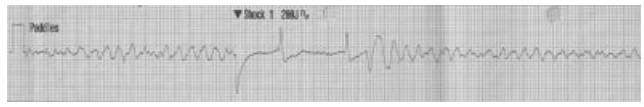

Figure 36.10 Ventricular fibrillation.

even in the absence of heart disease is an indicator of risk. It is important to note that frequent PVCs or VT may occur as a consequence of electrolyte imbalance or drug adverse effect. In patients who have a history of previous myocardial infarction, the frequency of PVDs (>10 per hour), runs of PVDs or NSVT and reduced left ventricular ejection fraction are all independently associated with new coronary events and mortality.[107,108] Ventricular arrhythmias during first 24–48 h after acute myocardial infarction do not indicate continuing risk. In patients with non-ST elevation myocardial infarction, the long-term risk and mortality are variable and may depend on the extent of initial myocardial damage.

Pathogenesis

For a ventricular tachyarrhythmia to develop, a substrate and a triggering factor are required. The substrate can either be structural (infarcted or hypertrophic myocardium resulting in myocytes of differing refractory periods forming a potential re-entrant circuit) or electrical (the occurrence of early or delayed after-depolarizations). The triggering factor is typically a transient influence such as electrolyte imbalance, acute ischemia or even an anti-arrhythmic medication, such as in the case of torsades de pointes.

Management

Appropriate management of ventricular arrhythmias requires not only knowledge of aetiology and mechanism

of the arrhythmia, but also an understanding of other associated medical problems and the risk–benefit profile of any anti-arrhythmic therapy. The presence of reversible precipitants needs to be excluded. Treatment of heart failure, myocardial ischaemia, drug toxicity, electrolyte imbalance (e.g. hypo- or hyperkalaemia, hypomagnesaemia) can abolish or reduce the occurrences of ventricular arrhythmias. Investigations include serum electrolyte levels, 12-lead or ambulatory ECG monitoring, exercise testing to exclude cardiac ischaemia or to diagnose exercise-related arrhythmias, cardiac catheterization, echocardiography or other forms of imaging (MRI, perfusion scans) and electrophysiological testing.

The ultimate aim should be to prevent such an arrhythmia occurring in the first instance. Overall management of ventricular arrhythmias in the elderly does not differ from that recommended for the general population, but necessitates taking into account other factors such as involvement of other organ systems, presence of other comorbidities and physiological changes that occur with advancing age. These factors strongly influence the choice and appropriateness of any pharmacological or non-pharmacological management.

Drug therapy

With the exception of β-blockers, currently available anti-arrhythmic drugs have not shown any prognostic benefit in the management of complex ventricular arrhythmias or prevention of SCD. As a general rule, anti-arrhythmic drugs are recommended as adjunctive therapy to β-blockers due to potential pro-arrhythmic or systemic side effects. There is increased susceptibility to adverse cardiac events with advancing age, particularly in relation to class Ic anti-arrhythmic drugs (e.g. flecainide; Vaughan Williams classification). Sotalol is less frequently used in the elderly due to a propensity towards pro-arrhythmia by increasing the QT interval, especially in the presence electrolyte imbalance or other major organ involvement. Treatment with flecainide[109] or D-sotalol,[110] despite successfully suppressing PVDs, both agents lead to an increased mortality in patients after myocardial infarction as compared with placebo. In survivors of cardiac arrest, amiodarone may improve prognosis.[11] A meta-analysis of 13 randomized controlled trials of prophylactic amiodarone in patients with recent myocardial infarction or congestive heart failure demonstrated a statistically significant relative risk reduction of 29% in arrhythmic/sudden death.[112] A relative risk reduction in total mortality of 13–15% was marginal, but importantly there was no increase in non-arrhythmic deaths. However, two large primary prevention trials of amiodarone post-myocardial infarction both demonstrated reductions in arrhythmic deaths, but had no effect on total mortality,[113,114] raising concerns that reductions in fatal arrhythmias are offset by increased mortality from other causes. In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT),[115] a, primary prevention study comparing placebo, amiodarone and implantable cardioverter defibrillator (ICD) in patients with NYHA functional class II or III and left ventricular ejection fraction (EF) <35%, amiodarone failed to show reduction in all-cause mortality compared with placebo.

Therefore, amiodarone, with which there is considerable clinical experience in the treatment of ventricular tachycardia, is useful in preventing arrhythmic deaths and is safe in the context of ischaemia and heart failure, but the beneficial effect on total mortality appears to be small with too little evidence to justify its routine prophylactic use.[116]

Amiodarone is associated with many side effects, particularly in elderly patients who are already on multiple drug therapy, increasing the risk of drug interaction. Systemic side effects of amiodarone include thyroid and liver dysfunction, skin sensitivity and corneal deposits.

β-Blockers remain the mainstay of treating ventricular arrhythmias and, either alone or in combination with non-arrhythmic agents (ACE inhibitors, angiotensin receptor blockers, statins), have consistently been shown to reduce SCD and all-cause mortality in patients with heart failure or after myocardial infarction in all age groups, including the elderly. There is also some evidence that omega-3 polyunsaturated fatty acids and statins may have anti-arrhythmic properties of their own due to a membrane-stabilizing effect.

Despite the proven efficacy of β-blockers, these agents remain underused in the elderly population with an independent negative association with age. A retrospective analysis on use of β-blockers after myocardial infarction in patients >65 years of age found that only 21% of 3737 patients received β-blockers despite the absence of any contraindications. The study also found 43% lower 2 year mortality in those who had received β-blockers.[117]

Role of implantable cardioverter defibrillator

Beyond medication, the ICD has now emerged as the most effective therapy for primary and secondary prevention of fatal ventricular tachyarrhythmias (see Figures 36.11 and 36.12). The addition of an antitachycardia pacing facility can effectively terminate some tachyarrhythmias prior to shock delivery. The primary prevention Multicenter Automatic Defibrillator Implantation Trial (MADIT)[118] and Multicenter Unsustained Tachycardia Trial (MUSTT)[119] studies have both demonstrated statistically significant reductions in overall mortality as compared to anti-arrhythmic medication in patients with previous myocardial infarction (MI), reduced LV ejection fraction and non-sustained VT who were referred for electrophysiological studies (EPS). The subsequent MADIT 2 study[120] enrolled patients with prior

Figure 36.11 Implantable cardioverter defibrillator.

Figure 36.12 Chest X-ray of a patient with an ICD (atrial and ventricular leads).

MI and ejection fraction <30% with no requirement for the occurrence of ventricular arrhythmia or need for EPS. There was a statistically significant reduction in overall mortality as compared to conventional medical therapy alone, which persisted for both sexes in all age groups in subgroup analysis.

Two major trials have now defined the role of ICD therapy for primary prevention in patients with dilated cardiomyopathy (DCM). The SCD-HeFT consisted of 2521 patients with a mean age of 60 years. It included patients with ischaemic DCM, no history of prior sustained VT or VF, left ventricular ejection fraction <35% and NYHA functional class II or III on optimal medical therapy with ACE inhibitor and β-blocker use. ICD therapy was associated with a statistically significant reduction in all-cause mortality compared with best medical therapy alone or in combination with amiodarone.[115] The Defibrillators in Non-ischaemic Cardiomyopathy Treatment Evaluation (DEFINITE) consisted of patients with non-ischaemic DCM on optimal heart failure medication including ACE inhibitor and β-blocker, but not on amiodarone therapy. ICD therapy was associated with a statistically significant reduction in arrhythmic death compared with best medical therapy alone, but only a trend towards reduction in all-cause mortality. Based on these data, ICD therapy should be considered on an individual basis for patients with severe left ventricular dysfunction and non-ischaemic DCM.[121]

There have been three prospective randomized trials comparing ICD therapy with medication for secondary prevention. The Anti-arrhythmics Versus Implantable Defibrillators (AVID) trial[122] was the largest of these and was the only one to show a statistically significant risk reduction in mortality with ICD therapy compared with medication. Patients with episodes of VF or haemodynamically significant VT were randomized to ICD or anti-arrhythmic medication (amiodarone or sotalol). The majority of patients had ischaemic heart disease and the mean left ventricular ejection fraction (LVEF) was 32%. The mean age of participants was 65 years, but subgroup analysis showed no difference in outcome for those aged over 70 years. The Canadian Implantable Defibrillator Study (CIDS) trial[123] included patients with syncope probably secondary to VT and compared ICD therapy with amiodarone. In a multivariate analysis of CIDS,[124] the patients at highest risk of cardiovascular death (age ≥70 years, LVEF ≤35% and NYHA class III or IV) were found to benefit the most from ICD therapy. The Cardiac Arrest Study Hamburg (CASH) trial[125] also had metoprolol and propafenone treatment limbs. The propafenone limb was stopped early because of excess mortality. A meta-analysis of these trials concluded a 28% relative reduction in death with ICD therapy in patients with LVEF of <35%.[126]

Implantable cardioverter defibrillators in the elderly

All major ICD trials have included a substantial number of patients >65 years of age. Subgroup analyses of these trials show equivalent benefit from ICD between younger and elderly populations and it is appropriate to consider ICD implantation irrespective of the age. Nevertheless, ICD remains an invasive treatment that may not be suitable for all. There are sparse data on the procedure-related morbidity in the elderly. As previously discussed in the section on AF, the very elderly can present additional challenges

that have to be taken into account when analysing the risk versus benefits for any given therapy. Regular follow-up at a tertiary centre clinic is vital to ensure that the device continues to function effectively and safely. Appropriate and inappropriate shocks may prove intolerable for some patients and an ICD would be unsuitable for those with significant dementia or other major comorbidities with a projected lifespan of <1 year. Any reduction in medication will be beneficial in the elderly, but anti-arrhythmics may still be required in some patients to reduce the burden of arrhythmia and hence the shock frequency. Further studies will have to be undertaken to help further risk stratify elderly patients and identify those most likely to benefit from an ICD, but age alone is not a contraindication for this therapy. There are widening indications for implantation of ICD and selected elderly patients can gain significantly from the treatment.

Key points

- Arrhythmias are common in the elderly.
- The heart is subject to both ageing and disease-related changes that predispose to arrhythmia generation and persistence.
- Atrial fibrillation is the most common sustained arrhythmia in the elderly and carries a substantial risk of morbidity and mortality from thromboembolic stroke.
- Presence or absence of non-cardiac comorbidities in the elderly play a major role, not only in the genesis of arrhythmias, but also in their specific management based on assessment of risks versus benefits for each individual patient.

CHAPTER 37

Ischaemic heart disease

Wilbert S. Aronow
New York Medical College, Valhalla, NY, USA

Introduction

The most common cause of death in elderly persons is ischaemic heart disease (IHD). Coronary atherosclerosis is very common in the elderly, with autopsy studies demonstrating a prevalence of at least 70% in persons older than 70 years. The prevalence of IHD is similar in elderly women and men.[1] In one study, clinical IHD was present in 502 of 1160 men (43%), mean age 80 years, and in 1019 of 2464 women (41%), mean age 81 years. At 46-month follow-up, the incidence of new coronary events (myocardial infarction or sudden cardiac death) was 46% in the elderly men and 44% in the elderly women.[1]

IHD is diagnosed in elderly persons if they have either coronary angiographic evidence of significant IHD, a documented myocardial infarction (MI), a typical history of angina pectoris with myocardial ischaemia diagnosed by stress testing, or sudden cardiac death. The incidence of sudden cardiac death as the first clinical manifestation of IHD increases with age.

Clinical manifestations

Dyspnoea on exertion is a more common clinical manifestation of IHD in elderly persons than is the typical chest pain of angina pectoris. The dyspnoea is usually exertional and is related to a transient rise in left ventricular (LV) end-diastolic pressure caused by ischaemia superimposed on decreased LV compliance. Because elderly persons are more limited in their activities, angina pectoris in elderly persons is less often associated with exertion. Elderly persons with angina pectoris are less likely to have substernal chest pain, and they describe their anginal pain as less severe and of shorter duration than do younger persons. Angina pectoris in elderly persons may occur as a burning post-prandial epigastric pain or as pain in the back or shoulders. Acute pulmonary oedema unassociated with an acute MI may be a clinical manifestation of unstable angina pectoris due to extensive IHD in elderly persons.

Myocardial ischaemia, appearing as shoulder or back pain in elderly persons, may be misdiagnosed as degenerative joint disease. Myocardial ischaemia, appearing as epigastric pain, may be misdiagnosed as peptic ulcer disease. Nocturnal or post-prandial epigastric discomfort that is burning in quality may be misdiagnosed as hiatus hernia or oesophageal reflux instead of myocardial ischaemia due to IHD. The presence of comorbid conditions in elderly persons may also lead to misdiagnosis of symptoms due to myocardial ischaemia.

Elderly persons with IHD may have silent or asymptomatic myocardial ischaemia. In a prospective study, 133 of 195 men (34%), mean age 80 years, with IHD and 256 of 771 women (33%), mean age 81 years, with IHD had silent myocardial ischaemia detected by 24-hour ambulatory electrocardiograms (ECGs). At 45-month follow-up, the incidence of new coronary events in elderly men with IHD was 90% in men with silent myocardial ischaemia versus 44% in men without silent ischaemia. At 47-month follow-up, the incidence of new coronary events in elderly women with IHD was 88% in women with silent ischaemia versus 43% in women without silent ischaemia.[2]

Recognized and unrecognized MI

Pathy demonstrated in 387 elderly patients with acute MI that 19% had chest pain, 56% had dyspnoea or neurological symptoms or gastrointestinal symptoms, 8% had sudden death, and 17% had other symptoms.[3] Another study showed in 110 elderly patients with acute MI that 21% had no symptoms, 22% had chest pain, 35% had dyspnoea, 18% had neurological symptoms, and 4% had gastrointestinal symptoms (Table 37.1).[3] Other studies have also shown a high prevalence of dyspnoea and neurological symptoms in elderly patients with acute MI.[3] In these studies, dyspnoea was present in 22% of 87 patients, in 42% of 777 patients, and in 57% of 96 patients. Neurological

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 37.1 Presenting symptoms in 110 elderly patients with acute myocardial infarction.

Dyspnoea was present in 35% of patients
Chest pain was present in 22% of patients
Neurological symptoms were present in 18% of patients
Gastrointestinal symptoms were present in 4% of patients
No symptoms were present in 21% of patients

Source: Paper by Aronow WS discussed in Aronow and Fleg, 2008.[3]

symptoms were present in 16% of 87 patients, in 30% of 777 patients, and in 34% of 96 patients.

As with myocardial ischaemia, some patients with acute MI may be completely asymptomatic or the symptoms may be so vague that they are unrecognized by the patient or physician as an acute MI. Studies have reported that 21–68% of MIs in elderly patients are unrecognized or silent.[3] These studies also demonstrated that the incidence of new coronary events including recurrent myocardial infarction, ventricular fibrillation and sudden death in patients with unrecognized MI, is similar to that in patients with recognized MI.

Diagnostic techniques

Resting ECG

In addition to diagnosing recent or prior MI, the resting ECG may show ischaemic ST-segment depression, arrhythmias, conduction defects, and LV hypertrophy that are related to subsequent coronary events. At 37-month mean follow-up, elderly patients with ischaemic ST-segment depression 1 mm or greater on the resting ECG were 3.1 times more likely to develop new coronary events than were elderly patients with no significant ST-segment depression.[3] Elderly patients with ischaemic ST-segment depression 0.5 to 0.9 mm on the resting ECG were 1.9 times more likely to develop new coronary events during 37-month follow-up than were elderly patients with no significant ST-segment depression. At 45-month mean follow-up, pacemaker rhythm, atrial fibrillation, premature ventricular complexes, left bundle branch block, intraventricular conduction defect, and type II second-degree atrioventricular block were associated with a higher incidence of new coronary events in patients.[3] Numerous studies have also documented that elderly patients with ECG LV hypertrophy have an increased incidence of new coronary events.[3]

Many studies have shown that complex ventricular arrhythmias in elderly persons with IHD are associated with an increased incidence of new coronary events including sudden cardiac death.[3] The incidence of new coronary events is especially increased in elderly persons with complex ventricular arrhythmias and abnormal LV ejection fraction or LV hypertrophy. At 45-month follow-up of 395 men, mean age 80 years, with IHD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs increased the incidence of new coronary events 2.4 times.[4] At 47-month follow-up of 771 women, mean age 81 years, with IHD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs increased the incidence of new coronary events 2.5 times.[4]

Exercise stress testing

Hlatky *et al*. found the exercise ECG to have a sensitivity of 84% and a specificity of 70% for the diagnosis of IHD in persons older than 60 years of age.[3] Newman and Phillips found a sensitivity of 85%, a specificity of 56%, and a positive predictive value of 86% for the exercise ECG in diagnosing IHD.[3] The increased sensitivity of the exercise ECG with increasing age found in these two treadmill exercise studies was probably due to the increased prevalence and severity of IHD in elderly persons.

Exercise stress testing also has prognostic value in elderly patients with IHD. Deckers *et al*.[3] showed that the one-year mortality was 4% for 48 patients 65 years of age or older who were able to do an exercise stress test after acute MI and 37% for the 63 elderly patients unable to do the exercise stress test after acute MI.

Exercise stress testing using thallium perfusion scintigraphy, radionuclide ventriculography, and echocardiography are also useful in the diagnosis and prognosis of CHD. Iskandirian *et al*.[3] showed that exercise thallium-201 imaging can be used for risk stratification of elderly patients with IHD. The risk for cardiac death or non-fatal MI at 25-month follow-up in 449 patients 60 years of age or older was less than 1% in patients with normal images, 5% in patients with single-vessel thallium-201 abnormality, and 13% in patients with multivessel thallium-201 abnormality.

Pharmacological stress testing

Intravenous dipyridamole-thallium imaging may be used to determine the presence of IHD in elderly patients who are unable to undergo treadmill or bicycle exercise stress testing. In patients 70 years of age or older, the sensitivity of intravenous dipyridamole-thallium imaging for diagnosing significant IHD was 86%, and the specificity was 75%.[3] In 120 patients older than 70 years, adenosine echocardiography had a 66% sensitivity and a 90% specificity in diagnosing IHD.[3] An abnormal adenosine echocardiogram predicted a threefold risk of future coronary events, independent of coronary risk factors.[3] In 120 patients older than 70 years, dobutamine echocardiography had a 87% sensitivity and a 84% specificity in diagnosing IHD.[3] An

abnormal dobutamine echocardiogram predicted a 7.3-fold risk of future coronary events.[3]

Signal-averaged electrocardiography

Signal-averaged electrocardiography (SAECG) was performed in 121 elderly post-infarction patients with asymptomatic complex ventricular arrhythmias detected by 24-hour ambulatory ECGs and a LV ejection fraction of 40% or higher.[3] At 29-month follow-up, the sensitivity, specificity, positive predictive value, and negative predictive value for predicting sudden cardiac death were 52%, 68%, 32%, and 83%, respectively for a positive SAECG; 63%, 70%, 38%, and 87%, respectively for non-sustained ventricular tachycardia; and 26%, 89%, 41%, and 81%, respectively for a positive SAECG plus non-sustained ventricular tachycardia.[3]

Coronary risk factors

Cigarette smoking

The Cardiovascular Health Study demonstrated in 5201 men and women 65 years of age or older that >50 pack-years of smoking increased five-year mortality 1.6 times.[5] The Systolic Hypertension in the Elderly Program pilot project showed that smoking was a predictor of first cardiovascular event and MI/sudden death.[5] At five-year follow-up of 7178 persons ≥65 years of age in three communities, the relative risk for CVD mortality was 2.0 for male smokers and 1.6 for female smokers.[5] The incidence of CVD mortality in former smokers was similar to those who had never smoked.[5] At 40-month follow-up of 664 men, mean age 80 years, and at 48-month follow-up of 1488 women, mean age 82 years, current cigarette smoking increased the relative risk of new coronary events 2.2 times in men and 2.0 times in women.[6] At six-year follow-up of older men and women in the Coronary Artery Surgery Study registry, the relative risk of MI or death was 1.5 for persons 65–69 years of age and 2.9 for persons 70 years of age and older who continued smoking compared with quitters during the year before study enrolment.[5]

Elderly men and women who smoke cigarettes should be strongly encouraged to stop smoking to reduce the development of IHD. Smoking cessation will decrease mortality from IHD, other cardiovascular disease, and all-cause mortality in elderly men and women. A smoking cessation programme should strongly be recommended.

Hypertension

Systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mmHg or higher from two or more readings on two or more visits.[7] Diastolic hypertension in elderly persons is similarly diagnosed if the diastolic blood pressure is 90 mmHg or higher. In a study of 1819 persons, mean age 80 years, living in the community, the prevalence of hypertension was 71% in elderly African Americans, 64% in elderly Asians, 62% in elderly Hispanics, and 52% in elderly whites.[5] Isolated systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mmHg or higher with a diastolic blood pressure of less than 90 mmHg. Approximately two-thirds of elderly persons with hypertension have isolated systolic hypertension.

Isolated systolic hypertension and diastolic hypertension are both associated with increased IHD morbidity and mortality in elderly persons.[5] Increased systolic blood pressure is a greater risk factor for IHD morbidity and mortality than is increased diastolic blood pressure. The higher the systolic or diastolic blood pressure, the greater the morbidity and mortality from IHD in elderly women and men. The Cardiovascular Health Study demonstrated in 5202 elderly men and women that a brachial systolic blood pressure >169 mmHg was associated with a 2.4-fold greater five-year mortality.[5]

At 30-year follow-up of persons 65 years of age and older in the Framingham Heart Study, systolic hypertension was related to a greater incidence of IHD in elderly men and women.[5] Diastolic hypertension correlated with the incidence of IHD in elderly men but not in elderly women. At 40-month follow-up of 664 elderly men and 48-month follow-up of 1488 elderly women, systolic or diastolic hypertension was associated with a relative risk of new coronary events of 2.0 in men and 1.6 in women.[6] Data from Framingham also suggests the importance of increased pulse pressure, a measure of large artery stiffness. Among 1924 men and women aged 50–79 years, at any given level of systolic blood pressure of 120 mmHg or greater, the risk of IHD over 20 years rose with lower diastolic blood pressure, suggesting that higher pulse pressure was an important component of risk.[5] Among 1061 men and women aged 60–79 years in the Framingham Heart Study, the strongest predictor of IHD risk was pulse pressure [hazard ratio(HR) = 1.24].

Elderly persons with hypertension should be treated with salt restriction, weight reduction if necessary, discontinuation of drugs that increase blood pressure, avoidance of alcohol and tobacco, increase in physical activity, decrease of dietary saturated fat and cholesterol, and maintenance of adequate dietary potassium, calcium and magnesium intake. In addition, antihypertensive drugs have been shown to reduce IHD events in elderly men and in elderly women with hypertension.[7,8]

Despite multiple large randomized trials, treatment of hypertension in patients aged 80 years or older remained controversial until the publication of HYVET.[8] In HYVET, 3845 persons aged 80 years and older (mean age 83.6 years)

with a sustained systolic blood pressure of 160 mmHg or higher were randomized to indapamide (sustained-release 1.5 mg) or matching placebo. Perindopril 2 mg or 4 mg, or matching placebo, was added if needed to achieve the target blood pressure of 150/80 mmHg. The study was terminated early after a median follow-up of 1.8 years.

Antihypertensive drug treatment reduced the incidence of the primary endpoint (fatal or non-fatal stroke) by 30%, fatal stroke by 39%, all-cause mortality by 21%, death from cardiovascular causes by 23%, and heart failure by 64%. The significant 21% reduction in all-cause mortality by antihypertensive drug treatment was unexpected. The benefits of antihypertensive drug treatment appeared during the first year of follow-up.

The prevalence of cardiovascular disease was only 12% at baseline in HYVET patients (i.e. much lower than generally reported in community-based samples of octogenarians). For example, in a cohort of patients with hypertension, mean age 80 years, in a university geriatrics practice, 70% had cardiovascular disease, target organ damage, or diabetes mellitus.[5] The absolute reduction in cardiovascular events resulting from antihypertensive drug therapy in an elderly population with a high prevalence of cardiovascular disease could be much greater than observed in HYVET.

Elderly persons with IHD should have their blood pressure reduced to <135/85 mmHg and to less than 130/80 mmHg if diabetes mellitus or chronic renal disease is present.[7] JNC 7 pointed out that most patients with hypertension will require two or more antihypertensive drugs to achieve this blood pressure goal.[7] The drugs of choice for treating IHD with hypertension are beta-blockers and angiotensin-converting enzyme (ACE) inhibitors. If a third antihypertensive drug is needed, a thiazide diuretic should be administered.

Left ventricular hypertrophy

Elderly men and women with ECG LV hypertrophy and echocardiographic LV hypertrophy have an increased risk of developing new coronary events.[5] At four-year follow-up of 406 elderly men and 735 elderly women in the Framingham study, echocardiographic LV hypertrophy was 15.3 times more sensitive in predicting new coronary events in elderly men and 4.3 times more sensitive in predicting new coronary events in elderly women than was electrocardiographic LV hypertrophy.[5] At 37-month follow-up of 360 men and women, mean age 82 years, with hypertension or IHD, echocardiographic LV hypertrophy was 4.3 times more sensitive in predicting new coronary events than was electrocardiographic LV hypertrophy.[5]

Physicians should try to prevent LV hypertrophy from developing or progressing in elderly men and women with IHD. A meta-analysis of 109 treatment studies found that ACE inhibitors were more effective than other antihypertensive drugs in decreasing LV mass.[5]

Dyslipidemia

Numerous studies have demonstrated that a high serum total cholesterol is a risk factor for new or recurrent coronary events in elderly men and women.[5] At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, an increment of 10 mg dl^{-1} of serum total cholesterol was associated with an increase in the relative risk of 1.12 for new coronary events in both men and in women.[6]

A low serum high-density lipoprotein (HDL) cholesterol is a risk factor for new coronary events in elderly men and women.[5] In the Framingham study, in the Established Populations for Epidemiologic Studies of the Elderly study, and in a large cohort of convalescent home patients,[5] a low serum HDL cholesterol was a more powerful predictor of new coronary events than was serum total cholesterol. At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, a decrement of 10 mg dl^{-1} of serum HDL cholesterol increased the relative risk of new coronary events 1.70 times in men and 1.95 times in women.[6]

Hypertriglyceridemia is a risk factor for new coronary events in elderly women but not in elderly men.[5] At 40-month follow-up of elderly men and at 48-month follow-up of elderly women, the level of serum triglycerides was not a risk factor for new coronary events in men and was a very weak risk factor for new coronary events in women.[6]

Numerous studies have demonstrated that statins reduce new coronary events in elderly men and in elderly women with IHD.[9] The absolute reduction in new coronary events in these studies is greater for elderly persons than for younger persons. In an observational prospective study of 488 men and 922 women, mean age 81 years, with prior MI and a serum low-density lipoprotein (LDL) cholesterol of 125 mg dl^{-1} or higher, 48% of persons were treated with statins.[10] At three-year follow-up, statins reduced new coronary events by 50%. The lower the LDL cholesterol achieved by statin therapy, the greater the reduction in coronary events in elderly patients with prior MI.[10]

Current guidelines recommend lipid-lowering therapy in elderly men and women with IHD to reduce their serum LDL cholesterol to less than 70 mg dl^{-1}.[11,12] Data from the Heart Protection Study suggest that elderly men and women with IHD should be treated with statins regardless of initial levels of serum lipids.[13]

Diabetes mellitus

Diabetes mellitus is a risk factor for new coronary events in elderly men and women.[5] In the Cardiovascular Health

Study, an elevated fasting glucose level (>130 mg dl^{-1}) increased five-year mortality 1.9 times.[5] At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, diabetes mellitus increased the relative risk of new coronary events 1.9 times in men and 1.8 times in women.[6] Elderly diabetics without IHD have a higher incidence of new coronary events than elderly non-diabetics with IHD.[5]

Persons with diabetes mellitus are more often obese and have higher serum LDL cholesterol and triglyceride levels and lower serum HDL cholesterol levels than do non-diabetics. Diabetics also have a higher prevalence of hypertension and LV hypertrophy than do non-diabetics. These risk factors contribute to the increased incidence of new IHD events in diabetics compared to non-diabetics. Increased age can further amplify these risk factor differences and contribute to greater IHD risk.

Elderly persons with diabetes mellitus should be treated with dietary therapy, weight reduction if necessary, and appropriate drugs if necessary to control hyperglycaemia. The HbA1c level should be maintained at less than 7%.[5,12] Other risk factors such as smoking, hypertension, dyslipidemia, obesity and physical inactivity should be controlled. The serum LDL cholesterol level should be reduced to less than 70 mg dl^{-1}.[9,11,12] The blood pressure should be reduced to less than 130/80 mmHg. Sulfonylureas should be avoided in persons with IHD.[5]

Obesity

Obesity was an independent risk factor for new IHD events in elderly men and women in the Framingham Heart Study.[5] Disproportionate distribution of fat to the abdomen assessed by the waist:hip circumference ratio has also been shown to be a risk factor for cardiovascular disease, mortality from CHD, and total mortality in elderly men and women.[5]

Obese men and women with IHD must undergo weight reduction. Weight reduction is also a first approach to controlling mild hypertension, hyperglycaemia and dyslipidemia. Regular aerobic exercise should be used in addition to diet to treat obesity.

Physical inactivity

Physical inactivity is associated with obesity, hypertension, hyperglycaemia and dyslipidemia. At 12-year follow-up in the Honolulu Heart Program, physically active men 65 years of age or older had a relative risk of 0.43 for IHD compared with inactive men.[5] Lack of moderate or vigorous exercise increased five-year mortality in elderly men and women in the Cardiovascular Heart Study.[5]

Moderate exercise programmes suitable for elderly persons include walking, climbing stairs, swimming or bicycling. However, care must be taken in prescribing any exercise programme because of the high risk of injury in this age group. Group or supervised sessions, including aerobic classes, offered by senior healthcare plans are especially appealing. Exercise training programmes are not only beneficial in preventing CHD but have also been found to improve endurance and functional capacity in elderly persons after MI.[5]

Therapy of stable angina

Nitroglycerin is used for relief of the acute anginal attack. It is given either as a sublingual tablet or as a sublingual spray.[14] Long-acting nitrates prevent recurrent anginal attacks, improve exercise time until the onset of angina, and reduce exercise-induced ischaemic ST-segment depression. To prevent nitrate tolerance, it is recommended that a 12- to 14-hour nitrate-free interval be established when using long-acting nitrate preparations. During the nitrate-free interval, the use of another anti-anginal drug will be necessary.

Beta-blockers prevent recurrent anginal attacks and are the drug of choice to prevent new coronary events.[14] Beta-blockers also improve exercise time until the onset of angina and reduce exercise-induced ischaemic ST-segment depression. Beta-blockers should be administered along with long-acting nitrates to all patients with angina unless there are contraindications to the use of these drugs. Antiplatelet drugs such as aspirin or clopidogrel should also be administered to all patients with angina to reduce new coronary events.[14,15]

There are no class I indications for the use of calcium channel blockers in the treatment of patients with IHD.[12] However, if angina pectoris persists despite the use of beta blockers and nitrates, long-acting calcium-channel blockers such as diltiazem or verapamil should be used in elderly patients with IHD and normal LV systolic function and amlodipine or felodipine in patients with IHD and abnormal LV systolic function as anti-anginal agents.
